

# 18th International Conference on Accelerator and Large Experimental Physics Control Systems

## Tracks

### 1. General

Project Status Reports  
Control System Upgrades  
Device Control and Integrating Diverse Systems  
Experiment Control

### 2. Software

Software Technology Evolution  
User Interfaces and User eXperience (UX)  
Data Management  
Data Analytics

### 3. Hardware

Hardware Technology  
Timing Systems, Synchronization and Real-Time Applications  
Control System Infrastructure

### 4. Subsystems

Human Aspects, Collaborations, Management  
Functional Safety Systems for Machine Protection, Personnel Safety  
Feedback Control, Machine Tuning and Optimization

## ICALEPCS 2021 Virtual

14-22 October 2021

## Local Organizing Committee

Yongbin Leng, Conference Chair  
Yingbing Yan, Program Chair  
Zhichu Chen, Proceedings Chief Editor  
Pengxiang Yu, Conference Secretary  
Min Li, Finance Assistant  
Qingwen Xiao, IT Coordinator  
Xiaomin Liu, Oral Manager  
Danping Bai, Poster Manager  
Huihui Lv, Industrial Exhibition Manager  
Heyun Wang, Web & Whova Manager

# PROCEEDINGS

Hosted by :  
Shanghai Advanced Research Institute  
Chinese Academy of Sciences

## Foreword to the ICALEPCS 2021 Proceedings

The 18th International Conference on Accelerator and Large Experimental Physics Control Systems (ICALEPCS 2021) was held from the 14th October to the 22nd October in virtual format due to COVID-19 pandemic. It was hosted by Shanghai Advanced Research Institute. The conference was endorsed by the Chinese Academy of Sciences (CAS), the National Natural Science Foundation of China (NSFC), the European Physical Society (EPS), the American Physical Society (APS), and the Shanghai Nuclear Society. The conference's Local Organizing Committee was advised by two committees made up of members from the three regions – the International Scientific Advisory Committee (ISAC) and the Program Committee (PC). The ISAC was comprised of 38 members and chaired by Kazuro Furukawa from KEK. The PC was made up of 40 members and chaired by Yingbing Yan from SARI.

In total 552 participants registered. Of these, 39 were students. CERN was the most represented institute followed by SARI. The breakdown of attendees by region was as follows: 113 from Asia and Oceania, 371 from Europe, Middle East and Africa, and 68 from North and South America.

A total of 290 abstracts were accepted. Of these, 84 were selected as contributed orals and 206 were poster presentations. For the proceedings, 218 papers were uploaded and processed to be included.

ICALEPCS 2021 put a strong emphasis on having quality and diverse keynote speakers. Zhentang Zhao, from SARI, spoke on Highlights of Accelerator R&D at Shanghai Light Sources Cluster. Lei Ding, from SITP, spoke on Infrared Remote Sensors for Chinese Meteorological Satellites. Juan Yin, from USTC, spoke on Large-scale Quantum Communication Network. Dejun Ning, from SARI, spoke on Digital Transformation of Urban Economy and Case Study. And, Chen Lin, from Peking University, spoke on Laser Ion Accelerator and Its Applications.

The conference themes were chosen by the ISAC. The scientific program was drawn up by the PC. Both committees did an excellent job choosing topics and talks and encouraging experts to present their work. Parallel sessions were necessary, as have been in the past. Out of a total of 27 sessions, 20 were parallel.

There were 5 pre-conference workshops held on the Thursday (14th October) and Friday (15th October) before the conference. The workshop themes were: Linux Distribution and Ecosystem Evolution in Control Systems, TANGO, Data Science and Machine Learning, PLC Based Control Systems, and Motion Control. The attendance of the pre-conference workshops was very high. More than 450 people attended the workshops.

Two awards were given at ICALEPCS 2021, the ICALEPCS Lifetime Achievement Award (LAA) and the ICALEPCS Leadership in Mentoring Award (LMA). The ICALEPCS 2021 LAA award was presented to Andy Götz and Roland Müller. As members of ISAC and IEC, through their organizational skills and vision, as well as technical excellence and tireless activity, they have been the key to the success of two

decades of ICALEPCS conferences. The ICALEPCS 2021 LMA award was presented to Songqiang Liu. With his dedication to training and mentoring over the decades, he successfully grew highly qualified controls engineers, and contributed to the international accelerator community and EPICS collaboration.

The ISAC accepted the bid for ICALEPCS 2025 to be held in Chicago, USA, hosted by Advanced Photon Source (APS)/Argonne National Laboratory (ANL).

As chairs we would like to thank everyone who contributed to make ICALEPCS 2021 a successful and memorable event. The conference was the result of many people's work and support both financial and moral. It all started in 2017 in Barcelona, when the ISAC of ICALEPCS 2017 accepted the SSRF bid to host ICALEPCS 2021 in Shanghai. It continued with ICALEPCS 2019 who sponsored ICALEPCS 2021 with the earnings that remained from ICALEPCS 2019.

We thank all the sponsors and exhibitors who helped finance the conference. They were Beckhoff, Cosylab, D-TACQ Solutions, Instrumentation Technologies, nVent, Plant & Mill Supplies, RadiaSoft LLC, Technosystem and Teledyne SP Devices.

The ISAC chair and committee did a great job advising the LOC during the 2 years leading up to the conference. The PC did an excellent job shaping the scientific program. The editors did an excellent job editing the many abstracts and papers to ensure that the papers were of high quality. The delegates made the conference a success by participating with high quality talks and questions. A big thanks to SARI, the host institute, and all the colleagues who helped and provided support for ICALEPCS 2021.

We want to thank our JACoW team: Zhichu Chen, Volker RW Schaa, Raphael Müller, Akihiro Shirakawa, Lu Li, and the SPMS regional support from Takashi Kosuge.

Finally, we would like to thank all the LOC members who worked very hard to ensure ICALEPCS 2021 was a success!

We look forward to seeing everyone in Cape Town in 2023 and in Chicago in 2025!

Conference Chair: Yongbin Leng  
Program Chair: Yingbing Yan

Contents . . . . .	ix
<b>Papers</b>	<b>1</b>
MOAL01 – Maturity of the MAX IV Laboratory in Operation and Phase II Development . . . . .	1
MOAL02 – Status of the National Ignition Facility (NIF) Integrated Computer Control and Information Systems . . . . .	9
MOAL03 – From SKA to SKAO: Early Progress in the SKAO Construction . . . . .	14
MOAR01 – Modernizing the SNS Control System . . . . .	21
MOAR02 – Modernizing Digital Video Systems at the National Ignition Facility (NIF): Success Stories, Open Challenges and Future Directions . . . . .	26
MOAR03 – LOFAR2.0: Station Control Upgrade . . . . .	31
MOBL01 – The ELT Control System: Recent Developments . . . . .	37
MOBL02 – Real-Time Framework for ITER Control Systems . . . . .	45
MOBL03 – Machine Learning Platform: Deploying and Managing Models in the CERN Control System . . . . .	50
MOBL04 – Karabo Data Logging: InfluxDB Backend and Grafana UI . . . . .	56
MOBL05 – Photon Science Controls: A Flexible and Distributed LabVIEW Framework for Laser Systems . . . . .	62
MOBR01 – ROMULUSLib: An Autonomous, TCP/IP-Based, Multi-Architecture C Networking Library for DAQ and Control Applications . . . . .	69
MOBR02 – Control, Readout and Monitoring for the Medium-Sized Telescopes in the Cherenkov Telescope Array . . . . .	77
MOBR03 – Hexapod Control System Development Towards Arbitrary Trajectories Scans at Sirius/LNLS . . . . .	84
MOBR04 – Generic Data Acquisition Control System Stack on the MTCA Platform . . . . .	90
MOPV001 – Status of the SARAF-Phase2 Control System . . . . .	93
MOPV002 – CENBG Control System and Specific Instrumentation Developments for SPIRAL2-DESIR Setups . . . . .	98
MOPV003 – Laser Megajoule Facility Operating Software Overview . . . . .	104
MOPV005 – Towards a New Control System for PETRA IV . . . . .	108
MOPV006 – The New Small Wheel Low Voltage Power Supply DCS for the ATLAS Experiment . . . . .	111
MOPV009 – The HV DCS System for the New Small Wheel Upgrade of the ATLAS Experiment . . . . .	115
MOPV010 – Working under Pandemic Conditions: Contact Tracing Meets Technology . . . . .	121
MOPV011 – The Inclusion of White Rabbit into the Global Industry Standard IEEE 1588 . . . . .	126
MOPV012 – The ESRF-EBS Simulator: A Commissioning Booster . . . . .	132
MOPV013 – A Dynamic Beam Scheduling System for the FAIR Accelerator Facility . . . . .	138
MOPV014 – Upgrade of the NewSUBARU Control System . . . . .	143
MOPV015 – Control System of the SRILAC Project at RIBF . . . . .	147
MOPV016 – Design and Implement of Web Based SCADA System for HUST Field-Reversed Configuration Device . . . . .	153
MOPV017 – CERN SCADA Systems 2020 Large Upgrade Campaign Retrospective . . . . .	156
MOPV018 – Linac-200 Gun Control System: Status and Plans . . . . .	161
MOPV019 – PVEcho: Design of a Vista/EPICS Bridge for the ISIS Control System Transition . . . . .	164
MOPV020 – Digitisation of the Analogue Waveform System at ISIS . . . . .	169
MOPV021 – Upgrading the National Ignition Facility's (NIF) Integrated Computer Control System to Support Optical Thompson Scattering (OTS) Diagnostic . . . . .	173
MOPV024 – vscode-epics, a VSCode Module to Enlighten Your EPICS Code . . . . .	179
MOPV025 – TangoGraphQL: A GraphQL Binding for Tango Control System Web-Based Applications . . . . .	181
MOPV026 – Integrating OPC UA Devices in EPICS . . . . .	184
MOPV027 – The Evolution of the DOOCS C++ Code Base . . . . .	188
MOPV030 – Application of EPICS Software in Linear Accelerator . . . . .	193
MOPV031 – The Deployment Technology of EPICS Application Software Based on Docker . . . . .	197
MOPV032 – Design of a Component-Oriented Distributed Data Integration Model . . . . .	202
MOPV033 – Web Client for Panic Alarms Management System . . . . .	206
MOPV034 – Migration of Tango Controls Source Code Repositories . . . . .	209
Contents	ix

MOPV035 – Development of Alarm and Monitoring System Using Smartphone . . . . .	214
MOPV036 – Porting Control System Software From Python 2 to 3 - Challenges and Lessons . . . . .	217
MOPV037 – ALBA Controls System Software Stack Upgrade . . . . .	222
MOPV039 – UCAP: A Framework for Accelerator Controls Data Processing @ CERN . . . . .	230
MOPV040 – Introducing Python as a Supported Language for Accelerator Controls at CERN . . . . .	236
MOPV041 – Modernisation of the Toolchain and Continuous Integration of Front-End Computer Software at CERN . . . . .	242
MOPV042 – PLCverif: Status of a Formal Verification Tool for Programmable Logic Controller . . . . .	248
MOPV043 – CERN Controls Configuration Service - Event-Based Processing of Controls Changes . . . . .	253
MOPV044 – Lessons Learned Moving from Pharlap to Linux RT . . . . .	257
MOPV045 – Data-Centric Web Infrastructure for CERN Radiation and Environmental Protection Monitoring . . . . .	261
MOPV047 – Upgrading Oracle APEX Applications at the National Ignition Facility . . . . .	267
MOPV048 – Fast Multipole Method (FMM)-Based Particle Accelerator Simulations in the Context of Tune Depression Studies . . . . .	271
MOPV049 – Standardizing a Python Development Environment for Large Controls Systems . . . . .	277
MOPV050 – DevOps and CI/CD for WinCC Open Architecture Applications and Frameworks . . . . .	281
TUAL02 – Development of a Single Cavity Regulation Based on microTCA.4 for SAPS-TP . . . . .	286
TUAL03 – R&D Studies for the Atlas Tile Calorimeter Daughterboard . . . . .	290
TUAR01 – Upgrade of the CMS ECAL Detector Control System During the CERN Large Hadron Collider Long Shutdown II . . . . .	297
TUAR03 – The Control System of the Linac-200 Electron Accelerator at JINR . . . . .	302
TUBL01 – Distributed Caching at Cloud Scale with Apache Ignite for the C2MON Framework . . . . .	307
TUBL02 – Implementing an Event Tracing Solution with Consistently Formatted Logs for the SKA Telescope Control System . . . . .	311
TUBL03 – Tango Controls RFCs . . . . .	317

P. Sjöblom, D. Spruce, MAX IV Laboratory, Lund University, Lund, Sweden

## Abstract

MAX IV Laboratory, the first 4th generation synchrotron located in the south of Sweden, entered operation in 2017 with the first three experimental stations. In the past two years the project organisation has been focused on phase II of the MAX IV Laboratory development, aiming to raise the number of beamlines in operation to 16. The KITS group, responsible for the control and computing systems of the entire laboratory, was a major actor in the realisation of this phase as well as in the continuous up-keep of the user operation. The challenge consisted principally of establishing a clear project management plan for the support groups, including KITS, to handle this high load in an efficient and focused way, meanwhile gaining the experience of operating a 4th generation light source. The momentum gained was impacted by the last extensive shutdown due to the pandemic and shifted toward the remote user experiment, taking advantage of web technologies. This article focuses on how KITS has handled this growing phase in term of technology and organisation, to finally describe the new perspective for the MAX IV Laboratory, which will face a bright future.

## MAX IV GENERAL STATUS

MAX IV Laboratory [1] is a synchrotron based research facility which consists of two storage rings of 1.5 GeV and 3 GeV respectively fed by a full energy linear accelerator. These two rings provide X-rays to 16 beamlines, of which 14 are today in user operation (see Fig. 1) and the remaining two will come online during the period 2022-2023.

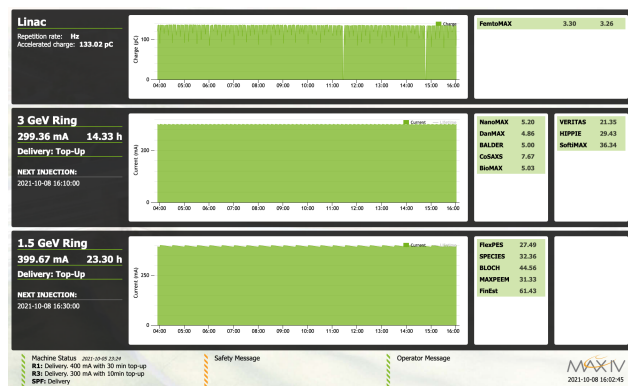

Figure 1: The Machine Status web application accessible for the public, showing all accelerators and beamlines in operation.

## Beamlines Status

The first phase beamlines have rolled out into their normal operation and the number of articles published by MAX IV compared to the previous MAX-Lab are rising (Fig. 2). Beamlines already in operation have increased their performance above the baseline, aided by the support from the KITS group.

Figure 2: Publication of MAX IV Laboratory vs MaxLab.

For example Balder has achieved a unique performance with a continuous scanning down to 30 s per EXAFS in combination with a powerful analysis software [2], opening up more experiments for environment science.

In the meantime the beamlines which started in 2020 are getting excellent commissioning results while welcoming expert user experiments, in preparation for general users. Four new beamlines have completed the portfolio of full user operation since then. After achieving baseline requirements, FemtoMAX could open its first user call with a time precision of 250 fs and enough signal to complete an experiment in a standard beamtime. Thanks to large resource investment, the X-Ray pulse of the LINAC has been upgraded to 10 Hz operation while on the beamline, a precise data acquisition system has been developed by KITS to acquire all the precious shots while applying a time-over-threshold computation within 10 ms.

In 2021 the new beamlines have started operation early 2021 with limited offer. These new phase II beamlines are increasing the global level of efficiency by profiting on new standards using more stable equipment such as the PandABox [3]. DanMAX has just finished the commissioning phase and started to accept expert Users for the PRXD experiment. In order to guarantee the expected performance of the experiment, KITS have developed a position-based hardware triggered continuous scan [4]. COSAXS started early in 2021 with a basic SAXS experiment based on time

constant continuous scan with a Eiger 4M detector. The unique Coherence properties of a 4th generation synchrotron light has been demonstrated [5] on CoSAXS which will also open unique XPCS experiments in few years. In continuous 6 months pace development, the beginning of the year brought time resolved capabilities, while WAXS is expected to be available by the end of the year.

## Accelerator Status

The 3 accelerators have been in operation since 2017 and they are continuously improving their characteristics with examples being the stability in the storage rings and the increase of repetition rate in the linear accelerator from 2 Hz to 10 Hz.

Several projects have been carried out over the past years such as X-ray beam position monitors on the front end of beamlines. New corrector magnets have been deployed and feed-forward control loops implemented to compensate the distortion in the beam orbit due to the motion of the undulators. To characterize the longitudinal phase space and slice parameters for the linac, a Transverse Deflecting Cavity (TDC) system has been developed and partly installed. This new system gives valuable information to tune beam parameters. These are some of many other projects to improve the stability and beam quality of the MAX IV accelerator.

Figure 3: The downtime of MAX IV from 2021-01-01 till 2021-10-06. Biggest downtime corresponds to RF system due to the long recovery time for RF cavity conditioning.

Since October 2020 combined Slow Orbit Feedback (SOFB) and Fast Orbit Feedback (FOFB) has been used during delivery in the 3 GeV ring, a key milestone in the machine for reaching its design goals in terms of beam stability. This system was developed between KITS and the Accelerator Development group and was the final step in this project following the implementation of a purely Tango [6]

software based SOFB, running at 10 Hz on the VM infrastructure [7]. The FOFB is implemented in custom hardware with a 10 kHz feedback loop but communicates via Tango with the SOFB in order to periodically offload the cumulative effects of the fast correctors to avoid their saturation.

The operators involved in the daily user operation have tracked and classified all the beam interruption via a web application [8]. Based on the accumulated data, and since 2020, the main efforts have been focused on tracking the Mean Time Between Failure (MTBF) which has led to different actions on the Machine and Beamline Protection System, specially to avoid human error. In 2021, the major downtime which requires a longer Mean Time To Repair corresponded to the RF section of the LINAC, mostly due to the inherent nature of time consuming conditioning, see Fig. 3. An application for accelerator failure prevention based on Machine Learning was develop to track the non obvious causes [9].

The total delivery plan for all MAX IV accelerators from the period 2021-01-01 till 2021-10-06 was 7104 hours, with a downtime of 310.68 hours. The control system represented 1.2 % of this downtime (3.72 hours) due to a control system failure over all three accelerators.

## KITS Improvement

In terms of development an important effort has been made in the last two years in a quite large number of projects. Partly due to the increased capabilities due to the growing numbers of staff, but also due to the demanding request coming from our stakeholders and the necessity of gaining knowledge to better support MAX IV needs. The following activities are the most remarkable ones.

**Hardware Standard** MAX IV has entered in the PandABox collaboration started by Soleil and Diamond synchrotron facilities. This has become a standard with so far, 20 units manufactured and 15 units deployed in the facility mainly at the endstations. The main purpose of the PandABox is synchronized triggering as they can receive time stamped bunch clock triggering from accelerators and fan it out with configurable delay. The PandABox are also often equipped with a D-tAcq 1 MSps 18 bit analog input and 25 018 kSpsbit 16 bit analog output card integrated into the 1u 19 inch rack.

With maintaining the philosophy that electronics are closely integrated with the control system software, which is a collaborative environment at MAX IV, much of the work revolves around collaborative projects, e.g. the IcePAP motor driver [10] and Em# electrometer [11].

**Monitoring** On the Hardware part, important and labor-intensive task moving into operation of a synchrotron facility is continuously monitoring and refining performance of commissioned equipment. This is done in a systematic way as e.g. described in [12] for monochromators at the soft x-ray beamlines and in [13] for many of the mirror chambers in the facility.

In general a substantial effort has been focused on the monitoring infrastructure using Prometheus and the Elastic Stack (Filebeat, Logstash, Graphana). The alarm system has the potential to profit from this ecosystem and some projects like the notification system by Android or IOS [14].

**Deployment** In terms of software infrastructure Conda [15] is also used for the deployment when system dependency does not fulfill the requirement of the application. As no decision has been made on the CentOS 8 replacement after the announce of Red Hat to change its scope, the current CentOS 7 became quickly obsolete. In addition, the continuous integration has been fully migrated from Jenkins to Gitlab pipeline.

**Detector and Streaming** Particle Detectors are the most complex piece of hardware to integrate in the experimental stations. Previously a reliance on reusing existing software meant that diagnosing problems in operation was difficult due to the lack of knowledge of the detector systems. In 2019, 2 Full Time Equivalents (FTE) were dedicated to increase the group knowledge in Particle Detectors. The major development was to focus on the data retrieval in order to match the performance of the detector and slowly gain expertise in this challenging domain.

Approximately half the KITS software effort is now spent on data acquisition (DAQ) mainly on high frame and data rate photon counting detectors. There is an ongoing effort to unify all detectors under a common data and metadata streaming standard. In term of infrastructure the architecture has been shifted from file exchange paradigm to streaming data with ZMQ over 40 Gb/s links to a central DAQ cluster (see next section). The data can be consumed directly by online processing pipelines which simplify the all process. In combination with this activity, the KITS group has validating the physics performance of the detectors, for example in site acceptance tests, and offering the beamlines support in case of issues, for example in liaising with the companies.

**Continuous Scanning** The stability of the scanning system has increased by mastering the behaviour of the detectors and simplification of the data retrieval. In order to deliver the top performance, the continuous scanning of the sample has become the standard implementation and the development has been streamlined by the use of the PandABox to manage the synchronisation between motion, triggers and I/O, consequently making the previously used delay generators and counter cards obsolete.

The accelerators have continuously made a series of changes to the insertion devices described in [16] to allow for synchronized motion between monochromators and insertion devices. With this feature fully implemented the insertion device will be integrated into the overall scan capability.

**Taranta** In the User Interface (UI) domain, web technology has started to replace the traditional desktop applica-

tions. Inspired by Taurus, a Taranta application [17] allows the user to compose themselves their dashboards by drag and drop of basic widgets. The resulting UI is immediately usable in the real control system.

**Remote Operation** During the pandemic the laboratory has been in limited operation. Remote users were supported by beamline staff working extra hours for tasks that are not automated, for example mounting samples. In some limited examples like Macromolecular Crystallography (MX), the MXCuBE web application is already prepared and facilitates the users remote interaction with the beamline. Simultaneously, a large effort went into making safe use of the hardware in remote operation on other beamlines similarly to the BioMAX beamline, which was MAX IV's first beamline to run fully remotely. For other cases, a low cost solution via remote desktop has been used for bringing the experiment control room to the users home, and being able to share the experience with a user elsewhere. Additional steps have been made to ensure the safety of the remote operation, i.e. prohibiting certain motions from happening and, preventing users from accessing critical control system parameters while being remote.

### *Kubernetes Clusters*

Various systems at MAX IV are relying on containerization technologies for a flexible and reproducible way of application management. This includes classical web-applications, computing workloads and data acquisition pipelines. With a growing demand on running containerised workloads, introducing the container orchestration was a step forward for the facility. Currently the IT infrastructure team at MAX IV is operating several on-premises Kubernetes (K8S) clusters, targeting different application vectors:

- General Services cluster based on OKD, the community upstream of RedHat OpenShift, is targeting web-services (e.g. wiki, AWX, Taranta, etc.).
- DAQ cluster with high performance bare-metal worker nodes is used for acquiring the experimental data (Fig. 4). The nodes are connected to a high-speed 40 Gbps network fabric for data ingest, another 40 Gbps for streaming data out and to the IBM Spectrum Scale (GPFS) filesystem via InfiniBand fabric.
- JupyterHub cluster nodes with GPU accelerators are used for high performance processing. Similar architecture than the DAQ cluster specific application-level feature (LXCFS) improves the user experience of resource visibility.

Infrastructure side also includes two shared HAProxy load-balancer machines with Keepalived to route the HTTP traffic mainly towards the K8S Ingress controllers.

MAX IV chose Helm Chart and GitLab CI pipelines for the application deployments on K8S. For example the “daq-pipeline” Helm Chart creates the necessary set of resources to start the data acquisition for the specified beamline, the detector and DCU network endpoints.

Figure 4: The kubernetes architecture for the Data Acquisition Cluster.

## Scientific Software

With the improvement brought by the 4th generation synchrotron, many experiments have improve the rate of their data acquisition moving the bottleneck to preparatory phase or data processing. In Macromolecular X-ray crystallography (MX) an automatic sample centring would streamline the process avoiding human intervention which is possible with a Machine Learning processing [18]. Another development in MX, FragMax [19] has been developed to speed up the interpretation of the results and to facilitate processing by running multiple user configured analysis on a set of datasets. In Small Angle X-ray Scattering and Power Diffraction, the Azimuthal Integration is the first qualitative appreciation of the raw data. A real time processing with FPGA would give substantial advantage for the User [20].

## Data Management

SciCat is database together with a web user interface to display information for the data acquisitions performed by a user. It includes a detailed set of metadata information for adding appropriate context to the experiments. Metadata keys range from common beamline parameters, the particular experiment setup but also free comments added by the user. It is under development as part of a collaboration with ESS and PSI facilities. A companion application has been developed in MAX IV, Scanlog, that provides a different user interface on top of exisiting Scicat database, the main different is that this new ui is desgined to provide a quick overview of the scans during the beamtime. It also provides some filtering so the user can customize the view. It is also possible to rate your data and write comments for a quick overview of if a scan was successful or not.

SciDog is used to choose which metadata should be stored. The beamline staff in this case, can save a configuration with selected metadata, or use all the device/attribute combinations that are in the database. This metadata is gathered

mostly by specific Sardana recorders, but there is also ongoing development to allow other beamlines to store metadata that do not rely on Sardana for data acquisition, e.g. commercial spectroscopy solutions.

## KITS OPERATION

Having three accelerators and 14 beamlines in operation has been a major change for the KITS group, together with the shift of focus toward a stable and reliable system.

The Controls groups are responsible for the development and maintenance of the experimental system formed by the stack from hardware to software component. For the operation, a system based on Kanban handle a continuous flow of high priority support tasks, representing 15 % of the Controls groups resources. While other operational maintenance represented 25 % of the resource, the figure has even rocketed during the pandemic period to rose above 50 %.

A support system has been established to answer rapidly by phone to any blocking issue regarding user operation. Each call is registered in the electronic logbook Elogy [21] in order to follow up on any critical issues.

In parallel a local contact system follows up closely the issues that arose during beam delivery. When the resolution is minor, the contact can fix it directly by documenting (case UI), by the reconfiguration the system, or by diagnosing a more complex issue. The role of this contact is important to understand the context and usage of the Control system at each beamlines and accelerators. Issues are raised to a two weeks plan revision when it involves more than one resource groups or days of work.

## Main Issues

The lab-wise issues are not quantified in regards of User beam time loss, nevertheless the issues are mainly due to the maturity of the system. The more a system is used in production, the more corner cases are solved. But the challenge comes when many beamline are operating while introducing changes e.g. a new usage, a new firmware, a new model of equipment, etc. which is often a necessity for the development of the new features. Others cause have been identified.

**Priority on the Feature** by the product owner or, in other cases, quality requirement are skipped by the accumulated delay in the project with fixed deadline. Since the development in the project phase is mainly focusing on new features, the new system appears in operation with its most optimised "happy" path.

**Behaviour of the Equipment** is the cause of many instabilities, mainly visible through the data acquisition system. After the strong focus on detectors, the focus has shifted in 2021 toward the scanning orchestration system which is the main interface for the user to generate experimental data.

**User Friendliness** is one of the main weakness of the current software solution which generates confusion by hiding the true cause of failure. Thus the importance of the

software group and the KITS contact to be present during the commissioning phase and the first experts users experiments, until the usage forces the non-nominal cases to surface. Additionally Software developers, by knowing the intrinsic details of the system, can easily accommodate with a complex user interface [22].

**Resource** of the SW group was impacted by a huge turnover while the projects management estimated 160 % of SW resource to reach the new beamlines in operation. A successful recruitment campaign was established to increase the SW staff from 12 to 18 while maintaining the effort with 4 FTE from the consultant companies S2Innovation and DVel.

### *KITs Operations Service (KITOS)*

From summer 2021 the operation support is increasing its quality of service in order to minimise the downtime of User operation. Due to the restriction of time many project were focus on the functionality of the system rather than the non-functional side like the usability and the reliability of the system, which is usual focus for the commissioning period. By consequence the operation, especially on the new beamlines, suffers from the all the non nominal cases which need a reactive support. The phenomena was multiplied by the new beamlines coming in operation at the same time. The follow up of the main important cases could help to improve the situation although the effort to cover all the cases often required synchronisation of several stakeholders. Previous choice of standard are being reconsidered to obtain a sustainable maintenance, while other are improve to follow the expectation above baseline.

On the critical path of generating data the scanning and data acquisition system is highly sensitive to the weakest element in the chain. Since most of the time the 3rd party components are hardly possible to improve, a large effort is being roll-out to increase the robustness of the Sardana, appearing like the top of the iceberg.

The concept for a KITs Operations Service (KITOS) will provide a stronger focus and wider access to expertise through a single number on support from the KITS group. Inspired by the EuXFEL this service will be dedicated only to supporting actual user operation which includes accelerator operational support, beam line commissioning and setup for experiments, but not the daily work which consists of tasks and project development activities.

The support crew of the week will be covered by two shift crews consisting of 2 people each. Members of the shift crew will be drawn primarily from the KITS team and will consist of a shift leader and shift deputy. During the initial phase it will be important to look for complementary pairings in expertise and experience for the crew, for example experienced and inexperienced. Ideally the shift crew will perform shifts over the on call period to provide continuity.

A KITS Run Coordinator (KRC) will be assigned over one week periods. The role of the KRC will be to support the KITOS and facilitate communication on a wider basis which

will allow the KITOS to prioritise supporting the accelerator and beamlines for the running experiments. Issues which arise that require more time and involvement from several parties, possibly with the scheduling of ad-hoc meetings will be addressed by the KRC. In general, the KRC cannot be a member of the shift crew while they are acting as KRC, although in cases where a shift crew member is unable to perform their duties, the KRC may step in until an alternative solution is found. KRC will attend important meetings for reporting.

The shift leader will be responsible for operational decision-making related to KITS systems during x-ray delivery, but shall seek advice from 2nd level oncall in cases of doubt. If the shift leader does not feel able to take a certain operational decision, this decision may be escalated to the KITS run coordinator. The next, and final level of escalation will be the head of KITS, or appointed substitute.

## PROJECT MANAGEMENT

The new Central Project Office (CPO) project management organisation made visible the resource demanding schedule for the beamlines' projects. With the new time plan established in 2019 the projects responsible have been able to identified what and when the resource groups could realistically work (Fig. 5). After the identification of several bottlenecks, a lab-wise priority was determined to avoid competing resource and unsustainable deadlines.

Figure 5: Evolution of the workload distribution over the years. In 2019 the new project management was established.

The new approach breaks down the projects into limited scope i.e optic installation, 1st experimental set up, etc., making the request of resource more formal. The control of feature and time at the beginning of the project introduces an overhead which become less insignificant along the timeline of the project. The enumerated specifications help to define the close-out of the project, freeing resource for the next one. On the overall the gain allows to efficiently manage the resource groups.

On the other hand small jobs don't fit the project schema, becoming very bureaucratic. Also simple request can trigger unnecessary long discussion and often complex organisation of the conception, instead of reusing the standard solution with known but acceptable drawbacks. For this purpose these small requests are routed toward the operation management with much less overhead. Newly created in 2020

the Beamline Project Advisory Group (BPAG), a group of Science Division representatives, acts as toll gate to manage the priority and appoint a dedicated manager to follow up the request with the resource groups. It's expected to streamline the process by adapting step by step the process of each resource group to the operation management.

## KITS Integration

The KITS Controls groups were involved in 28 priority projects in 2020 and 21 in 2021. The projects portfolio has included two beamlines delivered for operation per year representing approximately 25 % of the work load while the improvement of the beamlines in operation and the accelerators above baseline representing respectively 50 % and 25 %. The tight schedule to deliver the new beamlines ready for user operation in their baseline configuration was the main concerning challenge.

The new phase II beamlines projects have profited a lot of the standardisation and improvement of their optics section from the phase I beamlines. In return the new development has improved the current infrastructure which has indirectly profited to the system already in operation.

From the Control System point of view the new project management organisation settled in 2019 has allowed to increase to 1 year the visibility in term of minimal requirement and priority of projects. The development could foresee a shift in domain from control and monitoring to data acquisition.

A first approximation of the workload, made by comparing the new plan in 2020 helps to identify a 75 % (250 % including low priority request) increase of work load mainly due to the increase of required feature above baseline design of the system.

On the macroscopic view the waterfall based CPO process has been replaced by a more iterative approach in 2020, although still keeping a focus on requirement and specification in order to define the backbone milestone. The KITS Controls activities arrived late in the overall process which the Agile methodology could not compensate the risk of unclear requirement.

A lot of effort has been initiated to make compatible the global management and the local Control System project management. Figure 6 introduces a streamlined process in which a stronger focus is put on requirements and validation. In this sense, a new key role has been introduced, the beamline software owner, who is the main contact for KITS Controls for a given project, and it also must ensure that validations can be properly scheduled and completed, an issue that was not the case in the past in all cases.

In this sense the project managers have been flexible to accommodate their process to the know-unknown. For example the commissioning of the beamline end station has now been integrated into the project process which helps the quality in order to make operable a minimum viable product, although the constraint of the User call deadline at the end of the project does not cover for a full user friendly system.

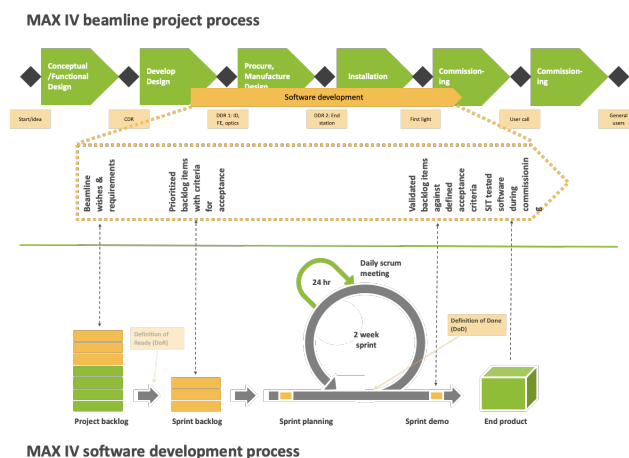

Figure 6: Workflow of SW development integrated in the global management.

During the COVID pandemic the Agile process had accumulated over several months many new features which were awaiting for validation from the requestors mainly due to the low availability of beam time. This has decreased the efficiency of the Agile method based on rapid feedback.

## Lessons Learned

The role of CPO to determine where we invest effort was definitely needed, even if it brings an overhead. It is a price to pay but we would have had difficulties without them. Looking at lessons learned regarding the CPO project structure, it is based on a fixed scope and allows very few deviations which fits perfectly with installation projects. On the other hand experimental projects need flexibility for the development of very new features. Change management with impact analysis may improve the process if working on a fixed budget and time. The CPO project management has also improved the testing phase to include a longer commissioning time to verify and validate the operation of new systems (2021).

When BPAG and CPO manage projects with a dedicated project manager (PM), the process becomes more efficient contrary to a mixed position with conflicting responsibilities.

Moving away from pure installation, it is increasingly hard to close the projects due to difficulties pinning down the scope. CPO is trying to move towards a more agile way of working. CPO is also raising the understanding among the stakeholders for the importance of timely validation, and adjusting the ambition depending on how complex a feature turns out to be. There have been examples of arbitrary closure/end point without actual commissioning. In reality, the most successful projects are the ones where the KITS contact (a member with very tight contact with the beamline needs) has played an important role as technical project leader, leaving the big picture for the project manager avoiding to be involved in the details.

The unclear responsibility of which resource group the development has been assigned to was a recurrent impediment although not identified as risk in the project organisation but

causing a substantial effort. Two major cases were identified which have caused delays, waste of resource and conflicts.

In the first case causing 3–4 months delay, resource stakeholders were identified at the start of the project but not the responsibility of the subsystem delivery which led to the reconsideration of an important standard. In order to mitigate any future issue, the PM process has been revised to include a risk assessment session to complete the kick off of a project. Also, in parallel, a technical forum has been established to identify in advance any change in the standard portfolio and assess the impact on all the MAX IV resource groups before it appears in a project timeline.

The second case happened when one resource stakeholder were not clearly identified as being part of the project which led to a competitive situation triggered by the request to multiple channels of communication. By passing the project management, the waste of resource was the direct consequence but minor compared to the indirect consequence on the MAX IV organisation. Whereas 2 resource groups should collaborate on a gray zone (shared responsibility), this led to a confused direction, protective division and resource competition between engineering and scientific concerns for which a cohesion is a fundamental for big research facility such as MAX IV. An investigation for a clear organisation of responsibility is in progress in coherence with the latest recommendation from the Swedish Research Council (VR) review committee [23].

## FUTURE

### SXL FEL

To allow the study of dynamic phenomena at the atomic and molecular scales a X-Ray free-electron laser (FEL) is necessary in order to provide X-ray beams of sufficient intensity and coherence in short enough pulse duration. MAX IV is designing a Soft X-ray Laser (SXL) beamline [24]. SXL consists of four parts: the already operating MAX IV linear accelerator, a new 40 m undulator, a corresponding beamline and a set of experimental stations. SXL thus capitalizes on the capabilities of the MAX IV linear accelerator. SXL will be placed in a building extension of the Short Pulse Facility (SPF), today housing the FemtoMAX beamline.

Figure 7: Layout of the SXL FEL line.

The Fig. 7 illustrates FEL SXL with 20 APPLE-X helical undulators, a combined phase shifter and delay chicane. This will trigger updates and new challenges for the MAX IV control system such as a more accurate timing system, synchronized motion control for all undulators, more feedback and feed-forward control loops.

### Improve Beamline Capabilities

Among the existing operational beamlines the challenge will be to continue the development of the End Stations' increased capabilities and then new upcoming sample environments. This requires a more streamlined experimental orchestration synchronization with the data acquisition in order to achieve higher rates. Moreover, new sample environments demand a user friendly setup change which in turns requires an increased stability of the overall control system.

Two new beamlines are already in advanced phase of development. They will both bring a high challenge to KITS. MicroMAX [25] aims at improving further data acquisition capabilities for Macromolecular Crystallography (MX) at MAX IV, expanding the current MX capabilities with new SSX techniques as well as a new high performance detector Jungfrau [26]. A high degree of automation and complex web user interfaces are required, as well as increased capabilities of the existing computing infrastructure. ForMAX will offer to the users full-field tomographic imaging with small- and wide-angle x-ray scattering focused on wood related materials. The fast acquisition not only requires the capability of ingesting a high data rate and volume, but is also needs to provide very precise synchronization on the acquisition axis.

New detectors and techniques will require dedicated and specialised efforts, for example:

- measuring and applying count rate correction.
- gaining expertise in FPGA frame grabber for the tomography cameras.
- rethink the DAQ architecture for ever higher rates, e.g. for the Jungfrau with dedicated 100G connection.

Just as trying to standardise the DAQ, all these subjects needs custom solutions and deep knowledge of each system, from the hardware to the scientific processing which challenges the organisation of the KITS group.

## ACKNOWLEDGMENT

The authors would like to thank the whole of the Controls and IT (KITS) group, the Beamline Office and the Accelerator Deputy at the MAX IV Laboratory, along with the physicists, engineers and beamline staff, without the collaboration of whom this work would not have been possible. The authors also appreciate the support of the Knut And Alice Wallenberg foundation for funding the DataSTAMP project.

# STATUS OF THE NATIONAL IGNITION FACILITY (NIF) INTEGRATED COMPUTER CONTROL AND INFORMATION SYSTEMS

M. Fedorov, A. Barnes, L. Beaulac, G. Brunton, A. Casey, J. Castro Morales, J. Dixon, C. Estes, M. Flegel, V. Gopalan, S. Heerey, R. Lacuata, V. Miller Kamm, M. Paul, B. Van Wonterghem, S. Weaver, Lawrence Livermore National Laboratory, P.O. Box 808, Livermore 94550, CA

## Abstract

The National Ignition Facility (NIF) is the world's most energetic laser system used for Inertial Confinement Fusion (ICF) and High Energy Density Physics (HEDP) experimentation. Each laser shot delivers up to 1.9 MJ of ultraviolet light, driving target temperatures to more than 180 million K and pressures 100 billion times atmospheric, making possible direct study of conditions mimicking interiors of stars and planets, as well as our primary scientific applications: stockpile stewardship and fusion power. NIF control and diagnostic systems allow physicists to precisely manipulate, measure and image this extremely dense and hot matter. A major focus in the past two years has been adding comprehensive new diagnostic instruments to evaluate increasing energy and power of the laser drive. When COVID-19 struck, the controls team leveraged remote access technology to provide efficient operational support without stress of on-site presence. NIF continued to mitigate inevitable technology obsolescence after 20 years since construction. In this talk, we will discuss successes and challenges, including NIF progress towards ignition, achieving record neutron yields in 2021.

## INTRODUCTION

The National Ignition Facility is a large (3 football fields) and complex (192 laser beams) experimental physics system (Fig. 1) [1]. It is efficiently operated 24x7 by a shift of the 12-14 Control Room operators with the help of the Integrated Computer Control System (ICCS). Over 66,000 devices with rich APIs are distributed over 2,300 front-end-processors (FEPs) and embedded controllers (ECs).

Figure 1: NIF building layout.

NIF experiments are structured around laser shots. Each shot takes 4-8 hours and involves the control system to execute over 2 million device operations.

Experiments at NIF support several programmatic missions, such as Stockpile Stewardship, Discovery Science, National Security Applications, and Inertial Confinement Fusion (ICF). For ICF, thermonuclear ignition has been the

long-term goal of the facility, defined as producing more energy from the DT target fusion than the 3w laser energy on the target (for example, 1.9 MJ). The NIF was pursuing the ignition goal for almost 10 years, and it proved to be a scientific and engineering challenge. During 2011-2020, the target energy yield maxed at about 50 kJ, well below the ignition goal.

## UNEXPECTED INTERRUPTION

The NIF's quest for ignition and scientific discovery was abruptly interrupted when in March of 2020 a "shelter-in-place" order was issued at our location to quench a spike of COVID-19 infections. Facility shifted to minimal safe operations, shots paused, and the Control Room staff reduced from 14 to 3 operators. Controls and IT teams have supported the change, assuring continuity of operations of the networks, hardware and ICCS in a non-shot, monitoring mode.

Figure 2: NIF Control with COVID-19 personnel protections: plexiglass screens, masks, traffic barriers.

Soon after the U.S. Center for Disease Control (CDC) recommendations became available, the NIF started to reorganize facility operations. Ventilation flows were adjusted, plexiglass screens between the consoles were installed and personnel traffic was directed with barriers to assure social distancing of at least 7.5ft (Fig. 2,3). Our teams have supported gradual restoration of normal shot operations, by May 2020. Quick restart of experiments was welcomed by the U.S. National Nuclear Security Administration [2,3].

While initially the restarted operations progressed slowly and deliberately, soon the shot rate had ramped up to normal, and control teams had to address the need for support and maintenance activities such as ICCS releases. Traditionally, for major software releases as well as testing and troubleshooting, ICCS software engineers were

present in the NIF Control Room (Fig. 4). Now, with the Control Room access limited to operator shift only, and most of the software groups and IT teams working remotely from their homes, we had to come up with new processes and tools.

Figure 3: Access to the Control Room is restricted.

Control software engineers, in collaboration with IT, have enthusiastically explored remote access and collaboration tools available on our enterprise networks.

Figure 4: Before COVID-19, ICCS software engineers can often be seen joining operators in the Control Room.

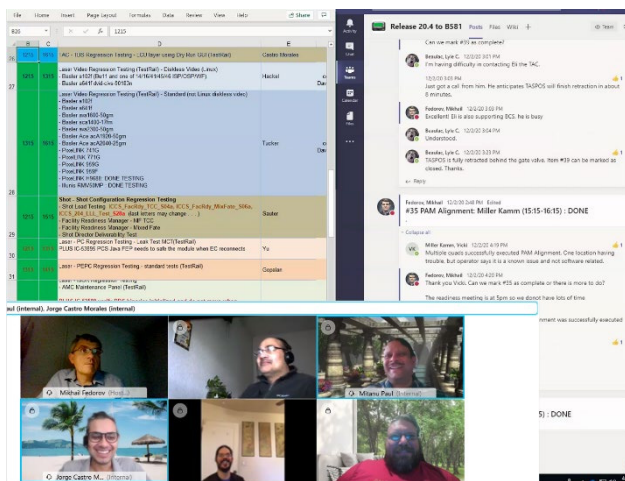

Figure 5: New all-remote software release process.

Our team has settled on Cisco WebEx for remote teleconferencing (similar to Zoom), Microsoft Teams for persistent group chat (similar to Slack) and Microsoft Office

365 for distributed “cloud” collaboration (similar to Google Docs). Both software release coordination and off-hours support have moved to these platforms (Fig. 5) [4].

## EXPANDING LASER AND DIAGNOSTICS CONTROLS CAPABILITIES

With COVID-19 concerns addressed and mitigated, the control teams have returned to their primary mission of expanding and maintaining capabilities to the benefit of the NIF programmatic missions.

### Target Diagnostics Controls

The NIF is well equipped with target diagnostic instruments to capture laser-target interactions in time and space using various bands of electromagnetic spectrum and particles. Over 87 of the active target diagnostics are controlled by ICCS software control system, combining over 600 rich API devices of 55 types (cameras, oscilloscopes, alignment, etc.).

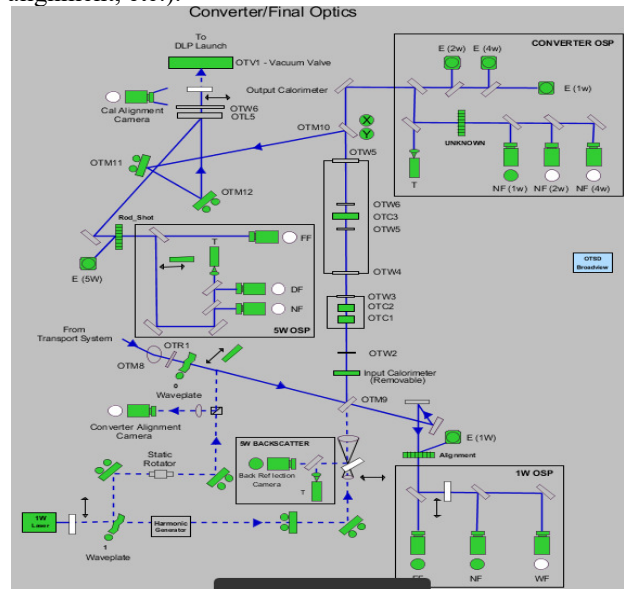

Figure 6: One of user interface panels developed for new Optical Thomson Scattering (OTS) Laser and Diagnostic.

Several new diagnostic instruments, of varying complexity, are being added to ICCS every quarter. One of the most sophisticated, the Optical Thomson Scattering (OTS), combines a high-power 5w deep ultraviolet (UV) 210 nm laser with a set of spectrometers to serve as a “plasma laser probe” (Fig. 6, 7)

Figure 7: OTS instrument.

The design of the OTS control system and its alignment algorithms are covered by separate presentations at this conference [5,6].

## Laser Diagnostics Controls

While ICCS Target Diagnostics capture a variety of data about behaviors of the targets, it is equally important to precisely characterize the “driver”, the 3w laser light which compresses NIF targets. Due to the design of Final Optics Assemblies (FOAs), the conversion of light from infrared 1w to ultraviolet 3w happens right at the vacuum windows where beams enter the target chamber. While a fraction of the converted 3w light is split off and delivered to ICCS diagnostics, it was a long-standing question how precisely these measurements correspond to energy of light on the target.

New Target Chamber Calorimeter (TC-CAL) was designed to obtain the energy measurements by placing a set of NIST-calibrated calorimeters into the target chamber, with a pinhole to separate 3w from unconverted 1w and 2w light (Fig. 8).

Figure 8: Target Chamber Calorimeter.

TC-CAL is a large (4.5 m+) and heavy (350 kg) mechanical device. ICCS developed a precise motion control and alignment system based on ATLAS [7], achieving excellent alignment of beams on the calorimeters, confirmed by a built-in alignment video camera.

Figure 9: Layout of Precision Diagnostic System.

Another approach to study the 1w light and non-linear process of conversion to 3w is to redirect a full 40 cm x

40 cm NIF laser beam into the specialized lab, Precision Diagnostic System (PDS), (Fig. 9). PDS was recently reactivated, adding over 400 control devices. In addition, a new motorized mirror pickoff was implemented, so a selected beam is automatically routed for a detailed characterization by calorimeters, oscilloscopes, cameras, and spectrometers on multiple 1w and 3w diagnostic tables.

## Expanding Laser Master Oscillator Controls

In addition to diagnostics, the laser pulse generation continued to improve as well. In ICCS architecture, the Master Oscillator Room (MOR) subsystem is responsible for the devices which generate the initial fiber laser pulse, and then shape it in time and space. For some experiments, it is desirable to have independent wavelength (or “color”) control of NIF laser beam cones. In 2020, we have added a fourth master oscillator, for Outer 50 cones (Fig. 10).

Figure 10: New dedicated laser wavelength “color” was added for Outer 50 cone of laser beams.

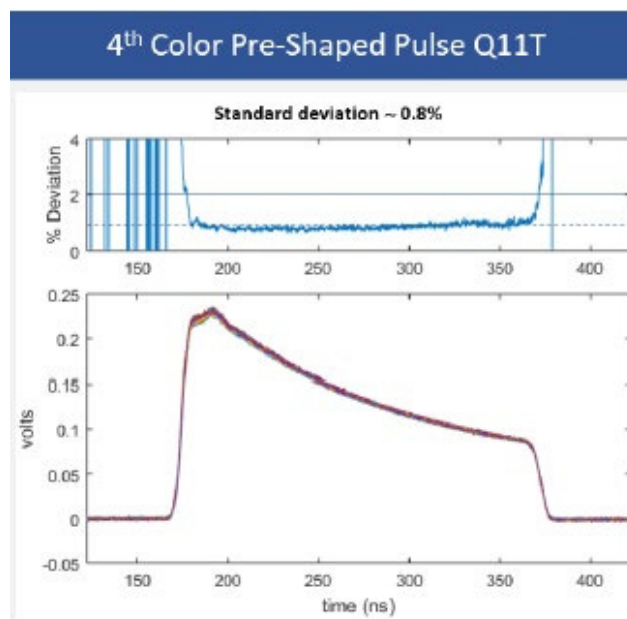

Figure 11: Laser pulse shape stability shot-to-shot improved 3X with the completion of 4th Color project.

Once the new hardware components and new enhanced design, the Pre-Shaped Pulse Generation (PSPG), were utilized, the effort also resulted in 3X improvement in shot-to-shot stability of the laser pulse shapes (Fig. 11) [8].

The precision of the laser pulses, their reproducibility and energy balance are critical for the quality of scientific data produced by NIF. These efforts will continue, with the next phase of the High-Fidelity Pulse Shaping (HiFiPS) effort starting in 2021-22. The software development work is already underway to develop low-level interfaces for new pulse shaping hardware, to fine-tune new shaping algorithms. The goal is to achieve 4X better short-term pulse shape stability, and better than 0.5% accuracy of actual waveform relative to the requested.

### Recent Achievements

The multi-year efforts by NIF, LLNL and the broad scientific community to better understand and control ICF processes continue to pay off. The progress towards the ignition goal was remarkable this year, breaking both 100 kJ and 1 MJ fusion energy barriers.

The most recent record shot on August 8, 2021, produced over 1.3 MJ of fusion energy, putting researchers at the threshold of ignition (Fig. 12) [9].

Figure 12: Recent progress toward ignition goal.

### LONG-TERM SUSTAINMENT

Multiple priorities are driving control system organizations at large experimental physics facilities: assuring high 24x7 availability, continuous expansion of capabilities, and efficiency optimizations to produce even more high-quality data. And since our facilities represent significant investment of public funds and human capital, we also need to assure that facilities will continue to produce knowledge for the next 10-20 years.

Increasing uptick in failures of aging hardware, and obsolescence of computing platforms call for a broad technology refresh effort. By 2020, NIF ICCS software team has successfully completed a multi-year effort to migrate from legacy Ada 95 codebase to Java, from PowerPC VxWorks and Sun Solaris to Intel Linux – all without stopping 24x7 facility operations [10].

Our focus for 2020-2021 is to migrate hundreds of NIF video acquisition systems from proprietary Windows software to Linux, employing open-source FireWire and GigE drivers, making these systems diskless for high availability, consistency, and cyber security [11].

Looking further, we will be migrating a variety of NIF embedded controllers from aging PC104/VxWorks units to a modern, small factor platform. To support a broader range of R&D laser projects within Photon Sciences, we have proposed and continue to advance a lightweight framework for distributed LabVIEW-based control systems [12].

### CONCLUSION

The NIF control systems teams: hardware, IT and software have successfully mitigated the unexpected challenge of COVID-19, adapting to “New Normal” with more health protections, social distancing, and remote work.

Broad and deep 10-year investigation of the most fundamental behaviours of laser, plasma and target interactions has started to pay off, with fusion energy outputs rising, bringing NIF to the threshold of thermonuclear ignition.

Increased neutron yields attach new urgency to already planned sustainability efforts. Some of the video camera systems in the Target Bay will need to be replaced sooner than originally planned: the Target Alignment System (TAS 2.0), Chamber Center Reference (CCRS), Final Optics Inspection (FODI).

NIF entered a new experimental regime of much higher fusion yields, requiring a new generation of time-resolved diagnostics, such as Magnetic Recoil Spectrometer (MRSt).

### ACKNOWLEDGEMENTS

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. Document number: LLNL-CONF-827321

## Abstract

The Square Kilometre Array telescopes have recently started their construction phase, after years of pre-construction effort. The new SKA Observatory (SKAO) intergovernmental organisation has been created, and the start of construction ( $T_0$ ) has already happened. In this talk, we summarise the construction progress of our facility, and the role that agile software development and open-source collaboration, and in particular the development of our TANGO-based control system, is playing.

## INTRODUCTION

The Square Kilometre Array (SKA) is an international project that has the aim of building two multi-purpose radio telescope arrays. One of them will be built in South Africa in the Karoo desert, and the other will be constructed in the Murchison Shire in Western Australia. The name comes from the initial intention for these telescopes to provide the equivalent collecting area of at least one square kilometre, and thus unprecedented sensitivity, which would allow key questions in modern astrophysics and cosmology to be answered.

The original *Hydrogen Array* concept of an array that was sensitive enough through a very large collecting area of up to one square kilometre was described by Peter Wilkinson in 1991 [1]. One of the main concepts took the name of the Square Kilometre Array project, and several milestones were achieved in order to make this project a reality.

After several forms (from an interest group to the International SKA Project Office, later the SKA Project Office in Manchester University), and several EU framework programs (SKADS, the SKA Design Study; PrepSKA, preparation for SKA), the SKA Organisation was founded in November 2011 as a non-for-profit limited responsibility company established in England and Wales.

As part of SKADS, the first SKA Science book was published in 2004 [2]. After the official start of the SKA Pre-Construction in 2014, an update to the SKA science book was published [3] in 2015 after a decade of development of the SKA concept, incorporating more than 130 scientific use cases that will be possible thanks to the SKA telescopes.

Those science cases cover Galaxy Evolution, Cosmology and Dark Energy<sup>1</sup>, Strong-Field Tests of Gravity<sup>2</sup>, Cosmic Magnetism<sup>3</sup>, The Cosmic Dawn and the Epoch of Reioni-

sation<sup>4</sup>, and research on the Cradle of Life<sup>5</sup>. The amount of physical disciplines foreseen to be encompassed by the SKA telescopes is one of the largest for any ground based facility to date.

The SKA project is currently in what is known as SKA Phase 1, or SKA1, in which two telescopes approximately with 10% of the target collecting area are being built, namely SKA1-Mid, and SKA1-Low, in order to prove the feasibility of the techniques and derisk the construction of the next phase of the project, SKA Phase 2, or SKA2.

The goal is to have a single observatory entity, that will construct and operate two SKA1 telescopes (SKA1-Mid and SKA1-Low), with presence in three sites: Australia (SKA1-Low), South Africa (SKA1-Mid), and United Kingdom (Headquarters and central operations).

This talk focuses on the progress and status of the SKA project from our last status report [4] in ICALEPCS'17. It starts by describing how we have migrated from the SKA Organisation and pre-construction towards the SKA Observatory (SKAO) in FROM SKA TO SKAO AND START OF CONSTRUCTION. We later indicate the role of software in the SKA project in SOFTWARE IN THE SKA PROJECT, and we provide an update on the status of our efforts in CURRENT STATUS. We continue by describing the difficulties that we have been facing up to the start of construction in CHALLENGES, and we describe future work in NEXT STEPS, with some short CONCLUSIONS at the end.

## FROM SKA TO SKAO AND START OF CONSTRUCTION

As indicated in Sec. Introduction, the Hydrogen Array concept was first published in 1991. Several studies were made to come with a concept for the realisation of that square kilometre array, and in 2008 the EU Framework Programme called SKA Design Studies (SKADS) was started, and then followed by PrepSKA. After PrepSKA, the SKA Organisation was founded as a non-for-profit, limited liability company registered in England and Wales, but it also set in motion the process for finding what would be the ultimate legal form for the SKA Observatory (SKAO), and it was finally decided that an Inter-Governmental Organisation (IGO) was the way to go.

After PrepSKA, which set up the first contacts towards the IGO, the first round of negotiations towards the SKAO IGO took place in October 2015. Several rounds of negotiations

\* juande.santander-vela@skao.int

<sup>1</sup> <http://skatelescope.org/galaxyevolution/>

<sup>2</sup> <http://skatelescope.org/gravity-einstein-pulsars/>

<sup>3</sup> <http://skatelescope.org/magnetism/>

<sup>4</sup> <http://skatelescope.org/cosmicdawn/>

<sup>5</sup> <http://skatelescope.org/cradle-life/>

where required, and they culminated with the signature of the SKAO Treaty in Rome in March 2019.

For the treaty to enter into force, it was required that the three site countries (UK, Australia, and South Africa) had to ratify the treaty, plus two more countries. The process was finally complete with the ratification of the Treaty in December 2020, and the entry into force of the Treaty happened in January 15th, 2021.

After that, the first SKAO Council met on February 4th, 2021, setting up the way for the acquisition of the assets of the SKA Organisation, with personal transferred through the TUPE process. All company assets and staff were transferred to the IGO in May 1st, 2021.

All of this process can be seen in detail in Fig. 1.

In June 2021 the SKA1 Construction Proposal (CP), and the SKA Observatory Establishment and Delivery Plan (OEDP) were submitted by the SKAO Director-General with a recommendation for approval by the Council. The CP describes the science requirements for the project; what the scope of the project is; how the project will be executed, monitored, and controlled; wider benefits of the project to society; and a guide to the detailed project documentation, reference information, and its organisation; whereas the OEDP details staffing and costs for the SKA Observatory own delivery and supporting functions: Business enabling functions, Observatory operations, Observatory development, and Construction support. The Council approved both documents, and hence the start of construction ( $T_0$ ) took place on July 1st, 2021.

## SOFTWARE IN THE SKA PROJECT

Software plays a major role in the SKA project. A notional data flow view of the two telescopes is shown in Fig. 2. In there, some of the major blocks of the telescope requiring software are displayed:

- The Science Data Processor for both telescopes includes the real-time ingest of the data being generated by the whole of the array. This is a big-data stream of up to 9 Terabits per second, and apart from the ingest of the bulk data and its relevant metadata, some real-time calibrations need to be executed in pseudo-realtime. Moreover, the system uses batch processing on those datasets to produce science-ready data for the network of SKA Regional Centres (SRCs) to proceed and deliver to our Principal Investigators and Co-Investigators.
- The SRCs themselves are supercomputing facilities that need to be able to perform High-Performance Computing analysis on demand from the community of SKA researchers.
- The Central Signal Processor are supercomputers in their own right, but instead of being general purpose they are mostly concerned with floating-point Multiply and Accumulate operations in support of Fast-Fourier

Transform of the data, implemented as Field Programmable Gate Arrays (FPGAs). The firmware/bitimages that configure those FPGAs are also being managed through the same software processes as the rest of our software.

In addition, two more large systems are software systems: the Telescope Management and Control (TMC) system is the control software that orchestrates and manages our telescopes, and is based on TANGO; and the Observatory and Science Operations (OSO) systems is the interface for researchers to submit observation proposals, and then convert them into the Scheduling Blocks that will be run by the TMC in order to carry out the observations.

## CURRENT STATUS

As indicated in Sec. From SKA to SKAO and Start of Construction, the Construction phase has just started, but for software – including the SKA telescopes' control system – the development started in August 2018, using the bridging phase between pre-construction and construction to derisk our development processes and code. From that time until July 1st, 2021 we have gone already through ten full Program Increments, and the first PI to be partially in the construction phase was PI11, with PI12 – our current PI as of the writing of this article – being the first one fully within the SKA Phase 1 (SKA1) construction phase.

We are using the Scaled Agile Framework<sup>6</sup> (SAFe®) as the version of agile to be scaled to the needs of the SKA1 construction project. SAFe groups agile teams into Agile Release Trains (ARTs). Each ART is built around a stream of value to be delivered. Initially, we started with a single train, which delivered all software required for the SKA telescopes. When the number of people and teams increased, we moved to two trains: one of them delivering the value for the Science Data Handling and Processing (SDH&P) part, and another one for Observation Management and Controls (and Correlation; OMC). In PI11, we soft-launched a third ART, the Services ART, which provides value to both the DP and OMC ARTs in the form of System services (development platform, versioning, continuous integration and continuous delivery), Platform services (definition and furnishing of the middleware that helps run all software, such as Kubernetes or Open Stack), and Networking services.

Key to the success of our software developments is providing a joined up Vision of what we want to deliver. And we update that Vision to the nearest horizon that is useful for our teams. There are 5 main milestones for the SKA telescope development, that we call Array Assemblies (AAs). In our initial roll-out plan, we had four AAs (AA1 to AA4). However, it was decided that an earlier integration testing point should be considered, and we call that milestone AA0.5.

Table 1 provides information on the different AA milestones, together with the capabilities that we expect to be

<sup>6</sup> <https://scaledagileframework.com>

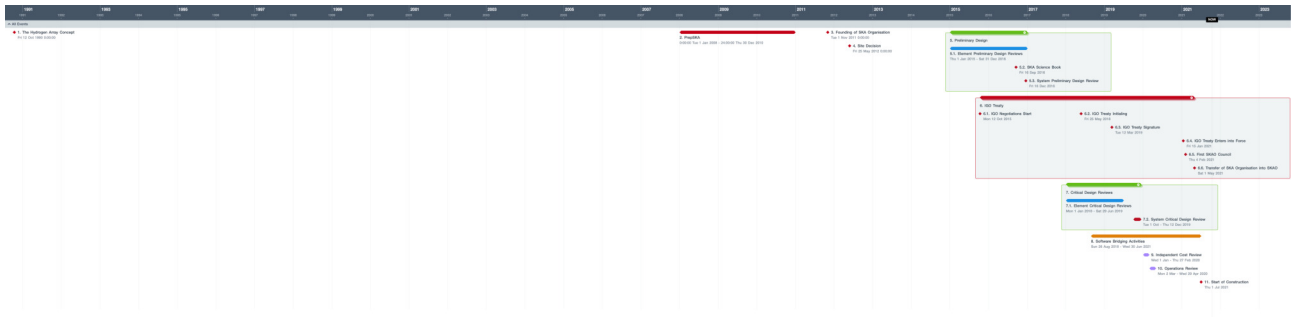

Figure 1: Timeline of the SKA project pre-construction phase. The earliest milestone took place in 1991 with the first concept of *The Hydrogen Array*. The boxes in green represent the design phases, while the items in read represent progress towards the establishment of the SKA project and the SKAO IGO. The final date for the pre-construction phase is  $T_0$ , the Start of Construction.

able to test for each one, and when we currently expect to finish those milestones.

Table 1: Sensing elements per Array Assembly

Milestone	Sensing Elements	
	Mid	Low
AA0.5	4	6
AA1	8	16
AA2	64	64
AA3	121	256
AA4	197	512

In the same vein of early testing, we started developing and planning the SKA software with our first Program Increment (PI1) in December 2018. The decision was to create a Minimum Viable Product (MVP) in the sense of Eric Rees [5]: the minimum set of features that can solve a problem and that allows learning from early adopters to be incorporated. In this case, our MVP is for the first integration prototype, and we named it the SKA MVP Product Integration, or SKAMPI.

An important part of SKAMPI is the support of the Continuous Integration/Continuous Deployment pipelines in order to test and verify our software. The work done so far is summarised by Matteo Di Carlo [6] in this conference.

The development of SKAMPI in paraticular, and of all SKA software in general, needs to address the needs of each of the AAs indicated in Table 1. To indicate what needs to be done in each moment, we have developed a Solution-level roadmap, which is updated at least every PI. And starting in PI11 we are also developing a joint TDT-level roadmap, that is then interpreted at software level. However, we have not yet managed to provide that joined up TDT/Solution-level roadmap view. The closest we have is the Solution level roadmap that can be seen in Fig. 3.

That roadmap follows three main development streams:

- **SKAMPI development:** This stream includes all development effort required to provide working, useful SKAMPI software at each stage.

- **SKAMPI integration support:** This stream comprises development effort required to help the Assembly, Integration, and Verification (AIV) teams to test the SKA hardware and software.

- **Architectural Runway:** This final stream includes all development effort required to incrementally change the architecture of the software to address the needs of each of the individual AAs.

As indicated at the beginning of this section, we are currently executing PI12, and preparing the backlog and features to be planned in PI13, to be held in December 2021.

## CHALLENGES

During the pre-construction PIs, and in this first construction PI, we have faced several challenges:

- Using TANGO in an event-oriented way
- Containerisation and Orchestration
- Computing Scaling
- Team Scaling

### Using TANGO in an Event-Oriented Way

Most facilities using TANGO for control rely heavily on polling, as they control hardware systems for which it is expensive to obtain many of the monitoring values that might be required.

For SKA software, many of the controlled entities are other TANGO DeviceServers (DSs), and below those DSs additional software exists, which can easily change and/or generate values as required. In those cases, it is preferred to have an event-based system, in which data is only updated when an change-event is required.

Most SKA software has moved away from polling, and this has found some edge cases around the TANGO event mechanism, and the need for more TANGO expertise, and potentially the ability to contribute to change the TANGO event engine is required.

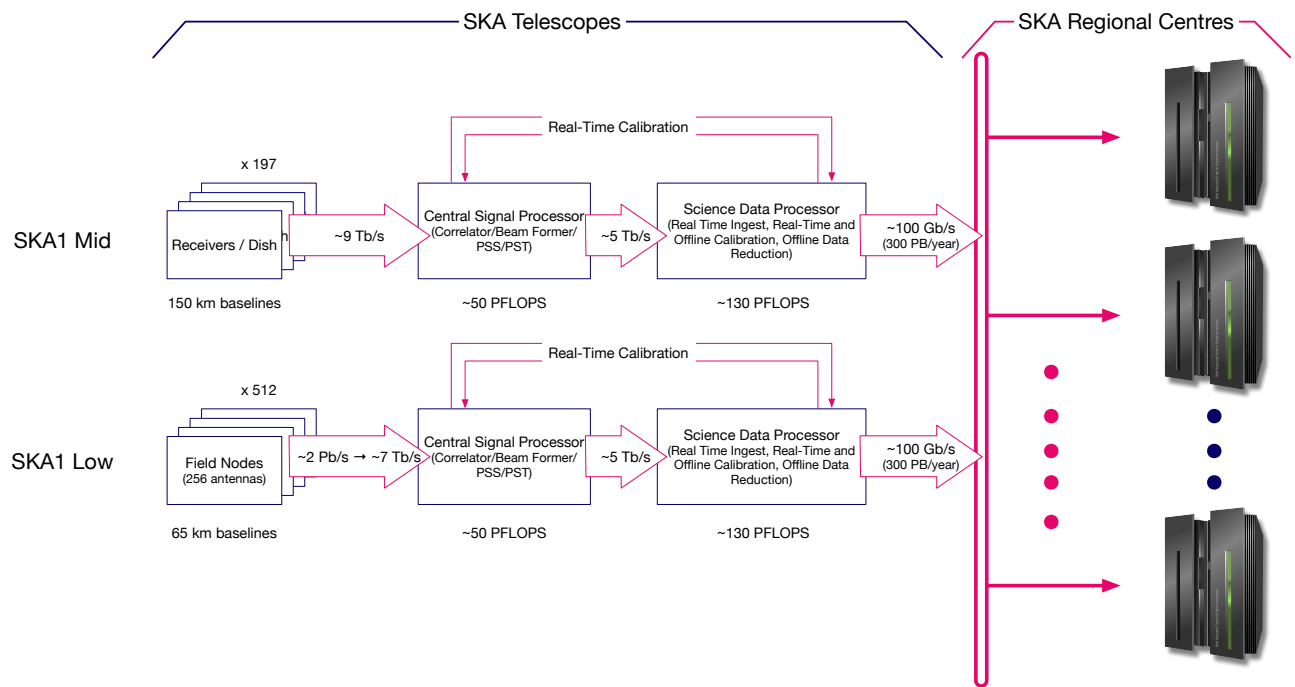

Figure 2: Notional data flow of the two SKA1 telescopes, SKA1-Mid and SKA1-Low. The different maximum bandwidths for each flow are shown in each arrow. The data generated by the telescopes is distributed to the network of SKA Regional Centres which are not in the scope of the SKA1 construction project.

There are additional issues coming from the interaction of the event system with containerisation and orchestration, but we will discuss those in the next subsection.

To try to resolve those issues, we have hired a new member of staff at SKAO that will contribute 50% of their time to support the TANGO kernel, while providing additional TANGO development support to the teams. This is part of SKAO's contribution to the TANGO Collaboration, since we joined in October 2017.

We have also developed ways to log and trace events, as indicated by Samuel Twum [7] in this conference.

### Containerisation and Orchestration

In order to be able to scale the execution and deployment of SKA software, and to orchestrate both its deployment and runtime environment, we are using Open Container Initiative (OCI) containers<sup>7</sup> – although we started with Docker<sup>8</sup> containers. For orchestration, we started using Docker Compose<sup>9</sup>, but we have recently moved to use Kubernetes<sup>10</sup> (K8s), and Helm<sup>11</sup> charts for managing all packaging, deployment, and software sequencing.

Figure 4 shows the different labeled groupings of software, and how they are mapped into services, pods, and containers. Currently, a single TANGO DS leaves inside a container.

<sup>7</sup> [urlhttps://opencontainers.org](https://opencontainers.org)

<sup>8</sup> <http://docker.com>

<sup>9</sup> <https://docs.docker.com/compose/>

<sup>10</sup> <http://kubernetes.io>

<sup>11</sup> <https://helm.sh>

We are currently being challenged by the learning curve of K8s and Helm for some of our developers. This is another instance in which having an standardise approach within the TANGO community will be beneficial, and SKAO would like to foster such an outcome.

### Computing Scaling

As indicated in the previous subsection, we are currently using a 1:1 mapping between containers and TANGO DS, but also a 1:1 mapping between DSs and TANGO Devices. However, that granularity seems to impose a high-overhead, and we are looking into how to better combine DSs within containers, and Devices within Device Servers.

We are also finding some issues in how to express some of the dependencies, and linkages, through the Helm charts, to that we can properly map software releases, and combine them into a single product.

### Team Scaling

The last challenge has to do with how our software development processes are scaling.

A large infrastructure project such as the construction of the SKA telescopes requires strong project management skills, and fixing a number of milestones to ensure proper monitoring of the progress. There is an Integrated Product Schedule (IPS) which is the source of truth for the major project milestones, and includes both schedule and costing information.

Converting that IPS into actionable information for the software development teams requires a lot of bandwidth

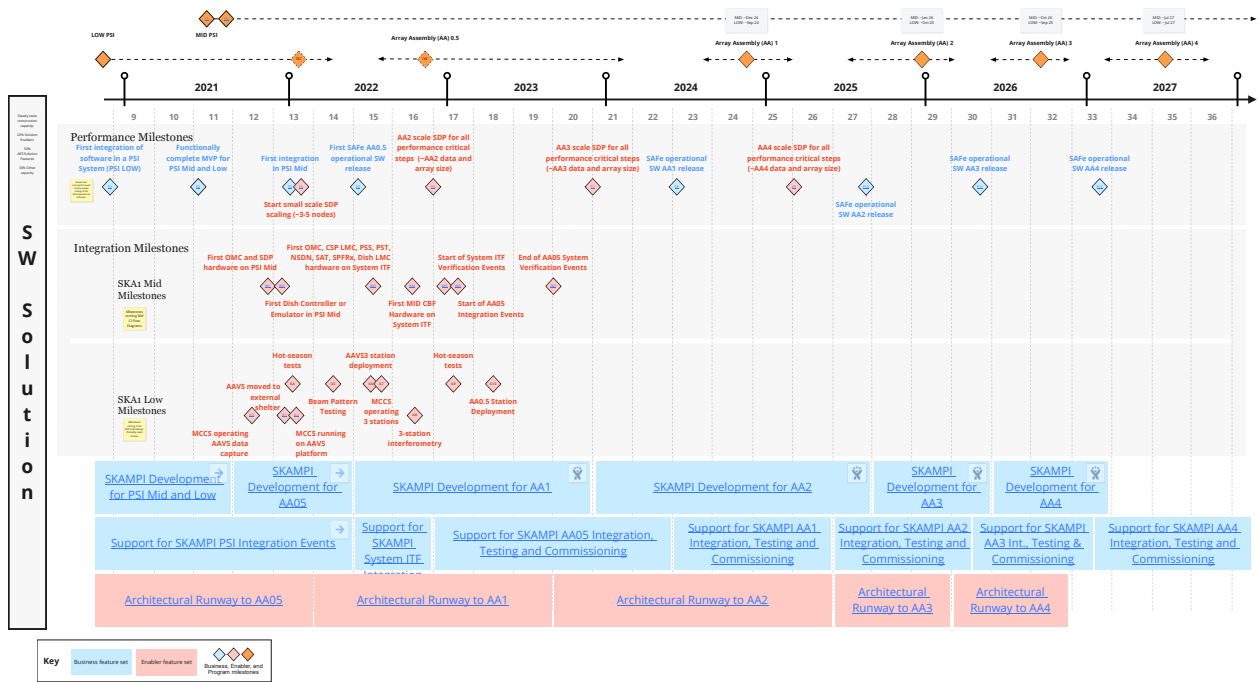

Figure 3: Long term Software Solution roadmap for all SKAO construction, and part of the pre-construction. Each Program Increment (PI) corresponds to 13 weeks, so there are exactly 4 PIs per year, and each PI planning event tends to happen within the same week every year, which helps with the predictability for the dates. The rhombs above the years corresponds to milestones that have to do with the telescope roll-out plans: PSIs stand for Prototype System Integrations. AA stands for Array Assembly, and each Array Assembly corresponds to increased number of equipment delivered, and additional capabilities. Performance Milestones have to do with when particular levels of performance, or non-functional requirements (NFRs), need to be met, in order to achieve the right level of performance when delivering the final system. Integration Milestones, on the other hand, indicate when particular functionality of the software needs to be available because of integration and testing requirements. The bottom row corresponds to three lanes of work: a) development stream of the SKA Minimum-viable-product Prototype Integration (SKAMPI); b) support stream of the usage of SKAMPI in several environments, including the AAs; and c) changes and evolution required in the software architecture related to the requirements of the different AAs.

between the TDTs and the software teams, and is something that we are working on to improve.

We are also starting to develop better rules for contribution and release management, that we expect to have in place soon.

## NEXT STEPS

In order to address the previously outlined challenges, we are working to improve the communication and alignment between the IPS and the Software Roadmap: we start of TDT Planning as part of PI planning is helping with that, and we have also started to run dedicated roadmap alignment workshops to make sure that all dependencies and team needs are surfaced well ahead of PI planning.

We are also finishing with the qualification of suppliers, so that we can start proper contracting under construction funds, and finally move from bridging to construction funding.

Some of the issues with both Team Scaling and Computing Scaling have to do with lack of appropriate funding of effort to the System and Platform teams. We expect that

setting up the contracting framework should help with this, by both accessing *in-kind*, and commercial contributors to these teams.

Finally, we will keep iterating on our TANGO base software (as described by Sonja Vrcic [8] in this same conference), and keep iterating our MVP of Product Integration in order to move to the first releases of proper SKAO Telescope Software.

## CONCLUSIONS

The construction phase that will deliver the transformational SKA telescopes has just started. After passing  $T_0$  in July 1st, 2021, we have already issued several contracts for construction ( $C_0$ ), but have also already been taking advantage of bridging funding in order to kickstart the development of the software. We have found some challenges, but we are doing so at the very start of the project, which makes it easier to resolve. We expect to be able to deliver our software on time, and to the satisfaction of our customers,

which are primarily the AIV and Commissioning and Science Verification (CSV) teams.

## ACKNOWLEDGMENTS

J. Santander-Vela wants to dedicate this paper to the memory of his recently passed-away father-in-law, Mr. Demetrio Sababa. He also wishes to acknowledge the work of all SKAO engineers, and the support of the co-authors.

# MODERNIZING THE SNS CONTROL SYSTEM\*

K. S. White†, K. Kasemir, K. Mahoney, K. Vodopivec, D. Williams,  
Oak Ridge National Laboratory, Oak Ridge, USA

## Abstract

The Spallation Neutron Source at Oak Ridge National Laboratory has been operating since 2006. An upgrade to double the machine power from 1.4 MW to 2.8 MW is currently underway and a project to add a second target station is in the preliminary design phase. While each project will add the controls needed for their specific scope, the existing control system hardware, software, and infrastructure require upgrades to maintain high availability and ensure the system will meet facility requirements into the future. While some systems have received new hardware due to obsolescence, much of the system is original apart from some maintenance and technology refresh. Software will also become obsolete and must be upgraded for sustainability. Further, requirements for system capacity can be expected to increase as more subsystems upgrade to smarter devices capable of higher data rates. This paper covers planned improvements to the integrated control system with a focus on reliability, sustainability, and future capability.

## BACKGROUND

The Spallation Neutron Source (SNS) is an accelerator-based neutron facility that provides the world's most intense source of pulsed neutrons for research. The machine was originally commissioned in 2006 and began operating for users in 2007. The facility was constructed by a collaboration of six laboratories who delivered controls along with their systems. The SNS Controls Group was responsible for global systems, control system infrastructure and integration of the partner contributions to create a single Integrated Control System (ICS) [1]. Hardware and software standards were adopted for the control system including the selection of the Experimental Physics and Industrial Control System (EPICS) toolkit for control, communication, and operational services. Using EPICS then allowed a diverse set of hardware to be integrated into a cohesive system.

The client/server architecture of the SNS control system consists of three layers shown in Fig. 1. The front-end layer employs input/output controllers (IOCs) as servers to connect to devices in the field and execute run-time control

functions. The communication layer passes data in the form of EPICS process variables (PVs) between front-end IOCs and client applications. The back-end layer uses workstations to execute client applications to provide operational interfaces and tools.

Figure 1: SNS ICS Architecture.

A key advantage of this type of architecture, where control functions, communications, and operational tools are decoupled, combined with the inherently distributed design of EPICS, is the ability to upgrade the layers, or individual components of a layer, independently thus providing a minimally disruptive path for upgrades which is essential for operating facilities.

The ICS, as originally constructed, employed commercial Linux servers and workstations for client layer and standard ethernet networking for communication. EPICS client applications providing operator interfaces included a custom alarm handler, the Extensible Display Manager (EDM) and the Channel Archiver. Several different types of IOCs were used, including VME/VXI Motorola single board computers running VxWorks, Allen Bradley Programmable Logic Controllers (PLCs) interfaced to Linux based (soft) IOCs or VME IOCs, and Windows PCs running Labview for Beam Instrumentation Devices. Table 1 shows the number of IOCs, PLCs, and EPICS PVs during initial operations and the present, pointing out where the system has expanded. While the number of VME IOCs has remained about the same, the number of soft IOCs has tripled supporting requests for new features as well as new devices and subsystems and the number of PVs has grown by ~50%.

\* Notice: This manuscript has been authored by UT-Battelle, LLC, under contract DE-AC05-00OR22725 with the US Department of Energy (DOE). DOE will provide public access to these results of federally sponsored research in accordance with the DOE Public Access Plan (<http://energy.gov/downloads/doe-public-access-plan>).

† ksw@ornl.gov

Table 1: ICS Growth

	2006	2021
VME IOCs	168	167
Linux IOCs	46	152
$\mu$ TCA	0	9
Windows IOCs	248	170
PLCs	100	189
MPS inputs	923	1000
PVs	395000	603000

This combination of hardware and software, integrated using EPICS, provided a reliable control system, built on a foundation that could be extended by adding new IOCs and applications. However, it was recognized during early operations that improvements to the alarm handler would be necessary and some premature PLC hardware failures pointed to manufacturing defects that led to early upgrades of these processors. The availability history of the ICS is shown in Fig. 2. After an initial operations period where many problems were addressed with many systems, the original control system design and architecture are meeting the needs of the facility, however, many system components are aging and without upgrades, the ability to maintain high availability and support additional devices for new systems will be increasingly challenged.

Figure 2: ICS Operational Availability.

## LOOKING FORWARD

Over time, experience with the control system and performance analysis has informed planning for various upgrades. Predictably, hardware failure rates increase with years of operation and as parts become obsolete, the ability to repair failed hardware erodes. While not failing in the same way as hardware, software and firmware become compromised over time as vendors withdraw support for

older versions or operating system upgrades are required, often to maintain an essential level of cyber security. Eventually, without upgrades, it becomes impossible to maintain platforms capable of compiling software or the tools needed to generate executable files creating an untenable situation for machine support and ruling out upgrades or any changes to system functionality. As smarter field devices are introduced due to upgrades of other systems the control system must also be prepared to support more modern hardware, often capable of higher data rates than original systems. The SNS also has two facility upgrade projects underway which will require additional control system capability.

The SNS facility has evolved since initial low power commissioning to run the full design beam power of 1.4 MW with > 90% availability. The initial suite of four instrument beamlines has been expanded to twenty and there are two construction projects underway that will expand the facility capabilities [2]. The Proton Power Upgrade project, scheduled to be completed in 2024, will increase the machine power from 1.4 MW to 2.8 MW by adding seven cryomodels in the Linac, replacing some Ring magnets and power supplies and upgrading the target design along with some elements of conventional and target utilities. The ICS will be extended to provide controls for the additional and upgraded systems.

The Second Target Station (STS), also in progress, will use the increased beam power to provide neutrons in an additional target station, initially with eight instrument beamlines and space for fourteen more. To create neutrons for the new target station, the 60 Hz proton beam will be shared between the existing target and the new one, typically by delivering 45 pulses to the first target station and 15 pulses to the second. The accelerator control system will be extended to new devices installed to create a new beam transport line. Further, the ability to provide independent operation of beam power to two destinations will require modifications to the timing system, machine protection system (MPS), kickers and the low-level RF (LLRF).

## UPGRADES

Due to the flexibility and scalability of EPICS, upgrades can be pursued in parallel for the various control system layers and components while keeping the same underlying system architecture. While the primary motivation for most upgrades is to ensure the control system remains sustainable and capable of high availability operations and extensible such as is needed by the PPU project, the STS project will require a new capability to split the beam pulses between two destinations at different power levels.

### Global Systems

The global systems in the SNS control system include the timing system, MPS and EPICS software along with the network and computing infrastructure. These systems can be complicated to upgrade due to their interaction with most devices on the controls network.

**Timing** The timing system generates and distributes timing events as well as real-time data for each 60 Hz machine cycle to accelerator and instrument systems to synchronize system operations across the complex [3]. The original timing system, developed by partner labs, was based on the design and hardware of the existing Relativistic Heavy Ion Collider timing system at Brookhaven National Laboratory. The timing master was implemented using a collection of commercial and custom VME cards along with a complex real-time software application. The master communicated to a distributed network of fanout and receiver cards to deliver triggers and events.

While this system implementation performed the required functions, the installed hardware was relatively old technology and parts obsolescence became an issue after only a few years of operations [4]. Goals for an upgrade to this system included reducing the system complexity, improving availability and sustainability, and providing a phased upgrade path that would allow a gradual replacement of obsolete hardware without an extended machine outage period. Three custom boards were designed to replace a variety of VME boards, and the new design moved most of the previous software functionality into an FPGA. The new fan-out and timing receiver hardware was phased in during maintenance outages over several years and the timing master was commissioned and turned over to operations in October 2019. In addition to the original event and real-time data distribution based on twinaxial copper cabling, the new fan-outs also support a more convenient single-link fiber for newer timing receiver hardware. The firmware for the new timing system will be modified to provide the appropriate information, such as pulse destination, to hardware subsystems to support two beam operations for STS.

**Machine Protection** The machine protection system is designed to trip the beam within 20  $\mu$ sec in the event an off normal condition is detected to prevent damage to the machine. This system is currently being upgraded due to sustainability issues with legacy hardware components that have reached end-of-life, and for which limited spares are available. The new design for this system utilizes commercial  $\mu$ TCA hardware with field replaceable units to reduce mean time to repair and minimize the number of custom interface components and therefore the probability of failure. The system consists of one master unit and ~64 field nodes connected to ~1000 devices which can signal the need to shut down the beam. The new MPS hardware has been installed and corresponding firmware and software have been developed to support witness testing during the run cycle in early 2022. For this test, the system will collect data without shutting down the machine, to verify it provides the same protection as the original system before the system is phased into machine operations. New MPS nodes for the PPU project will be built with the new MPS hardware.

**EPICS** The EPICS toolkit is used throughout the ICS to provide processing of control algorithms, communications, and operator interfaces. EPICS software is written and supported by a community of control system developers distributed across several national laboratories. The SNS started operations using EPICS 3.14.7. Various incremental updates have been applied over the years and the current operational version for most IOCs is EPICS 3.14.12.8. EPICS 3.14 is no longer being upgraded.

The EPICS Collaboration worked for nearly a decade to develop EPICS 4, to support a richer set of data types for more advanced devices and applications along with a new communication layer, PVAccess, to support higher bandwidth data transfers. Unfortunately, upgrading from and EPICS 3 system to EPICS 4 is virtually impossible for such a large operational EPICS installation due to the need to upgrade all devices and clients at the same time [5]. Recognizing that the modern features of EPICS 4 would only be available for new installations, the collaboration then produced a combined release, EPICS 7, which allows the simultaneous operation of EPICS 3 and EPICS 4 systems and both corresponding communication protocols within the same EPICS namespace [6]. This gives the ICS a viable upgrade path and work is underway to test EPICS 7 in our operational environment to ensure compatibility prior to widespread IOC and client upgrades.

After the SNS began operations, new operator tools were developed, primarily at the SNS, and shared throughout the EPICS collaboration [7]. These tools, packaged as Control System Studio (CS-Studio), include tools for archiving, data browsing, alarms, display building and graphical user interfaces and feature a common look, feel and behavior along with interoperability which was missing in the earlier tools which were each developed independently. These tools are now used in the SNS Central Control Room, and local control rooms, except for the new display manager for which the migration is in process but requires significant testing time due to the installed base of over 4,500 screens. Many of these screens are used as templates in specific applications or run custom scripts which complicates the conversion process. The new display manager tool is used throughout the SNS instrument beamlines which also have EPICS based control systems.

While software generally requires more frequent update cycles than hardware, this is especially true for graphical tools like operator interfaces. The original CS-Studio toolkit had to be refactored to remove its dependency on the aging Eclipse Rich Client Platform, which resulted in more efficient execution and a better development environment. These tools were adopted for the SNS instrument beamlines when they were upgraded to use EPICS and a new tool, Scan Server, was added for experiment setup and control. In parallel to the CS-Studio desktop version for control room usage, a web display version has been developed. While it is read-only and not meant to support the full feature set of the desktop version, it provides control system and beam line experts with very convenient remote access.

**Infrastructure** The computing and network infrastructure of the control system benefits from on-going technology refresh. At least 10% and up to 25% of the network switches, servers and workstations are replaced each year to keep the equipment within the expected lifetime limits.

In addition to the in-place upgrade of network equipment, the overall network layout would benefit from a certain level of redesign. The original SNS ICS network was based on several VLANs. Over time, all VLANs have been merged into one large broadcast domain that EPICS servers and clients use to interconnect. The latency of the large domain has reached the point where network clients regularly need to broadcast several search requests before they see a reply. A redesign which for example separates the different types of network traffic and thus isolates the EPICS communication will be necessary before extending the existing network to cover many additional devices.

The servers and workstations are currently undergoing a major revision of the underlying operating system to 64-bit Linux as hardware is no longer available to run the older 32-bit versions. This requires recompiling the substantial installed base of server hosted software and extensive testing with machine operators to ensure functionality is maintained while this upgrade to a supported version of Linux is implemented. The advent of EPICS 7 is another motivation for developing a different network topology to fully benefit from the more efficient higher data transfer rate which should be expected from newer devices.

Along with the Linux upgrade, the software development environment is being restructured and the original CVS code management system is being replaced by Git, a more modern tool with a richer code management feature set. These changes will make software development, which may require multiple branches, easier to manage and merge into a final product for release. It will also simplify the process of installing different software versions.

### *Slow Controls*

Industrial process controls solutions are used on the device control level for the many machine systems which do not require real-time functionality. These include the superconducting cryomodules, cryogenics plant, target facility, vacuum, and conventional facilities. Many of the PLC processors used in these systems were upgraded in 2009 following failures that were tied to manufacturing issues. While these systems have proven reliable, most of our installed base is at or near end-of-life when spares and firmware patches will no longer be available, leaving these systems vulnerable especially to security issues. Additionally, the underlying network technology (ControlNet, DeviceNet) exposes weaknesses that can be rectified by upgrading to the more modern Ethernet solution. In some cases, the segmentation of these systems, either by design or growth, is not ideal. Hosting multiple unrelated applications on a single processor expands the consequences of a single failure therefore these systems will be segregated. The future upgrade path includes new processors and I/O

modules to run supportable firmware and reduce the probability of hardware failure during operations.

To minimize disruption, PLCs upgrades will be packaged to install new hardware and replace ControlNet or DeviceNet communication with Ethernet at the same time. Multiple PLCs are typically grouped into ControlNet clusters and all PLCs and communication modules in a cluster will be upgraded at the same time to avoid rescheduling ControlNet multiple times and the extra effort otherwise needed to reprogram and test the PLCs for each change. DeviceNet upgrades may prove more challenging due to the communication module being embedded in vendor supplied equipment. The small number of PLCs which host multiple unrelated applications will be prioritized for upgrades first. Due to resource availability, this work will most like follow the substantial completion of PPU controls in 2023.

### *Real-time Systems*

The control system applications that require performance beyond that possible using industrial process controls technology were originally built using VME hardware and the VxWorks operating system. The original Motorola 2100 model processors lacked the required performance for some applications, most notably the LLRF. This model also suffers from poor network stack performance and is particularly vulnerable to reconnection failures. These processors are being replaced with the 5500 model which successfully addresses both issues. An upgraded VxWorks kernel is available to support the new hardware and fix the network stack issues. About 70% of the original processors have been replaced so far.

Some of these high-performance systems, built on VME or custom technology, have started to experience obsolescence issues and we have developed a common  $\mu$ TCA based approach to upgrade these systems. The concept was initially proven on the Ring LLRF which was originally very different from the Linac LLRF and suffered from early obsolescence and sustainability issues. The new Linac LLRF system being developed for PPU follows the  $\mu$ TCA model along with the new MPS and recent upgrades for the high-performance waveform generation and monitoring systems. Originally developed for the high energy physics community,  $\mu$ TCA provides a commercially available open-standard architecture with built in high availability options such as redundant power supplies and cooling. With a variety of commercially available modules and features to support high speed applications,  $\mu$ TCA is increasingly selected for new accelerator real-time systems providing an opportunity for collaboration. The nine systems installed so far have proven reliable.

### *Personnel Protection Systems*

The SNS Personnel Protection Systems (PPS) are credited engineered controls designed to prevent people from harm due to hazards associated with operating the accelerator such as radiation and oxygen deficient environments. This is primarily achieved by providing access controls and interlocks linked to the machine status and monitoring

radiation and oxygen levels. In the case of unexpected, elevated radiation levels, the machine is shut down and the source investigated. In the case of depleted oxygen levels, alarming beacons are activated triggering an area evacuation and investigation.

These systems were originally engineered using the same industrial controls technology discussed in the Slow Controls section of this paper but deployed on isolated networks and with additional processes in place for the development and testing of credited systems. These systems are being updated to use more recently available safety rated PLCs and I/O and Ethernet based communication modules. The PPS for at least one machine sector is upgraded each year. Recently, these upgrades have been combined with the requirement to provide additional PPS I/O for the PPU project. The radiation monitors are obsolete and will be replaced with commercial units and a low maintenance ODH sensor design is underway.

## CONCLUSION

The three-tier architecture and distributed nature of the SNS EPICS based ICS has proven reliable for the first fifteen years of SNS operations. As the systems age, hardware and software can be upgraded with new designs in a minimally disruptive manner, during scheduled machine outages, by evolving layers and components individually or in groups. EPICS 7 provides a viable upgrade path for the run-time execution engine and communications layer. The configurable nature of the operational tools allows new displays to be created and added during operations and new alarm and archive parameters can be added by inserting an entry in a database even during machine operations. While this architecture is serving the facility well, it is clear many systems require technology updates in the coming years due to obsolescence.

While PLCs and IOCs can be replaced without changes to the underlying system, significant engineering effort in the form of design, documentation and testing is required to provide reliable replacement systems therefore the upgrade efforts will be paced by resource availability and should be considered an ongoing effort. With careful prioritization and adequate resource investment, procurement and labor, the ICS can evolve and serve the SNS well into the future. Confidence in this architecture and technical implementation is evidenced by the selection of EPICS for upgrades to the SNS instrument beamlines and the design of the control system for the STS which leverages the same EPICS based architecture of the original SNS ICS. Key to the success of the SNS ICS has been the free exchange of software and cooperative development efforts which are the hallmark of the EPICS Collaboration.

## ACKNOWLEDGEMENTS

Sincere thanks to the countless engineers, designers and technicians who have designed, built, maintained, and upgraded the SNS control system over the last twenty years and to EPICS developers everywhere who not only share their code, but also generously contribute their time and share their experience help others solve problems. The

fingerprints on the SNS ICS come not only from SNS staff, but from the partner laboratories and other EPICS sites. The many exceptional individuals working together has truly made an unlikely collaboration work beyond what could have been imagined when EPICS was born over 32 years ago.

# MODERNIZING DIGITAL VIDEO SYSTEMS AT THE NATIONAL IGNITION FACILITY (NIF): SUCCESS STORIES, OPEN CHALLENGES AND FUTURE DIRECTIONS

V. Gopalan, A. Barnes, G. Brunton, J. Dixon, C. M. Estes, M. Fedorov,

## Abstract

The National Ignition Facility (NIF), the world's most energetic laser, completed a multi-year project for migrating control software platforms from Ada to Java in 2019. Following that work, a technology refresh of NIF's Digital Video (DVID) systems was identified as the next important step. The DVIDs were facing long-term maintenance risk due to its obsolete Window XP platform, with over 500 computers to be individually upgraded and patched, 24 camera types with a variety of I/O interfaces and proprietary drivers/software with their licensing needs. In this presentation, we discuss how we leveraged the strengths of NIF's distributed, cross platform architecture and our system migration expertise to migrate the DVID platforms to diskless clients booting off a single purpose-built immutable Linux image and replacing proprietary camera drivers with open-source drivers. The in-place upgrades with well-defined fallback strategies ensured minimal impact to the continuous 24/7 shot operations. We will also present our strategy for continuous build, test, and release of the Linux OS image to keep up with future security patches and package upgrades.

## INTRODUCTION

Digital Video (DVID) systems are an integral part of the NIF control system. They participate in a variety of automatic loops (e.g., automatic alignment), provide critical diagnostics to study the laser, and allow operators to observe the state of the system in real time. The cameras may be used for still captures, streaming video or both. The capture may be precisely timed using triggers, synchronized to the arrival of the laser pulse, or may be manually captured by an operator on demand. It can be used for spatial measurements – e.g., for measuring the spatial aberrations of the NIF beam's optical wavefront. With over 500 DVIDs deployed along the laser path leading to the target, the DVIDs provide machine vision functions to NIF including optics inspection, automation, application-oriented machine vision processing, and vision-guided automatic alignment/positioning systems.

## LONG TERM MAINTENANCE CHALLENGE

The NIF Integrated Computer Control System (ICCS) underwent a phase of modernization which concluded in 2019 [1]. As part of that work, the low-level, hardware-facing Front-End-Processors (FEPs) were migrated from Ada to Java based software and associated Java frameworks and

libraries. The DVID FEPs also benefitted from the overall NIF ICCS modernization, however, the unique nature of the DVIDs called for further upgrades to DVID hardware and software to counter obsolescence and avoid future maintenance jeopardy. The various challenges specific to DVIDs are described in the following sections.

## Obsolete OS

The DVID FEPs run on the unsupported Windows XP Operating System (OS) with inherent security issues and lack of hardware support as newer computer hardware discontinue support for older operating system versions. Non-availability of machines that can install Windows XP on them means that replacing or upgrading hardware will only become a bigger challenge with time. Stop gap measures such as upgrading random access memory (RAM) in existing systems to improve application performance also does not help much due to XP's limitation on maximum supported memory (4GB).

## Large Number of FEP Images

Each DVID FEP has its own Windows image installed in the local hard disk and these OS images are required to be individually upgraded and patched. Deployment of OS/driver upgrades and patches are expensive and difficult due to the large number of machines that needs to be individually patched and tested for every modification.

## Multiple Camera Interface Types

The DVIDs use several interface types to talk to the different types of cameras. Figure 1 shows how the interface types are split across all the DVID FEPs.

Interface type	No. of FEPs
FireWire	487
GigE	318
Analog-FireWire	110
Analog-PCIe	2

Figure 1: Camera interface types and usage count.

Cameras that use FireWire, also commonly known as IEEE 1394, use DCAM protocol that describes the exchange of data over the FireWire bus interface. GigE based cameras use GigE Vision [2], a standard for video transfer and device control over Ethernet networks. Analog cameras typically provide an RS-170 analog signal, which then

gets digitized for further image processing by using a Video-To-FireWire converter or a PCI Express (PCIe) frame grabber computer adapter card.

### Multiple Camera Types

The NIF control system employs multiple camera types from multiple manufacturers as shown in Fig. 2. The selection of a particular camera is based on the requirements for the specific application associated with the control function such as image resolution, streaming frame rates, or specialized features such as radiation or vibration tolerance. In some specific use cases, cameras have NIF specific customizations to satisfy the requirements for use in the control system. Each of these camera types comes with its associated Windows drivers/software and often have proprietary licensing schemes that are different across the different manufacturers or camera software vendor.

Interface type	Camera Manufacturers	Camera Models
FireWire	4	7
GigE	4	15
Analog-FireWire	1	1
Analog-PCIe	1	1

Figure 2: NIF DVID camera types.

### Hard Disks – A Potential Point of Failure

The hard disks in the DVIDs are a potential point of failure and can cause downtimes due to data loss or corruption. With over 500 DVIDs deployed, the collective MTBF of the disks is a potential risk to the NIF's high expectations for availability and reliability, which essentially dictates a "zero tolerance for error". Disk based systems continue to pose a challenge to meet this level of fault tolerance, unless fault tolerant, redundant storage is implemented in every DVID.

### Aging FEP Computer Hardware

The deployed FEP machines belong to different generations of CPU and hardware, and many of them do not have enough memory (RAM) or CPU horsepower to run a modern OS. Regardless of the OS upgrade path chosen, newer OS technologies demand more capable machines.

From the perspective of running a modern OS on it, Fig. 3 shows the percentage of FEP hardware that needs to be replaced or upgraded.

## POTENTIAL STRATEGIES, OPTIONS AND CONSTRAINTS

Hardware/software changes typically require facility downtime to support modifications, tests, and qualification. Continuous run of experiments at NIF means that an extended downtime for upgrade of hardware and software of the video systems is not an acceptable option. The DVID

Figure 3: DVID FEP machines.

upgrades will also need to be "In-Place" in parallel with scientific operations – an approach that the facility has tolerated well as part of the prior NIF modernization phase [1].

With the success of "In-Place" upgrade strategy as described in [1], the digital video control system modernization naturally adopts the same overall strategy and best practices, with incremental deployment of new hardware/software components keeping compatibility with the existing system. This allows a smooth upgrade and progressive replacement with minimal impact to the running system.

### OS Upgrade / Replacement

With the DVIDs currently running Windows XP, the obvious upgrade path may appear to be to install a newer version of Windows. However, this will not solve the challenge of maintaining a large number of separate OS images. Furthermore, opensource support for Windows based driver software for cameras is limited, and the proprietary nature of Windows will limit our ability to create a custom OS image with tightly controlled image size, tailored to run on the specific set of FEP hardware with available memory and CPU performance constraints.

A compelling option for DVID OS candidate originated from an ICCS maintained custom Linux OS distribution based on Gentoo Linux [3] that has already been successfully deployed to VME FEPs in NIF, including support for network boot mode. The already available Diskless Gentoo OS (DGOS1) offered us a platform where we would be able to incrementally add support for specific features required by DVID systems.

The 3<sup>rd</sup> option was to explore other Linux distributions such as RHEL, Debian and other Linux distributions. With Gentoo based systems already successfully deployed in NIF, this alternative option which involves significant additional effort, would be justified only if the existing Gentoo based OS could not be enhanced to meet the DVID requirements.

Even if Linux is selected as the primary DVID OS, the possibility of having specialized DVID systems that can only function with proprietary/commercial software needs to be considered as well. We expect a small percentage of

DVIDs (less than 5%) that may still need a Windows based solution to support specialized camera, drivers, or image processing software.

### Camera Drivers

There were two broad categories to consider: Open-source drivers and proprietary drivers.

**Proprietary Drivers** Proprietary drivers include drivers provided by the camera manufacturer or supplied by a third-party software vendor. The proprietary drivers typically come with license costs and restrictions (e.g., node locked, hardware dongles, license built into camera).

**Open-Source Drivers** This includes drivers available with one of the many open-source licenses either distributed via open internet (e.g., through GitHub), or distributed by the manufacturer itself in source code.

The manufacturer provided drivers only work with the specific vendor's cameras, so even though the driver is standard compliant, it is generally not possible to use it across cameras from different vendors.

With the above considerations, the best approach was determined to be using open-source drivers for FireWire and GigE cameras, that would be manufacturer / model agnostic, if the cameras are standards compliant.

### Camera Maintenance Tools

To enable testing of cameras in production during installation, repair or troubleshooting, operators need GUI (Graphical User Interface) tools that can query the camera parameters, capture image, and perform streaming tests. The Windows DVID with the manufacturer or third-party vendor supplied software provides a variety of GUI tools for debugging the cameras outside the ICCS framework. If we replace Windows with Linux and open-source drivers, these tools must be replaced with equivalent functionality. Since the Diskless DVID will be headless, it is also required to launch the GUI remotely.

We considered the following options for developing the camera GUI tools:

1. Use GUI sample applications that come with the opensource camera drivers. The UI must be launched remotely using X11 forwarding.
2. Use manufacturer provided Linux based applications, either by running binaries or building from source. The UI must be launched remotely using X11 forwarding.
3. Build our own custom GUI app based on web-based technologies and launch the UI remotely on the client web browser.

The UI application in option 1 and 2 above has dependencies on additional Linux libraries such as Gnome, SDL and others, and the Gentoo system should support these dependencies so that the app can be launched successfully. This could increase the OS image size significantly.

## MODERNIZED ARCHITECTURE

### FEP Operating System

The legacy Windows OS will be replaced with Linux OS, which will be a single image that will be configured and built to run on all DVIDs. This new Diskless Gentoo OS Version 2 (DGOS2) will be derived from the VME diskless Gentoo (DGOS1) with the following enhancements:

- Upgrade to latest Gentoo packages
- The CPU architecture type is selected from an Intel architecture version that ensures compatibility with existing DVID machines. The “core2” architecture was chosen, which provides a good balance of compatibility with older processors while not taking a performance hit on the newer processors with architecture later than core2.
- Upgrade Linux kernel to a long-term support (LTS) version: v4.14 LTS with Projected EOL Jan 2024 was chosen.
- Enable FireWire support in the kernel.
- Support additional network interfaces required for GigE DVIDs. This requires a private subnet to be created for attaching GigE cameras.
- Tune kernel network buffer size to optimize GigE performance and prevent frame drops.
- Enable NIS user authentication.
- Add FireWire hot-plug support.

The distribution builder builds all the packages from source with the selected CPU architecture. This is required, since a package binary that is built for a slightly different hardware configuration can cause the boot to fail or specific packages to malfunction.

### Booting Mechanism

The DVIDs boot off a common Linux OS image over the network. The network boot is implemented using Preboot Execution Environment (PXE) [4], Dynamic Host Configuration Protocol (DHCP) and Trivial File Transfer Protocol (TFTP).

When the diskless DVID client is booted up, the PXE boot process will request the IP Address from the DHCP Server (Fig. 4). The DHCP server responds by sending the

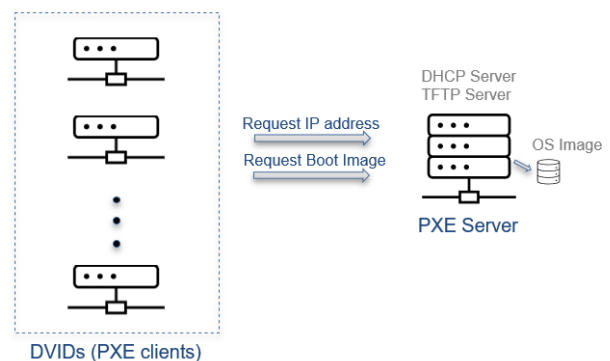

Figure 4: Diskless clients boot architecture.

IP Address and information about the boot image. In the second step of PXE boot, the boot image is requested and loaded into the DVID's Random Access Memory (RAM) by using TFTP. After all the image data loaded, the DVID automatically loads the OS and executes the OS boot sequence.

### Driver Level Redesign

The proprietary drivers in the FEP will be swapped out and replaced with opensource variants. After prototyping and verifying functionality and performance, the following opensource drivers were selected:

- FireWire: **libdc1394** library with support of over 500 camera models, provides a complete API for controlling cameras conforming to DCAM specifications.
- GigE: **Aravis** library implements the Gigabit Ethernet protocols used by GigE cameras.

Although the opensource drivers support most of the required features, there are specific instances where we had to enhance it. For e.g., libdc1394 does not support access to shutter time base register which is required for supporting full range of exposure times for some cameras.

### CORBA Interfaces and FEP Java Code

ICCS uses CORBA middleware technology to build a distributed control system network. Carrying over CORBA IDL interfaces intact from legacy Windows to Linux FEP software is a vital requirement for achieving smooth In-Place migration [1].

Existing Windows based FEPs were designed such that the Java support classes were selected and instantiated based on the camera vendor. Each support class is an API class whose native methods were Java Native Interface (JNI) calls to a lightweight ICCS-maintained wrapper that dispatches the calls to vendor-supplied and vendor-maintained library calls (DLL) for command/control.

Moving to Linux requires a re-architecture since most camera vendors do not provide out-of-the-box support for Linux. ICCS already maintains a vendor-agnostic approach to instantiating support classes. We designed the Linux FEP to leverage the existing methodology, abstract it to support all new Linux DVID FEPs including generic support for multiple camera bus types.

Cameras are described by text-based, human-readable YAML files, with one YAML file per camera make/model which is then stored in the file system. These camera description files are controlled alongside source code, deployed to production along with software release and gets loaded and parsed by FEP during initialization. Contents of the file determines support class instantiation and supported feature configuration for command and control of each camera defined per process in the database. FEP loads ICCS-maintained thin wrapper library (written in C, compiled for Linux) that dispatches native calls from Java FEP to the FireWire/GigE driver.

### FEP Hardware Upgrade

For each DVID that is converted to Diskless Linux, the FEP computer will be either replaced with a newer ma-

chine, upgraded with higher RAM (16 GB) or used without any changes. The modification depends on the category of the machine as described in Fig. 3.

### Performance Considerations

Two major areas required performance considerations: CPU performance and network performance.

**CPU Performance** Windows video FEPs used Intel's Integrated Performance Primitives (IPP) library to perform image compression (JPEG) and decimation. Current Windows FEP implementation utilizes IPP version 4 that dates back to 2003. To be able to run IPP on Linux, we discovered that this requires an update to bring the latest IPP support into the image processing library compiled for Linux. After the update was successfully integrated into the Linux FEP, verification of new image processing libraries was performed with the help of Automatic Alignment tests by comparing centroid locations obtained from test images decimated with current Windows 32-bit version of image processing libraries with those using new 64-bit Linux version of the library.

Image capture and streaming tests (Fig. 5) were conducted with various FEPs to measure, improve and verify that the capture response times, and streaming frame rates met or exceeded the Windows FEPs that were being replaced.

**Network Performance** The Windows FEP used a vendor supplied performance driver that optimized GigE Vision network traffic for adapters that use specific Intel chipsets. The advantage of the performance driver is that it offloads network traffic processing to the adapter and lowers the CPU load. With Linux FEPs, our testing did not indicate a need for the performance drivers, and the streaming performance was comparable to Windows FEPs without using the performance driver.

Figure 5: Fragment of streaming performance test results.

### Database and FEP Identity

A change in database schema not required for the Linux conversions since the strategy is to maintain the configuration and capability of the FEP. Reusing the same tables between legacy Windows and new Linux implementations also allows for easy switching between Windows/Linux software.

However, there will be minor changes to database to configure Linux specific start-up parameters. This will impact the data stored in the tables – but not the schema itself.

Taxonomical name and identity of the FEP will not change and the Linux FEPs will continue to be identified using the same identify of the Windows FEPs that they are replacing. This ensures that the conversion is transparent to the other components in the control system. This aspect is also very important for the In-Place upgrade strategy to work.

## VERIFICATION AND DEPLOYMENT

Test and verification are first done in the offline (non-production) environments which consists of development, integration, and QA. One of more setups of each DVID type is available across these environments, which assure robustness of these conversions before we apply it in production. A full suite of manual and automated endurance tests is run and compared against the corresponding Windows FEP to ensure that the In-Place replacement will work as expected.

Deployment to NIF requires extensive coordination between controls hardware teams, IT, operators, subsystem leads, and testers during conversion. A typical Windows DVID FEP to Linux conversion consists of the following steps:

1. Shut down FEP's running processes
2. Configure BIOS to PXE boot instead of booting from disk.
3. Configure DHCP server to add the FEP's IP and PXE boot configuration
4. Reboot the FEP and verify successful boot-up into Diskless Linux.
5. Apply database changes to modify Linux FEP configuration parameters.
6. Startup the FEP's processes
7. Verify functionality using image capture and streaming tests.

### *Status of Deployments to NIF*

The Diskless Linux solution has been successfully deployed to DVIDs in NIF, and functionality and performance is now proven by operation in the NIF's control system that is running a 24x7 scientific experimental schedule. With the modernized solution, our team has successfully accomplished a technology refresh of NIF's Digital Video systems and effectively solved the Digital Video systems' long term maintenance challenge.

## FUTURE DIRECTIONS

### *Diskless Gentoo OS Roadmap*

The official Gentoo Linux releases use a rolling release model, where packages are made available to the distribution as soon as they are released upstream. It has been a challenge to keep DGOS up to date with the official re-

leases, since new versions of DGOS are currently released only as needed - typically for adding specific new features required by NIF or for applying security patches. Going forward, our plan is to release DGOS at least every 6 months to keep it current with the official Gentoo packages.

The DGOS releases are currently not integrated into the NIF ICCS continuous integration (CI) system, and verification depends primarily on manual tests. CI integration is a work in progress, and we plan to progressively integrate the DGOS build, test and release into the overall CI system which will enable us to support faster rate of release and quicker fault isolation.

### *Diskless Video FEP Enhancements*

As part of the diskless video conversions, a large subset of DVIDs were successfully configured to handle two cameras simultaneously, significantly reducing the number of deployed FEP hardware which reduces maintenance costs and thermal stress. The upgraded DVID computers offer the possibility of further consolidation of camera functionality into the same FEP (for e.g., handle 4 cameras in the same DVID). The possibility of such efficiency improvements will be explored in the future.

Current implementation only supports FireWire and Gig cameras. Support for analog/PCIe cameras is planned in the future.

### *Camera Maintenance GUI Tools*

We are working on deploying a maintenance GUI framework, based on web technologies, that will securely expose the camera command and control over a RESTful API, and allow testing of cameras in production during installation, repair or troubleshooting remotely from a web browser.

## ACKNOWLEDGMENT

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. LLNL-CONF-827589.

## Abstract

After 10 years of operation, the LOw Frequency ARray (LOFAR) telescope is undergoing a significant hardware upgrade towards LOFAR2.0. The hardware upgrade will enable the phased array telescope to observe at 10-90 MHz and at 120-240 MHz frequencies at the same time. With the upgrade comes also the chance to review LOFAR's Control System and to make it ready for the next 10 years of operation at the forefront of low-frequency astronomy. In this work we will give a brief overview over the LOFAR telescope with its more than 50 geographically distributed receiver locations (LOFAR Stations), and the software that is necessary to monitor and control every single one of them. We will then describe the Station Control architecture, with its software design and how it is implemented in Python 3 with Tango Controls, OPC-UA clients and deployed as Docker containers. Lastly we will report on the successful use of open stack software like ELK and, Grafana.

## LOFAR TELESCOPE OVERVIEW

LOFAR [1] is a geographically distributed radio telescope array, consisting of around 60,000 dipole antennas. The antennas are grouped into 56 *stations*, 38 of which are deployed in the Netherlands, and the remaining 14 in other countries across Europe. The scientific data from these stations are streamed to our real-time GPU correlator [2] in Groningen, the Netherlands. Thusly correlated (and beamformed) data products are subsequently post processed. We send the end result to our tape archives in the Netherlands, Germany, and Poland. There the data products are made available for download by the scientists.

### LOFAR2.0 Station Upgrade

A LOFAR2.0 station will, like the current LOFAR stations, consist of up to 96 high-band dipole tiles (110–250 MHz), and 96 low-band dipole antennas (10–80 MHz). The tiles and antennas are connected to 64 Receiver Control Units (RCUs), which apply a configurable analog filter.

LOFAR2.0 will redesign these RCUs to have improved filters. The new RCUs will also have the ability to process data from all antennas simultaneously [3].

The RCU output is sent to station signal-processing boards, to be beamformed and converted into UDP pack-

ets. These packets are streamed over 10 GbE fibres to the correlator.

### Station Signal Processing

A station will contain up to 8 Uniboard<sup>2</sup> processing boards [4]. The boards use 32 FPGAs in total to sample and digitise the signal at 200 MHz and calibrate, exchange, beam form, and correlate their input. The end result is a 3–9 GBit/s data stream to the correlator per station, as well as up to 300 Mbit/s of statistical information.

## STATION MONITORING AND CONTROL

The hardware in each station exposes tens of thousands of monitoring and control points through various interfaces and protocols. Basically the Monitoring and Control of a LOFAR2.0 station can be condensed into two simple operations at a station:

- Modify the behaviour of our hardware over time, e.g. point at different sources in the sky.
- Verify that the dynamic behaviour has been successfully modified.

In addition to the basic concepts of station operation, the nature of the distributed telescope requires that we also keep track of the system health and let the station autonomously act on extreme scenarios such as overheating of the equipment.

Finally, we are interested in monitoring the quality of the data recorded through our antennas and produced by our processing boards. To this purpose, the signal-processing boards continuously emit statistical information from several points in the signal chain.

### OPC UA as a Common Hardware Interface

The hardware that is to be monitored and controlled in a LOFAR2.0 station comes in various shapes and forms. This could imply that a station's Monitor and Control system would have to support a variety of different hardware interfaces and protocols. We have, for example:

- Uniboard<sup>2</sup> processing boards: I<sup>2</sup>C
- FPGAs on Uniboard<sup>2</sup>: UCP (Uniboard Control Protocol) over IP
- RCUs: I<sup>2</sup>C
- Power supplies: PLC interface
- Temperature sensors: PLC interface
- Network switch: SNMP

From prior experience in LOFAR1, as well as in other telescope monitor and control systems (ALMA, WSRT), we

\* thomas.juerges@skao.int

† mol@astron.nl

‡ snijder@astron.nl

learned that a common hardware communications protocol minimises software complexity. Engineering and maintenance personnel also benefits from a common hardware interface on site as well as remote. The tooling can be unified and be kept simple to use, yet powerful enough to debug hardware at an acceptable low enough level.

Thus we expect a common hardware protocol to have the following properties:

- Open tooling available for remote hardware and interface debugging
- No need for specialised equipment to communicate with the hardware (JTAG dongles, I<sup>2</sup>C cards, etc.)
- Protocol client implementation available in Python 3 to integrate seamlessly with the Station Control software
- Single server supports multiple clients
- Support for a direct mapping of Monitor and Control points from hardware to software.

The widely adopted OPC UA protocol [5] supports all of the properties above. In addition, OPC UA supports the following aspects in a client-server system:

- OPC UA protocol is based on TCP/IP: Connection reliability, simplicity of software integration
- Protocol insensitive to specific hardware timing: We chose to implement timing sensitive behaviour server side.
- Ability to browse self-describing attributes and methods: Enables introspection of the available Monitor and Control points (name, type, dimensionality)
- Server implementations in C/C++ and Python 3: Allows hardware engineers to implement the servers observing timing specific behaviour and other details of the hardware.

OPC UA is a feature-rich protocol, but does not require the user to make use of the full set of features. For LOFAR2.0 we chose to limit the use of OPC UA features to:

- Browsing of attributes and methods
- Reading and writing of attributes
- Calling of methods
- Use of OPC UA native data types only

### *OPC UA Hardware Translators*

We run a dozen of OPC UA servers on Raspberry Pis in the LOFAR2.0 station as interfaces to the station's hardware. These servers „translate“ the hardware-specific communications protocols<sup>1</sup> into OPC UA attributes and methods. Thus the name Hardware Translator, or Translator for short, for the OPC UA server.

## **HIGHER-LEVEL MONITOR AND CONTROL WITH TANGO CONTROLS**

For the LOFAR2.0 Station Control software Tango Controls [6], an open source and distributed object-oriented Monitor and Control system, has been chosen as the core software framework. It enables the software engineers to

focus on designing and implementing feature rich Monitor and Control application hierarchies, that consist of an arbitrary number of abstraction levels. The software engineer does not have to implement low level functionality, like for example automatic polling of an attribute's value from a source, attribute value on-change events, attribute value alarm subscriptions or a system wide logging system. It also provides a transparent and configuration-independent component discovery through its underlying CORBA [7] foundation. Tango Controls also provides a lot of tooling for rapid prototyping and supports native Python 3 bindings.

### *Devices and Device Servers*

A LOFAR2.0 station has no moving parts — the station is controlled through Station Control, the software stack hosted on a computer located in each station. It manages the thousands of control and monitoring points exposed by the Hardware Translators.

In order to map the Translators into the Tango Controls realm, we represent each Translator in Tango Controls as one or more Devices. These Devices are implemented in Python 3 with PyTango [8], the high-level Python 3 API for Tango Controls.

Devices are executed in Device Servers, which can run one or more Devices using multithreading. In order to avoid a shared process space and thus shared crashes and performance bottlenecks, we chose to run each Device in a dedicated Device Server.

### *The Station Control Devices*

We designed a hierarchy of Devices that together form the Station Control Devices landscape, as shown in Fig. 1. The lowest layer Devices communicate with the Hardware Translators, while the highest layer exposes business-logic functionality to our central Telescope Manager.

Especially our signal-processing boards expose a lot of functionality through numeric properties that can be set. In order to keep the responsibilities of each Device manageable, we divide the functionality exposed by some of the Hardware Translators into multiple Devices. OPC UA makes this a seamless experience because it does not enforce and one-to-one mapping between clients and servers.

To further limit the number of attributes per Device, we group most hardware Monitor points into arrays. For example, in one Translator, an array of 16 booleans can flag communication issues with the 16 FPGAs that the Translator monitors and controls. About a hundred arrays remain, ranging from tens to tens of thousands of elements per array.

### *Tango Controls Attribute Wrapper*

The multitude of Tango Controls attributes forced us to look at representing them as efficiently as possible in our source code. For that we developed a generic „attribute wrapper“ framework. It allows us to map almost any source of information to a set of Tango Controls attributes. The Attribute Wrapper takes care of the interaction and management of the data source, while the software engineer provides

<sup>1</sup> See section "OPC UA as a common hardware interface".

33

the actual OPC UA connection and the relevant OPC UA attribute (and unlinked on de-initialisation).

The result is a very efficient and simple to use framework which we extended to cover the management of, among others, SNMP devices, Docker containers and INI-format files.

### Statistical Data Streams

The FPGAs produce streams of statistical data about their main 3–9 Gbps data streams flowing out of the station: crosslet statistics (XSTs) revealing phase and amplitude differences between the inputs, frequency & amplitude plots of each individual antenna (SSTs), and power spectra of the output data stream (BSTs). These statistical data are divided over UDP packets, sent collectively by all FPGAs.

The FPGAs require to be configured with the MAC and IP address of the receiver, of which there can be only one, as UDP Multicast is tricky to set up, especially across switch boundaries. Yet multiple users are interested in these statistics: telescope operators and maintainers use them to verify the data quality and expert users record the stream to produce additional scientific data products.

In LOFAR1, we allow the UDP stream to be configured by any interested user, but learned that such a solution gives an awful user experience. Receiving and recording UDP streams tends to require low-level programming, easily leads to data loss and demands that the user does not forget to turn off the stream explicitly.

The conclusion from past experiences is that we designed a more elegant solution. Each type of statistical data is configured to be sent to a dedicated Device Server. The Statistics Device, that runs in that Device Server, collects the UDP streams from all FPGAs. With the help of our Attribute Wrapper framework, we easily expose the resulting statistical data matrices, the metadata, such as timestamps and other properties, and meta-statistics, such as packet and error counters.

These statistical data matrices represent the most recent statistical values as computed by the processing board. The Statistics Devices expose the matrices as arrays of f.e. 192x512 floats, or 192x192x8 complex values, which typically get updated every second or faster.

**Statistics Replicator** Monitoring these matrices automatically is rather computing expensive, so we added another interface to record these statistics over time: We expose a TCP port per type of statistic. Any connecting user receives the raw UDP packet stream over this TCP connection until the user disconnects or the Device is shut down. The Device allows as many connections as the available bandwidth allows. Monitoring points for this „Statistics Replicator“ are exposed through our Attribute Wrapper as well.

**Statistics Writer** Furthermore, we provide the user with a Statistics Writer. It reuses the same classes to convert the Statistical Data Stream into matrices on the client side. Then it just writes them as an HDF5-file to disk. The HDF5-file

contains proper data structures and attributes of the Statistical Data Stream.

### Observation and Tracking Devices

A station's main task is to partake in observations performed by one to all stations in concert. Observations carry many configuration settings and require parts of the hardware to be reconfigured every second. The adjustments of hardware parameters are necessary to track the observed source across the sky as Earth rotates. We are in the process of managing this behaviour by implementing a Tracking Device to perform the necessary computations.

For each observation, dedicated Observation and Tracking Devices are dynamically created and started. Both work together to maintain the station in a state such that it fulfills the observational requirements throughout an observation. This is done without interfering with observations that are executed in parallel on the same station. The Tango Controls system seamlessly allows this dynamism.

## DEPLOYMENT

The core of our Station Control software stack is based on the Docker image framework for Tango Controls, originally provided by the Square Kilometre Array Observatory (SKAO) [9]. A part of the SKAO framework provides a basic setup of Docker containers that run the core Tango processes and an example Device Server. We have significantly extended this part of the framework, for example, by:

- Making the Device Servers that run inside Docker externally reachable, by adjusting the underlying CORBA [7] parameters
- Running each Device Server in a dedicated Docker container
- Added a rich set of integrations with modern tool chains, such as ELK [10], Prometheus [11], Grafana [12], and Jupyter Notebooks [13] (see below)
- Added an integration and unit-test framework, run from Gitlab CI/CD

### Stacking Open Interfaces

Modern toolchains make it easier to attain high levels of integration between complex software stacks. We added a significant number of web interfaces by adding off-the-shelf Docker images that needed only little configuration. The separation of services into Docker containers and linking them through open interfaces proved to be a powerful combination.

**Jupyter Notebooks** A Jupyter Notebook server [13] allows users to access all control and monitoring points in a station. It comes with PyTango [8] pre-installed and pre-configured for easy access to all Station Control Devices. We provide example Notebooks (see Fig. 3) and the user can save and load their own. Plotting libraries are pre-installed as well which makes the Jupyter Notebooks a powerful engineering interface.

```

```

Figure 3: Example of using the station's Jupyter Notebook to read the state of the Devices and one of the Device attributes.

**ELK stack** An ELK stack [10] collects logs from all Devices, Device Servers and several of the other services that we run. We added Python LogHandlers and Filters to automatically route all Python log output to Tango's log system, our ELK stack and stdout. Each log line is annotated with the name of the Tango Device that generated it. This both leads to richer logs and alleviates the need of having to forward the Tango log streams to our utility classes, as all classes can now just use Python's native logging interface yet still log to Tango.

**Grafana** We added and adjusted the SKA's experimental TANGO-Grafana exporter [14] to allow all but the biggest arrays of monitoring points to be periodically scraped by a

Prometheus time-series server [11]. A Grafana [12] dashboard system (see Fig. 4), also installed on the station, has this Prometheus server configured as its data source, along with the Tango Archiver database, Tango database, and our station's ELK stack. Pre-configured dashboards provide a rich overview of the station's state and state history, from temperature sensors to current hardware settings and active software and firmware versions and the state of all Docker containers.

**Sphinx & Read the Docs** Finally, we generate user documentation through a Sphinx [15] integration and a web hook from our Gitlab server to Read the Docs [16]. Having our source code publicly available made this trivial to setup.

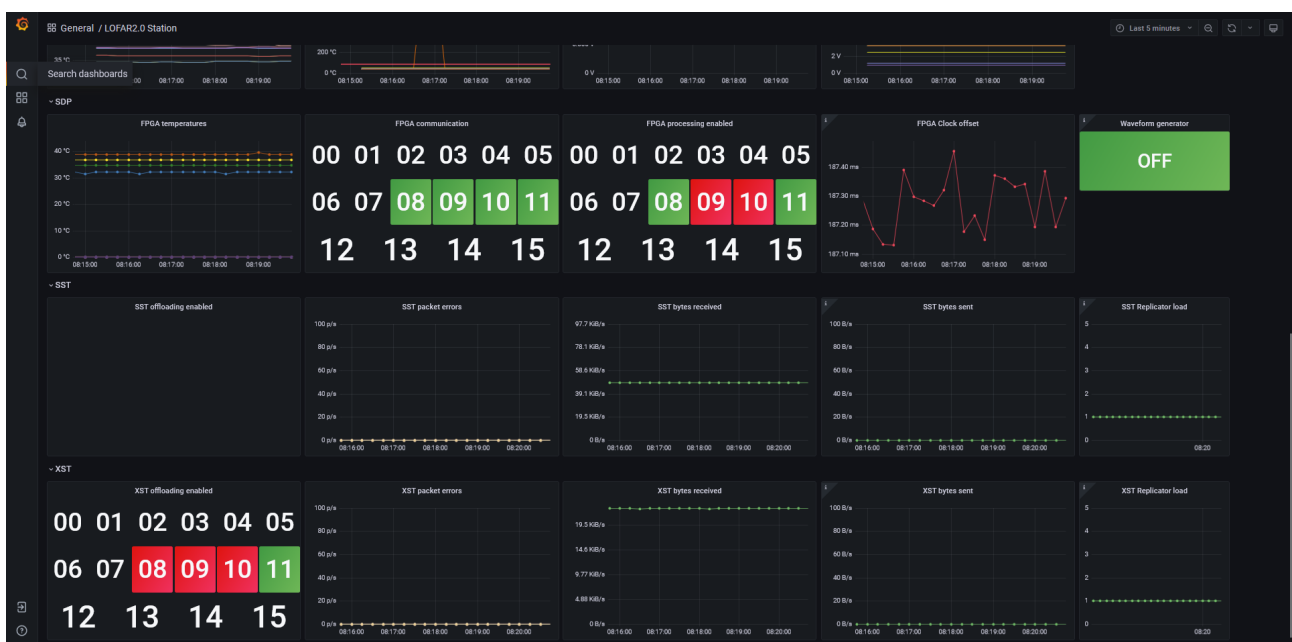

Figure 4: An excerpt from one of our Grafana dashboards.

## Benefits of Simulating the Hardware Interfaces

The LOFAR2.0 station contains custom hardware that the software engineers do not necessarily have access to. We discovered early the benefits of simulation of the interfaces that hardware exposes. Our Translator setup is such, that it allows us to run them stand-alone in Docker containers and simulate the hardware in a very basic and static fashion. While these instances do not have access to backing hardware, they do expose the OPC UA interface just like the actual equipment would. This allows us to write integration tests to verify the attribute names, types, dimensionalities, and other basic properties.

## CONCLUSION

Over the past 18 months we found Tango Controls [6] to be a very powerful Monitor and Control framework that makes the life of our software engineers much easier. Development of software devices in Python 3 became a simple task. Rapid prototyping with quick cycles of testing, debugging, bug fixing showed to be extremely valuable not only for software-only devices but also for devices that represented parts or all of one of our Hardware Translators. Especially when hardware was involved, our Attribute Wrapper has shown its incredible power due to its built-in separation of Tango Controls on one side and interfacing with hardware on the other side.

Without Tango Controls, our Attribute Wrapper, OPC UA and the SKAO Docker images for Tango Controls, we would not have been able to deliver the wealth of functionality with the little manpower that we had at our disposal.

The entire source code of the LOFAR2.0 Station Control project [17] is made publicly available under the Apache, Version 2.0, Open Source license [18]. The SKAO Docker images that we use are publicly available at the SKAO's artefact repository [19].

- Feed-forward control is used mainly during the "blind phases" of the Telescope when on-sky loops are open. E.g. a pointing system is used to preset the telescope to a new target, with the feed forward model taking into account astrometry and telescope deformations due to gravity and temperature to bring the telescope within the acquisition range of on-sky sensors [3].
- Feedback loops based on telescope internal metrology (as opposed to on-sky loops) are used to control the state of the telescope. E.g. the large segmented primary mirror consisting of 798 hexagonal segments, and the M1 control system moves each segment in piston, tip, and tilt (2394 degrees of freedom) to control the shape of M1 based on measurements of relative displacements between segments using 4524 Edge Sensors. The M1 Figure Loop can reduce relative edge displacements to several nm and can keep low order deformations (in the mm range due to gravity) at levels that are within the capture range of M4 [4].
- Stroke Management is a background task to redistribute the slowly building non-zero-mean components in low order modes of M4 to other degrees of freedom:
  - tip and tilt modes are controlled in a collaborative control scheme together with M5 and Telescope Main Axes, which desaturates M4 eventually through a Main Axes guide correction. This process is referred to as Field Stabilization [5,6].
  - focus and coma are transferred to M2 occasionally, at most every 5 minutes [7].
  - higher orders are continuously offloaded to M1, essentially by commanding the low pass filtered modal amplitudes accumulated on M4 to the M1 figure loop control system.

Moving optical surfaces changes the wavefront error measured by the Adaptive Optics system and causes the M4 to desaturate, i.e. saturation management requires a closed on-sky loop. Stroke management redistributes stroke between the optics degrees of freedom but does not aim on maintaining the telescope at its prescription [7].

While the control strategies outlined above are simulated [8] and tested [9,10,11] in detail, it is important to note that the unprecedented size of ELT is expected to lead to surprises during commissioning. Changes in the control strategy are hence expected, and therefore the control system is built such that well understood subsystem control is decoupled from less defined high-level (on-sky) control, and the latter one is developed in a way that allows for the flexible adjustment of algorithms during commissioning.

## CONTROL SYSTEM ARCHITECTURE

The ELT Control System architecture has been described in [12] and since then we have consolidated and further developed it in the details, using the feedback from prototypes and the first applications. Here and in the next sections we will describe just some key aspects to have a context and we will describe the most important developments since the publication of [12].

The architecture enforces a distinction between a telescope device (*the System Under Control - SUC*, e.g. the M2 unit) and the component controlling that device (*the Control System - CS*). This terminology is adopted from the State Analysis (SA) methodology developed at JPL [13].

As a system of systems, the ELT contains layers of controllers. A lower level component comprising a CS and SUC appears as a SUC to a higher-level CS. For example, the primary mirror segment position actuators (PACT) with embedded position controller and course and fine stage actuators appear as components of the SUC to the M1 CS responsible for figure control.

Figure 2 shows an overview of the ELT CS, with some simplifications and omissions for readability (numbers circled in orange are used to identify items referenced with Fig. 2-# in the text below).

The first breakdown of the ELT CS is into the many individual control systems associated with Telescope subsystems (called the Local Control Systems (LCS)) (Fig. 2-1), and the single system that integrates these, termed the Central Control System (CCS) (Fig. 2-2), whose internal structure is described in the corresponding section below.

The LCS-CCS discrimination not only separates unit-level from telescope-level safety and control, it also matches organizational boundaries in-line with the ELT procurement strategy: individual subsystems (mirror units, main structure, ...) are designed, built and delivered by industrial partners; their integration is ESO responsibility.

On the other side of CCS are instruments (Fig. 2-3), developed by Consortia of ESO partner institutes. Each instrument includes an independent Instrument Control System (ICS) developed following the ELT standards, and interfacing with the telescope through the CCS interface, split over a control and a deterministic network (Fig. 2-4).

The interfaces between LCSs, CCS, and instruments are defined in a series of ICDs specifying the logical addresses, data types, formats, rates and characteristics of the data communication. The same applies to the interfaces between the internal components of CCS, even if that is fully developed inside ESO. This strict interface management is key, given the distributed nature of the ELT CS and the range of developers and suppliers.

From State Analysis we have also adopted the *State Variable* and *Estimator-Controller-Adapter* patterns[13].

The term *State Variable (SV)* refers to an element of the CS that represents a physical state of the SUC. For example, a limit switch in the SUC will physically be in an opened/closed state and the CS will use evidence such as sensor measurements to *estimate* the state of the switch as opened/closed. SVs are observable by clients.

The *Estimator-Controller-Adapter* pattern is based on:

- The Adapter that allows to communicate with the SUC to command and measure.
- The Estimator that receives measurements from the SUC via the Adapter and computes State Variables. Estimators do not send commands to the SUC.
- The Controller that is responsible to control the SUC via the Adapter. It can access State Variables if needed.

39

in particular on the Rapid Application Development (RAD) framework [15]. RAD helps in the development of event driven applications by imposing a common design and providing tools to quickly produce application skeletons ready to use. RAD applications are built around a BOOST ASIO event loop [16] integrated with a SCXML state machine interpreter [17]. Anonymous publisher-subscriber communication and shared access to an Online Database are used to keep the coupling as loose as possible.

## LSVs

Within CCS, a Local Supervisor (LSV) (Fig. 2-6) is a software component that provides access to specific Local Control System (LCS) functionalities. The LSV is responsible for implementing the telescope domain logic and translating the telescope concepts into the device domain handled by the corresponding LCS. For example, the M1 LSV is responsible for controlling and maintaining a certain optical quality of the whole telescope primary mirror surface while the M1 LCS is managing the actuators and sensors installed on each segment of the mirror.

There is one LSV for each of the following telescope LCSs: M1, M2, M3, M4, M5, Pre-Focal Stations, Main Structure, Dome, and Laser Guide Star. Each is independent from the other LSVs and can use only the services of the corresponding LCS. For instance, M1 LSV is not allowed to communicate directly to M4 LSV and can send commands only to M1 LCS.

The services provided by an LSV are grouped in "subsystem functions". Each subsystem function corresponds to a set of functionalities implemented by the LCS. For example, since the Main Structure LCS allows to position the altitude and azimuth axes independently, the Main Structure LSV provides two subsystem functions, one to deal with altitude and one for azimuth. For each subsystem function an operational state is estimated by the LSV using the published LCS measurements. The subsystem functions are supposed to be, as far as possible, independent (e.g. it should be possible to use altitude axis even if azimuth is not available and vice-versa).

Each subsystem function is made of an adapter library, one or more estimator applications, and zero or more controller applications following the Estimator-Controller-Adapter design pattern. Each estimator and each controller are implemented by a dedicated application. LSV estimator and controller applications share the same architecture to allow faster development and easier maintenance.

Common requirements across all LSVs and specific requirements have been identified, a set of common design patterns has been drawn and implemented in pathfinder LSV applications. Detailed design for the individual LSVs is being analyzed and the development has started and will be the main activity for the coming years until deployment in the ELT Control Model[12] and at the telescope.

## HLCC

The High-Level Coordination and Control (HLCC) software layer lies above the LSVs (Fig. 2-7). It offers a single interface of the whole telescope toward operators

and the instrument control software. Its main task is for supervisory applications to coordinate the various telescope subsystems.

The main challenge for HLCC is to implement a well-structured system that at the same time can be modified to a large extent during telescope commissioning.

To reach this objective we have identified the building blocks that can be seen in Fig. 2. An important role will be played by the SequencerProcedures (Fig. 2-8). These will be developed around *features*[12], independent supervisory applications designed to perform a complete operational function/use case of value to the users of the system.

We have planned for a long period of integration and commissioning[18], during which we will discover how to operate our machine and how the elementary functions provided by the LSVs will have to be composed together. Implementing *features* as independent components, using an interpreted language (Python) accessible to the commissioning team (not necessarily SW developers) allows us to evolve them in an easy way, with minimal impact on other *features*.

In the last two years we have developed a prototype to validate our architecture and design with respect to the software infrastructure and the application framework. We chose a vertical slice from a dashboard GUI down to several services representing a telescope tracking the sky. Here we give a few examples of design choices that differ from existing software at other ESO telescopes.

Measurement data was treated using estimators subscribing to the publishers that deliver input data to them, processing this data in Java code or in external Python scripts (Jep framework[19]), and pushing results out through StateVariables. Estimators form a hierarchy, e.g. with 2 estimators for incoming Alt and Az positions of the telescope, and downstream estimators that combine or convert this data. The use of pub-sub communication makes deployment of estimators in one or many processes a flexible choice. We got smooth data flow through these estimators when feeding them with simulated data at 20 Hz. One of the estimators for derived data produced the telescope's actual state, e.g. as "tracking" or "moving".

The first HLCC prototype of the RAD applications was implemented in Java, that we considered better suited than C++ for high-level coordination, without demanding performance requirements.

For the current implementation of the HLCC applications, we decided to change from using Java and Python to using C++ and Python. Java worked very well for the prototype, and likely would have worked well also for the final applications. But LSV and instrumentation applications are being developed in C++ to leverage the huge experience in the ELT software development team and to avoid potential performance problems coming from JVM garbage collection, which could introduce unwanted jitter to applications. We hope that the lower efficiency we experience working with C++ will be compensated by synergies and code reuse across subsystems as well as less maintenance in the lower level infrastructure software through decreased support for the Java language.

We identified the HLCC interfaces and applications in a first design iteration and we have started now with the implementation. The Telescope Interface implements the ICD between all of CCS and the instruments. All requests from Telescope Interface will be served by delegating to other HLCC or LSV applications or to the Telescope Real-time Executor (TReX), described below.

As an alternative, especially during early development when these other applications do not yet exist or do not yet provide simulation capabilities of their own, the TelescopeInterface (Fig. 2-9) will delegate to the CcsSimulator (Fig. 2-10). The CcsSimulator will be also delivered to the consortia developing instruments, to have a frontend for testing their interactions with CCS.

In addition to the request-reply and publish-subscribe communication described in the ICD, instruments, as well as operators, will be able to access dedicated telescope data published in the Online Database.

The PointingKernel (Fig. 2-11) application controls all telescope subsystems. It interacts with TReX for most of the pointing logic, but also commands the LSVs directly.

The CentralFDIR (Fig. 2-12) application monitors those aspects of quality and failures that involve more than a single subsystem.

Other dedicated applications exist for star catalogues, monitoring and configuration, alarms, or specific tasks such as segment exchanges.

## TReX

Control loops with demanding real-time requirements described in the Control Strategy section are not part of HLCC; instead, they are allocated to the Telescope Real-time Executor (TReX) (Fig. 2-13), which communicates directly with LSVs and LCSs using, when necessary, the deterministic network (not shown in the figure). HLCC commands and monitors TReX.

This component of the system is now in the requirements' collection phase. What is clear is that the WFC and stroke management strategy and algorithms will, for a big part, be developed as part of commissioning, while gaining experience on the as-built telescope.

For this purpose, a flexible software framework for real-time control applications is required. The framework must be suitable for use by control engineers and a visual programming environment, comprising a palette of data analysis and algorithmic building blocks, is foreseen. The framework should not require detailed knowledge of real-time systems when mapping the application to the underlying hardware resources.

A demonstration prototype was developed in 2019 based on GNU Radio[20], a free open-source development toolkit to implement signal processing tasks. Although GNU Radio is not built with low-latency and control systems in mind, it seems possible to overcome the limitations with minor adaptations and by tailoring our use to the pure algorithmic domain. CS specific functions (e.g. I/O, monitoring, error handling and recovery) should be handled in a separate entity that interfaces the real world with GNU Radio. GNU Radio comes with a GUI usable by

non-software engineers and integrates well with C++ and Python.

Results with a computational load comparable to TReX show that 1kHz loop rates are reliably achievable. Measurements indicate that 2kHz loop rates may be possible.

## RTC AND ADAPTIVE OPTICS

The core component of any AO system is the Real Time Computer (RTC) which measures the incoming wavefront aberrations by means of sensors and corrects for them by means of a deformable mirror.

During scientific observation, the ELT telescope performs only guide probe AO, i.e. measurements done with a wavefront sensor (WFS) installed on the pre-focal station (PFS) and limited to the first few modes are used to reject low and mid spatial/temporal frequency wavefront. This is required to provide an image quality sufficient for handover to an instrument. Guide probe AO is performed by TReX, which stops performing it after INS handover; at this point the instrument drives the M4 to achieve the desired image quality [7].

There will be therefore one RTC per each instrument to implement high order AO modes and one RTC used on the telescope for commissioning and diagnostic (the Phasing and Diagnostic Station).

The ELT RTC architecture [21] is defined by ESO not only for the telescope, but also for the instruments, with the aim of streamlining development and leveraging re-usability. This architecture identifies two distinct components (Fig. 3).

Figure 3: RTC architecture.

Each of them targets functions in a specific domain and timescale and follows its own technology roadmap.

The Hard Real-Time Core (HRTC) implements the main AO control loops, which perform demanding computations on incoming WFS measurements and command actuators within tight timing constraints. The HRTC is interfaced to the AO WFSs and actuators on the Instrument via a dedicated RTC Real-Time Network. The HRTC commands both the M4 and the M5 via the Deterministic Network.

The Soft Real-Time Cluster (SRTC) is a set of computing nodes in charge of the high-level supervision and optimization of the HRTC. It is driven by requests from Instrument Control Software (ICS), as well as by the reception and automatic processing of telemetry data (e.g. measurements, commands). Computations elapse from seconds to minutes and involve algorithms operating on large data sets. A dedicated AO RTC Telemetry Network

interconnects the HRTC and SRTC. ESO has defined standards for the SRTC technology and delivers the AO RTC Toolkit: common RTC functions are addressed by a suite of software tools, libraries and reference implementations.

The HRTC is on the cutting edge of technology, and therefore rather than standardizing technology, we have decided to specify only interfaces, to achieve full replaceability as mitigation of obsolescence.

Nonetheless, the HRTC prototype (HRTCP) has been developed to explore the feasibility of building an ELT-size, AO RTC based on mainstream CPU and Ethernet technology - i.e. without accelerators or specific-purpose hardware. Key aspects to be assessed are modularity, scalability, long-term maintainability and upgradeability.

The HRTCP addresses a Multi-Conjugate AO (MCAO) configuration with six LGS WFS and adopts a functional breakdown that enables scaling it down to Single Conjugate AO (SCAO), such as the ELT Wavefront RTC (WFRTC), i.e. the RTC to be used in combination with the PFS and during commissioning for verification of telescope SCAO capabilities. The HRTCP operates at 500 Hz and implements a pseudo open-loop control (POLC) algorithm dominated by two memory-bound, Matrix-Vector-Multiplication (MVM) operations of size  $6,316 \times 55,392$  per loop cycle. All the external interfaces use 10 GbE signaling to ingest an aggregate 44.4 Gbps incoming pixel traffic and produce 87 Mbps actuator commands and 2.7 Gbps telemetry data towards the SRTC. Simultaneously, the system continuously receives disturbance data at 1 Gbps.

The *as built* HRTCP is comprised of 14 mainstream servers: two front-end nodes (namely A and B) per LGS WFS, one shared back-end node and one low-level supervisory node. Front-end node A implements the MVM in the direct control path using 48 CPU cores on a dual-socket AMD EPYC 7742 server. Front-end node B is responsible for the MVM in the offline control path (burst computation) and employs 56 cores on a dual-socket AMD EPYC 7501 server. Aggregate, each pair of front-end nodes delivers in excess of 600 GB/s memory bandwidth and 300 GFLOP/s only for these operations.

The internal communications employ 10 GbE, except for the collection of results from the front-end A nodes by the back-end node. Early tests showed that this is a major serialization point (contributing a 100  $\mu$ s delay over 10 GbE), thus dictating the use of single 100 GbE link. With this, the current HRTCP end-to-end latency (measured from last pixel image packet received to last command packet sent) is 244  $\mu$ s. The associated deviation is below 4  $\mu$ s over 2-minute intervals, with maximum excursions of 25  $\mu$ s.

The key challenge has been to achieve the required performance using only hardware platforms and software techniques with long-term maintainability and upgrade paths. A key mandate was to widen the profiles that could contribute to RTC development by targeting knowledge domains (i.e. CPU-based computation and Ethernet networking) available at ESO.

The development was started in early 2018 and the system is currently in operation at ESO premises. Important picks from this prototype development are:

- Recent, mainstream CPU architectures targeting High Performance Computing and providing fine NUMA granularity can be leveraged to fit our problem.
- Deterministic networking can be achieved with the native Linux network stack, using interrupt routing and controlling packet coalescence. Deterministic, overall latency performance is possible exploiting real-time techniques such as NUMA affinity, core isolation, thread pinning and inter-thread polling.
- It is possible to write maintainable C++ software that implements the above techniques, with little or no explicit vectorization (i.e. offloading this to the compiler). The current trend for increased CPU core count in CPU families helps mitigate the architectural constraints derived from core isolation and thread pinning.

The HRTCP will be used as a flexible platform where upcoming CPU families and networking devices can be benchmarked. In addition, several of the HRTCP design choices will be at the core of the ELT WFRTC.

A subset of the techniques developed within the HRTCP scope have been ported to the VLT domain. An upgrade of the VLT SPARTA systems will replace the obsolete, FPGA-based real-time core with a single server, while respecting the legacy (non-Ethernet) I/O interfaces.

## THE MINUSCULE ELT (MELT)

The Miniscule ELT (MELT) [9] is an optomechanical test bench comprised of key components such as a segmented primary mirror, a secondary mirror on a hexapod, an adaptive fourth mirror, and a fast tip/tilt mirror together that mimic certain functionalities of the ELT.

It is meant for testing and validating key functionalities to be used on the ELT during system verification, wavefront control commissioning, through the handover to science, up to regular diagnostic, monitoring, or validation during operations.

The main objectives of MELT are to deploy and validate the telescope control system as well as wavefront control algorithms for commissioning and operations.

The optomechanical setup uses the Active Segmented Mirror (ASM) with 61 piezo-driven segments and a diameter of 15 cm. It was used on sky on a VLT telescope during the Active Phasing Experiment (APE)[22].

Several beam paths after the optical train on MELT are conditioned and guided to wavefront sensors and cameras, sensitive to wavelength bands in the visible and infrared to emulate wavefront commissioning and phasing tasks.

In MELT, the ELT main axis control is emulated with a moveable diffraction-limited source that emits white light from the visible up to the K band through a turbulence generator. A single conjugate adaptive optics Shack Hartmann (SH) WFS is used in closed loop with an ELT RTC and M4 to test and validate offloading scenarios to M5 and the main axis. In addition, it is used to deploy and

validate wavefront control algorithms and the influence of AO on M1 phasing using the baseline SH high order WFS, but also M4 phasing issues with its petals, and scalloping. The bench also allows to test different phasing concepts.

The MELT Control System applies the same architectural concepts as the ELT. Furthermore, the central services developed for the ELT, are deployed in MELT as soon as they are released, such that their usage provides early feedback. MELT is therefore an excellent testbed also for the whole control SW architecture and tools.

The bench will help us to be as much as possible prepared when the telescope will send the star light through the optical train to be able to tackle the unforeseeable problems and not be caught up with the foreseeable ones.

## COMMON SW INFRASTRUCTURE

The control software of the ELT is built on top of a common software infrastructure, comprising libraries, frameworks and development tools for building, deploying, documenting and testing the applications.

Among these, particularly important is the Core Integration Infrastructure (CII). CII comprises communication libraries, configuration infrastructure, network value cache, and logging infrastructure for control applications. The communication part includes an interface definition language for defining the request/reply interfaces as well as the publish/subscribe contracts, independent from the actual protocol (ZMQ, DDS, OPC/UA, and others) used. CII provides APIs in three languages (C++, Python, and Java).

CII relies on a number of third-party products. For example, the Online Database (a central value cache on the control network) keeps its data split over three third-party databases: elasticsearch, redis, minIO. While we benefit from the stability and feature richness of these products, mastering them is a challenge. We also often find the need of creating additional tooling, in particular when we aim to allow our users to handle them on their development set-ups without direct support from the CII team.

Navigating in the problem space of performance versus usability versus maintainability, we are frequently discussing whether a given usage pattern should be supported in the CII infrastructure layer or not. A clear cut would be desirable between functionality implemented in ground-layer infrastructure, versus middle-layer frameworks, versus higher-layer subsystems. Defining this cut, or clear criteria for it, is an on-going challenge.

CII has been developed by Cosylab for ESO, from a specification of about 800 requirements in three years; the first version is being adopted by the control subsystems.

Different subsystems have different usage patterns for using the CII software, and currently the main activity consists in adjusting functionality according to user feedback and moving features between software layers.

We have recently transferred the user documentation from documents (word / pdf) to a collaborative platform (GitLab / reST / Sphinx / Jenkins). This enables users to prepare and propose improvements, while still being governed by a well-defined process. This has well

decreased the turn-around time for documentation updates and makes our documentation more helpful.

While CII gets more and more used in the control subsystems, we are getting ready to deal with the resulting higher amount of user feedback and support requests.

The development of GUIs is addressed instead by the Control UI Toolkit (CUT). CUT is a set of libraries, widgets and graphical design patterns tailored to the ELT Control System requirements. Qt is used for graphical rendering; Taurus [23,24] as an abstraction layer that provides a powerful MVC pattern specifically designed with control systems in mind. Additional custom widgets, utilities, color schemes, and documentation based in Taurus and Qt complete the GUI development environment.

Taurus was selected due to similarities in requirements to our own specification, offering:

- Extension capabilities: plugins for Taurus can be developed to enhance its communication capabilities, model access, plotting and image rendering.
- MVC design: allows decoupling widget and views development from models. While we develop models to access CII services, we can still continue development of application views using the "eval" model plugin, or any other plugin.
- Multiple expertise levels: developers in ELT varies in GUI software development experience. Taurus offers three ways to develop GUIs, from a very simple no-code approach, to complete freedom [24].
- Declarative binding: supports declaration in UI specification of binding between datapoints and widgets.
- Subscription, polling, filtering, customization and declarative configuration of UI.

Taurus is extensible by design, a fact that is appreciated and allows us to provide support for CII communication libraries and infrastructure as they are integrated in the development environment. At this moment, ELT includes Taurus in its Software Development environment, and we contribute our bug fixes and development directly to the upstream project. It also includes the Taurus CII Online Database Plugin. The Control UI Toolkit has been used until now to implement prototype and engineering GUIs.

## CONCLUSION

The ELT Control System faces major challenges that are expected to be overcome by the development of a System of Systems flexible up to the commissioning phase. After the requirements and design phase and the development of the technical infrastructure and of (large scale) prototypes, we are now moving to the serial development of the actual system components. The LCSs, primarily developed externally by outsourced contractors, LSVs and HLCC, shall be integrated into one single System user interface. Specific validation test benches (MELT) are operational and following the evolution of the project.

The Scientific First Light for the ELT is foreseen for the end of 2027 and our schedule is in line with this target.

## Abstract

The ITER Real-Time Framework (RTF) is a middleware providing common services and capabilities to build real-time control applications in ITER such as the Plasma Control System (PCS) and plasma diagnostics.

The RTF dynamically constructs applications at runtime from the configuration. The principal building blocks that compose an application process are called Function Blocks (FB), which follow a modular structure pattern. The application configuration defines the information that can influence control behaviour, such as the connections among FBs, their corresponding parameters, and event handlers. The consecutive pipeline process in a busy-waiting mode and a data-driven pattern minimizes jitter and hardens the deterministic system behaviour. In contrast, infrastructural capabilities are managed differently in the service layer using non-real-time threads. The deployment configuration covers the final placement of a program instance and thread allocation to the appropriate computing infrastructure.

In this paper, we will introduce the architecture and design patterns of the framework as well as the real-life examples used to benchmark the RTF.

## INTRODUCTION

The Plasma Control System is a dominant factor for the ITER pulsed operation, it controls all aspects of the plasma discharge from powering the superconducting magnets up to plasma termination [1]. PCS takes data from sensors and applies sophisticated algorithms to generate commands that are sent to actuators to control plasma parameters, such as position, shape or stability in a real-time context. Design, development and verification of real-time software in general is a complex and often lengthy process requiring multiple iterations until all timing relationships are satisfied and the application is stable and predictable.

The RTF is a flexible high-performance software base that facilitates the development and deployment of complex real-time applications [2]. Originally developed with the aim of control algorithms, the RTF can also be the basis for real-time data processing applications in ITER diagnostic systems.

The architecture design fully considered the modularity and portability of the software, and is applicable and extendable even in non-ITER environments. It hides many details specific to real-time systems (e.g., thread management, inter-thread data transfers, etc.), making the design and development of real-time software much easier and faster.

<sup>†</sup> email address: woongryol.lee@iter.org

Strict Quality Assurance (QA) process and code audits enforced software integrity to bring reliable system operation. Along with the EPICS pvAccess interface that enriches functionality for operation, the Simulink wrapper block allows control model transition from the design to the application in an agnostic way.

## ARCHITECTURE

### Overview

The RTF infrastructure provides a modular, fully abstracted environment with the following key features [3]:

- FBs are self-contained and do not have any dependency on hardware, inputs, and outputs or operating system within the code. All relevant information for the modules is delivered via configuration, fully reusable in any context.
- Full configurability of FBs, which can be chained together at the developer's discretion by configuration.
- Fully data-driven workflow. The FBs can be scheduled automatically based on the availability of input data.
- Configuration-based distribution of processing logic over different threads, processes and computer nodes (hosts).
- Support integrated operability using generated code from graphical system modelling tools (e.g. Simulink [4]).
- Full integration with ITER Control Data Access and Communication (CODAC). Out of the box support for multiple interfaces to other CODAC components (e.g. networks, archive, supervision, etc.).

Figure 1 shows the architecture of the RTF and a Real Time (RT) application including their main elements and how they interact. The main elements are:

- The **RT application** contains the processing logic that runs on different threads, processes or computer nodes (hosts) and contains:
  - The scheduler handling the execution of processing of FBs.
  - The FBs representing an operation with inputs and outputs.
  - The gateways responsible for ensuring that the data is transported between the FBs running in different threads, processes or nodes.
  - The RT applications running within multiple instances of the real-time process.

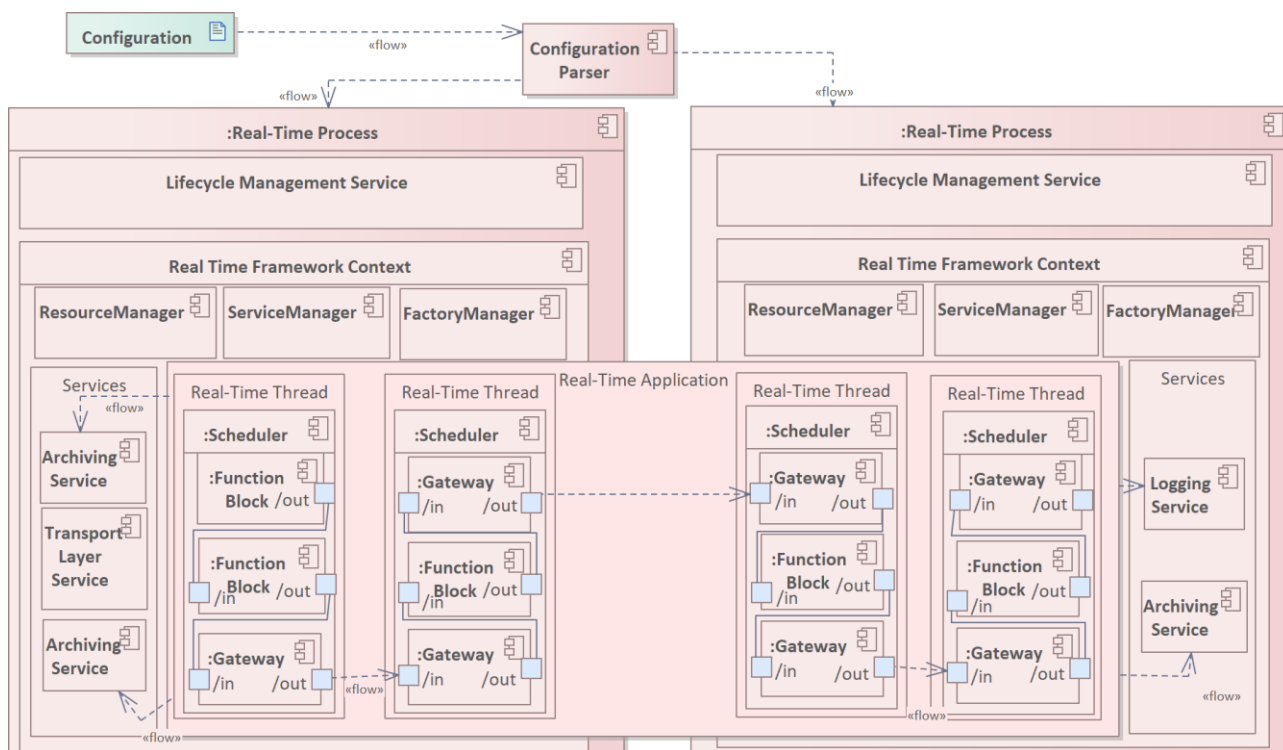

Figure 1: Context diagram of the Real-time Framework.

- The **real-time process** is the main process that runs on a node. This process has been specifically configured for real-time. It contains the following:
  - A life cycle management service managing the life cycle of the framework.
  - The real-time framework context - the key element of the real-time process consisting of Buffer, Queue and Thread Managers that help with tasks like allocating memory, transporting data and executing FBs. RTF context also includes Threads that execute the RT application and Services that provide high-level functionality for the RT application, e.g., logging and archiving.

### RT Application

Figure 2 shows a simple RT application that acquires data from two inputs, adds them together and applies them to an output. Each component in Fig. 2 represents a FB, and the links show the connection between input ports (on the left of the component) to output ports (on the right of the component). The framework handles the dependency-based execution of FBs in either single-threaded or multi-threaded environments as specified in the deployment configuration.

### Function Block

The Function Block is a representative atomic component to build application. The FB is similar terminology to the Blocks in the Simulink or the Functions in the LabView [5].

The FB is a function responsible for the desired operation, from primitive to complex process algorithms,

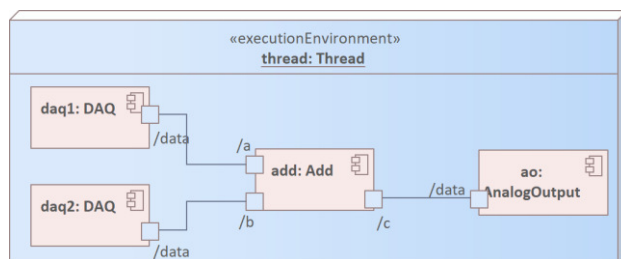

Figure 2: Example of an RT application executing in a single thread.

depending on the design intent. Each FB contains essential interface points: parameters, input signals and output signals that are constructed using a factory design pattern. Additionally it supports event trigger/handler along with parameter writers for asynchronous operation shown in Fig. 3.

FBs can be delivered as shared libraries and loaded to RTF-based applications in run-time as dynamic plugins. It allows decoupling user applications from core of the RTF. Designers can develop, maintain and share their custom libraries under different lifecycles and purposes. Only few of common FBs such as reading from and writing to console or file, and basic mathematical operations are provided with the framework.

FBs can encapsulate other FBs giving the RT application an apparent hierarchical structure. In the case of composite FBs, such encapsulation can either have functional implications on e.g., scheduling or conditional execution of contained FBs, or is used to simply group FBs for entirely conceptual or convenience reasons.

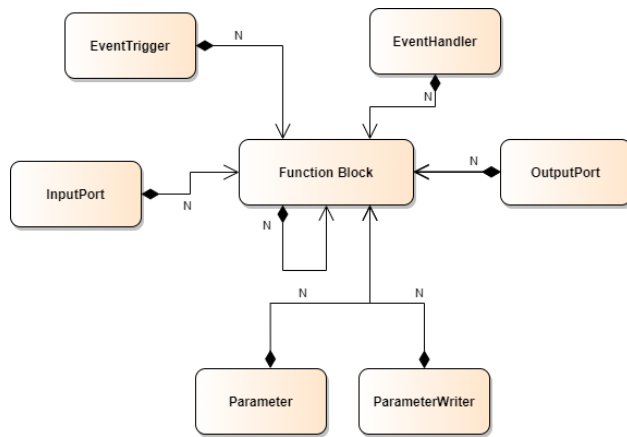

Figure 3: Schematic of a function block.

### Processing of Function Blocks in a Thread

FBs are instantiated and serialized in the loading phase of the RTF context. Thereby, multiple function blocks execute as a chain on the thread where they are deployed. The ordering of function blocks is determined by the relation between function blocks once the configuration is parsed.

Synchronization in real-time threads executing the FBs is implemented with busy-wait rather than through interrupts or callbacks to avoid context switching and effectively minimize jitter and response times. Thus, RT application runs properly once it has an appropriate CPU allocation, schedule policy and priority attributes.

On start (or re-entry) of the thread, all FBs are reset. Then, the thread enters the active state, which has the following stages (Fig. 4).

Figure 4: Processing of Function Block in a Thread.

- **RT process:** handles processing of the logic. All the inputs/outputs get updated in this stage.
- **Process events:** handles processing of all the events that have been triggered.
- **Process parameters:** updates the mutable parameters.
- **Validate:** validates the execution times and/or parameters to be validated.
- **Archive:** archives signals and all archivable objects.

The RT process is ideal for a hard real-time mode operation and should be constant over all the cycles. The underneath rule of execution of FB is to execute process method periodically under rt-thread, and thus ensure predictability of execution times. Fully data-driven mechanism requires the FB processing logic to be implemented in a non-blocking way. The remaining four consecutive jobs are executed in the offline real-time mode.

### Framework Life Cycle Management

Since the framework is a part of a distributed control system, multiple instances must be centrally controlled in an organized manner. The Life Cycle Management Service (LCMS) allows to centrally orchestrate the state transition along with loading of the configuration.

In order to increase performance and reliability, it is desired to maintain the core real-time engine of RTF as lightweight as possible, and handle all configuration loading, parsing and expansion logic in an external system/process. Portability is also ensured by exposing LCMS interfaces through an API which allows site-specific protocol implementations. Two protocols are currently supported; pvAccess protocol from EPICS v7 and native TCP/IP.

Although EPICS has been selected as a standard middleware for ITER control, the evolution of configuration propagation and the need for improvement of code in terms of the software QA process have been raised. RTF renovated the primarily interface function based on the PVXS [6] as thereby.

Figure 5 shows limited number of PVs that are created just after instantiation of the RTF and are ideal for operational control. Fig. 6 depicts RTF state machine operation addressed through the {}-RTF-OPSTATE PV. After loading the configuration, additional application specific PVs will be dynamically created and published. In order to support client in a conventional manner, RTF uses the normative type, which creates a structure holding the value, alarm, and time structure.

```

Figure 5: Default PVs shown by EPICS bundle Command Line Interface (CLI) tool, which are minimized for configuration transmission and operation after RTF instantiation.

## CONFIGURATION AND DEPLOYMENT

The RTF provides four types of configurations in an XML-based format.

- **Environment configuration** defines the computer nodes (hosts), processes and threads that host the RTF services and RT applications.
- **Service configuration** defines the services of the RTF that provide infrastructural capabilities such as a console, logging, archiving and communications between processes and across hosts.
- **RT application configuration** defines the RT applications in terms of configurable interlinked FBs that take inputs, perform processing and produce outputs.
- **Deployment configuration** assigns the services and RT applications to threads defined by the environment.

### Configuration Parser

## INTERFACE SUPPORT

The RTF also supports Simulink interface based on automatic code generation function. A direct transfer of a Simulink model to a real-time framework FB can be achieved and successfully executed. Fig. 7 shows how compiled library from Simulink can be used inside RTF through the application configuration. This offers an extremely powerful method to obtain the necessary code directly from a model.

</FunctionBlock>
```

## CASE STUDY USING RTE

## PCS Prototyping

The PCS Compact Controller (CC) is a continuous controller among architectural components for versatile control purpose. It is representative as a Proportional, Integral, and Derivative (PID) controller with fine-tuned attributes tailored for plasma parameter control. As first work, CODAC group implemented 19 FBs including trajectory block and plant model for the simulation. The FBs are nearly map to the individual Simulink block, verified fidelity of outputs between Simulink and RTF traces [7].

## Software Technology Evolution

Consequently, Simulink wrapper function had been devised and verified proper transposition from model to application with high fidelity of result. Customised FB, “*SimulinkBlock*”, loads the compiled library, which was automatically built by the RTF CLI.

Underlying concept is supporting the mutable parameter in the same manner as conventional FB. Therefore, model designer configures the desired function only by changing parameters, while maintaining the same external interface to the other FB. Even if model changed, thereby recompile the generated code, RTF FB always persists independently.

### *Plasma Diagnostics Data Processing*

Edge Thomson Scattering (ETS) diagnostics has been demonstrated in the running tokamak. The Thomson Scattering diagnostics gives reliable electron temperature and density profiles in magnetically confined plasma. A 5GS/CAEN DT5742 digitizer [9] operates in pulse mode synchronized with Nd:YAG Laser system where has up to 50Hz injection rate [10]. The customized data acquisition FB archives raw data through RTF transport layer whilst the output links to the fitting FB to eliminate back scattered signal. Passed series of signal conditioning, electron temperature is measured using lookup table where calibrated data is stored as per the wavelength from the polychromator signal.

The developed prototype covering complete data acquisition, processing path, archiving as well as measurements publishing can be used as a reference example for other ITER diagnostic systems.

### *Poloidal Field Coil Control for Plasma Start-up*

The most fundamental control module of PCS is coil power supply for discharge control. Poloidal Field (PF) coil is a main actuator for plasma breakdown and thereafter shape and position control. CODAC commenced implementing a real-life controller in order to evaluate both functional and non-functional behaviour of the PCS with collaboration of Korea Superconducting Tokamak Advanced Research (KSTAR) control team.

The full-featured mini-CODAC provides all ITER standard networking protocols such as real-time data communication, experimental data archiver and time synchronization. Additional installation of the RTF along with the PCS platform library facilitates building controller following the PCS architecture design.

11 PF controllers were devised complying with KSTAR native function model. Minimum protection function took into accounted, verified 20kHz run cycle in consecutive process pipeline such as exception handler, waveform generator, and PID function. Integrated operability was verified by implementing site-dependent interface functions such as for MDSplus, Reflective Memory network, and EPICS CA.

## CONCLUSION

The RTF is a flexible high-performance software platform that facilitates the development and deployment of complex real-time applications. It was designed to be portable and modular, enabling high reusability and maintainability of components constituting the real-time applications.

Factory design pattern, and rich function for multi-threaded program enables building application through configuration-driven process.

Prototyping activities on some of the operating Tokamaks have demonstrated its applicability for the implementation of ITER real-time control systems.

# MACHINE LEARNING PLATFORM: DEPLOYING AND MANAGING MODELS IN THE CERN CONTROL SYSTEM

J.-B. de Martel, R. Gorbonosov, Dr. N. Madysa, CERN, Geneva, Switzerland

## Abstract

Recent advances make machine learning (ML) a powerful tool to cope with the inherent complexity of accelerators, the large number of degrees of freedom and continuously drifting machine characteristics.

A diverse set of ML ecosystems, frameworks and tools are already being used at CERN for a variety of use cases such as optimization, anomaly detection and forecasting. We have adopted a unified approach to model storage, versioning and deployment which accommodates this diversity, and we apply software engineering best practices to achieve the reproducibility needed in the mission-critical context of particle accelerator controls.

This paper describes CERN Machine Learning Platform (MLP) - our central platform for storing, versioning and deploying ML models in the CERN Control Center. We present a unified solution which allows users to create, update and deploy models with minimal effort, without constraining their workflow or restricting their choice of tools. It also provides tooling to automate seamless model updates as the machine characteristics evolve. Moreover, the system allows model developers to focus on domain-specific development by abstracting infrastructural concerns.

## MOTIVATION

Machine learning techniques and in particular neural networks are well suited to the unique challenges of particle accelerator controls [1]. Neural networks are already being used in CERN controls for a variety of use cases including anomaly detection [2], trajectory steering at LINAC4 and AWAKE [3], beam measurements [4] and collimator alignment [5] in the LHC.

In recent years, the rapid expansion of the ML ecosystem and the emergence of MLOps has created a multitude of tools and frameworks to assist data scientists with different aspects of the ML development workflow. These include tooling for experiment tracking and model management (e.g. Neptune [6], Comet [7]), feature storage (e.g. Feast [8]), pipeline and workflow automation (e.g. Pachyderm [9], Airflow [10]), hyper-parameter tuning (e.g. Katib [11], Sigopt [12]), deployment (e.g. Seldon [13]) and monitoring (e.g. Fiddler [14], Evidently [15]). Comprehensive tools which aim to address the whole ML lifecycle also exist, both open source (e.g. MLFlow [16], Kubeflow [17]) and proprietary (e.g. AWS Sagemaker [18], GCP Vertex AI [19]).

However, none of these comprehensive tools fit the use-cases required by CERN controls – they either constrain model developers' workflows or require in-depth knowledge

of infrastructural tooling. Furthermore, these tools do not fully address requirements specific to accelerator controls such as high criticality, continuously drifting machine characteristics, variety of use-cases (online and offline, embedded and standalone) and the need to maintain different model configurations for each accelerator beam type.

For these reasons we present a machine learning platform (MLP) specific to CERN controls. It addresses the aforementioned issues by abstracting and simplifying model management, storage, and deployment concerns. In addition, it is open and extensible by design to cope with the rapidly evolving ML landscape and lack of generally accepted industry standard for MLOps. For the same reason, it is designed to be compatible with diverse ML model training environments (local, CERN infrastructure, and public cloud). Helping with rapid development of new models with tools such as experiment tracking or workflow automation are not goals of MLP – instead, it is designed to integrate with existing solutions.

## CONCEPTS

We define models as the combination of a model type and model parameters. Model types contain the algorithm and logic of the model, e.g., the neural network architecture, the framework, and data pre- and post-processing. Model parameters are the data which configures the model type, e.g. trained weights of neural networks, and any other configuration variables. As the format of model parameters is highly dependent on the framework used<sup>1</sup>, we decided to treat model parameters as opaque data, which we store but don't inspect within MLP.

A given model type can be associated with multiple model parameters. One use case for this is the use of different model parameters for each type of particle beam produced by the accelerators. The opposite is also true, given model parameters can be associated with different model types. For example, a given set of trained neural network weights can be used by a same model surrounded by different pre- and post- processing logic for different use cases.

Model types and model parameters evolve independently and are versioned separately, so we define model type versions (MTV) and model parameters versions (MPV). MTVs and MPVs compatibility follows a many-to-many relationship, as shown in Fig. 1.

The combination of an MTV and a compatible MPV forms a model. Models are fully configured neural networks or

<sup>1</sup> Common formats such as ONNX [20] exist but don't support certain operations such as custom layers or loss functions.

Figure 1: Model types, models parameters and compatibility.

other algorithms which can perform predictions. They expose a uniform prediction API. Models can be both embedded into a client process or deployed as a standalone process and accessed remotely.

## MODEL DEVELOPMENT AND USAGE WORKFLOW

MLP has been designed in collaboration with ML model developers and follows their general workflow without restricting it. This section describes MLP features in the order in which they appear in a typical workflow.

### Defining a Model

Developers define models exposing a common interface, the MLP Model API. This interface defines four operations:

1. a *fit* operation to train the model on the provided input data;
2. an *export parameters* operation to extract the current values of all model parameters;
3. an *import parameters* operation to configure the model using the provided parameters;
4. and a *predict* operation to return a prediction from the input data.

### Registering Model Types

MLP aims to minimize the impact on model developers' workflow by automating management actions as much as possible. Nowadays the majority of model developers use Git as a version control system for their source code, and often use git tags to label particular versions of interest. MLP leverages git tags to automate model type registration: model types are registered automatically when developers push new tagged versions of their model code. A single project can contain multiple models (for example, this is crucial for composite models such as Auto-Encoders [21]). When a new version of the project code is pushed, one MTV is automatically registered within MLP for each model belonging to the project.

### Publishing Model Parameters

Model parameters registration cannot re-use the same mechanism as model types since model parameters are created programmatically, practically never stored in git due to their large size and usually created at the end of a lengthy training process. Without using MLP, many model developers at CERN export the trained parameters to disk or an

external service within the training script. This requires handling infrastructural concerns such as where to store these weights, how to version them, how to share them with other developers, monitoring the disk space available, etc. This often results in inconsistent naming patterns and file locations which creates additional complexity and a maintenance challenge.

MLP addresses these concerns by providing a client library to register trained parameters. Developers simply provide the model instance, a name for the trained parameters and a version number.

In continuous retraining use-cases, users can also leverage the version generation feature and let MLP decide which version number to assign to the new model parameters version to avoid implementing a complex versioning algorithm themselves.

Based on semantic versioning [22], the automated versioning logic is optimized for common use cases and looks at a limited amount of information to make an informed decision: the currently used MTV and the compatible MPVs registered in MLP. It will refuse to guess in the face of ambiguity. Table 1 illustrates the version guessing behavior for the most common cases.

Table 1: Model Parameters Version Number Generation

MTV	Highest MPV	⇒	Generated MPV
1.0.0	none exist yet	⇒	1.0
1.0.0	1.0	⇒	1.1
1.6.0	1.1	⇒	1.2
2.0.0	1.2	⇒	2.0
3.3.0	4.0 (no 3.x)	⇒	ambiguity
3.3.0	4.0 (3.3 exists)	⇒	3.4

### Managing Compatibility

The default behavior of the platform is optimized for the common use case while leaving the model developer in full control. When a MPV is published from a MTV instance, a compatibility link between them is created automatically.

Furthermore, MLP, based on semantic versioning, makes new MTVs inherit all the compatible MPVs from the previous MTV with the same major version number. The same applies to MPVs. When a breaking change is made to a model type or model parameters and compatibilities should not be copied from the previous version, model developers should bump the major version to indicate the backward-incompatibility to MLP and then the compatibilities will not be copied. For niche use cases, it is also possible to disable compatibility copying on creation. Compatibility links can also be added and removed manually using the client library.

### Using Embedded Models

To embed an MLP model in an application written in the same language as the model, developers should use the client library to instantiate an embedded model. The client

application must specify the class of the locally available model type version and provide a parameters name and version. The client library will then take care of retrieving the appropriate MPV and load them into the model.

Users can also choose to always use the latest compatible parameters version. This is the right choice for most use cases. Together with automatic versioning, this provides a way to update running models automatically.

Using Standalone Models

MLP models can also be used as standalone models and accessed remotely using the standalone model API. Users connect to the model by specifying the model type name and model parameters name; they can then use the model as if it was available locally.

This not only allows models to be called from any language that supports HTTP requests, but also enables client applications to always use the latest models with no effort required from application developers. Standalone models serve prediction requests over the network, allowing them to be called from any language, not just the language in which they were written.

IMPLEMENTATION

The main components of the implementation are the model API, the client library, the model registry server, and the standalone serving cluster. A simplified overview of the system architecture is presented in Fig. 2.

Model API

Today, the machine learning landscape is heavily dominated by Python and virtually all models at CERN are implemented in the Python language. For this reason, MLP models are currently restricted to Python and the model API is implemented using Python abstract base classes [23]. A model class must implement the *MlpModel* interface (see Fig. 3) to be considered a model type by the Machine Learning Platform. This is usually accomplished through direct inheritance, although other methods for niche use cases exist. Default extensible implementations of parameter saving and

loading logic are provided for commonly used frameworks (tensorflow [24], pytorch [25], scikit-learn [26]) to facilitate the implementation.

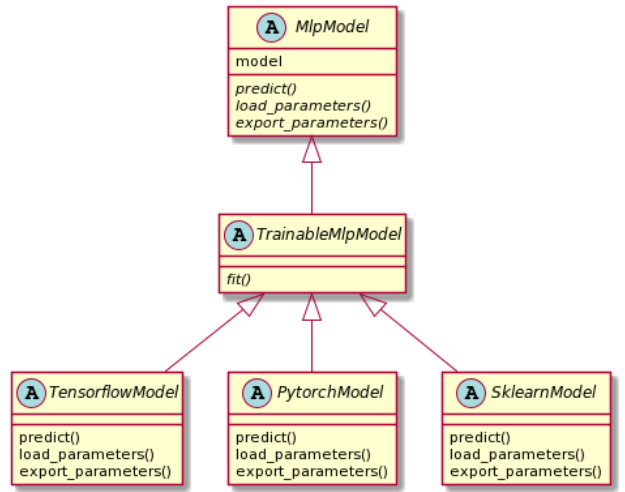

Figure 3: Class Diagram of the MLP Model API.

Model Registry Server

The model registry server is responsible for storing and managing MTVs, MPVs and their compatibilities. It also provides the version generation logic described above. It is implemented as a standard Java/Spring Boot application exposing REST endpoints and documented with Swagger. It uses a relational database to store MTV, MPV and compatibility metadata and an object storage service to store MPV binary objects (trained weights). The relational database is an Oracle database versioned with Liquibase [27]. The object storage service currently uses a CERN NFS service but will change to the Openstack Object Store (Swift) in the near future.

Client Library

MLP provides a single client library for model developers and users alike. Distributed as a Python package, it allows

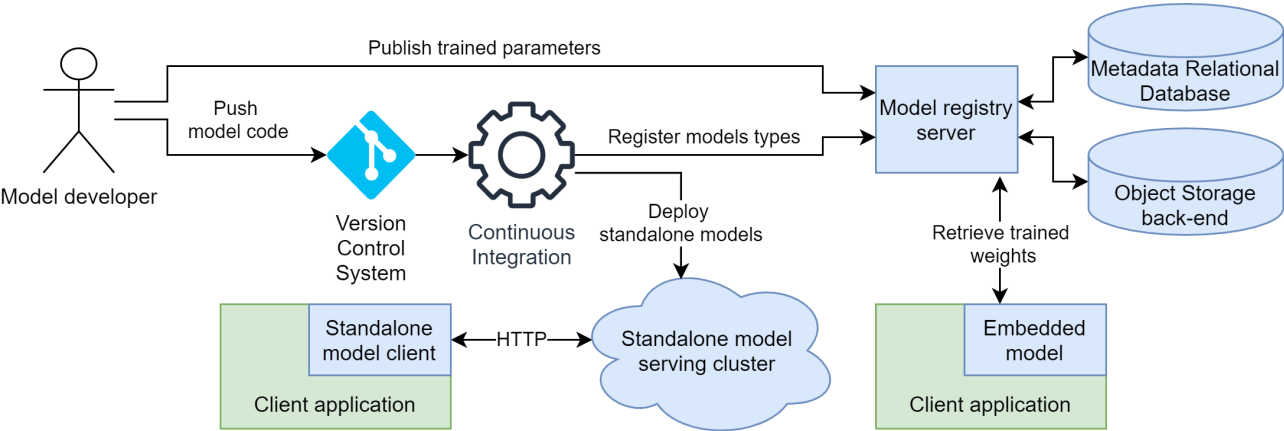

Figure 2: Simplified architecture diagram. Highlighted in blue are the components provided by MLP.

model users to publish model parameters, perform search queries against the model registry, and instantiate and use both embedded (see Listing 2) and standalone (see Listing 5) models.

To publish the model parameters of a trained model to MLP, model developers instantiate the MLP client and call a publishing method, providing the trained model, a name for the parameters, and an optional version number, as shown in Listing 1.

```
from mlp_client import Client, Profile, AUTO
from my_model import MyModel
```

```
model = BeamLineModel()
model.fit(...)

client = Client(Profile.PRO)
client.publish_model_parameters_version(
    model,
    name="proton_beam_config",
    version=AUTO, # generated by server
)
```

Listing 1: Publishing model parameters versions

When re-training a model continuously, the combination of automatic version generation in the training process (Listing 1) and automatic version selection in the consumer process (Listing 2) makes it easy to set up continuous retraining processes without implementing complex version management logic on both the training and consumer sides.

### Registration Automation

Automatic model type registration is accomplished using Continuous Integration (CI). Model developers only need to include a Gitlab CI template provided by MLP. As a single project can contain multiple models, model developers must also register their models as Python entry points under a specific key, as shown in Listing 3.

When model developers push a git tag, the CI jobs defined by the template will publish the package containing the model code to a central repository. It will then iterate over all the models declared in the package and publish them to the

```
from mlp_client import Client, Profile, AUTO
from my_model import MyModel
```

```
client = Client(Profile.PRO)
model = client.create_model(
    model_class=BeamLineModel,
    params_name="ion_beam_config",
    params_version=AUTO
)

result = model.predict(data)
```

Listing 2: Using embedded models

```
[options.entry_points]
mlp_models =
    model_1 = awake:VaeEncoder
    model_2 = awake:VaeDecoder
```

Listing 3: Model type declaration in setup.cfg

model registry server. The version of the new model types is determined from the name of the tag. The provided CI template can be extended with custom steps, such as linting and testing jobs, as shown in Listing 4, leaving model developers complete control of their CI pipelines and allowing them to add additional model validation steps if appropriate.

```
include:
- project: machine-learning-platform/mlp-ci
  file: mlp-ci-template.yml

variables:
  project_name: simple_ann

my_custom_test_job:
  script: ./custom-test-script.py
```

Listing 4: Including and extending the Gitlab CI template

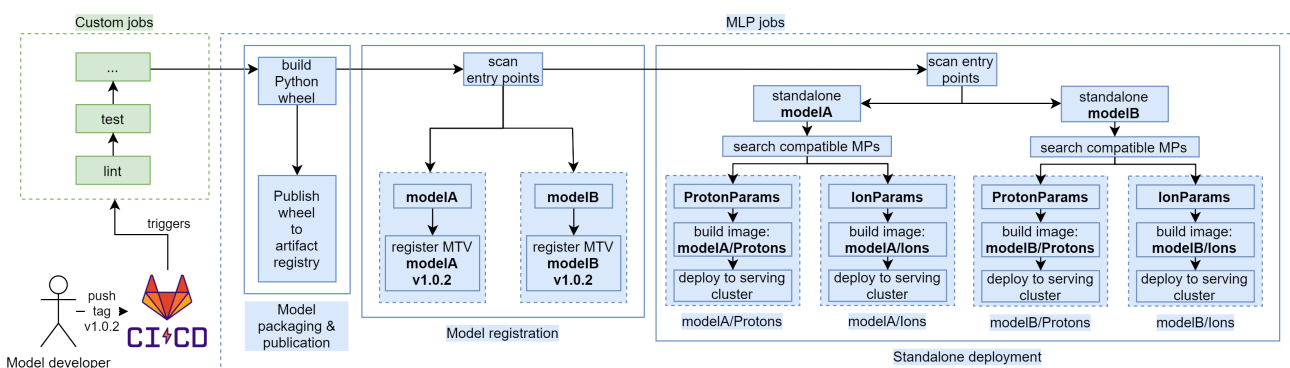

Figure 4: Simplified CI diagram.

## Standalone Deployment

If the model is declared as standalone, a standalone deployment job is also run. For each model type declared in the model developer's project, the standalone deployment job will identify all compatible model type / model parameters combinations and deploy the latest version of each pair to the standalone serving cluster. To deploy the models to the serving cluster, the standalone deployment job first builds container images which include the MTV, the MPV and a light Python web server. The produced images are deployed to the standalone serving cluster in a subsequent CI job, replacing outdated models if applicable. A simplified diagram of the pipeline is shown in Fig. 4. When the container is started, the web server listens for prediction requests, forwards them to the MTV/MPV combination, and returns a serialized result to the remote caller.

## Standalone Serving

The standalone serving component, still in the prototype phase [28], is responsible for serving model predictions to remote clients over HTTP. It is currently implemented as a Kubernetes cluster with an Nginx ingress which listens for prediction requests and forwards them to the appropriate model container. Users can access standalone models using the Python client and use them in a similar way to embedded models, as shown in Listing 5. At the moment, a simple json-based serialization mechanism is used and will be improved in the future.

```
from mlp_client import Client, Profile, AUTO
from my_model import MyModel

client = Client(Profile.PRO)
model = client.create_standalone_model(
    model_class="BeamLineModel",
    params_name="proton_beam_config",
    params_version=AUTO
)
result = model.predict(data)
```

Listing 5: Using standalone models

Technical solutions to autoscale model containers based on usage are currently under investigation. Candidates include the Kubernetes Horizontal Pod Autoscaler [29], KEDA [30] and KFServing [31].

## ACHIEVEMENTS AND FUTURE PLANS

Despite its early prototype status, MLP is already undergoing user testing for an application in the AWAKE experiment [32] using embedded models. It is also being evaluated for prediction tasks at the Super Proton Synchrotron, CERN's second largest accelerator, using convolutional neural networks.

The future plans of MLP are primarily focused on integration with other systems, including ML-specific tools and

CERN internal services. ML-specific tools include experiment management tools such as Neptune [6] or Weights & Biases [33] and workflow and pipeline automation tools such as Apache Airflow [10]. CERN internal tools include a generic GUI application for numeric optimization, the accelerator time-series data logging service (NXCALS [34]), and settings management tools (INCA/LSA [35]).

Other plans include opening MLP to public cloud services to simplify model training on external infrastructure and adding user-defined metadata to models to enhance search capabilities.

### Abstract

The photon beam lines and instruments at the European XFEL (EuXFEL) are operated using the Karabo control system that has been developed in house since 2011. Monitoring and incident analysis requires quick access to historic values of control data. While Karabo's original custom-built text-file-based data logging system suits well for small systems, a time series data base offers in general a faster data access, as well as advanced data filtering, aggregation and reduction options. EuXFEL has chosen InfluxDB as backend that is operated since summer 2020. Historic data can be displayed as before via the Karabo GUI or now also via the powerful Grafana web interface. The latter is e.g. used heavily in the new Data Operation Center of the EuXFEL. This contribution describes the InfluxDB setup, its transparent integration into Karabo and the experiences gained since it is in operation.

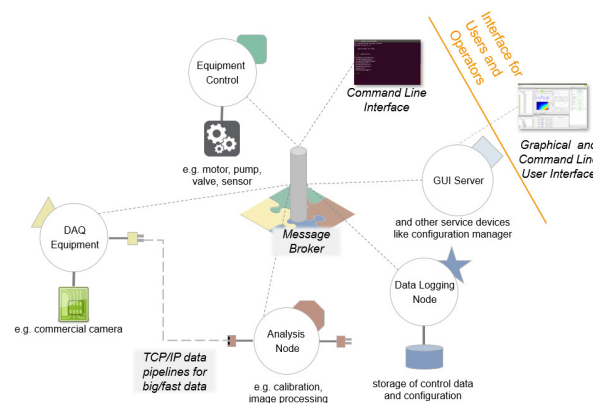

Figure 1: A Karabo installation showing Karabo devices with various tasks. Broker and pipeline communication lines are indicated.

### KARABO AND THE EuXFEL

The European X-ray Free Electron Laser (EuXFEL) facility [1] provides hard and soft X-ray beams at three photon beamlines to six instruments. Up to 27,000 photon pulses per second are arranged into 10 Hz trains with an intra-train pulse repetition rate of 4.5 MHz. The Karabo framework [2–4] has been designed and developed in-house since 2011 for control, online data analysis, and data acquisition at the photon beam lines and the scientific instruments.

In Karabo, so-called devices communicate via a central message broker. All devices using the same broker *topic* form a Karabo installation. Whereas broker communication is considered to be “slow” data, big or “fast” data like images are sent via TCP/IP data pipelines that can be flexibly configured, e.g. for calibration, analysis, or preview purposes. Figure 1 gives an overview of a Karabo installation.

A Karabo device exposes a self-description of its control interface, i.e. its *schema*. Karabo's generic graphical user interface (GUI) uses the schema to render the representation of a device. Devices can have one of manifold tasks:

- interface some hardware like a pump or a motor,
- control a detector and read out its data,
- analyse data,
- orchestrate other devices,

- provide a system service like serving as entry point for the GUI, logging data, managing alarm states, or managing configurations.

To communicate with each other, the Karabo devices expose methods that can be called remotely in the distributed system. Besides being directly called, these *slots* can be subscribed to *signals* of other devices. When such a signal is emitted with arguments, all subscribed slots are called with these arguments. In the process, only a single message is sent to the broker that distributes the message according to the subscriptions, as is shown in Fig. 2. This signal/slot mechanism allows Karabo to be fully event-driven, regular polling of e.g. device properties is not needed. That a single message to the broker is sufficient also for a device with a signal that many other devices have subscribed to, ensures that there is no overhead for such a “popular” device.

### FIRST KARABO DATA LOGGING IMPLEMENTATION

Data logging in a Karabo installation is organised via a few dedicated devices. A “data logger” device (or several that share the load) subscribes to the signal for property updates of the other devices. Properties are configuration parameters or read-only values like the reading of a temperature sensor. Via the signal/slot mechanism, the logger is informed about every property update and when this update occurred, i.e. the timestamp of the update, and stores it in the backend of the logger. Similarly, the device schema and its potential

\* gero.flucke@xfel.eu

Figure 2: Karabo signal/slot messaging via the broker.

run-time updates are stored. “Data log reader” devices are responsible to read back the stored data. One can query either the changes of a property in a time interval (*trendline* data) or all properties of a device and its schema at a given point in time. A single “Data logger manager” device per Karabo installation orchestrates loggers and readers.

The first Karabo data logging implementation, started in 2014, was based on human readable ascii files. Each file logs properties of a single device with one line per property:

```

20200719T184128.573059Z
|1595184088.573059|804227972
|actualPosition|FLOAT|35.91043||VALID
  
```

Besides the timestamp in two formats and the corresponding id of the EuXFEL train of photon bunches, the name, type and value of the property, and some meta information is logged. A further file stores the device schema, serialised to an XML format. To reasonably speed-up reading all property updates in a time interval, binary index files are created per property of interest. Figure 3 shows the result of such trendline requests in the Karabo GUI. The actual position of a motor and its state are displayed, as part of an incident analysis. Since Karabo is event-driven, no new data points exist when the motor is not moving. The zoom into the end of the curve shows that the motor decelerated and got stuck – in fact, the detector moved by the motor collided with another object since, after a change of the setup, the limit switch that would prevent such collisions was unfortunately not adjusted.

Due to limited screen resolution, a GUI cannot display arbitrary details of a trendline. Therefore, the trendline data request specifies a maximum number of points to return. If the requested time interval contains more data points, a simple down-sampling algorithm is applied: just every 2<sup>nd</sup>, 3<sup>rd</sup>, etc. data point is returned.

### Drawbacks

Deployment of such a logging and data retrieval mechanism is easy since it depends only on the availability of disc space and therefore suits well for small Karabo installations. On the other hand, operation at EuXFEL reveals some (obvious) drawbacks. Storing data in text files does not scale well concerning disc space. At EuXFEL, data older than three months were automatically moved to an archival

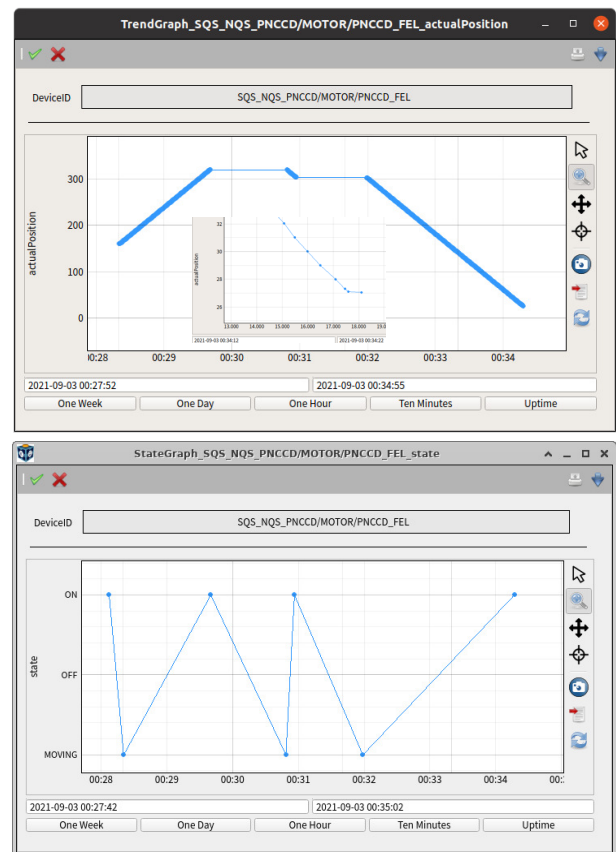

Figure 3: Historic trendline data for the position in mm of a motor that is moved back and forth, overlaid with a zoom into the right end of the curve (top), and the corresponding motor state changes (bottom).

location. Hence, access to such data required extra effort. Furthermore, data read-out could be slow: depending on the number of property updates since a device was last restarted, reading back the configuration of a device at a given point in time could take in the order of minutes. The lack of statistical methods for data downsampling could result in the loss of short timescale features in the data. Two requests of the same data with only slightly differing time intervals could return markedly different data, due to the sparsing algorithm that was implemented.

## TRANSITION TO AN INFLUXDB BACKEND

Given the drawbacks of the ascii file based solution, the Karabo development team looked for a better storage backend. Timeseries databases were considered to be particularly well suited, as they are optimised for retrieving data along the time axis. InfluxDB [5], Prometheus [6], and Timescale [7] were considered and finally InfluxDB was chosen. A prototype Karabo device interacting with an InfluxDB proved the feasibility in 2018.

In order to allow for a transparent transition and to keep the text based logging backend available for small Karabo

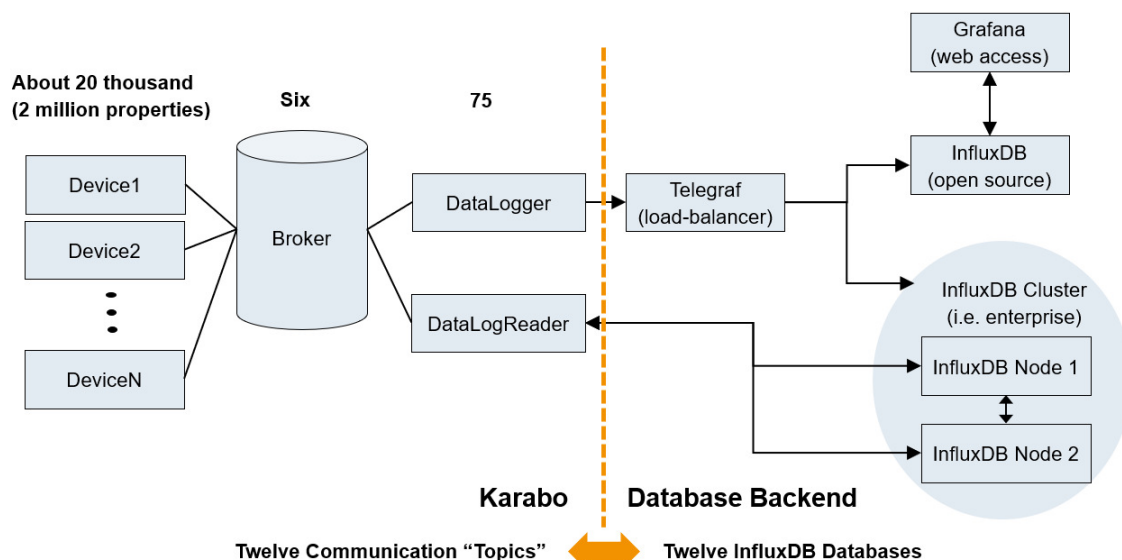

Figure 4: Schematic view of Karabo data logging and its InfluxDB backend.

installations, a new logger and a new log reader device were developed. The logger manager device is now configurable to switch between ascii file and InfluxDB backend.

An InfluxDB installation can host many independent *databases*. All data of a Karabo installation is stored in one such database, identified by the broker topic of the Karabo installation. Each device is mapped to three InfluxDB *measurements*, one for the schema, one for events like device instantiation and shutdown, and the main one for the device properties. InfluxDB *fields* relate to Karabo properties. To ease schema evolution of devices like changing the data type of a property, the field name is suffixed with its type, e.g. `actualPosition-FLOAT`. The mapping between the Karabo and InfluxDB supported types is straight forward for integer or floating point numbers, booleans and strings. Special treatments are needed for the following cases: Non-numeric floating point values (`nan`, `inf`) are stored as strings in fields with an extended field name suffix (e.g. `-FLOAT_INF`), unsigned 64-bit integers are re-interpreted as signed integers, and newline characters in strings have to be mangled. Since InfluxDB does not support arrays, vectors of numbers are stored as comma separated strings. To overcome the ambiguity between an empty vector of strings and a vector with a single empty string, vectors of strings are stored as the base64 encoded JSON representation. Only the Karabo specific data types like raw binary data, table data, and the schema require Karabo for de- and encoding. These types are stored as base64 encoded result of Karabo's binary serialisation.

Many devices update their schema regularly at run time, but typically only a few schema variants exist. Since the serialised binary of a schema (i.e. the self-description of a device) can easily surpass 500 kB, only a schema digest is stored for every update. The schema itself is only stored when the value of such a digest is not yet stored in InfluxDB.

Property updates are transmitted from the data logger device to database backend using the InfluxDB line protocol. By default, data is flushed when at least 200 lines are accumulated.

Figure 4 shows a schematic overview of the Karabo data logging infrastructure with its InfluxDB backend. About 20,000 devices with roughly 2 million properties are distributed among twelve Karabo installations that communicate via six broker instances. In total, 75 data logger devices write to a single load-balancer. The balancer duplicates and forwards the data, once to a standalone InfluxDB instance running the open source edition, and once to a cluster of two instances for data and service redundancy. Running instances in a cluster requires the InfluxDB enterprise edition. In case one of the two storage locations is down, the balancer caches the data in memory. The cluster is the main backend, serving Karabo initiated read requests, whereas the open source instance can be used by other services, without interfering with the control system.

## Performance and Operational Experience

InfluxDB data logging at the EuXFEL is in production since summer 2020; data from January 2020 onward has been migrated into the new system. So far, more than 240 billion property updates have been stored, increasing by about 10 billion each month. In total, about 14 TB of disc space is needed per InfluxDB node so far.

The network input to the load balancer is typically about 20 Mb/s, but varies, reflecting that Karabo is event-driven and that the list of Karabo devices that are online at any given point in time can vary. Usually, the data is available for reading with a delay of about 30 s only. This performance was significantly compromised when a Karabo device injected data with timestamps months in the future. Due to the internal data layout in InfluxDB *shards* containing temporal blocks of data, the database frequently internally reorganised

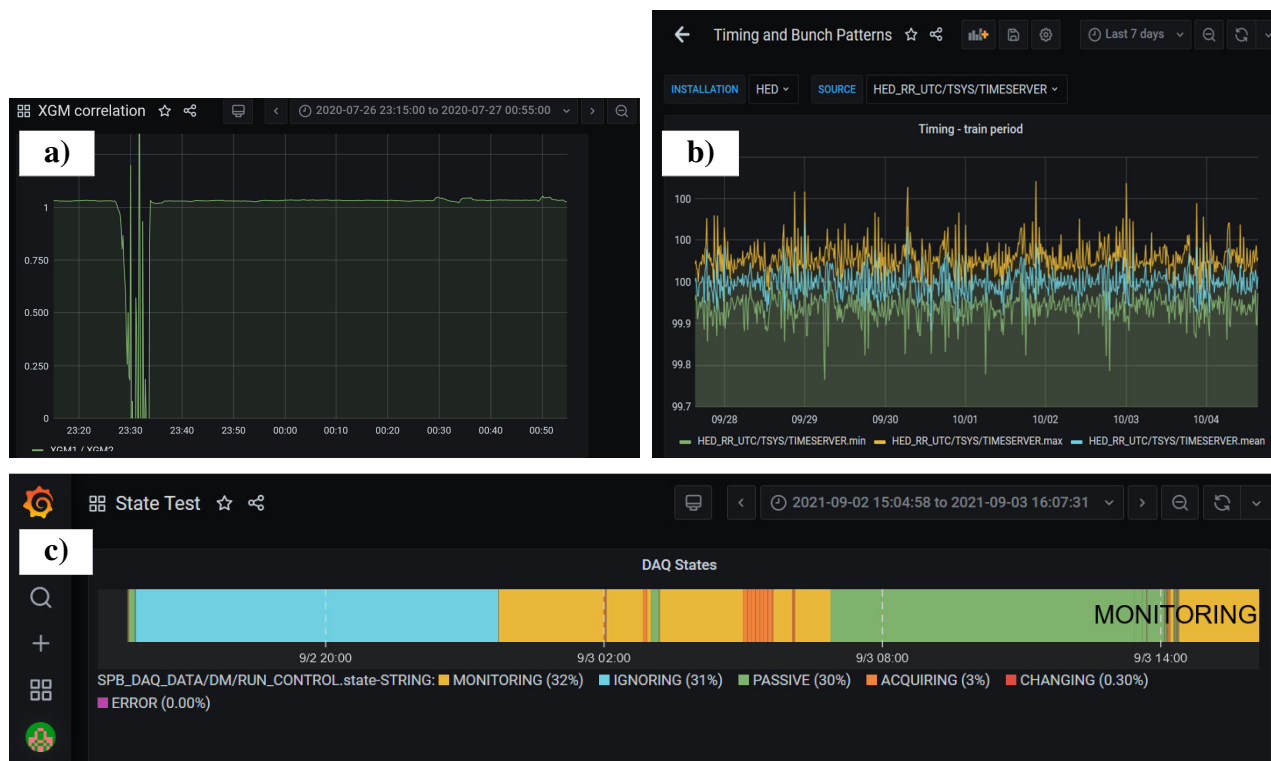

Figure 5: Examples of data displays using Grafana: The ratio of properties from two different devices (a), an overlay of minimum, mean, and maximum of a data trendline that has too many points to show them all (b), and the visualisation of the time development of a string property (c).

data, and the latency increased to over an hour. If there are too many points in a requested time span, down-sampling of trendline data is done in InfluxDB by querying averaged data in equally spaced time intervals. Therefore, short-term features are better preserved and data requested for only slightly different time intervals is more uniform.

All the data stored so far (> 1.5 years) is quickly available. A GUI request to display one week of data of a property that updates every 5 s (and therefore needs averaging) is almost instantaneous.

The planned 3 years of data retention will be affordable. In addition, the InfluxDB internal organisation of the data in shards offers the possibility to keep a reduced set of the data (e.g. averages) for even longer.

## GRAFANA USER INTERFACE

Using InfluxDB instead of a custom data storage backend allows external tools to query, retrieve and visualise the data. At the EuXFEL, Grafana [8] has been chosen due to its rich feature set, the fact that both Influx query languages, InfluxQM and Flux, are exposed, and due to a large and active online community that provides many examples.

The resulting low entry threshold enables non-developers to create data views in so-called dashboards, available for others. A nice example of a simple data display that is not easily available within Karabo is the correlation of properties of different devices, see Fig. 5a). When down-sampling

is needed, further statistical options besides averaging are available, e.g. minimum and maximum value within the evaluated interval. Overlaying all three as in Fig. 5b) allows efficient visualisation of trends alongside outlier preservation. Grafana can even be extended by plugins. The one used in Fig. 5c) displays the time evolution of a string that changes between a few discrete values.

Besides usage in the instrument hutches, Grafana dashboards have become a key element of the Data Operation Center (DOC) at the EuXFEL. The DOC is a co-effort of EuXFEL's Data Department groups: Controls, Electronic and Electrical Engineering, Data Analysis, IT & Data Management, and Detector Operation. The DOC monitors services that the department provides during X-ray operation, and gives pro-active support for the scientific instruments. The main Grafana dashboard of the DOC gives an overview of the status of the most important services and displays alerts if something is outside its expected range, e.g. the frame rate of centrally triggered cameras, see Fig. 6. In this example, the status overviews show no errors whereas the DOC alerts show some long lasting, non-critical problems<sup>1</sup>. Scientific data taking and detector calibration processing are followed closely. For similar systems placed at several instruments, the pull-down menu of a generic dashboard can be used to switch between the different installations, enabling the

<sup>1</sup> Further fine tuning is needed to avoid their appearance on the main page.

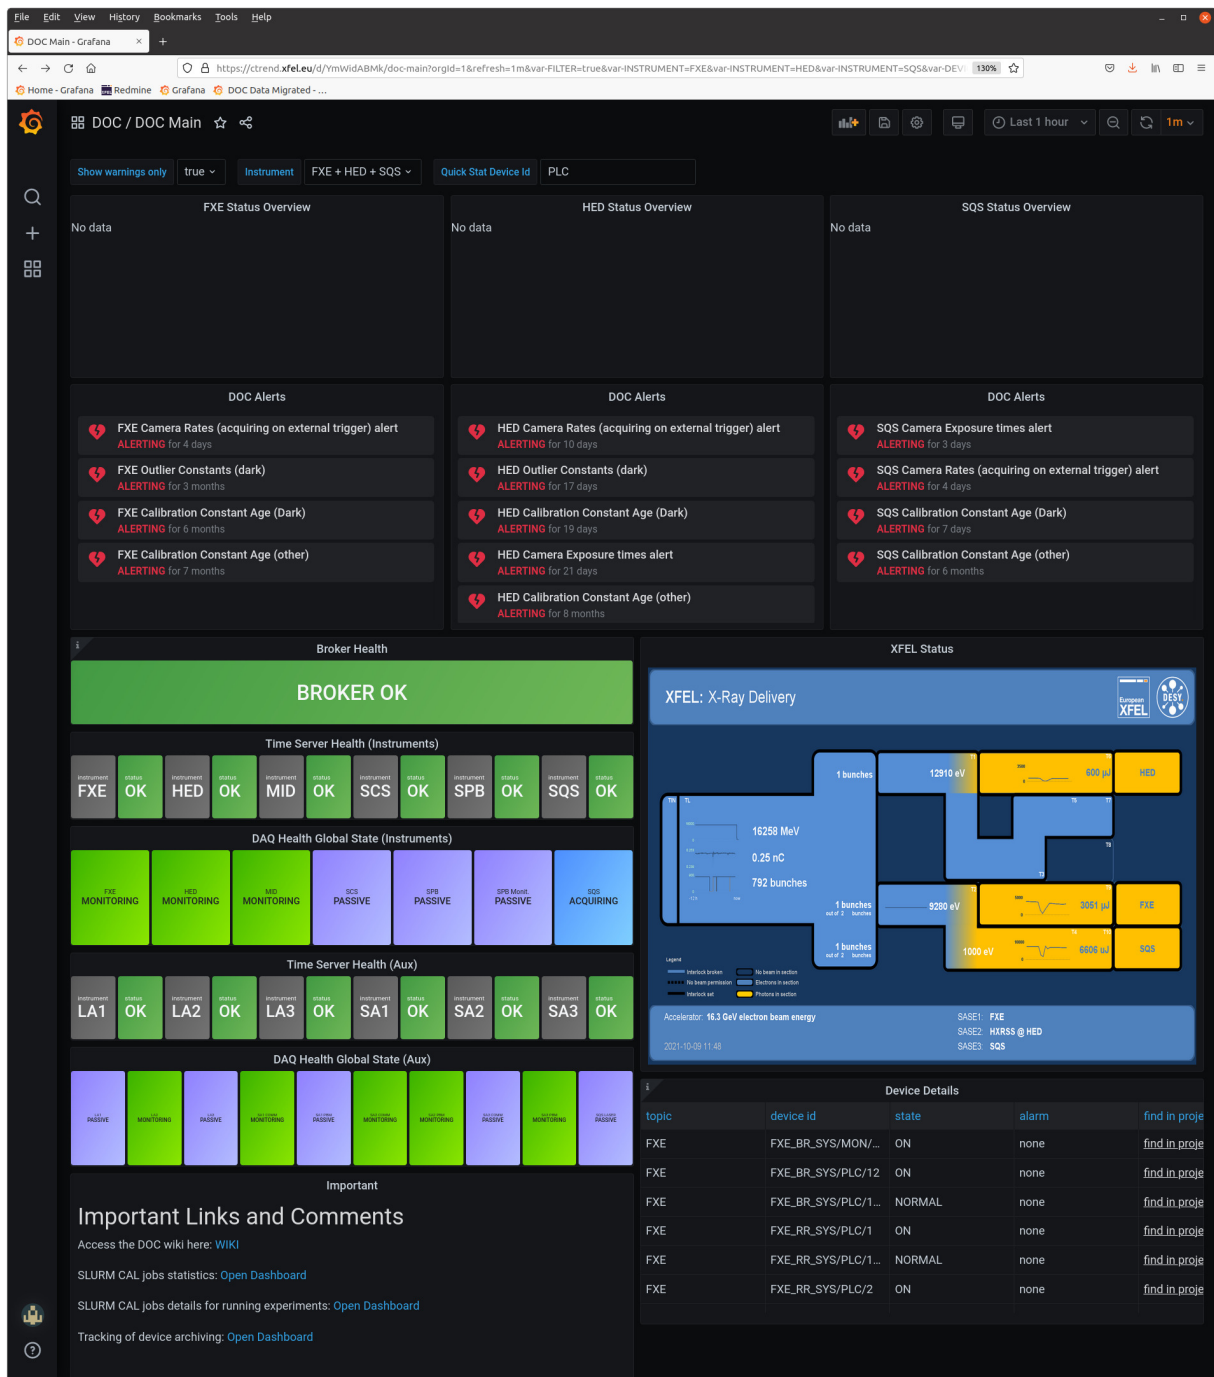

Figure 6: The main Grafana dashboard of the EuXFEL Data Operation Center (DOC), selected to focus on the HED, FXE and SQS instruments.

DOC shift crew to change focus, depending on the running scientific programme, but keeping a unified layout.

## CONCLUSIONS

The event-driven, broker-based control system Karabo is used to operate the photon tunnels and scientific instruments at the EuXFEL. Its first ascii file based data logging system was able to fulfil the initial needs, but the longer the facility operated, the clearer it became that the file based backend

does not scale well with long term operation. Furthermore, the poor down-sampling capability sometimes confused operators interested in the past state of their system.

A new storage backend using InfluxDB has been developed and is now in operation at the EuXFEL since summer 2020. The goals to overcome slow responses and the lack of statistical methods for data read-back have been met.

Even more, the storage in a community-driven backend allows using a well developed data display and analysis tool,

Grafana, without interference with the control system. Its wealth of features and online examples made Grafana dashboards a key ingredient of the new EuXFEL Data Operation Center that focuses the support of the scientific programme given by the EuXFEL Data Department.

All together, the efforts to interface Karabo data logging with InfluxDB and to setup a reliable database infrastructure have surpassed the expectations to improve the user experience when interacting with historic data in the Karabo control system.

# PHOTON SCIENCE CONTROLS: A FLEXIBLE AND DISTRIBUTED LabVIEW™ FRAMEWORK FOR LASER SYSTEMS

B. A. Davis\*, B. T. Fishler, R. J. McDonald

Lawrence Livermore National Laboratory, Livermore, California, USA

## Abstract

LabVIEW™ software is often chosen for developing small scale control systems, especially for novice software developers. However, because of its ease of use, many functional LabVIEW™ applications suffer from limits to extensibility and scalability. Developing highly extensible and scalable applications requires significant skill and time investment. To close this gap between new and experienced developers we present an object-oriented application framework that offloads complex architecture tasks from the developer. The framework provides native functionality for data acquisition, logging, and publishing over HTTP and WebSocket with extensibility for adding further capabilities. The system is scalable and supports both single server applications and small to medium sized distributed systems. By leveraging the application framework, developers can produce robust applications that are easily integrated into a unified architecture for simple and distributed systems. This allows for decreased system development time, improved onboarding for new developers, and simple framework extension for new capabilities.

## INTRODUCTION

In contrast to large experimental physics programs, small to medium size experiments and test-beds generally have less resources in terms of manpower, funding, and schedule. Developers are often faced with the task of standing up a distributed control system from scratch under tight deadlines with limited personnel. In these situations, it is imperative to choose a programming language that allows for quick hardware integration and prototyping.

Under these circumstances, NI LabVIEW™ software is often chosen for several reasons. First, it has an extensive hardware ecosystem with options for benchtop, distributed, and embedded hardware systems [1]. Interfacing with these systems from the LabVIEW™ development environment is streamlined and there are offerings for systems across the spectrum of determinism. Simple DAQs provide baseline functionality for non-deterministic applications, and soft and hard real-time situations are handled by RTOS and FPGA applications, respectively.

LabVIEW™ software is also attractive due to its shallow learning curve and low barrier to entry for those without a classical programming background. It uses a graphical programming style combined with a “dataflow” paradigm for organizing functionals and variables and defining execution order [2]. Many workflows for data acquisition, analysis, and logging are built in, and examples and documentation

abound. It is simple for novice developers or even end users to create a baseline DAQ system to collect experimental data.

The result is an attractive platform for developing small scale experimental systems. In many cases, control system developers need not get involved at all - scientists and operators can quickly develop the skills to work with LabVIEW™ programming. However, this story becomes less clear when moving from small scale systems to medium scale systems with multiple distributed Front-End Processors (FEPs). Leveraging NI hardware remains an attractive prospect, as it eliminates the need for custom RTOS machines or FPGA boards to handle deterministic applications. However, the very advantage of easy software development can quickly become a burden instead.

Simple LabVIEW™ applications are singular in purpose – they interface with a small number of devices, acquire data, perhaps execute a sequence, and log data to disk. This can be accomplished by a novice developer, or even an end user, as previously mentioned. However, more often than not, such simple systems suffer from a lack of scalability and extensibility. Of course, a piece of software designed to control a single experiment has no need for scaling or extension, provided that system requirements are well-defined before the development begins (a tall assumption, but one we take for granted here).

The disconnect arises when taking similar software development practices and applying them to a larger scale, distributed system. While developing LabVIEW code to control a single system can be accomplished by those with little to no previous software engineering background, developing a distributed, extensible, and scalable system for a larger system requires more experience, skill, and rigor.

Often for a simple system, there is a single developer who creates an application to run the experiment. But for systems of increased complexity, multiple developers of varying skill levels must work together to create a series of interconnected applications across a number of FEPs. In such a situation, a unified architecture must be developed to ensure scalability across the system. Similarly, extensibility becomes key to adding new capabilities over time as the system evolves, as a larger scale system will likely be in operation for longer than a small testbed.

Thus the ideal architecture for developing LabVIEW™ applications for mid-scale distributed control systems must be scalable for any number of devices and FEPs, extensible for adding capabilities across the lifetime of a project (and ideally to future projects as well), and – most importantly – accessible to developers at all skill levels.

To accomplish these goals, we have developed an object-oriented distributed architecture for LabVIEW™ applica-

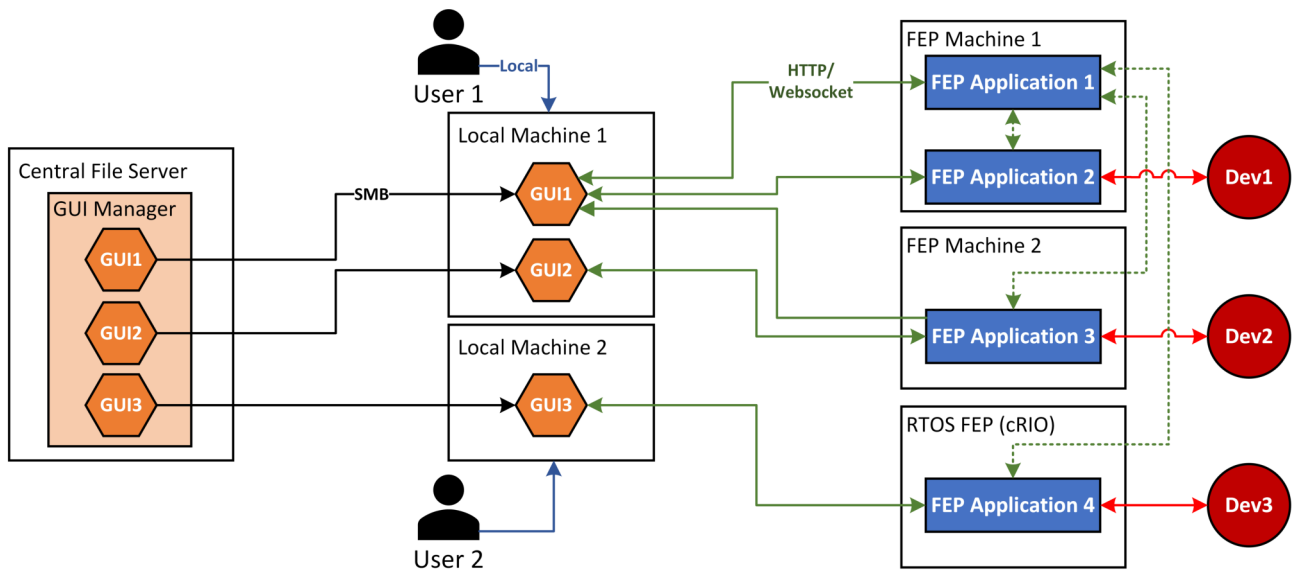

Figure 1: An example system architecture for a small project. Arrows represent communication over the LAN. Black arrows represent Server Message Block (SMB) protocol (mapped network drives), blue arrows represent local (mouse/keyboard) interaction, green arrows represent HTTP or Websocket connections, and red arrows represent device communication.

tions entitled Photon Science Controls (PSC). The architecture leverages inheritance and polymorphism to provide an extensible framework with discrete, encapsulated components. It natively provides flexible inter-application communication over HTTP and Websocket to support systems distributed over a Local Area Network (LAN), with capability to support other protocols as well.

Perhaps most importantly, it is designed to offload common software tasks from developers so that they can focus on discrete functional blocks. Tasks such as intra-application communication, logging, system health, and the aforementioned inter-application communication are pre-packaged and separately source-controlled. This ensures that the architecture remains accessible for novice and experienced users alike, while guaranteeing that functionality remains equivalent across all system applications.

## SYSTEM ARCHITECTURE OVERVIEW

Systems using the PSC architecture are designed as peer-to-peer systems composed of FEP applications and client applications. FEP applications are designed to handle device interfacing, sequencing, supervisory logic, and real-time calculation. These are the applications that use the PSC architecture. Client applications include GUIs, real-time status verifiers, and data displays. FEP application peers can communicate with any other FEP application on the network. Client applications can also communicate with any FEP application, but do not connect with each other. Figure 2 shows a example representation of this network architecture.

Combining FEP applications and client applications allows for the development of a distributed control system with user access available from any connected terminal. Figure

Figure 2: Peer to peer network architecture with FEP applications and client applications.

1 shows an example distributed system designed under this paradigm. The example system has four FEP applications distributed across three FEPs. Applications two through four handle device communication, and application one runs some supervisory application that requires data from the other three. The client GUI applications are served up from a central file server, which ensures that they are available from any local machine on the LAN.

All communication between client applications and FEP applications, and between FEP applications is done over TCP - specifically using HTTP and Websocket. Users interact with the FEP applications through the remote client GUIs, which can send commands and receive data from the FEP applications. FEP applications can manage multiple connections from clients and peers, allowing for simultaneous monitoring from multiple local workstations. This is espe-

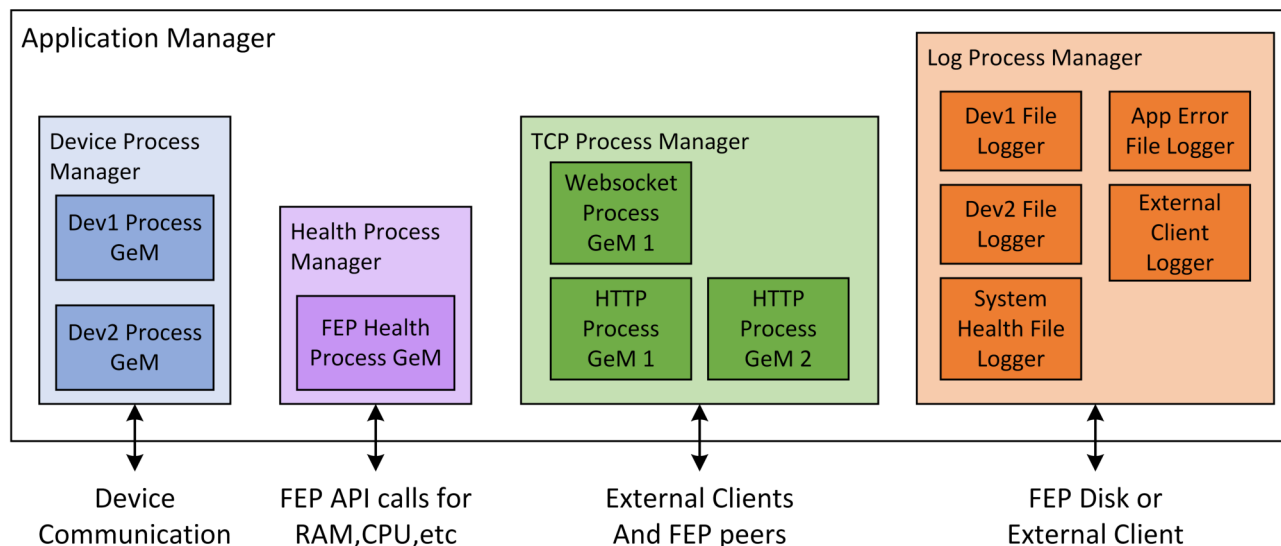

Figure 3: Sample FEP application with hierarchical architecture. Each Manager and Process is a self-encapsulated process running asynchronously.

cially important to support system designers and operators through the commissioning, qualification, and operational lifetime of the system as UI and workstation needs change.

The flexibility of the PSC architecture allows for it to be used on any target with a LabVIEW runtime. This includes Windows machines for non-deterministic applications, and NI hardware targets such as cDAQ and cRIO embedded processors for RT applications. These hardware devices run Linux RT as their RTOS, and cRIO targets also include an FPGA layer for hard real time applications. This allows the architecture to cover the full range of determinism needs for the system without requiring rework or adaptation.

## FEP APPLICATION ARCHITECTURE

### Application Architecture Overview

FEP applications form the core of the distributed control system and cover most of the functional requirements of the project. They communicate with devices; acquire, process and log data; broadcast and request data from other peers; and handle communication with client applications to send and receive data and commands from users.

The functions of a given FEP application are broken into discrete chunks called Generic Messengers (GeMs). Each GeM is a self-contained asynchronous process that handles a defined subset of the FEP application functionality. GeMs in an FEP application are launched in a manager-worker hierarchy. There is a top-level Application Manager GeM, one to many mid-level Process Manager GeMs, and one to many Process GeMs. Process GeMs control the core behavior and provide the main functionality of the application. Process Managers and the Application Manager allow for data roll-up from the Process GeMs as well as high-level application management functionality.

Figure 3 shows an example of this application hierarchy with some typical GeMs. This particular application would communicate with two devices, monitor the health of the FEP (CPU usage, RAM, etc), manage communications with external applications, and log device and application data to disk and an external client like an industrial Historian. Process managers and the Application manager would handle high level application behavior - monitoring the health of different processes, managing processes closing or being instantiated, etc.

There is no defined limit to the number or type of GeMs present in a single application. Different classes, devices, protocols, and loggers can be supported to accomplish the purposes of the application as long as they conform to the structure of the GeM ancestor class.

### Flexible Functionality Distribution

Intra-application communication between GeMs is a microcosm of the peer to peer inter-application communication scheme of the distributed system. Each GeM is individually addressable so that data can be passed around the application as necessary. For example, the Dev1 CSV File Logger in Fig. 3 would subscribe to data from the Dev1 Process stream to log it to disk. Like the peer-to-peer relationship between FEP applications at the system level, any GeM can get data from or issue commands to any other GeM in the FEP application.

This nested approach to communication allows for maximum flexibility in defining application and system organization. Depending on system requirements, FEP applications can be organized by functionality, device type, or logical subsystem grouping. GeM processes that fulfill the system requirements are then distributed across the FEP applications to match these functional groups. System hardware archi-

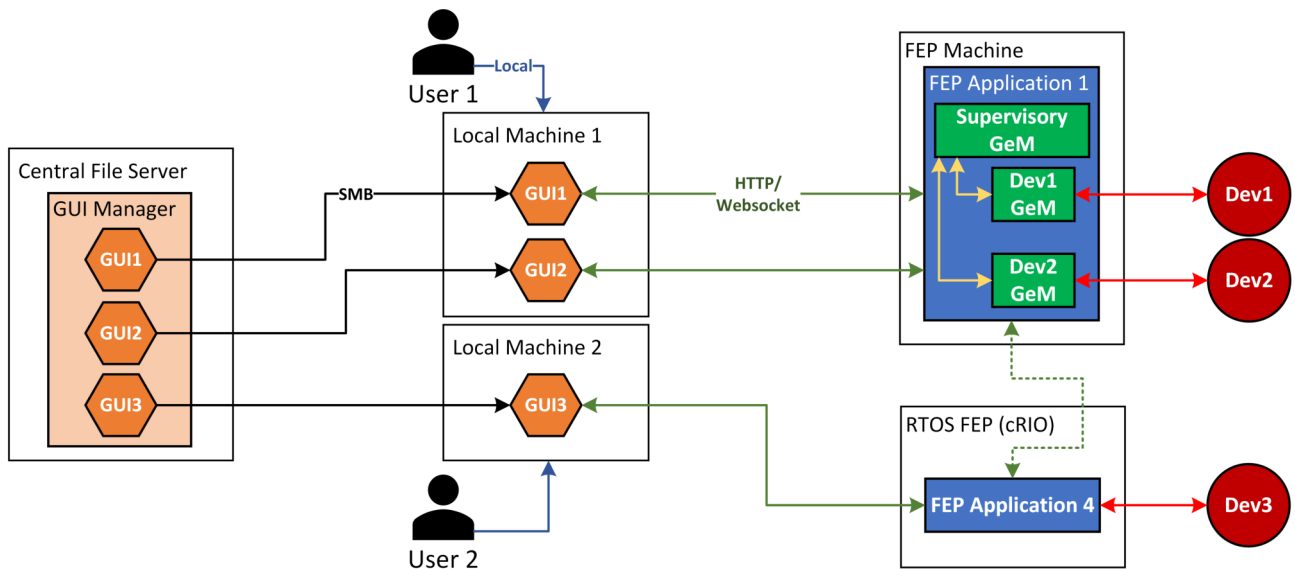

Figure 4: Redistributed architecture from Fig. 1. Note that the functionality of applications two and three has been moved into GeMs in application one. Yellow arrows denote internal communication (queues). This architecture is functionally identical but may provide different performance characteristics that would prefer its usage. Not pictured are the GeMs handling the external communication.

ture, performance requirements, and logical delineations can all drive these decisions.

For example, Fig. 4 shows how the example system in Fig. 1 could be rearranged. We have consumed the functionality of FEP applications two and three into FEP application one, and instead used the internal data lines for the supervisor rather than external (HTTP, Websocket) to get their data. Note that FEP application four remains on a different FEP, so FEP application one still uses external communication for its data.

This reorganized system would perform the same tasks as the architecture presented in Fig. 1, but may provide performance benefits that would make it preferable. In short, a PSC2 system architecture provides the capability to tune the level of distribution to match physical and performance needs at the macro “distributed system” level and the micro “application GeM” level.

### Class Hierarchy and GeM Functionality

Figure 5 shows a class diagram for the Generic Messenger ancestor class. Note that most GeM classes are descendants of the Process class, as that is where the core functionality of an application is executed. However, Process Managers and the Application Manager also inherit from the GeM ancestor class, which means they inherit similar functionality to Process classes.

The functionality provided by the GeM ancestor includes five key items. The ancestor provides a common process main that ensures these five items are all implemented identically across all descendant GeMs.

**Data polling / creation** Every GeM includes a method to poll and create data at a predefined rate. For device process classes, this would include the device status data. For other GeMs, this provides an internal status. As an example, a logger class would provide information on its logging speed, how many items are left in the logging buffer, the current file, etc. Data is generically typed in a key-value structure for easy handling across GeMs and peer applications.

**Command Handling** Every GeM has a command handler that allows it to receive messages from other GeMs in the system. This is the method by which data is passed throughout the application. A command message is usually bundled with a response queue, which allows for a response to be sent back upon command action completion.

**Lossy and Non-Lossy Data Streams** After the GeM data is produced in the polling loop, it is piped into two data streams. The first, a lossy stream, is a single element queue. The element is overwritten upon each polling cycle, hence the designation as lossy. This is what the command handler can use to report the latest data sample upon request. It is often used for discrete requests, like by a TCP process for sending data to a GUI.

The second data stream is a non-lossy stream. Data is pushed into a buffered queue so that each sample is captured. This is the preferred method for passing data to loggers or other processes that need a complete data history. GeMs can subscribe to this data stream by sending a subscription request over the command handler.

**Thresholding and Alarming** Particularly for device process GeMs, it is important to monitor data values for

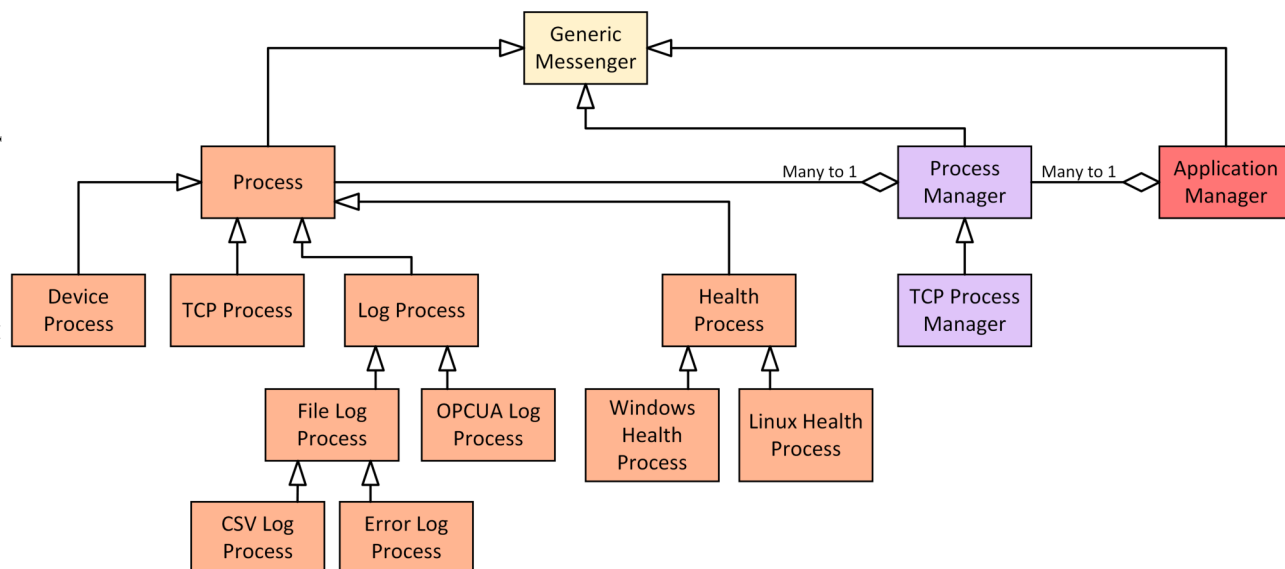

Figure 5: Generic Messenger Class Hierarchy. Most available architecture GeMs are of the “Process” descendency, as this is where functionality is most heavily defined.

anomalies and take actions if they exceed pre-defined levels. Every GeM has a built in threshold handler that allows for definition of levels and actions to take based on named data values. These thresholds can be numeric or boolean. Based on the level of the data under review, UI warnings and alerts or Machine Safety System (MSS) actions can be taken.

**Internal Error Handling** Occasionally GeMs will encounter an internal error and self-terminate. The error handling built into all GeMs ensures that these errors are logged to disk for review. This is essential for addressing issues that occur during commissioning and operations.

### GeM Lifeline and Application Startup

Each GeM in the system goes through a similar lifeline. They are instantiated and initialized, then spun off to run an asynchronous process main. They are then terminated upon task completion or application end and run a cleanup routine.

PSC uses a Factory style object creation scheme [3] upon application startup. When a PSC application is loaded, an application factory is created. This factory object (not a GeM) loads a configuration file that defines the objects needed for the application to run. It then loads the necessary classes into memory and instantiates them.

The launch process at application startup is recursive in nature, based on the application hierarchy. The factory creates an application manager GeM, within which are a number of process manager GeMs who each contain a number of process GeMs. GeMs are then launched from the bottom of the hierarchy to the top – processes are each spun off, then the corresponding process managers, and then finally the application manager. This ensures a consistent boot order that is defined in the application configuration. A defined

boot order is important to ensure that GeMs that depend on other GeMs are initiated in dependency order.

Not all GeMs are initiated at application startup. It is entirely possible for GeMs to be initiated by events that occur during application operation. As an example, a TCP Process Manager (see Fig. 3) listens for external connections and instantiates TCP processes to handle them during runtime. These processes persist until the connection is closed or timed out, and then self-terminate.

### Data Recursion

All GeM data is wrapped up recursively through the application hierarchy (Process -> Process Manager -> Application Manager) (see Fig. 6) In other words, each Process Manager’s data packet contains all the data packets of its worker Processes, and the Application Manager’s data packet contains all the data packets of its worker Process Managers. This allows for an external client or peer to get all the data from an application by making a single query to the top-level Application Manager.

### Addressing and External Communication

As previously mentioned, GeMs can communicate with other GeMs in a specific FEP application, and FEP applications can communicate with other peers and client applications. Every FEP application in a distributed PSC2 system has an IP address and associated TCP ports. Furthermore, each GeM within an application is assigned a URL based on the application hierarchy. This URL serves as an address for both external and internal communication. URLs are generated by the following pattern: **IPAddress:port/ApplicationName/ProcessManager/Process**.

As an illustrative example, **185.20.20.1:5437/SampleApplication/DeviceManager/Device1** would refer to the Device1 process of the Device Manager Process Manager on

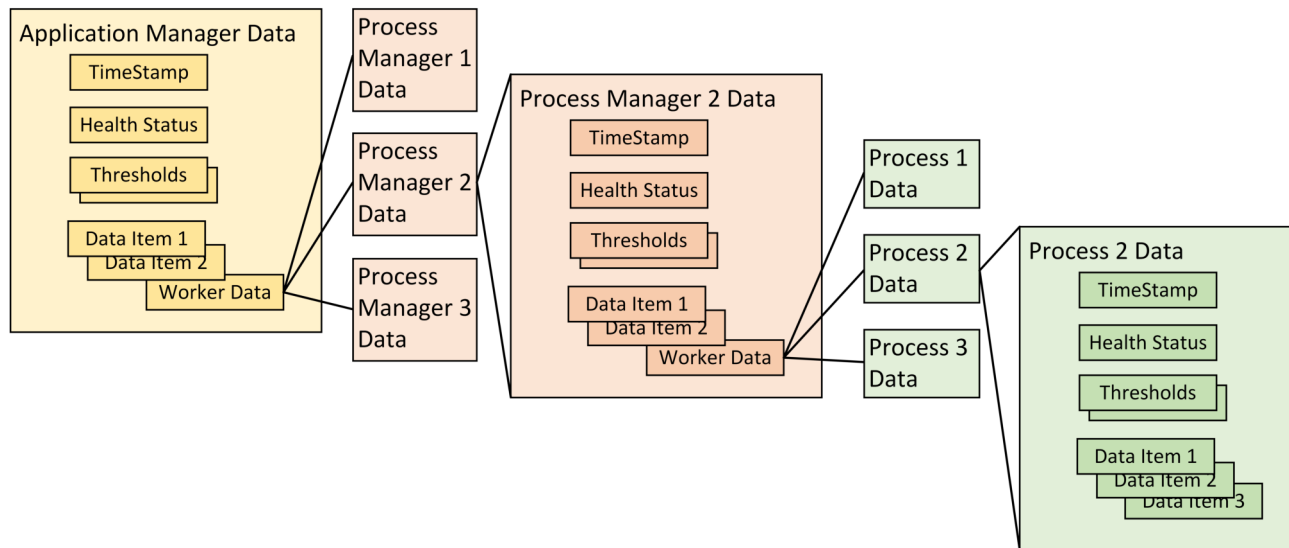

Figure 6: Data Recursion in FEP applications. The top-level application manager contains all the data from the GeMs in the application.

the Sample Application hosted on 185.20.20.1. The port 5437 may be the port setup for HTTP, Websocket, or some other protocol.

The same URLs are used as identifiers for the command queues of each GeM in the application. GeM peers send commands to others' command queues by name. Thus, the unique identifier URL for a GeM serves as a routing path for both external and internal communication.

External communication is routed through a TCP Process Manager GeM, which instantiates worker TCP Processes, one for each connection. Figure 7 shows the dataflow for connecting to an external application. The TCP Process Manager maintains a listener on the specified TCP port. Upon receiving a connection request, it instantiates and launches a TCP Process GeM. This GeM establishes the TCP socket connection with the external application. Messages are sent from the external application to the TCP Process, which then forwards them to other GeMs by URL. The TCP Process GeM persists until the connection closes or times out, at which point it self-terminates.

The TCP Process Manager can instantiate any number of TCP Process GeMs to support multiple connections. These TCP Process GeMs can be HTTP connections, Websocket connections, or other TCP protocols. There is a single connection for each external application, which ensures that data is not corrupted by multiple writers/readers on a single socket.

### Application Configuration and User Sets

Configuration items in a PSC application exist across three levels of accessibility - "hard-coded" (lowest accessibility), "static," and "configurable" (highest accessibility). Hard-coded items are configuration items that cannot be modified without rebuilding the application. These are protected by source control and are collected in an Application Configura-

tion file. Static items can be modified without rebuilding the application, but are only applied on startup. Configurable items can be loaded and saved during runtime. Both static and configurable items are collected in User Sets.

**Application Configuration File** Every GeM maintains a list of configuration items that define its behavior. These form the basis of the Application Configuration that defines the GeMs included in a specific application build. The Application Configuration is loaded upon application startup, and is used by the Application Factory to instantiate all the GeM objects of the application. It lists the participating GeMs, and their configuration parameters that define their behavior. These can include polling rates, timeouts, links to other GeMs, etc. These values are considered hard-coded because they define the behavior of the final application. Because of this, application configuration files are protected as source code, and require rebuild upon changing.

**User Sets** Device Process GeMs maintain a series of separate configuration files known as User Sets. User Set files allow operators to save and recall device states in order to facilitate different modes of system operation. As with application configuration items, each Device Process GeM maintains a list of user set items. Each item in a user set list is tagged as "startup only" or not. This tag is what separates static and configurable items. Static items are only applied when the application is restarted, so changes to such items in a user set will not be applied immediately. Configurable items, on the other hand, can be recalled at any time during operations.

As an example, imagine a flow controller that is handled by a Device Process GeM. Perhaps there are some warning/alarm thresholds associated with the device that we would like to have the flexibility to change without rebuilding the application (i.e., they cannot be hard-coded in the

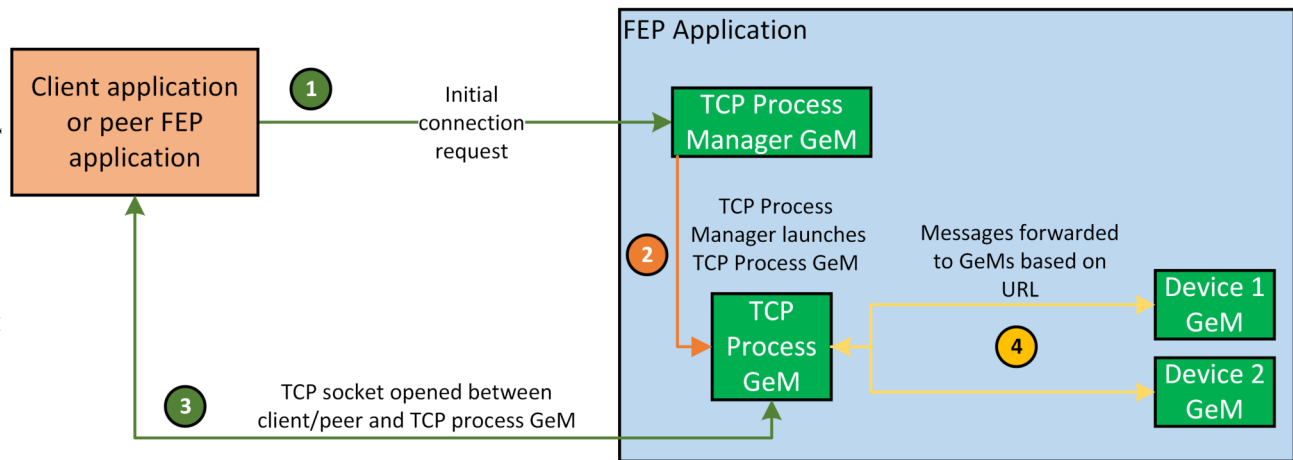

Figure 7: External Communication Process. The TCP Process Manager listens on the specific port for an initial message. Once the message is sent, the Process Manager instantiates a TCP Process to handle the socket connection. The TCP Process persists until the connection is closed or times out. Commands are sent by the client or peer to the TCP Process GeM, which forwards them to their destination based on URL.

application configuration). However, we do not want them to change without review and management approval. These would be an appropriate candidate for static (startup-only) behavior. We may also have a setpoint for the flow controller that needs to change based on what phase of an experiment is currently running. This may be a good configurable item - we can save one user set for each phase, and recall the appropriate one at runtime.

User sets are organized by name, and can be saved and loaded from client UI applications. This gives operators flexibility in defining, modifying, and managing the user sets that need to be applied for continuous operation. Table 1 summarizes the three types of configuration items.

Table 1: Configuration Item Summary

Type	Associated File	Accessibility
Hard-Coded	Application Configuration	Rebuild Application
Static	User Set (startup-only tag)	Restart Application
Configurable	User Set	On Demand

## CONCLUSION

The use of the PSC architecture helps to bridge the gap between small and large scale experimental systems by providing a scalable and extensible framework for rapid development timelines. Encapsulating functionality into interconnected Generic Messenger objects allows for unlimited flexibility in defining the distribution of system requirements over the system LAN. By leveraging inheritance and polymorphism, base functionality is preserved across all descendant

GeM classes, providing a simple workflow for developing new features and capabilities.

By abstracting functionality into the classes that form the architecture, developers can focus solely on developing code that fulfills system requirements without having to deal with high level processes like communication and logging. Taken all together, the architecture provides an excellent solution for medium scale distributed systems and projects with funding, time, and personnel limitations.

## ACKNOWLEDGMENTS

The authors would like to acknowledge the work of Daniel Smith, Chen Lim, and Sridhar Kuppaswamy for their work on the previous iteration of the architecture.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. Released as LLNL-CONF-827711.

# ROMULUSlib: AN AUTONOMOUS, TCP/IP-BASED, MULTI-ARCHITECTURE C NETWORKING LIBRARY FOR DAQ AND CONTROL APPLICATIONS

A. Yadav, H. Boukabache\*, N. Gerber†, K. Ceesay-Seitz, D. Perrin  
European Organization for Nuclear Research (CERN), Geneva, Switzerland

## Abstract

The new generation of Radiation Monitoring electronics developed at CERN, called the CERN RadiatiOn Monitoring Electronics (CROME), is a Zynq-7000 SoC-based Data Acquisition and Control system that replaces the previous generation to offer a higher safety standard, flexible integration and parallel communication with devices installed throughout the CERN complex. A TCP/IP protocol based C networking library, ROMULUSlib, was developed that forms the interface between CROME and the SCADA supervision software through the ROMULUS protocol. ROMULUSlib encapsulates Real-Time and Historical data, parameters and acknowledgement data in TCP/IP frames that offers high reliability and flexibility, full-duplex communication with the CROME devices and supports multi-architecture development by utilization of the POSIX standard. ROMULUSlib is autonomous as it works as a standalone library that can support integration with supervision applications by addition or modification of parameters of the data frame. This paper discusses the ROMULUS protocol, the ROMULUS Data frame and the complete set of commands and parameters implemented in the ROMULUSlib for CROME supervision.

## INTRODUCTION

The Occupational Health & Safety and Environmental Protection (HSE) at CERN obliges to the protection of CERN personnel and the public from any unjustified exposure to ionising radiation. The radiation protection group (RP) at HSE has the mandate to monitor the radiological impact of CERN's accelerators and installations by active monitoring and logging of radiation levels at different experimental sites spanning the CERN complex. To facilitate this, the new generation of CERN RadiatiOn Monitoring Electronics, called CROME [1], was developed by the CROME team of the Instrumentation and Logistics (IL) section within the RP group and is responsible for the design, development, installation and maintenance of these specialised radiation monitoring systems. Starting from Long Shutdown 2 (LS2) of the Large Hadron Collider (LHC) in 2019, the older generation of radiation monitors, namely The Area Controller (ARCON) is being replaced by the new CROME devices and will be operational for the Run 3 of the LHC in February 2022. The consolidation of the current generation of Radiation Monitoring System for the Environment and Safety

(RAMSES) monitors by CROME is planned to be completed by the Long Shutdown 3 (LS3) in late 2027.

The CROME devices consist of the autonomous Monitoring Units, Alarm Units, a Junction Box and an Uninterruptible Power Supply. [2–4] The autonomous monitoring units, called the CROME Measuring and Processing Units (CMPUs), consist of an ionization chamber and an electronic readout system. The CMPU can be either a wall-mounted system where the CMPU is directly attached to the ionization chamber or it can be a rack-mounted system where the CMPU is connected to the ionization chamber with a specialized cable. The rack-mounted system is used for monitoring areas with high radiation levels that can damage the readout electronics. In this case, a custom plastic ionization chamber with graphite coating is placed directly into that area with high radiation levels, whereas the readout electronics are placed in an area of lower radiation for their protection. The ionization chamber detects ionizing radiation and converts it to a readable current value. A read-out chip measures this current, which can be within 2 fA to 1  $\mu$ A. Because these currents can be so low, a specialized cable SPA6 was developed by the RP team at CERN for the rack-mounted system. The SPA6 cable is used for Signal and High Voltage lines up to one kilometer distance. The CMPU's front-end readout interface transmits the current value to the FPGA programmable logic (PL) of a Zync-7000-based System-on-Chip (SoC), which uses it to calculate the real-time radiation dose rate as well as the total radiation dose received in the monitored area at the ionization chamber location. All safety-critical decisions and actions such as measurement, dose rate calculation, temperature compensation, alarm generation and interlock generation are performed by the PL. This is done to ensure system reliability by implementing operations within a Finite-State Machine. A complex programmable logic device (CPLD)-based watchdog works in tandem with the SoC. It monitors the PL state machine to ensure correct dose rate calculations and overall functionality. It is allowed to reset/reboot the SoC when it is in an undefined state. At the detection of dangerous conditions, e.g. if the radiation dose or dose rate exceeds a defined limit, the CMPU automatically generates local and remote alarms and a beam interlock signal that stops the concerned accelerator or machine. Parameters like dose and dose rate limits, current-to-radiation conversion factors, and many more can be configured remotely by the authorized members of the radiation protection group. A schematic of the CROME devices and its part is shown in Fig. 1.

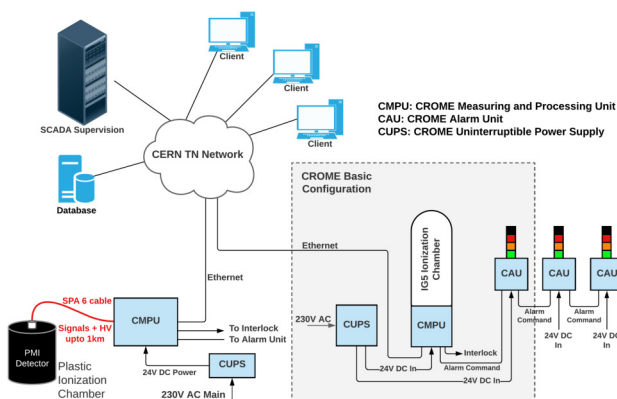

Figure 1: CROME Radiation Monitor components and basic configuration.

The radiation monitoring CROME devices at CERN are required to fulfil safety requirement in accordance with the IEC 60532 standard for radiation protection instrumentation. This is in compliance to the task of interlock triggering of machines in case of high radiation levels. Therefore, CROME devices have been developed to satisfy Safety Integrity Level 2 (SIL 2), as defined in the IEC 61508 standard in accordance with the IEC 60532 for functional safety of Electrical/Electronic/Programmable Electronic Safety-related Systems. We have therefore followed a process and implemented measures to reduce the risk of dangerous failures during the development and operation while following stringent methodology to avoid both random and systematic faults for both firmware [5] and hardware [6].

The CROME hardware deployed throughout the CERN complex communicates with a SCADA supervision system, called Radiation and Environment Monitoring Unified Supervision (REMUS) [7, 8]. In order to facilitate reliable connectivity and logging capabilities, the development of a dedicated TCP/IP-based C networking library, ROMULUSlib was initiated by the CROME team. ROMULUSlib is the communication interface between CROME and REMUS. It sits in the userspace of a POSIX compliant OS and allows multi-user full-duplex communication with CROME devices through REMUS and/or an ‘expert application’ connected to the devices through the network via Ethernet connection. ROMULUSlib compiles on multiple architectures and at present, ROMULUSlib has been built and tested successfully with gcc 4.8.5 on x84\_64, arm32 and with Apple clang version 11.0.3 on x86\_64 Darwin MacOS Kernel 19.4.0. In this paper we present the details of ROMULUSlib, the construction of the data packets for command and data communication over the TCP/IP network. We present the overall structure of the ROMULUSlib code base and a set of utilities that are a useful aid for anyone instantiating ROMULUSlib for their DAQ and Control use case. Beside this, an independent project, RomLibEmu [9] was initiated to develop a regression testing framework for debugging systematic faults during development and before the release of every new version of the ROMULUSlib.

This paper is organized as follows: in background and related work, we discuss some of the previous library implementations developed for TCP/IP supervision and how ROMULUSlib compares to the same. In the next section, we give a brief overview of the CROME radiation monitoring system architecture and the REMUS Supervision system, followed by the details of the implementation of ROMULUSlib that forms the interface for the SoC to SCADA communication. In this section we present the details of the TCP/IP frame, supported commands, parameters and ranges with their corresponding acknowledgement response and test utilities. ROMULUSlib supports both real-time stream and buffered data stream such as status request, historical record and events that are discussed here. In the end, we present the current application use cases and tests deployed at CERN and at the European Spallation Source (ESS) followed by the future work and adaption of ROMULUSlib library for varied use cases.

## BACKGROUND AND RELATED WORKS

Early control operations at CERN radiation protection employed PLC to SCADA based communication for control application. CERN also uses this for LHC Cryogenics control in accelerator and experimental control, Gas systems, Cooling systems, HVAC etc. For control and monitoring, Ethernet based communication protocols such as Profinet and Ethernet/IP are employed [10]. The UNICOS framework is one example of the same [11]. Another example of the communication protocol used for real-time automation is the MODBUS TCP/IP which uses the MODBUS protocol for communication encapsulated within the TCP/IP wrapper for communication over the ethernet.

CERN currently started very recently using Zynq-based SoCs for a wide range of applications in detector control and front-end data acquisition electronics designs. These SoCs offer greater flexibility to the user for design on programmable logic, offers an embedded linux platform on the processing system for high-level software development and provides faster performance due to the PS-PL interface. The open-source WinCC OA is the currently widely adopted SCADA framework for detector control applications which is also used by REMUS supervision [8]. One of the adopted communication frameworks in ATLAS Detector for DAQ to DCS communication is the Quasar framework [12] which allows building of OPC UA servers for client-server communication. It is employed at ATLAS’s Tile Calorimeter measurement[13] and Global Feature Extrator (gFEX) Hardware Trigger[14] among others. Quasar’s client-server communication model integrates with the WinCC OA SCADA and allows read/write of predefined variables, and creation of multiple OPC servers. A new library, MilkyWay, based on FreeOpcUa is further being developed in Python [15].

While PLC-to-SCADA based communication frameworks exist; with the introduction of SoC-to-SCADA systems, fast and reliable safety critical communications framework needed to be developed. Therefore, the development of com-

munications protocol for safety-critical radiation monitoring and control was initiated in 2015 by the CROME team at CERN. The communications specifications provided by the ROMULUSlib allows user to have communication reliability of TCP/IP while having greater control over creation of variable length data frames for DAQ and control applications. ROMULUSlib runs on each communicating device and communicates with the WinCC OA based SCADA through a driver. The users have the flexibility to update their own parameters of interest which compiles seamlessly with ROMULUSlib. This further simplifies integration with embedded linux userspace application development which makes ROMULUSlib suitable for adoption for SoC-to-SCADA TCP/IP communication systems.

## CROME: RADIATION MONITORING ELECTRONICS AT CERN

The CROME device is developed to provide a versatile interface for:

1. Continuous real-time monitoring of ambient dose equivalent rates over up to nine orders of magnitude.
2. Alarm and interlock functionality with a probability of failure down to  $10e^{-7}$ .
3. Long term permanent and reliable data logging by linking to a SCADA supervision or an expert application running on a portable PC via Ethernet.
4. Edge computing with powerful processing capabilities for embedded calculation.

The basic configuration of the CROME device consists of the three main parts: CROME Measuring and Processing Unit (CMPU), the CROME Alarm Unit (CAU) and the CROME Uninterruptible Power Supply (CUPS). These are connected to the global supervision structure as shown in Fig. 1. The CMPU hosts the System-on-Module board which implements a Zynq-7020. This SoC is composed of the 32-bit ARM Processing System (PS) which runs CROMiX-18 a custom embedded Linux distribution developed using the YOCTO project and the Programmable Logic (PL) FPGA fabric that is programmed with a parameterizable hardware implementation for readout, calculations and safety-critical controls.

The front-end electronics is also part of the CMPU. It performs analogue-to-digital conversion of the current signal generated by the radiation detector to which it is attached providing a continuous real-time measurement of ambient dose equivalent rates. The CMPU in turn generates radiation alarm and interlock signals and enables long-term and data logging by integration with REMUS. The communication interface for the CROME devices and the REMUS supervision is the ROMULUSlib and it provides four main functionalities:

1. Networking: All communications happening over TCP/IP frame is handled by the functions defined in ROMULUSlib.

2. TCP/IP frame construction: ROMULUSlib provides structs to encapsulate different data variables with support for nearly all C data types. This can be easily updated by updating the struct table. The construction of ROMULUS frame is handled by the ROMULUSlib, including functions to access and modify specific parts of the frame which provides much more flexibility and control to the user.

3. Multiple Communication Modes: ROMULUSlib provides full-duplex communication over TCP/IP via multiple communication modes to transmit single, multiple and infinite frames which can be used for streaming data in multiple ways as per application requirement.

4. Utilities: Multiple utilities are provided within the ROMULUSlib for utilities such as log reporting of application flow, warnings and errors, functions to print frame, struct and internal data struct, checksum check functions and check functions for memory allocation and free memory.

CERN's REMUS supervision [7, 8], is a WinCC OA based SCADA supervision system which is used for communication and parameterization of CROME devices. REMUS integrates the SCADA system with the open-source streaming platform Apache Kafka, a widely adopted technology, that allows data-streaming in near real-time data to the Data Visualization Tools and Web Interfaces. REMUS provides a secure interface for full-duplex communication interface with external Control devices. A functional architecture of the REMUS supervisory control along with the application of ROMULUSlib for data streaming and control from WinCC OA is shown in Fig. 2.

## ROMULUSLIB

The CROME devices communicate with REMUS using the full-fledged TCP/IP protocol which is implemented in ROMULUSlib, a stand-alone TCP/IP networking library developed in C that supports cross-compilation and portability by making use of the POSIX-standard, more specifically sockets. TCP/IP communication has been chosen to ensure high reliability and automatic data reordering. Therefore, all data communicated as ROMULUS data packets are encapsulated in TCP/IP frames. The device responds to most of the messages sent from the supervision. This is reconfigurable by defining the structure of the ROMULUS frames and defining the response packets as per requirements specifications. For each received message the device returns an acknowledgement message. The acknowledgement messages also ensure correct functionality of devices by having unique request-acknowledge pair. Specific error messages are communicated to be returned to ensure that there is a consistent answer from the device (e.g. malformed or unknown message). All packages received by the devices also contain a Sequence ID of the sender. The response or acknowledge message will include this Sequence ID. This ensures that the device can have multiple concurrent users. Besides SCADA

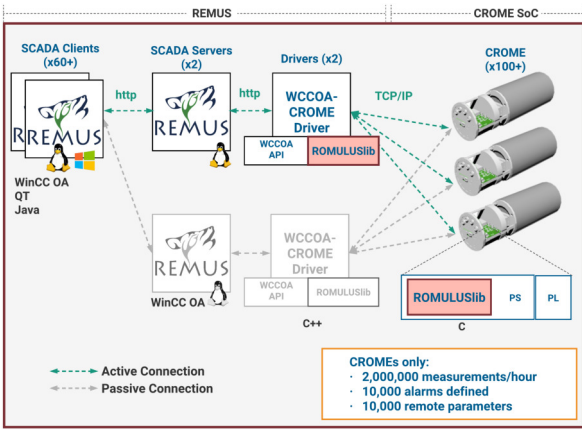

Figure 2: REMUS Supervisory Control and Data Acquisition Architecture [7, 8], Courtesy of Adrien Ledeuil.

supervision, the device is also fully configurable and parameterizable by a dedicated standalone ‘expert application’ that runs on a portable computer and is connected either directly to the device or through the network via the Ethernet socket. For this application, the CROME Team has developed a standalone application in NI LabVIEW that can connect to the CROME devices through the network.

In this section, we present the protocol used for the communication between the CROME devices and the REMUS supervision. The protocol is also used to communicate with the NI LabVIEW-based expert application.

### ROMULUS Data Frame

The ROMULUS data packet, as shown in Fig. 3, is encapsulated into a TCP/IP frame whose payload is limited to ETHERNET\_MTU (1500 Bytes) while having no fixed length for data packet itself in order to obtain more flexibility. Within the ROMULUS Data packet, the header is formed by: data length of the DATA, ID of the source of the message, ID of the message, the command code and the number of parameters. This is followed by the Data corresponding to the command code and the footer, which is the checksum.

Figure 3: ROMULUS TCP/IP Data Packet.

The maximum data length of the DATA in bytes can be calculated as follows:

$$maxDLC = ETHERNET\_MTU - [sizeof(IP\ header) + sizeof(TCP\ header) + sizeof(romulus\_frame\_header) + sizeof(romulus\_frame\_footer)]$$

Both, command and response packets have the same structure. A generic DATA segment of the ROMULUS Data Frame for Get/Set commands is shown in Fig. 4. Note that, multiple parameters can be communicated within one data

ACK	PARAM ID 1	VALUE 1	PARAM ID 2	VALUE 2	...	PARAM ID N	VALUE N
-----	------------	---------	------------	---------	-----	------------	---------

Figure 4: Data segment of any generic get/set command in ROMULUSlib.

frame. Therefore, it is possible to initiate multiple operations through a single message. Thus, the variable length of the ROMULUS data frame is due to the field DATA whose length is variable. In the response frame, if no error has occurred, the content of the DATA field of response will begin with an Acknowledgement (ACK) code. Otherwise, if an error occurs, the device returns an error code corresponding to one of the related errors, such as Acknowledgment, Illegal command, Illegal value etc.

We have provided command definition and data frame construction support for Simple and Complex Request-Response Schemes of communication within ROMULUSlib, which are discussed in the following section.

### ROMULUSlib Commands

ROMULUSlib commands define how the device and supervision can communicate using the ROMULUS protocol. ROMULUSlib currently supports 18 commands to interact with the CERN’s REMUS/ROMULUS protocol. These commands are categorized into two different schemes of communication within ROMULUSlib. These are namely Simple Request-Response Scheme and Complex Request-Response Scheme.

**ROMULUS Simple Request-Response Scheme:** This is the most common mode for communication using the ROMULUS protocol. The supervision sends a request to the measurement device, which is then responded to with a response frame as shown in Fig. 5. Example of this Simple Request-Response scheme is Get and Set Parameter Request and Response, Get and Set Status Request and Response, and Get and Set Timestamp Request and Response.

**ROMULUS Complex Request-Response Scheme:** Within the complex Request-Response scheme the communication

Simple Request-Response Scheme:

Supervision	Direction	Measurement Device
1 frame of ROMULUS_STATUS_REQUEST	→	
	←	1 frame of ROMULUS_STATUS_RESPONSE

Figure 5: ROMULUS Simple Request-Response Scheme.

could be a Real request-response scheme or a Streaming request-response scheme, as shown in Fig. 6.

The Real request-response scheme communication mode is similar to the simple request-response scheme, with the only difference in being that the measurement device can reply with multiple response frames while the last possible response frame is always fixed to indicate the end of the communication. Example of Real Request-Response scheme is Historical Data Request and Response frames, which initiates communication of multiple frames with the last frame being the Historical Data Done command frame.

In the Streaming request-response scheme, the supervision sends one request to initiate streaming and then the measurement device sends a possibly infinite number of responses until either side breaks the connection or sends a stop command to terminate the stream. Example of Streaming Request-Response scheme is Real-Time Stream request and response which can be terminated by Real-Time Stream Stop command.

Real Request-Response Scheme:

Supervision	Direction	Measurement Device
1 frame of ROMULUS_DATA_REQUEST	→	
	←	0 to $n$ frames of ROMULUS_DATA_RESPONSE
	←	1 frame of ROMULUS_DONE_RESPONSE

Streaming-Like Scheme:

Supervision	Direction	Measurement Device
1 frame of ROMULUS_RTSTREAM_REQUEST	→	
	←	0 to infinite frames of ROMULUS_RTSTREAM_RESPONSE
1 frame of ROMULUS_RTSTREAM_RESPONSE	→	1 frame of ROMULUS_RTSTREAM_RESPONSE

Figure 6: ROMULUS Complex Request-Response Scheme.

Associated with each command are the certain set of user defined parameters and value pair that the user would want to create for their own applications. This is implemented as C Struct data type. Within the structs, the user can define all the different parameters for which a unique ID is automatically generated by ROMULUSlib at compile time which is used in ROMULUS frame construction. Within the C struct, the library currently supports all essential data types: bool, unsigned char/uint8, int32, int64 and float. To categorically define the communicated parameters, eight structs each with a different use case, are defined. A summary of the C struct is provided in Table 1.

### ROMULUSlib Architecture and Functions

The data to be communicated is prepared by the CROME devices and handled by ROMULUSlib for communication. ROMULUSlib provides functions for constructing and communicating TCP/IP frames with the supervision system. Frame construction is carried out by functions defined within romulus\_frame.h; including function to define the life cycle of a frame, access functions to access and modify specific

parts of the frame, validator function for checking the validity of the frame and utility functions to print and debug the frame. Once a valid frame is constructed, functions defined within romulus\_net.h are responsible for TCP/IP communication with the supervision system. This includes functions to control and send and receive romulus frames. ROMULUSlib also provides functions to report version and along with run logs, warning and error messages, and also generates timestamps in both, UNIX epoch and human readable form. A brief summary of all important functions of ROMULUSlib with it's placement in the corresponding header is given in Table 2 and a dependency graph of all the ROMULUSlib headers is shown in Fig. 7.

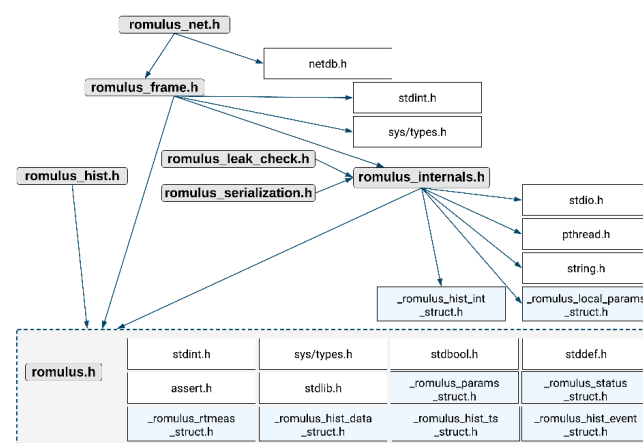

Figure 7: Dependency Graph of all ROMULUSlib Headers.

### ROMULUSlib Utilities

ROMULUSlib works as a standalone library for Linux User Space application. In order to facilitate debugging, ROMULUSlib also provides additional utilities. These utilities are meant to aid the developer in writing complete embed-

Table 1: Summary of Supported Data from CROME Organized in C Struct

Struct	Description
romulus_hist_data_struct	Struct for historic data variables.
romulus_hist_event_struct	Struct for hist event variables.
romulus_hist_int_struct	Struct for historic data that is not used by the supervision.
romulus_hist_ts_struct	Struct to define time ranges.
romulus_local_params_struct	Struct for Local parameters to parameterize the system locally.
romulus_params_struct	Struct for Romulus parameters used to parameterize the system and read back inherent parameters from the system.
romulus_rtmeas_struct	Struct which contains real time measurements.
romulus_status_struct	Struct which contains variables to indicate system status .

Table 2: Summary of ROMULUSlib Functionalities.

File	Description
romulus.c	Contains: - all the different structs which are used by the ROMULUS library, - all debug functions to query and manipulate the amount of log, - time function definitions to generate timestamp in machine and human readable form, - all function definitions to read the version of the library, - all function and data type definitions for ROMULUSlib's internal types, - definitions to create parameter protection masks to specify the write-protected parameters.
romulus_frame.c	Contains: - all structure definitions including data types and constants related to romulus frames, - all functions required to define the life-cycle of a TCP/IP frame such as header allocation, initialization, allocation, sequence ID generation and free frame memory, - all functions required to access parts of the TCP/IP frame such as, read header, footer, response code and data with offset and append header, footer and data to the frame, - a specific function to create request and response frames, including functions to check validity of the frames, - a specific function to update the parameters of the struct with contents of the TCP/IP frame, - a specific function which are used to manipulate/use status frames, historical data and events frame and real-time measurement frame, - utility functions such as print frame for debugging.
romulus_serialisation.c	Functions to read struct data from files.
romulus_hist.c	All definitions concerning historic data and events.
romulus_internals.c	- Struct, variable & function definition for romulus local parameters, internal historical data. - Definition of printing and IO functions. - Definition of internal data structures. - Struct, variable and function definition for romulus checksum. - Definition of some utility macros.
romulus_leak_check.c	Functions for leak checking, The leakcheck functions print information about memory allocations and calls to free().
romulus_net.c	- All type definitions for romulus frame based network connections. - All functions required to manage the life-cycle of connections to transmit romulus frames - All functions required to send and receive romulus frames. - All functions required to control the sending and reception of romulus frames.

ded applications. Some of these utility applications are as follows:

1. remote\_stream: Remote Stream application queries the Embedded Application running on PS and prints the TCP/IP frames for Real-Time Data streaming on port n+1.
2. struct\_info\_printer: Prints the all Struct Information such as member name, ID and data type as defined by the user.
3. remote\_dump: Remote Dump application queries the Embedded Application running on PS and prints status, parameters and hist data by fetching the TCP/IP frames streaming on port n.

## RESULTS

At present, 150 CROME devices have been deployed at CERN as the new generation of radiation monitors, all communicating simultaneously with the REMUS supervision via

ROMULUSlib ver6.2. The next major release for ROMULUSlib ver7.0 is tested and is scheduled for deployment in December 2021. All tests of ROMULUSlib are performed by a standalone regression testing framework, RomLibEmu[9]. RomLibEmu is developed in Python and works independently of ROMULUSlib to test CROME device's reaction to misconfigurations. This provides a stress testing framework for the application's network interface and test the overall robustness of the software towards the injected faults errors.

## EPICS Integration

CROME radiation monitors equipped with ROMULUSlib are currently also in use at the European Spallation Source (ESS) in Lund, Sweden. The ESS' Radiological and Environmental Monitoring System (REMS)[16] uses a two fold approach: Influx DB and Grafana approach for quick online integration, and EPICS integration for real time DAQ and control.

The ESS REMS development team has integrated EPICS [17], the software infrastructure for development

of distributed control systems widely used in particle accelerators, large physics experiments and telescopes. The ESS made use of the asynDriver module, a general purpose driver that integrates the device code to the hardware-level code. To integrate EPICS with CROME, initialization files to establish communication link to CROME devices have to be defined using ROMULUSlib. Suitable database files to describe the record types and names of the process variables have to be defined. The CROME devices communicate with the EPICS Input-Output-Controllers that are deployed on a dedicated virtual machine as services and launched at start-up. The collected measurements are posted to an influx database which is then made available via the Grafana interface on the ESS network.

## CONCLUSION AND FUTURE WORK

In this paper, we have presented ROMULUSlib, a standalone TCP/IP networking library developed in C. We have presented the ROMULUS data packet structure within the TCP/IP frame, and the communication protocol through request-response mechanism which allows supervision system to request single frame, multiple frames or streaming data frames. Besides this, a comprehensive feature list of all ROMULUSlib functionalities is presented along with debug tools. ROMULUSlib communicates seamlessly with SCADA supervision systems for DAQ and control applications while reliably carrying out millions of data packet transactions every hour (e.g. REMUS supervision handles 2,000,000 measurements/hour from CROME devices currently operational at CERN).

ROMULUSlib makes use of C Struct for storage of application variables of corresponding data types. These C Struct representation allows users to define their own variables as per the application requirement and recompile to autonomously generate ROMULUSlib executable in either arm32 or x86\_64 architectures with the new set of application variables. ROMULUSlib currently supports bool, unsigned char/uint8, int32, int64 and float data types to define application variables. Support for uint32 and uint64 will be added in the next versions.

The library has also been developed into a Labview VI using native Labview primitives which allows fast testing of new features and debugging applications. ROMULUSlib currently has been tested for reliability using RomLibEmu, an independent software framework developed in Python; and is presently operational with REMUS supervision system at CERN in Geneva, Switzerland and REMS EPICS supervision system at ESS in Lund, Sweden. In the future versions, we intend to add more regression tests for the library and while robust in application, we would be adding further to the instruction set as per application requirement, along with scaling the library to support varied processor architectures.

## ACKNOWLEDGEMENTS

The authors would like to thank Markus Witorski (CERN) for REMUS integration tests, Alasdair Day (ESS) and Juha Hast (ESS) for the performance tests at ESS and the integration of the library into EPICS supervisory system.

## Abstract

The Cherenkov Telescope Array (CTA) is the next-generation ground-based gamma-ray observatory. Its design comprises several ten imaging atmospheric Cherenkov telescopes deployed at two sites in the southern and northern hemisphere. The inclusion of various array elements, like large-sized, medium-sized and small-sized telescopes, instruments for atmosphere monitoring, etc, into the Array Control and Data Acquisition System (ACADA) poses a particular challenge which is met by an appropriate software architecture and a well-defined interface for array elements. This paper describes exemplarily how the interface is implemented for the Medium-Sized Telescopes (MSTs, 12 m diameter). The implementation uses the ALMA Common Software (ACS) as a framework for software applications facilitating the readout and control of telescope subsystems like the drive system or the pointing camera; the communication with subsystems takes advantage of the OPC UA protocol.

## INTRODUCTION AND OVERVIEW

The Cherenkov Telescope Array (CTA) is the next-generation ground-based observatory for gamma-rays in the energy band between some 10 GeV and several 100 TeV. CTA will comprise two arrays of Imaging Atmospheric Cherenkov Telescopes (IACTs) located in the southern (Paranal, Chile) and northern (La Palma, Canary Islands, Spain) hemisphere, respectively. IACTs with different mirror areas (dubbed Large-Sized Telescopes (LSTs), Medium-Sized Telescopes (MSTs) and Small-Sized Telescopes (SSTs)) ensure proper detection efficiencies for gamma-rays over four orders of magnitude in energy. The stereoscopic observation of showers with numerous IACTs results in an angular resolution and flux sensitivity that constitutes a substantial improvement compared to current IACT arrays (like H.E.S.S., MAGIC, and VERITAS). In CTA's (initial)  $\alpha$ -configuration, the northern installation will comprise 4 LSTs and 9 MSTs; 14 MSTs and 37 SSTs will be installed at the southern site.

The readout, control and monitoring of different array elements (telescopes and atmospheric monitoring devices) is the task of the Array Control and Data Acquisition (ACADA) system. The ACADA system is quite complex since it also

needs to cope with the concurrent automatic operation of multiple IACT sub-arrays and the rapid re-scheduling of observations in response to science alerts generated internally or by external astronomical facilities. The ACADA software is based on an architecture designed using the Unified Modeling Language (UML) and Systems Modeling (SysML) formalisms [1]. The implementation of applications takes advantage of the ALMA Common Software (ACS [2]) framework.

It adds to the challenge for the ACADA system that the three telescope types (LSTs, MSTs, SSTs) use different optics designs, employ different auxiliary hardware devices (e.g. reference lasers, pointing cameras, light flashers) and implement different operational procedures (observations, calibration, monitoring). A key assumption of the software design is that ACADA can control any telescope without knowing its type and that all telescopes implement a common stateful behaviour via a finite state machine (FSM). This paper describes the software aspects of the interface between ACADA and a telescope. It uses the MSTs as the primary example and starts therefore with a description of the telescope hardware. The implementation of the software interface using ACS and the entire MST software system are detailed as well.

## THE MSTs FOR CTA

### Telescope Optics

The MSTs [3] are IACTs with a field of view (FoV) of about  $8^\circ$  in diameter and an effective mirror area of about  $88 \text{ m}^2$ . In the CTA installations, they will be arranged at a typical distance of  $O(100) \text{ m}$  from each other and will cover the central energy range between 100 GeV and 30 TeV. The tessellated mirrors consist of 86 hexagonal spherical mirror facets with a focal length of  $f = 16.07 \text{ m}$  that are arranged on a sphere with a radius of curvature of  $R = 19.2 \text{ m}$ . The telescope focal length in this so-called modified Davies-Cotton design is  $F = 16 \text{ m}$ . The heart of the telescope is a camera<sup>1</sup> with a flat surface that is located in the telescope focal plane and uses about 1800 PMT pixels for the detection of Cherenkov light.

There are two Cherenkov camera projects differing in the number of pixels and the way of storing and processing PMT

<sup>\*</sup> schwanke@physik.hu-berlin.de

<sup>†</sup> Software for Science (Berlin)

<sup>1</sup> In the following, the term *camera* without further qualification is used only for the Cherenkov camera.

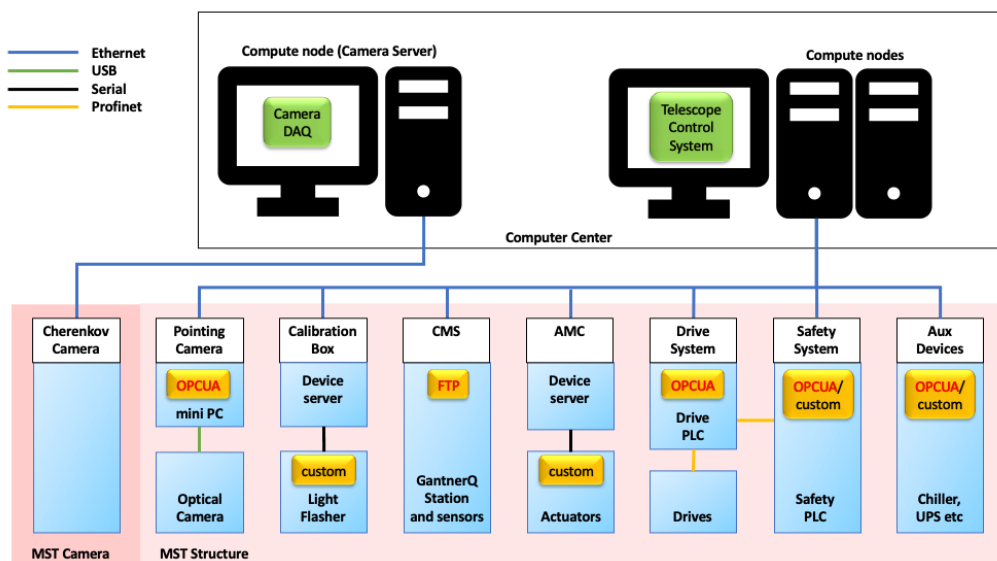

Figure 1: Breakdown of hardware and software systems involved in the operation of an MST. Rectangles denote hardware units. Protocols are denoted by yellow rectangles with rounded corners. See text for explanations.

signals. The MSTs in the southern CTA installation will be equipped with FlashCam cameras (1764 pixels, FADC-based data acquisition system [4]); NectarCAM cameras (1855 pixels, temporary storage of signals in an analogue ring buffer [5]) will be deployed in the north. It is beyond the scope of this paper to do justice to both camera projects. In the following, the focus will therefore be on the *MST structure* (everything but the Cherenkov camera). The description of the camera will be somewhat coarser and will only address those conceptual properties common to FlashCam and NectarCAM.

## Telescope Subsystems

The Cherenkov camera is the most important subsystem of an MST. The acquisition of camera data will result in data streams of about 1 GB/s per MST. Next to the camera there are the following subsystems that have to be handled by the telescope control software (cf. lower part of Fig. 1):

- **Pointing Camera:** The position of the Cherenkov camera with respect to the MST structure and stars in the sky is measured by a wide-FoV (about  $15^\circ \times 20^\circ$ ) optical camera. The pointing camera is located in the centre of the telescope mirror and roughly aligned with the optical axis of the MST. It images simultaneously stars in the sky and positional LEDs at the camera.
- **Calibration Box:** A light flasher<sup>2</sup> is mounted next to the pointing camera. It illuminates the Cherenkov camera with the aim of recording the response of the camera pixels to short light flashes. Equalizing the pixel response is part of the calibration of the Cherenkov camera.

<sup>2</sup> The description here and in the following refers to MSTs equipped with NectarCAMs.

- **Conditions Monitoring System (CMS):** Preventive maintenance of the telescope hardware shall be accomplished by the usage of a CMS [6] comprising  $O(10)$  acceleration and displacement sensors along with a dedicated data acquisition system for the sensor readings. The sensors are mounted at components of the drive system (motors, gear units, worm shaft) and at locations in the telescope structure. Time-dependent changes of the sensor response to external (e.g. wind) or internal (e.g. well-defined telescope movements) excitations would be indicative of problems.
- **Automatic Mirror Control (AMC):** The 86 mirror facets have to be aligned such that light from a point source is imaged into a small spot in the telescope focal plane. For this purpose, the mirror facets have a triangular fixation, and two fixation points of each facet can be moved with the help of stepper motors (actuators) by a few centimeters. The proper actuator settings are typically found in a calibration process using images of stars in the telescope focal plane recorded by the pointing camera [7].
- **Drive System:** The MSTs have an azimuth-elevation mount. Telescope movements are facilitated by four elevation ( $-20^\circ < el < 91^\circ$ ) and two azimuth ( $-270^\circ < az < 270^\circ$ ) motors moving the corresponding drives based on encoders readings.
- **Safety System:** Safety of humans and equipment is ensured by a number of sensors, hardware switches (e.g. emergency buttons) and interlocks. The corresponding signals are captured and processed by a safety system which also communicates with the other subsystems.
- **Auxiliary Devices:** There are a number of smaller subsystems (e.g. a chiller for the cooling of the Cherenkov

The drive system and the Cherenkov camera are vital for scientific observations. A failure of the pointing camera during observations would result in data sets with reduced pointing accuracy. It is expected that the mirror alignment obtained with the help of the AMC and the pointing camera is so stable that AMC only needs to be operated during the alignment or in emergency situations (e.g. to defocus the telescope to prevent damage due to the Sun). A CMS will be deployed and studied at the first MST scheduled for construction at the northern CTA site.

The diagram illustrates the state transitions of a machine. The states are represented by rounded rectangles, and the transitions are labeled with events and actions. The states are categorized into Machine State (light blue) and Operational State (orange). The states are: Off, Maintenance, Initializing, Initialized, Standby, Ready, Observing, Fault, and Technical. The transitions are: Off to Maintenance (switchOff), Maintenance to Off (switchOn), Maintenance to Off (switchOff), Off to Initializing (Execute Init), Initializing to Initialized (Init Complete), Initializing to Fault (Error), Initializing to Initializing (goToInitializing [Fault Fixed]), Initialized to Technical (goToTechnical), Technical to Initialized (goToInitialized), Initialized to Standby (goToStandby), Standby to Initialized (goToInitialized), Standby to Fault (error), Standby to Standby (goToStandby), Standby to Standby (goToTechnical), Standby to Standby (goToStandby), Standby to Ready (goToStandby), Ready to Standby (goToStandby), Ready to Ready (configure [Standby.idle]), Ready to Observing (startObserving [Ready.idle]), Observing to Ready (goToReady), Observing to Fault (error), Fault to Fault (error), Fault to Fault (goToStandby [[Fault Fixed] && (Previous State == Standby | Ready | Observing)]), and Fault to Fault (error).

The generic interface for CTA telescopes is primarily used by ACADA. This interface describes high-level methods that are primarily used to control telescopes (and other types of array elements, which will be omitted in the discussion below) and to obtain basic information about the state of the respective array element. The most important set of methods defined in the interface relate to state transitions of the array element. An incomplete list of relevant transitions is shown in Table 1. These transitions, together with the states and sub-states a telescope can assume, are also visible in Fig. 2. As can be seen from the table, these are high-level methods, and detailed control of e.g. individual hardware elements is not intended. The usage of configuration databases is assumed and reflected in certain interface method signatures. For example, both the telescope structure and the camera can load different configurations depending on the exact type of observations that shall be conducted. The respective

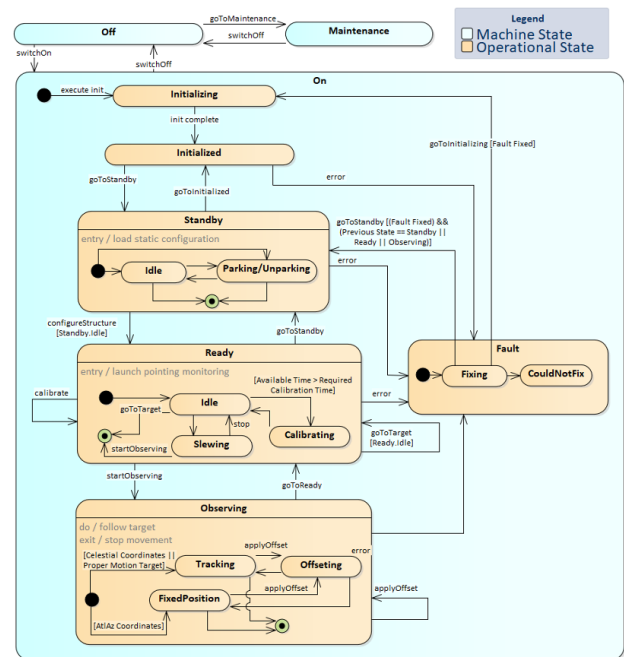

Table 1: Selection of the most relevant telescope transitions. These transitions represent the core of the telescope interface. The last three transitions can optionally start observations with the camera. See Fig. 2 for a list of telescope states and allowed transitions.

Transition	Description
goToInitialized	Puts telescope to the
goToStandby	Initialized/Standby/
goToReady	Ready/Technical
goToTechnical	state
startObserving	Starts observation of a previ- ously defined target
goToSkyTarget	Lets telescope track a celes- tial coordinate
goToProperMotionTarget	Lets telescope follow a tar- get by providing a trajectory
goToFixedPosition	Points telescope to a fixed position

For standard observations, the interface provides only methods for controlling the TelescopeManager. Access to subsystems, like the telescope structure or the camera, is not foreseen. For special-purpose operations the telescope

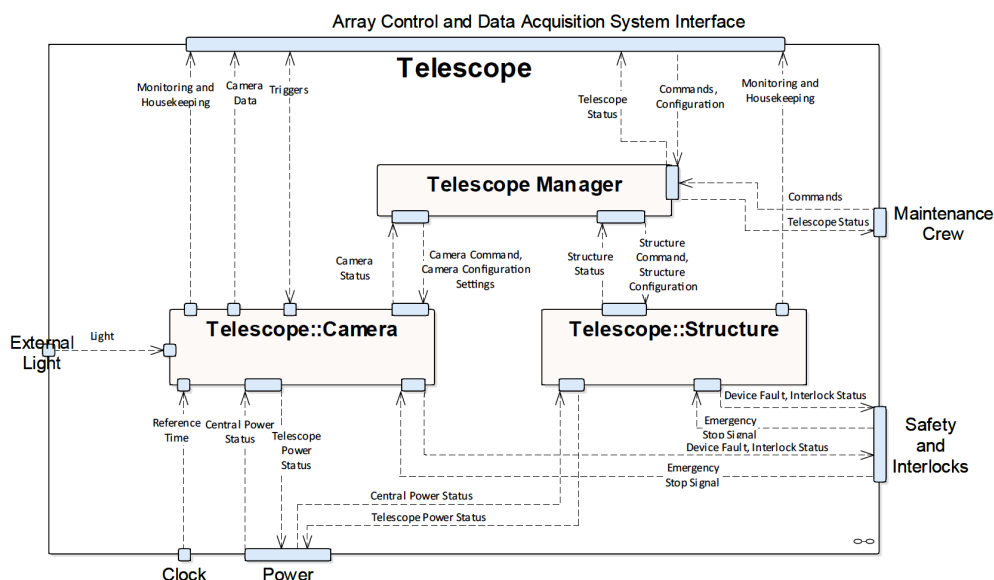

Figure 4: High-level view of the interfaces of the TelescopeManager, the camera and structure subsystems. When performing standard observations, ACADA only interacts with the TelescopeManager, which is in charge of supervising and controlling subsystems. When the telescope is in the Technical state, ACADA accesses and interacts with the two telescope subsystems directly. External devices and actors interacting with the telescope manager and subsystems are displayed as well. The exchange of commands and data is displayed through arrows.

can enter the Technical state. In this state, ACADA can request from the TelescopeManager access to an extended interface with direct control over the Cherenkov camera and the structure (CameraManager and StructureManager in Fig. 4). Also more detailed information about the telescope and subsystem statuses is available in this mode.

When maintenance work is ongoing at a telescope, the TelescopeManager shall reflect this by assuming the Maintenance state. The respective transition is initiated by a physical switch at the telescope. In this state, any remote control by e.g. ACADA is prohibited to ensure human safety. Obtaining monitoring data is still possible in this state, though.

The monitoring of telescope parameters and conditions is not part of the interface. Also the transfer of bulk data from the cameras is not specified through the interface discussed here.

The telescope interface is implemented from both sides. For the development of the user side, i.e. the ACADA system, a mock implementation of a generic telescope has been developed in Python. Telescope states, relevant transitions and subsystem transitions have been implemented to mimic realistic and configurable behaviour of telescopes. Threads are used to simulate long-lasting procedures and transitions, and callbacks are used as primary concept for notifying clients of the mock TelescopeManager about the progress of such operations. The mock implementation of the TelescopeManager is used in a variety of automated software tests of ACADA, such as verifications of high-level ACADA use cases.

The interfaces between the TelescopeManager or ACADA on the one side and the StructureManager and the Camera-

Manager on the other side are also defined. As indicated above, ACADA can only access these components when the telescope is in the Technical state.

As shown in Fig. 3, a state machine has also been defined for the structures of CTA telescopes. The TelescopeManager (or ACADA) requests transitions between operational states. Internal states as well as transitions between them are handled by the StructureManager. Sub-states only need to be implemented if applicable.

Several states and sub-states can be entered by the telescope (or subsystem) autonomously. For example, calibration routines can be performed automatically by the telescopes if the telescope was instructed by ACADA to start observing at a given time and there is enough time in advance to calibrate subsystems. In this case, the StructureManager can decide to enter and leave the Ready.Calibrating state. Also in case an error occurred the TelescopeManager can attempt to fix the problem, and if successful, the telescope (or the respective subsystem) can return to a non-Fault state by itself.

## READOUT, CONTROL AND MONITORING OF MSTs

### Protocols, Standards and Data Formats

The data stream from the camera is dominating the bandwidth that the ethernet network (blue lines in Fig. 1) between an MST and the local computer centre on a CTA site has to provide. In the event of a camera trigger, the digitised PMT signals are transferred to a dedicated computer (camera server in the upper left part of Fig. 1) which caches all

data for a period of about 1 s and processes the data further. Typically only events where at least one other telescope recorded useable camera data simultaneously are kept and stored on hard disk for offline analysis. The stereoscopy requirement (more than one telescope with data) is enforced by a central software array trigger (SWAT). The SWAT operates on trigger time stamps sent to it by all cameras in the array and informs the camera servers about data of interest. The transfer of camera data uses a highly-performant bulk-data transfer service that is based on the ZeroMQ messaging library and can also compress data [8].

All other data streams for readout, control and monitoring are fairly modest in size. The high number of different telescope subsystems and the need to upgrade their hardware and software over the anticipated lifetime of CTA (about 30 years) motivate, however, the prescription of standard protocols and mechanisms for the data transfer. For CTA, the combination of an ACS DeviceIO<sup>3</sup> with the OPC UA industrial communication protocol is the method of choice. OPC UA has been standardised by the OPC Foundation. It has growing support in industry and a number of software development kits exist. An implementation of an ACS DeviceIO for OPC UA has been made available to the telescope projects. To be practical, the following three options for the inclusion of a hardware device/telescope subsystem exist:

1. Devices that come with a vendor-side OPC UA server can be immediately integrated by means of the ACS DeviceIO for OPC UA.
2. For devices that communicate via a dedicated device protocol an OPC UA server needs to be developed. The server will translate between the device protocol and OPC UA and will be integrated as described above.
3. If the development of an OPC UA server is not an option a device with a dedicated protocol can be included by providing an ACS DeviceIO for this protocol.

### *Local Control Systems of the MST Structure*

The usage of ACS is confined to the Telescope Control System (TCS, cf. upper right part of Fig. 1). The TCS provides the higher-level control and implements the telescope interface described above. The division of labour between the TCS and the software systems located at the telescope is motivated by safety aspects and the wish to minimize future changes of the software at the telescope. The communication between the TCS in the computer centre and an MST structure uses ethernet. The chosen hardware and software solutions are as follows (cf. lower part of Fig. 1):

- **Pointing Camera:** The pointing camera consists of an optical camera and a mini PC in a custom-built housing. The housing provides temperature stabilization and features a number of internal sensors. The camera and the mini PC are connected by USB; the mini PC has an OPC UA server for control and image readout.

<sup>3</sup> An ACS DeviceIO provides a mapping between a node in a CORBA object (e.g. Property in an ACS Component) and a monitoring/control point in an external hardware device.

- **Calibration Box:** The LED-based light flasher is managed by firmware on an 8bit microcontroller using a custom protocol. A device server is used to convert the serial communication to ethernet.
- **Conditions Monitoring System:** The data acquisition for the conditions monitoring system uses a real-time board (Gantner Q.station) that digitises the arriving analogue sensor signals and buffers them. At present, the board sends the data to an FTP server in the computer centre. There are also ways to transmit data for storage.
- **Automatic Mirror Control:** The communication with the  $2 \times 86 = 172$  actuators uses serial lines and a custom protocol. The serial lines are converted to ethernet with the help of an device server. Each actuator provides not only the current position of the stepper motor but also monitoring information (e.g. a temperature). There is the option to choose between several actuator settings stored in the firmware.
- **Drive System:** The drive system at the telescope needs no knowledge about astronomy and basically only deals with time, azimuth and elevation. A programmable logic controller (PLC) accepts precalculated tables with azimuth and elevations as a function of time in discrete time steps. The PLC code interpolates the information in the table and controls the drive motors such that the intended path in the sky is followed (e.g. to implement siderial tracking). The interface to the outside world is an OPC UA server.
- **Safety System:** The safety system is also a PLC that bundles and processes all safety-relevant information. The communication with the outside world proceeds via an OPC UA server. The Safety PLC offers some extra monitoring data (e.g. tables with motor torques at rates much higher than a few Hz) via a custom protocol. All PLCs in the system (Drive PLC, Safety PLC) are connected via the Profinet bus.
- **Auxiliary Devices:** The readout and monitoring of chiller and UPS will depend on the exact models that will be chosen in the future. It is envisaged that the information (e.g. sensor readings or status flags) will be made available as an OPC UA server.

## THE TELESCOPE CONTROL SYSTEM

### *Structure of the TCS*

For the implementation of an MST-specific TelescopeManager, the Java programming language has been chosen. All relevant interface methods have been implemented, and their functionality is verified by a set of unit and component tests. Focus is put on achieving a good test coverage. In the following, only the StructureManager will be discussed in detail since the camera software design depends on the deployed hardware (FlashCam or NectarCAM).

For the MST StructureManager, the common interface has been extended by a set of custom methods that are required to control those subsystems (e.g. the AMC and the

pointing camera) that are only available for MSTs. ACADA is not aware of these methods, but the TelescopeManager makes use of them for both commissioning and regular operations. The extended interface of the StructureManager is described by an appropriate IDL<sup>4</sup> file. Placing the extended interface in the StructureManager has the advantage that the full functionality of an MST structure is available to clients. This removes the need for clients to interact directly with subsystems controlled by the StructureManager.

### Implementation as ACS Components

The TCS for an MST is implemented as a flat hierarchy of ACS components. The TelescopeManager (cf. Fig. 5) controls the CameraManager and StructureManager and calculates its state as a function of the states of the two subsystems. The StructureManager interacts directly with the Safety System to interrogate the hardware state (interlocks, emergency switches) of the MST structure and includes this information in the computation of its own state. There are four basic groups of ACS components that aid the StructureManager to read out and control the MST structure hardware:

- **Pointing Camera:** The top-level ACS component for the pointing camera receives configuration information (rates and exposures for image acquisition) and launches threads for the acquisition of images from the pointing camera. A *Bridge* ACS component is used for mapping to the OPC UA protocol.
- **Automatic Mirror Control:** The top-level ACS component for the AMC deals with the AMC configuration (number and arrangement of actuators) and accesses an OPC UA server via a *Bridge*. The OPC UA server for the AMC is executed locally and uses a custom protocol for the actual communication with the hardware.
- **Drive System:** The ACS component for the drive system forwards simple commands (e.g. pointing the telescope to a fixed position in azimuth and elevation) directly to the drives system hardware. For tracking of astronomical targets it generates the time-dependent trajectory in azimuth and elevation in time steps of about 250 ms. Pointing corrections<sup>5</sup> are applied through a pointing model in this step. About 1000 trajectory steps (corresponding to 250 seconds of tracking) are initially sent to the drive PLC and buffered there. The buffer is topped off whenever necessary.
- **Auxiliary Devices:** The readout and control of the auxiliary devices is managed by ACS components coupled to a *Bridge*.

### Clients and Graphical User Interfaces

ACADA is the most important user of the MST TCS. It regularly inspects the TelescopeManager state to check the availability of the TCS (and hence the telescope hardware)

for standard observations. For a typical night with observations ACADA prepares the telescopes well before dark time. In this preparatory phase, the telescopes leave the parking position and execute telescope-specific routines (attain the operating temperature for the Cherenkov camera, record calibration data). Observations of scheduled astronomical targets are conducted when the conditions are optimal (astronomical darkness, partial Moon). There is also a closing phase near dawn; it is complementary to the preparatory phase and ends with the telescopes returning to the parking positions.

In periods of telescope commissioning, extended calibration and trouble-shooting, expert personnel requires a more fine-grained access to the TCS. For this purpose, the TelescopeManager can be brought to the *Technical State* (cf. Fig. 2) and signals in this way that a remote control by ACADA is prohibited. There are then two mutually exclusive ways to control an MST: by means of a graphical user interface (GUI) and by means of scripts that manipulate the TCS directly. In both approaches, the TelescopeManager must finally leave the *Technical State* again so that ACADA can reclaim control.

Figure 6 shows a screenshot of the browser-GUI that can be used for the MST structure. The underlying server takes advantage of the same software technologies that are used for the CTA operator GUI. The server is written in Python as an application of the Pyramid<sup>6</sup> open-source web framework. It uses native Python features (`asyncio`) and the websockets library to implement concurrency and the communication with a client, respectively. Internally, the server gains access to ACS components of the TCS. The offered functionality comprises actions with the drive system (track astronomical targets, point the MST to a coordinate in azimuth and elevation etc) and basic tests with the AMC (actuator movements). A passive monitoring of basic telescope parameters (e.g. the current pointing direction, cf. Fig. 6) is available at all times while active control of the MST structure is only possible in the *Technical State*.

Client scripts (in Python) are the most flexible way to access the TCS. While ACADA works exclusively with the TelescopeManager the scripts can also approach the StructureManager, the CameraManager or any of the underlying ACS components. A typical example for the MST structure is a script implementing a procedure for mirror alignment. In this application, the script would use the standard interface of the TelescopeManager to initiate the tracking of a star. The extended interface of the StructureManager is then used to vary the orientation of the mirror facets (by means of the actuators) and to record images with the pointing camera.

### ACKNOWLEDGEMENTS

The authors acknowledge the work of numerous members of the CTA consortium in the ACADA and MST Projects which helped to shape the MST and ACADA software. We gratefully acknowledge financial support from the agencies

<sup>4</sup> interface definition language

<sup>5</sup> Pointing corrections are needed whenever the azimuth and elevation of the drive system are not identical with the astronomical azimuth and elevation.

# HEXAPOD CONTROL SYSTEM DEVELOPMENT TOWARDS ARBITRARY TRAJECTORIES SCANS AT SIRIUS/LNLS

A. Y. Horita \*, F. A. Del Nero, M. A. L. Moraes, G. N. Kontogiorgos, LNLS, Campinas, Brazil  
G. G. Silva, UNICAMP, Campinas, Brazil

Modern 4th generation synchrotron facilities demand high precision and dynamic manipulation systems capable of fine position control, aiming to improve the resolution and performance of their experiments. In this context, hexapods are widely used to obtain a flexible and accurate 6 Degrees of Freedom (DoF) positioning system, since it is based on Parallel Kinematic Mechanisms (PKM). Aiming the customization and governability of this type of motion control system, a software application was entirely modeled and implemented at Sirius. A Bestec hexapod was used and the control logic was embedded into an Omron Delta Tau Power Brick towards the standardization of Sirius control solutions with features which completely fill the beamline scan needs, e.g., tracing arbitrary trajectories. Newton-Raphson numerical method was applied to implement the PKM. Besides, the kinematics was implemented in C language, targeting a better runtime performance when comparing to script languages. This paper describes the design and implementation methods used in this control application development and presents its resulting performance.

## INTRODUCTION

Sirius is the 4th generation synchrotron light source being commissioned by the Brazilian Synchrotron Light Laboratory (LNLS), in Brazil [1]. Its low emittance (0.25 nm rad) makes it one of the world's brightest light sources of its kind [2]. In this sense, high precision control systems are required towards better beam quality and stability.

In Sirius IPE Beamline, a Bestec P468 Mirror Unit [3] was chosen as the motion system of a toroidal mirror. This unit contains a hexapod in its structure, which is illustrated in Fig. 1. Hexapods are widely used due to the parallel control capacity of its 6 degree of freedom (DoF), characterized in Parallel Kinematics Machines (PKM) [4].

Together with this unit, a Bestec P494 Motion Control System was also acquired, which embeds a Mint Linux distribution as Operating System (OS), containing a set of proprietary control software which implements the user interface, configuration files, system kinematics and the hexapod system interface.

Although the P494 control system meets the beamline expected stability and motion control accuracy, a customized system developed in-house was desired towards Sirius's systems standardization and independence when implementing new features, such as arbitrary trajectories scans. Under these circumstances, we decided to implement the control logics using an Omron Delta Tau Power Brick LV controller [5].

\* augusto.horita@lnls.br

Figure 1: Toroidal mirror supported by hexapod in the Bestec P468 Mirror Unit.

An important portion of the motion control logics consists of its kinematics, which is splitted into two algorithms. The inverse kinematics converts system positions to individual motors' positions and the forward kinematics calculates the system feedback positions based on encoders [6]. Towards a more productive and robust implementation process, the hexapod kinematics was first mathematically modeled using a Jupyter Notebook [7], which provided flexibility using software structures, e.g. mathematical libraries, and optimized the simulation and bugfixes process [8]. Due to the fact that the kinematics of a hexapod is non-linear [6], our model was based on Newton Raphson for root-finding, as it is widely used and has a fast convergence rate [9].

Based on the validated Jupyter Notebook model, it was possible to implement the control logics in the Delta Tau Power Brick LV system. Its performance was then compared to Bestec's control system for validation. Also, an example of arbitrary trajectory was implemented for functionality validation purposes.

The remaining sections of this paper presents in more details the used methods for this control system development and its validation.

## MOTION CONTROL DEVELOPMENT

In this section, we present the motion control system development, focusing on the kinematics modeling and implementation.

### Kinematics Model

In the presented application, the toroidal mirror is placed inside a vacuum chamber. Towards a more robust and easy

for maintenance architecture, Bestec's P468 Mirror Unit was designed placing the actuators outside the vacuum environment. In this context, this Mirror Unit hexapod design slightly differs from the usual hexapod configuration found in other applications and in literature [6], as illustrated in Fig. 1. In this design, the six manipulator's struts have constant length, and the platform movements are caused by the vertical displacement of six linear actuators placed outside the chamber, and connected to the struts by a spherical joint. As a consequence, the presented kinematics model also differs from models found in the literature.

For standardization purposes, the kinematics model and the mathematical formulation presented in this work are based on the Sirius coordinate system, in which the Z-axis points to beamlight direction, X-axis outward from the storage ring and Y-axis is pointed upwards, as shown in Fig. 2a. The Bestec motion control system is based on a different coordinate system, as illustrated in Fig. 2b. This difference is compensated during the data analysis by comparing the correspondent DoF of each control system. Aiming the simplification of methods description, the remaining of this paper refers to the Sirius coordinate system.

Figure 2: Coordinate system conventions

Two auxiliary frames are used to model the kinematics transformations: the platform's coordinate system  $O_p(u, v, w)$  (at platform centroid) and the granite plate coordinate system  $O_g(x, y, z)$ . In addition, a set of vectors is also necessary, as illustrated in Fig. 3. Let  $\vec{b}_i$  ( $i \in 1, \dots, 6$ ) be the vectors from  $O_g$  to the  $i^{th}$  granite joint. Similarly, let  $\vec{a}_i$  ( $i \in 1, \dots, 6$ ) be the vectors from  $O_p$  to the  $i^{th}$  platform joint, written with respect to platform's coordinate system. Moreover, let  $\vec{l}_i$  be the vector representing the  $i^{th}$  hexapod strut, with  $(\|\vec{l}_i\|)$  being constant. The  $\vec{s}_i$  links the  $i^{th}$  granite joint to the  $i^{th}$  platform joint, and  $\vec{c}_i$  the vertical vector representing the position of the  $i^{th}$  linear actuator, in reference to the granite plate. Finally, let  $\vec{p}$  be the position vector of the platform centroid  $O_p$  in reference to  $O_g$  and  $\vec{m}$  the position vector of the end-effector *i.e.*, the mirror centre, considering the  $O_g$  coordinate system.

We also define a rotation matrix  $R$  as the product of three consecutive rotations along each coordinate axis *i.e.*,  $R = R_x(\alpha)R_y(\beta)R_z(\gamma)$ , considering that:

$$R_x(\alpha) = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos \alpha & -\sin \alpha \\ 0 & \sin \alpha & \cos \alpha \end{bmatrix} \quad (1)$$

Figure 3: Coordinate systems and vectors applied to hexapod model.

$$R_y(\beta) = \begin{bmatrix} \cos \beta & 0 & \sin \beta \\ 0 & 1 & 0 \\ -\sin \beta & 0 & \cos \beta \end{bmatrix} \quad (2)$$

$$R_z(\gamma) = \begin{bmatrix} \cos \gamma & -\sin \gamma & 0 \\ \sin \gamma & \cos \gamma & 0 \\ 0 & 0 & 1 \end{bmatrix} \quad (3)$$

**Inverse Kinematics Model** Given a position  $(x, y, z, \alpha, \beta, \gamma)$  of the mirror centre, we present the algorithm to find each linear actuator displacement. Based on Fig. 3, and considering that the platform and the mirror are coupled, their angular position  $(\alpha, \beta, \gamma)$  are the same. In this sense, it is possible to find the platform's centroid  $O_p$  position, represented by vector  $\vec{p}$ , by subtracting the vector  $\vec{m}$ , of fixed module  $\|\vec{m}\|$ , from mirror centre position  $(x, y, z)$ . Figure 3 also illustrates that vector  $\vec{s}$  can be calculated as shown in Eqs. (4) and (5):

$$\vec{s}_i = \vec{p} + R \cdot \vec{a}_i - \vec{b}_i \quad (4)$$

$$\vec{s}_i = \vec{c}_i + \vec{l}_i \quad (5)$$

Considering  $\vec{c}_i = (0, y_{ci}, 0)$ , we can write:

$$\vec{s}_i - \vec{c}_i = (x_s, y_s - y_c, z_s) \quad (6)$$

As the hexapod struts lengths  $\|\vec{l}_i\| = \|\vec{s}_i - \vec{c}_i\|$  are constant:

$$y_{ci} = y_{si} - \sqrt{\|\vec{l}_i\|^2 - z_{si}^2 - x_{si}^2} \quad (7)$$

In summary, in order to calculate the vertical displacement of the linear actuators, one may calculate the  $s$  vector using Eq. (4) and then use this result in Eq. (7).

**Forward Kinematics Model** In the forward kinematics algorithm, the position of the end-effector is calculated based on the given linear actuators positions, measured by absolute encoders.

From Eqs. (4) and (5), we can write:

$$c_i = \|\vec{p} + R \cdot \vec{a}_i - \vec{b}_i - \vec{s}_i + \vec{l}_i\| \quad (8)$$

Which represents a set of six nonlinear equations that composes the forward kinematic model. From Eq. (8) we obtain the position of the end-effector traversing the  $\|\vec{m}\|$  distance in the direction perpendicular to the platform ( $\hat{v}$  direction). A possible approach for solving these equations is to use a numerical method. In this context, the Newton-Raphson method was chosen for root-finding, as it is widely used in similar problems due to its convergence rate and accuracy performance.

The Newton-Raphson is an iterative algorithm, therefore Eq. (9) defines  $f_i(x)$  as the square error between the given actuators position and the calculated position at the  $k^{th}$  iteration:

$$f_i(x) = (y_i)^2 - (y_i^{(k)})^2 = 0, \quad i = 1, \dots, 6 \quad (9)$$

Where the  $x$  variable denotes the six input variables vector, representing the end-effector coordinates, and  $y_i$  denotes  $i^{th}$  output variable, which is the vertical displacement of the  $i^{th}$  linear actuator. Let  $F(x)$  be the vector of  $f_i$  functions. Given an estimate  $x^{(k)}$  for the platform centroid position at the  $k^{th}$  iteration, the linear approximation around  $x^{(k)}$  can be calculated as:

$$F(x) = F(x^{(k)}) + (x - x^{(k)})F'(x^{(k)}) \quad (10)$$

Where  $F'(x) = (J)_{ij} = \frac{\partial f_i}{\partial x_j}$ . Hence, the Jacobian matrix is defined as:

$$J = \begin{bmatrix} \frac{\partial f_1(\mathbf{x})}{\partial x_1} & \dots & \frac{\partial f_1(\mathbf{x})}{\partial x_6} \\ \vdots & \ddots & \vdots \\ \frac{\partial f_6(\mathbf{x})}{\partial x_1} & \dots & \frac{\partial f_6(\mathbf{x})}{\partial x_6} \end{bmatrix} \quad (11)$$

Then, the input vector at the  $k^{th} + 1$  iteration is calculated as:

$$x^{(k+1)} = x^{(k)} + J^{-1}(x^{(k)})F(x^{(k)}) \quad (12)$$

The algorithm proceeds until the convergence criterion  $\|F(x^{(k)})\| < \epsilon$  is met or until the maximum number of 10 iterations is reached.

### Kinematics Implementation

The Delta Tau integrated development environment (IDE) supports two different ways to implement the control system kinematics. It can be done using the kinematics scripts (plc files), or implementing in C language, which is indicated when the application requires heavy mathematical calculations, due to the fact that compiled languages have better

runtime performance when compared to scripted ones. In this sense, our choice was to implement the C source coded kinematics.

There are some obstacles when implementing the C kinematics in Delta Tau system that had to be overcome. The Delta Tau IDE doesn't support the usage of additional C libraries, only the ones included in the software development kit (SDK), which made it necessary to adapt and use the proprietary functions included in SDK. In addition to that, the C kinematics logics have to be implemented in a specific function already defined in the SDK, the *CfromScript* function, which is called inside the script files.

On the other hand, the SDK includes functions that were useful aiming a motion control better performance. The *SegMoveTime* function splits the movement trajectory into time intervals of configured milliseconds. Before each segment execution, the kinematics are re-calculated. This improves the movements accuracy during the transient state by reducing the parasitic movements in other DoFs, although it costs computation resources. If the interval is set too low, there is a risk of starvation, where the controller may not be able to do all of its move calculations in the time allotted, stopping the motion program with a run-time error. As our application targets better positioning precision, we decided to use 1 ms interval configuration, which has shown to be enough for motion calculations during our tests.

## VALIDATION TESTS

The present section outlines the implemented motion control system validation tests, which includes its comparison with Bestec's P494 Motion Control System benchmark. Furthermore, it describes a simple example of the desired arbitrary trajectory functionality implementation.

### Performance Tests

Aiming the standardization of control systems for Sirius beamlines' PKMs, such as granite bases, hexapods and tripods, a motion control system was developed in in-House. For the validation of this system, comparative tests were performed against the Bestec P494 motion control system.

These tests consisted of making controlled movements in one hexapod DoF, setting the same motion range and speed in both control systems, while logging all DoF's positions to check the amplitude of parasitic movements. The movements were performed using one control platform at a time. The unit positions were logged, then acquired and analyzed afterwards. Due to the fact that P494 controller sample rate for the hexapod position is limited to 10 samples/s, we configured the Power Brick LV to acquire at the same sample rate.

For compilation purposes, this paper only presents two cases of the conducted comparative performance tests, one representing a translation DoF command and another illustrating a rotation DoF command.

Figure 4 depicts the comparison between the control systems performances when commanding the unit to move from

–1 mm to 1 mm in Z-axis. The Z-axis curve shows that the control systems reached stability at the target position with a difference of approximately 0.4 s. Although P494 control reaches the destination before, it presents significant position deviations at the transient state for all DoFs, while the Power Brick LV shows smaller control errors. The Fig. 4 curves also shows that cross-talk movement ranges were smaller for the Power Brick LV system. In  $X$ ,  $Y$ ,  $R_x$  and  $R_z$  axes, the noticed differences represent one order of magnitude.

Figure 4: Z-axis translation trajectory and parasitic motion comparison between Delta Tau Power Brick and Bestec P494 control systems.

The command of  $R_z$ -axis moving from –3 mrad to 3 mrad was the chosen rotation DoF, which is shown in Fig. 5. The  $R_z$ -axis curve exposes a similar behavior to the previous test. The P494 system reaches the target approximately 0.3 s before, although it presents position deviations, while the Power Brick course the trajectory without position hiccups. The remaining curves illustrate that parasitic movement ranges are smaller using the Power Brick LV system for all axes. In  $X$  and  $Y$  cases, the differences represent one order of magnitude. The rotation plot also shows that P464 may present stationary error before the movement, which is noted in  $P494 : -R_x$  curve.

### Arbitrary Trajectory Test

Many beamline applications are not covered by point-to-point traditional s-curve trajectories. For instance, if coordinated motion is required and the hexapod should follow an external motor towards a polynomial relation, the motion profile will demand velocities' profiles other than smooth trapezoids. Or if a crystal should be rotated to vary the beam incidence angle and to perform a motion profile whose energy derivative is trapezoidal, an arbitrary trajectory is needed. If all virtual axes of an hexapod can be controlled with low cross-talk and also to perform arbitrary trajectories, then a powerful tool for fly-scans was achieved.

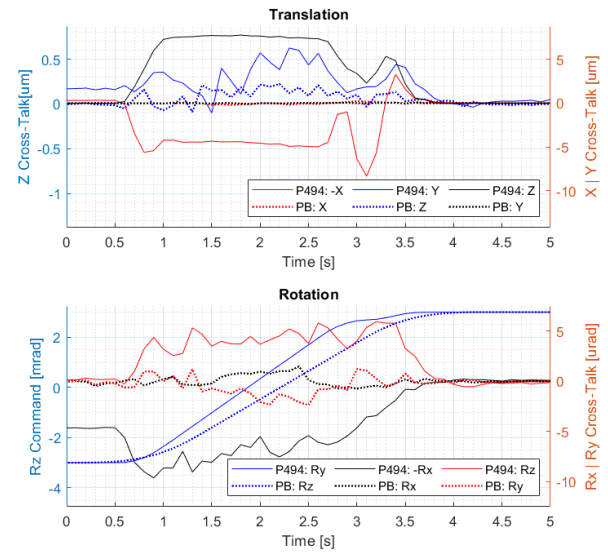

Figure 5: Z-axis rotation trajectory and parasitic motion comparison between Delta Tau Power Brick and Bestec P494 control systems.

In this context, the arbitrary trajectory functionality consists of performing system movements based on a previously defined sequence of DoFs positions and movements parameters, such as speed and step triggers. This may enhance the system runtime time performance and determinism, as a portion of the necessary calculations is done before the system motion execution.

When using this functionality, the trajectory parameters may be inputted into the system using different resources, e.g. they may be saved into the device memory and read during application runtime by a script, processed by a motion application. Another option is to use the EPICS interface through waveforms Process Variable (PV) to input the trajectory parameters. This paper presents a simple validation example of the second method, using a customized version of Power Brick LV and EPICS source codes implemented by Diamond Light Source (DLS) [10], which inputs the trajectory positions, time spent in each position and the speed curve mode in each step move.

For this test, the trajectory parameters were previously generated using a python script. Figure 6 illustrates the planned trajectory, which commands the hexapod to move in the 3 translations DoF.

Aiming a more realistic application, the generated trajectory also variates the speed and acceleration during the movement, which may be useful during beamline fly-scans. In this sense, a sinusoidal-exponential signal was chosen as arbitrary acceleration profile, in order to create a constantly varying velocity profile. Each trajectory edge is composed by two axes moves, one is a linear 0.001 mm increment or decrement in the range from 0 to 0.5 mm, and another is described by Eq. (13).

Figure 6: Generated arbitrary trajectory

$$pos_i = \frac{e^{(2*i)} * \sin(i) + 2 * i}{100} \quad (13)$$

Figure 7 illustrates the generated position, speed and acceleration data considering the non-linear movement component of a single trajectory edge movement.

Figure 7: Generated position, speed and acceleration

Based on the generated trajectory, the DLS algorithm was used to run the application and move the hexapod motion unit. Figure 8 depicts the motion system logged position in each translation DoF during the movement, while Fig. 9 shows that the position errors of each commanded DoF during the transient state ranges from  $-3$  to  $3 \mu\text{m}$ .

The analysis of the logged position data in comparison to the planned trajectory, in addition to the low range of the computed errors, shows that the motion system follows

the planned motion, which validates the arbitrary trajectory functionality implementation.

Figure 8: Time plot of arbitrary trajectory logged positions.

Figure 9: Time plot of transient state position errors.

## CONCLUSION

A motion control system for the Bestec P468 Mirror Unit hexapod was implemented using Delta Tau Power Brick LV, a standard motion controller used in Sirius. Although the Bestec P494 system can reach its specifications at steady state and perform step-scans, it is neither suitable for fly-scans nor distributed coordinated motion, as relevant cross-talks are present during commanded movements. The performance tests demonstrate that the in-house designed system's motion control accuracy at transient state overcomes the manufacturer one, specially when comparing the parasitic movements during a single DoF command, which is fundamental for fly-scans, where the detectors acquire images during transient motions. In addition, the arbitrary trajectory functionality was validated using the new control system,

which represents an additional step towards beamline coordinated motion.

Once the Delta Tau Power Brick LV is the standard controller for many Sirius' beamlines, the knowledge acquired within the present work can be applied to other systems, e.g. implementation of system kinematics in C language for granite bases [11] and the arbitrary trajectory and coordinated motion functionalities for monochromators [12].

## ACKNOWLEDGEMENT

The authors would like to gratefully acknowledge the funding by the Brazilian Ministry of Science, Technology, Innovation and Communication and the contribution of the LNLS team, and the Omron DeltaTau team for technical support, providing hexapod code examples. Besides, Diamond Light Source for sharing development knowledge through their open-source repositories.

# GENERIC DATA ACQUISITION CONTROL SYSTEM STACK ON THE MTCA PLATFORM

J. Krasna, J. Varlec, U. Legat, Cosylab, Ljubljana, Slovenia

## Abstract

Cosylab is the world leading integrator of control systems for big physics facilities. We frequently integrate high speed data acquisition devices on the MicroTCA platform for our customers. To simplify this process, we have developed a generic control system stack that allows us to support a large set of MicroTCA hardware boards with minimal firmware and software modifications. Our firmware supports generic data acquisition up to 32-bit sample width and also generic data generation. The firmware modules are implemented in a way so that support for MRF timing modules can be added and allow the board to act as a MRF timing receiver. On the software side we implemented the control software stack in NDS which means that we offer support for EPICS and TANGO control system out of the box.

## SYSTEM DESIGN

Cosylab had worked on multiple high-performance data acquisition (DAQ) solutions throughout the years and some of those DAQ solutions, like applications for beam Current monitors, beam profile monitors, LLRF, etc. had overlapping core functionality. Because of this an challenge arose to determine if a generic control system stack that would cover this fundamental, overlapping functionality could be implemented.

The main objective was to design a system that would improve code reusability and reduce time to support new hardware without sacrificing the ability to extend functionality for custom use-cases. Additionally, the requirement was to cover as many control system frameworks as possible and make the system agnostic to specific frameworks. One of the desired outcomes was to reduce expertise needed to support existing and custom use-cases and create a central, standardized, mature codebase that all engineers could learn from.

## Hardware

Looking at the generic form-factors currently available on the market that support DAQ use cases, especially for high-end applications, we can safely say that MicroTCA [1] has the most vendors supporting it and it is growing in popularity on the user-side as well. It is in use at different labs around the world for the already mentioned use cases (BCMs, BPMs, LLRF) and is commonly selected as the go-to platform for DAQ applications. The reasoning is high performance, customizability options through rear transition module expansions as well as advanced features, like IPMI [2] support and others. By working with multiple MicroTCA vendors, for example Cosylab and Teledyne developed DAQ drivers that are used at ITER [3], we have gained a lot of experience and insight into the

platform. When selecting a hardware platform for our own product, a Dose delivery system used in medical particle accelerators for cancer treatment, the decision to go towards MicroTCA was a straightforward one.

Figure 1: Vadatech AMC523 module.

After careful consideration which hardware was most appropriate for our general DAQ system or gDAQ for short, we decided to use AMC523 [4] from Vadatech as well as the MRT523 rear transition module [5] and MZ523B mezzanine [6], see Fig. 1. The boards support 12 analog input channels with variable gain, 2 analog output channels and can sample at 125 megasamples per second.

## Software

The application driver was implemented using NDS3 or Nominal Device Support [7] which is a public, open-source library that was developed at Cosylab to simplify integration of DAQ hardware for a variety of control system frameworks but is targeted mainly for EPICS [8] and TANGO [9]. The first iteration was built with the focus on EPICS, see Fig. 2. All GUI components were developed using Control System Studio Phoebe [10], see Fig. 3.

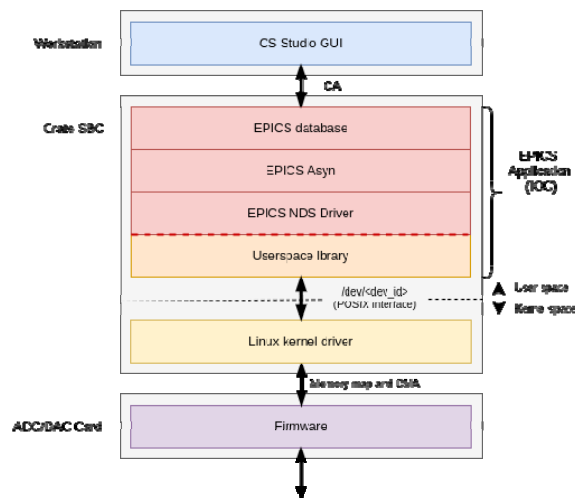

Figure 2: System architecture of the EPICS application.

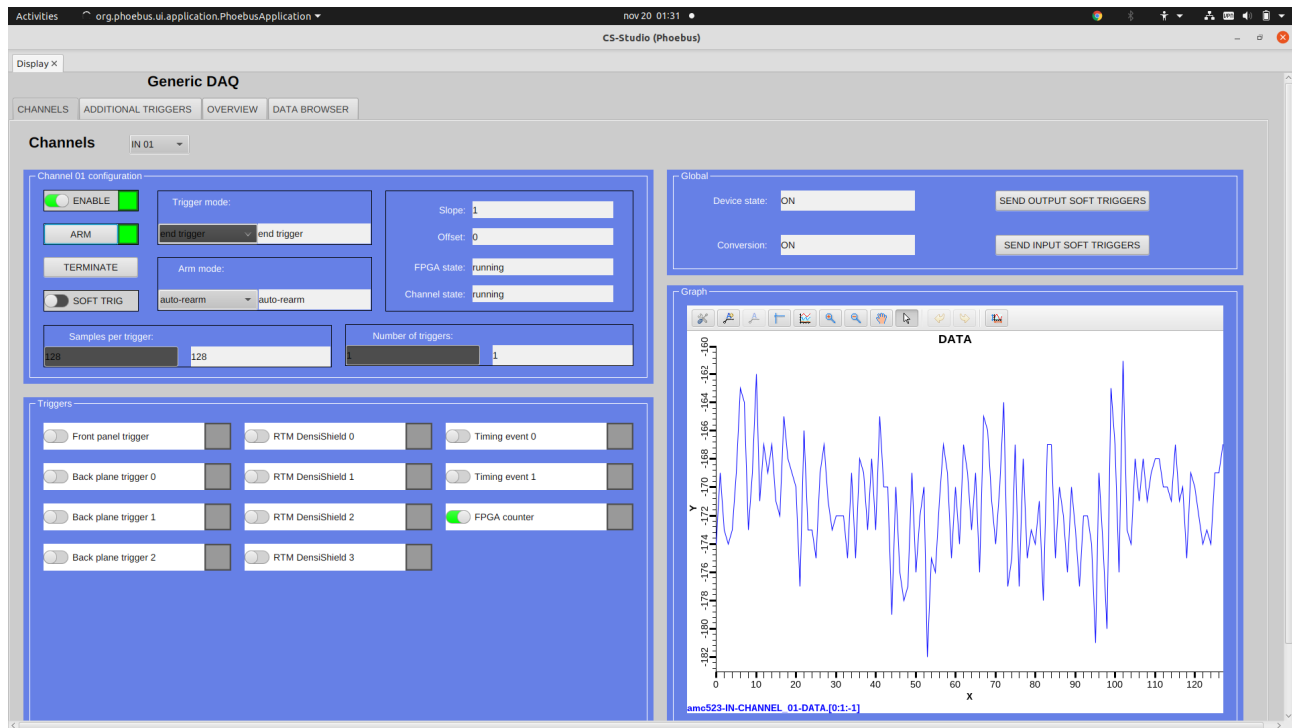

Figure 3: System GUI were implemented using the Control System Studio Phoebus.

In order to write a system that is hardware-agnostic and generalized we moved most hardware-specific parameters to a JSON [11] configuration file which is used by all components in the stack to adapt to a specific hardware board. The firmware is also configured by pushing the configuration data that is also stored in the JSON file through the userspace library.

The kernel driver was designed to include as little functionality as possible to reduce the amount of code running in the kernel and thus decreasing the likelihood of causing a kernel crash due to bugs or errors. The userspace library has a generalized but still rich and user-friendly C++ API which allows direct integrations, avoiding NDS altogether. The userspace library was written with extensibility in mind by exposing the firmware register set which makes adding support for new firmware logic simple and straightforward.

### Firmware

Nominal Device Support provides a general abstraction of the device and its signals and while it supports both EPICS and TANGO out of the box it can be extended to support other frameworks as long as the tree-like description of device and its channels and the state machine logic are versatile enough for the new interface. The main feature of NDS that made this generic stack possible is that NDS generates the EPICS database and TANGO device servers programmatically which enabled using the JSON configuration as input during generation.

Firmware was designed and implemented to support a wide variety of DAQ features that can be found on firmware modules from other vendors:

- Configurable data width up to 32-bit
- Configurable up to 32 data acquisition and 32 signal generation channels
- Configurable buffer allocation for each channel separately
- Separate enable/disable for each channel
- Multiple trigger sources including software
- Arm and automatic re-arm
- Trigger mode: Front trigger, end trigger (prebuffering)
- Multiple data generation sources: from RAM, internal data stream (NCO), digitally processed ADC data
- Data streaming options: on trigger, periodic

We are also confident that firmware can be ported to other hardware platforms with minimal changes as long as a similar FPGA chip is available as the one used on the AMC523 (Kintex-7) although no such ports are planned as of this moment.

### Timing Support

In order to support timing functionality an FPGA core was developed that implements Micro Research Finland (MRF) [12] receiver functionality. This core can be included on DAQ boards that provide an SFP or other compatible connector and in this way allow the timing to be connected directly to the board. The more typical use-case of having a separate MRF receiver and triggering DAQ over the backplane or through a front-panel connector is also supported out of the box.

## CONCLUSION

The gDAQ system was developed, tested and works as expected. We were able to cover all the generic functionality and therefore have a starting baseline for future projects. The system is currently in a prototype phase and was not yet deployed to a production environment.

## STATUS OF THE SARAF-PHASE2 CONTROL SYSTEM

F. Gougnaud<sup>†</sup>, F. Gohier<sup>†</sup>, P. Bargueden, D. Darde, G. Desmarchelier, G. Ferrand, A. Gaget, P. Guiho, T. Joannem, A. Lotode, Y. Mariette, S. Monnereau, V. Nadot, V. Silva, N. Solenne CEA Saclay IRFU, Gif sur Yvette, France

E. Reinfeld, I. Shmueli, H. Isakov, A. Perry, Y. Solomon, N. Tamim, T. Zchut, SNRC, Yavne, Israel

### Abstract

SNRC and CEA collaborate to the upgrade of the SARAF accelerator [1] to 5 mA CW 40 MeV deuteron and proton beams and also closely to the control system. CEA is in charge of the Control System (including cabinets) design and implementation for the Injector (upgrade), MEBT and Super Conducting Linac made up of 4 cryomodules hosting HWR cavities and solenoid packages.

This paper gives a detailed presentation of the control system architecture from hardware and EPICS software points of view. The hardware standardization relies on MTCA.4 that is used for LLRF, BPM, BLM and FC controls and on Siemens PLC 1500 series for vacuum, cryogenics and interlock.

CEA IRFU EPICS Environment (IEE) platform is used for the whole accelerator. IEE is based on virtual machines and our MTCA.4 solutions and enables us to have homogeneous EPICS modules. It also provides a development and production workflow. SNRC has integrated IEE into a new IT network based on advanced technology. The commissioning is planned to start late summer 2021.

### CONTEXT OF THE PANDEMIC

Because of the pandemic, the CEA team hadn't been able to go to the SNRC Lab since March 2020. The first impact was for the Injector. The CEA is in charge of the EPICS update of the Injector Control System. Four cabinets were delivered to SNRC in February 2020 as planned but the CEA could no longer go there and install software. Therefore, SNRC installed the four new cabinets and integrated the Injector control software by itself. At that time a remote connection between the 2 labs was not allowed. The CEA support was only by videoconferences and emails. Finally, there was a first beam on the Source on September 2<sup>nd</sup> 2021.

### GENERAL ARCHITECTURE

In summer 2018, our partner SNRC accepted CEA's recommendation to migrate to the CEA MTCA.4 platform for the SARAF control system. This platform was presented at ICALEPCS19 [2] and is based on the very compact NATIVE-R2 crate with this common core on each crate: the NAT-MCH-PHYS80 board offers an 80-port PCIe Gen3 switch and can be combined with the Rear Transition Module CPU NAT-MCH-RTM-COMex-E3.

<sup>†</sup> francoise.gougnaud@cea.fr, Francis.gohier@cea.fr

For semi-fast and fast acquisition, a set of IOxOS boards was also added to this common platform. See Figure 1. The intelligent FMC carrier IFC1410 (AMC form factor featuring an NXP QorIQ T series Power PC processor and one Xilinx Kintex UltraScale FPGA accessible by the user) is used with ADC-3117 and ADC-3111 FMC boards. The fast acquisition board ADC-3111 includes 8 channels with 16-bit/250Msps ADCs. The semi-fast acquisition board ADC-3117, whose sampling frequency is comprised between 1 and 5 Msps, has 20 channels and 2 channels DAC.

Figure 1: MTCA.4 NATIVE-R2 standardized platform.

The CEA team updated and standardized the IRFU EPICS Environment with MTCA.4 solutions based on IOxOS, MRF and NAT boards.

For the PLC domain essentially used for vacuum, cryogenics, tuning motorizations, current leads and interlocks, Siemens PLC 1500 series (CPU 1516) was selected with TIA Portal by CEA team.

Kontron Industrial PCs are also used in order to run EPICS IOCs for the communication with PLCs. This communication is based on Modbus/Tcp and S7plc.

### FARADAY CUPS, ACCTS AND NBLMS

On LEBT and MEBT, this common platform including IOxOS boards is used for Faraday Cups and ACCTs intensity measurement with the IOxOS ADC-3117 board.

An acquisition based on IOxOS ADC-3111 is used for the Neutron sensitive Beam Loss Monitors (gaseous detectors) designed by CEA for SARAF. This CEA design is already used for ESS and gives entire satisfaction.

### TIMING SYSTEM

The Timing System distributes trigger signals including the information for each RF pulse and manages timestamping mechanism that allows to date all the actions and events precisely. This timestamping is internally incremented and is periodically resynchronized with the Meridian II GPS by

the PPS (Pulse Per Second) clock to avoid drifts. The Timing System also distributes the 176 MHz reference frequency coming from the Master Oscillator.

MRF solution was decided early in the project. The timing system modules used are the MRF mTCA-EVM-300 used as Event Master and the MRF mTCA-EVR-300U as Event Receiver. In addition, mTCA-EVM-300 modules are used as fan-outs and concentrators. There is one EVR in each MTCA crate and one fan-out/concentrator almost in each one.

MTCA.4 backplane lines and Timing System signals have been standardized for all the MTCA EVRs, it means LLRF, BPMs, nBLMs and ACCT/Faraday Cup acquisitions as indicated in table 1.

The SARAF timing system is detailed in [3].

Table 1: MTCA.4 Backplane Lines and Timing Signals

Backplane standardization		
Crate bus line	Trigger code	Trigger nick-name
17_1	TS1	Trigger user buffer (TUB)
17_2	TS2	Beam presence or Acquisition (RoI)
18_1	TS3_m	Signals dedicated to the protection (m = instance of LLRF, BPM ...)
18_2	TS3_m	
19_1	TS3_m	
19_2	TS3_m	
20_1	TS4	RF gate
20_2	TS6	General post mortem (GPM)

## LLRF SYSTEMS

LLRFs have been outsourced to Seven Solutions [4] with the duty to use the common core (NATIVE-R2, COMex-E3, PHYS80 and MRF EVR) in the purpose of homogeneity of the control architecture. Seven Solutions has designed an AMC board running 2 LLRFs and the standardized NATIve-R2 can only include 2 LLRF AMC boards. Seven Solutions has designed, developed, manufactured and tested the system based on CEA technical specifications. The final version of this digital LLRF will be installed in the SARAF accelerator in Israel at the end of 2021.

RFQ and MEBT sections need four LLRFs, one for the RFQ and three for the 3 rebuncher cavities. In the Super Conducting Linac, there are 4 cryomodules including 6 and 7 cavities respectively for CryoModule 1 and CryoModules 2, 3 and 4. Therefore, there are 2 NATIve-R2 crates for each cryomodule and one for the set RFQ and MEBT. Globally 31 LLRFs are needed for the SARAF Linac.

Currently, the LLRF tests give satisfaction and the MEBT RF cabinet (Figure 2) is ready for the shipment to SNRC.

Figure 2: RF cabinet with MTCA LLRF crate.

## BEAM POSITION MONITORS

The beam position measurement function is spread over the linac with 24 BPMs and it is performed by analysing signals of the 4 buttons of each BPM, a total of 96 signals. The layout strategy is to group the BPMs operating at room temperature and those operating at temperatures close to 4 K degrees, respectively 4 in the MEBT and 20 in the 4 cryomodules of the superconducting linac (6 for CM1 and CM2, 4 for CM3 and CM4).

For BPMs, some requirements are very close to LLRF issues and finally the BPM control has also been outsourced to Seven Solutions.

BPM systems are included in MTCA NATIve-R2 crate. Each one can include up to 3 BPM boards, each board handling signal analysis of 2 BPMs. Overall, the linac BPM function is ensured by 5 MTCA crates: one BPM crate for the MEBT and one crate for each cryomodule. The BPM control development is in progress.

## HARPS

There are 5 Harps in the MEBT and SCL. The Harps and their electronics are outsourced to the Proactive company. They don't have an MTCA solution but only a VME solution. The VME will house 16 digitizer cards that will communicate with an EPICS standardized Kontron IPC through a USB hub. This IPC will include a PCIe-EVR 300DC for integration in the MRF Timing System network. This EVR300 is connected through a microSPCI card to an IFB300 box that delivers up to 16 TTL signals. See Figure 3.

Figure 3: Harps control based on VME, Kontron IPC and MRF.

## MEBT QUADRUPOLES, STEERERS AND SCL SUPERCONDUCTING MAGNETS

Different CAENels power supplies were chosen for all these magnets. There are 8 quadrupoles and steerers in the MEBT and 20 superconducting solenoid in the SCL. For the CAENels power supplies, the EPICS control is based on streamdevice and TCP/IP communication. Interlocks are managed by PLC. This control was installed at SNRC in 2020 for the MEBT.

### CONTROL OF THE 4 CRYOMODULES

The SARAF Super Conducting Linac offers four CryoModules (CM) including 6 cavities for CM1 and 7 cavities for CM2, CM3 and CM4 and 20 superconducting solenoids (6 solenoids for CM1 and CM2 and 4 for CM3 and CM4). Each cryomodule can be divided into four control type applications: cryogenics, vacuum, solenoid current lead and LLRF cold tuning system.

One PLC CPU manages every sensor, actuator and automatic processes through the remote input-output cards and also the communication protocols (TCP-IP or Modbus) and fieldbuses like Profinet and Profibus DP.

The field network Profinet is essentially used to control cryogenic temperatures, remote input-output channels, motorizations based on Phymotions [5] and Festo devices for pneumatic valves. Profibus DP is mainly used for vacuum controls (turbopump controllers and total pressure gauges TPG300 controllers).

This control architecture based on only one PLC CPU per cryomodule is duplicated for each one of the four cryomodules for homogeneity purpose but also to simplify the communication with the SOREQ helium liquefier.

Each cryomodule PLC will have to deal with data of the SNRC local liquefier and this will be done via one PLC interface that will be the unique communication partner of the Air Liquide liquefier PLC.

For each cryomodule, a Kontron Industrial PC is running an EPICS IOC that enables the communication between the PLC CPU with any other EPICS IOC of the architecture (Figure 4).

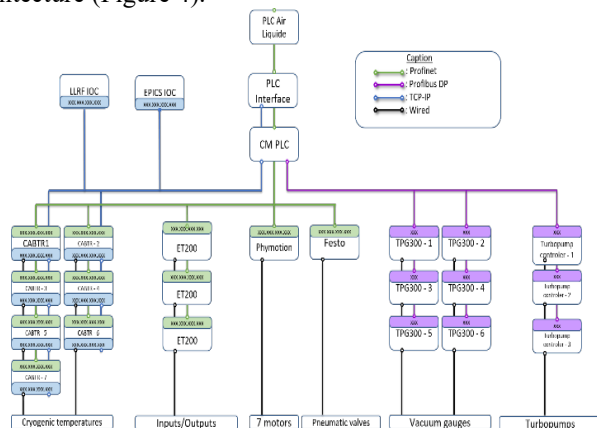

Figure 4: Architecture template for 1 of the 4 CryoModules.

## SARAF EPICS ENVIRONMENT

### Irfu EPICS Environment

The SARAF project uses the Irfu EPICS Environment (IEE) to deploy a homogenous and versioned EPICS environment. As detailed in a previous publication [6] the IEE relies mainly on the following aspects: a centralized EPICS installation is available from an NFS server; CPU devices use stateless network boot to load the same generic root file system; virtual machines (VM) are used for robustness and eased sharing; Ansible scripts under continuous integration enable to provision and update the IEE server and client machines. See Figure 5.

### IEE Ansible Scripts

IEE Ansible scripts were delivered in December 2020 and used successfully on premises at SNRC to provision the current production IEE server. The main difficulty has been that the accelerator network is not connected to the Internet, this was solved by provisioning the IEE server on another network before moving it to the production network through a cybersecurity check. This could be improved in the future by deploying a Yum repository server on the premises. Similarly, this lack of internet made the delivery of git packages more complicated, but also because the CEA Gitlab instance is not open to non-CEA users, this has been solved by setting up a continuous delivery pipeline to duplicate and keep updated the appropriate repositories on a shared Bitbucket-cloud instance. This bitbucket instance is then copied locally at SNRC onto the secured network.

### Running Ansible

Running Ansible scripts is not the only way used to distribute the IEE environment. To sum up, in practice only system administrators use the scripts: either to provision the production environment within virtual containers (CT) in Proxmox or Nutanix clusters, and also to provision “ready-to-use” VM for use with VirtualBox. These VMs are for instance shared with subcontractors to ensure the compatibility of their developments to the IEE, or by developers that need to have a working environment disconnected from the IEE server. VMs are also provided for acceptance tests, this way new hardware and software can be validated before being fully integrated into the production network. All these VMs provide the feature of an IEE server (local EPICS environment and if needed boot server) as well as an IEE DevEnv machine (users, CSS, VSCode [7]...). They are produced by running the same Ansible playbook that can configure either IEE servers or IEE DevEnv.

Unlike CTs running on a cluster, which are provisioned using an orchestration machine to run the Ansible playbook, on VM this playbook is executed locally (after installing Ansible on the VM later on). Therefore, the scripts are still available to update the VM easily. This is particularly useful when the VM is also used as a boot server.

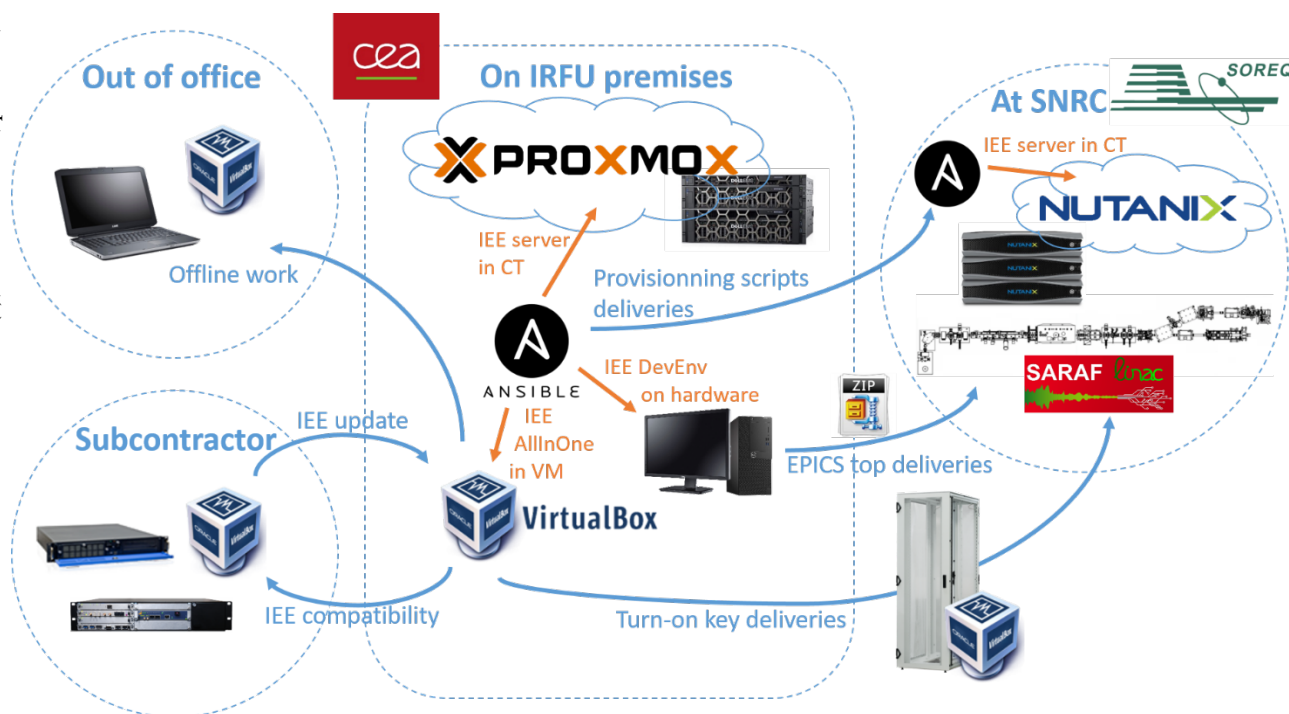

Figure 5: CEA and SARAF EPICS environment.

### Improvements

However, the ability to use the Ansible scripts to update, rather than configure a machine from scratch, has only been improved recently. This combined with the need to provision the machine on a separate network before moving it to the secured network, has made it such that producing a new IEE Server, was not fast enough to follow the delivery rate of developers. Therefore, bug fixes and major feature request of EPICS development are delivered by sending a top composed of git submodules.

### Prospects

Another drawback of Ansible scripts is that integrating new functionalities can be very time consuming, even if this change is anecdotal when performed manually. Automating is often costing when it must be done properly (researched, implemented, tested and CI maintenance). For this reason, outsourced developments have a pretty loose constraint on what it means to be compatible with the IEE environment. In the end it mainly involves using stateless network boot, and using a predefined NFS mount to export data. The EPICS version is fixed, and a naming must be followed. But cross-compilation tools and code source are not required to be integrated to the IEE Server unlike for CEA developments.

### CONCLUSION

The SARAF Linac control includes many new technologies as described herein that are very motivating for SNRC and CEA control teams. Furthermore, the relationship is very good between the two teams. The Injector and MEBT are already located at SNRC and the control tests are in finalization or in progress depending on the devices.

During the coming months, the CryoModule 1 will be tested on the CryoModule Test Stand at Saclay. Then, the four Super Conducting Linac cryomodules including cavities and solenoids will be shipped from CEA Saclay to SNRC during 2022.

# CENBG CONTROL SYSTEM AND SPECIFIC INSTRUMENTATION DEVELOPMENTS FOR SPIRAL2-DESIR SETUPS

L. Daudin<sup>†</sup>, P. Alfaut, A. Balana, M. Corne, M. Flayol, A. Husson, B. Lachacinski, CNRS/IN2P3  
Université de Bordeaux CENBG, Gradignan, France

## Abstract

The DESIR facility will be in few years the SPIRAL2 experimental hall at GANIL dedicated to the study of nuclear structure, astrophysics and weak interaction at low energy. Exotic ions produced by the S3 facility and SPIRAL1 complex will be transferred to high precision experiments in the DESIR building. To guaranty high purity beams to perform high precision measurements on specific nuclei, three main devices are currently being developed at CENBG: a High Resolution Separator (HRS), a General Purpose Ion Buncher (GPIB) and a double Penning Trap named “PIPERADE”. The Control System (CS) developments we made at CENBG are already used to commission these devices. We present here beamline equipment CS solutions and the global architecture of this SPIRAL2 EPICS based CS. To answer specific needs, instrumental solutions have been developed like PPG used to optimize bunch timing and also used as traps conductor. Recent development using the cost efficient Redpitaya board with an embedded EPICS server will be described. This device is used to drive an FCup amplifier and is also used for particle counting and time of flight measurements using our FPGA implementation called “RedPiTOF”.

## THE DESIR FACILITY

### Overview

In 2024 DESIR [1, 2] is planned to be the new low energy SPIRAL2 facility dedicated to the study of nuclear structure, astrophysics and weak interaction at GANIL (Caen, France). This experimental building will accept low energy (10-60 keV) RIB beams from both historical SPIRAL1 complex [3], delivering heavy ions beams since 1983 and the new SPIRAL2 linear accelerator [4] via the S3 facility [5] delivering high intensity light ion beams since 2019 (see Fig. 1). In DESIR, specific exotic ions will be separated in mass and transferred to high precision experiments to perform decay spectroscopy, laser spectroscopy and mass spectrometry.

### CENBG Developments

In order to provide highly purified beams previously introduced, three main devices have been entirely developed and are currently tested and commissioned at CENBG: a High Resolution Separator (HRS) [6], a RFQ-cooler-buncher called “General Purpose Ion Buncher” (GPIB) [7] and a double Penning Trap named “PIPERADE” [8].

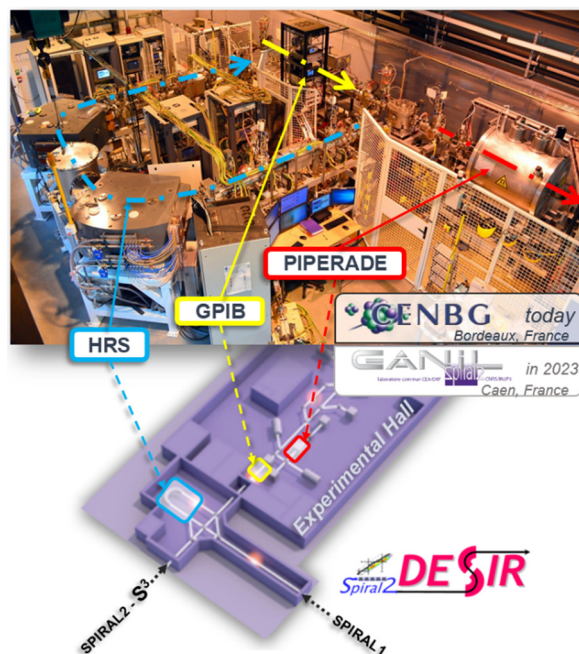

Figure 1: The CENBG setups today at CENBG and the future DE-SIR experimental area, coupling the GANIL building and the new SPIRAL2 facility.

The main concepts of the control system (CS) developed and currently used to test and commission the HRS, the GPIB and PIPERADE is presented in this paper. These CS developments done at CENBG will be extended to the entire DESIR project, meaning to the four DESIR transfer lines (180 meter long):

1. LS: beam transfer from S3 to the DESIR Hall.
2. LT: beam transfer from SPIRAL1 to the DESIR Hall.
3. LHR (High Resolution beamline) including a dedicated RFQ-Cooler SHIRAC (LPC-Caen) and the HRS.
4. LHD (DESIR Hall Beamline): Central delivery “fish-bone” line inside the DESIR Hall.

### Milestones

The DESIR beam-lines and the experimental Hall equipped with the first group of experiments are expected in 2023. The HRS separator and PIPERADE traps are already in the commissioning phase at CENBG using the first version of the DESIR control system.

## DESIR CONTROL SYSTEM (CS)

### SPIRAL2 Collaborative Developments

The DESIR CS and Automation developments for the whole beam-lines and purification devices including the

<sup>†</sup> laurent.daudin@in2p3.fr / ORCID(s) 0000-0002-3007-4217

PIPERADE apparatus are done at CENBG. In order to ensure the compatibility with the already existing SPIRAL2 LINAC accelerator and NFS, S3 experimental areas, these developments are carried out in close collaboration with the GANIL laboratory. It is based on the Experimental Physics and Industrial Control System (EPICS) architecture [9], basic framework for the SPIRAL2 control system [10, 11]. Among the accepted common rules is the naming convention used at SPIRAL2 applying to equipment names as well as CS Server names including EPICS process variables.

EPICS servers (IOC) are developed within the “topSP2” common software platform based on the CentOS Linux system running on PC configured like SP2 CS computers. All of them run the same EPICS base 3.14.9 and share versatile IOCs/EPICS modules dedicated to various equipment like GANIL beam profilers (harp wire monitors) or Hazemeyer power supplies for the HRS electromagnetic dipoles.

Up to now our CS software developments are directly saved and versioned on the GANIL SVN server and a migration to the Gitlab server of the CNRS/IN2P3 institute is planned next year. Software development tools are shared with the GANIL CS group like the Spiral2 version of CSS/BOY (CSS-Dev & CSS-Op) developed under ECLIPSE IDE [11] and used to build most of GUIs. Phoebus [12], the current variant of CSS not depending on Eclipse RCP, is planned to be used in the future to develop DESIR beamlines HMI. Some “Rich” Clients like the “ProfilSP2” Java Application developed at GANIL also operates at Bordeaux during the commissioning phase. Finally, the DESIR beam-lines IOCs for PLC driven equipment communicating with servers using Modbus-TCP protocol will be generated by the GenIOC utility [11].

### CS Architecture and Main Options Followed

The DESIR CS architecture is based on EPICS Client-Server system deployed on an Ethernet network using the Channel Access protocol. The management of the vacuum and interlock systems is made via automation as detailed in the following paragraph. This architecture is illustrated in Fig. 2 with the PIPERADE CS example.

For PIPERADE, some equipment are localized on a high voltage platform (~ 30 kV) because the Penning trap itself had to be at this potential to decelerate ions coming in. In this case, unmanaged Ethernet Moxa switches are used with fibber optic port to guaranty the galvanic insulation of equipment without reducing communication.

Most of the EPICS servers are executed as services on a Linux (CentOS) Machine. For DESIR, embedded IOCs have been considered for High Voltage Power Supplies (HV-PS) and Redpitaya boards described later in this paper.

VME crates with embedded EPICS servers are still used in SPIRAL2 for historical reasons to answer high speed data acquisition needs, but also low speed digitizing, digital I/O and analogue signal generation. In 2018, the DESIR project decided not to use VME at DESIR.

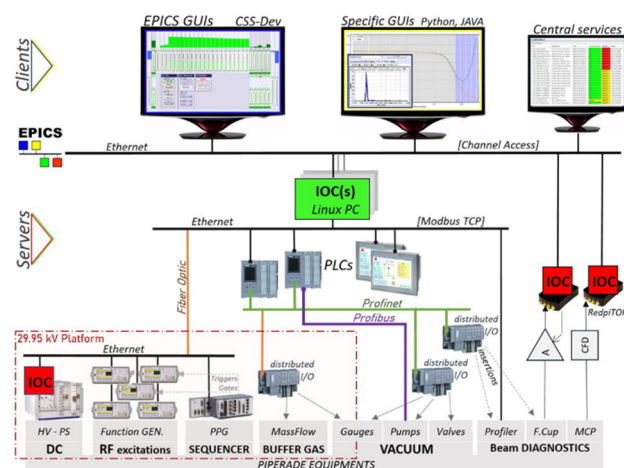

Figure 2: Overview of the PIPERADE CS architecture. Equipment are illustrated on the lower part of this figure. These hardware are controlled by PLCs (Automation part) or directly by EPICS servers (IOC). Ethernet network is the main communication media and Fieldbuses like Profibus and Profinet (Profibus on Ethernet network) are used by PLCs. On the upper part of this figure, Clients are the applications used to control the PIPERADE experiment.

An innovative solution, as detailed in the following automation section of this paper, has been experimented and validated at CENBG to replace VME boards regarding the low speed Faraday Cup (FCup) control and signal digitizing.

### Automation Overview

All SPIRAL2 vacuum systems and interlocks are managed using dedicated PLCs (Siemens S7-1500 series) [13]. They are similar to the systems developed by the GANIL CS & Automation group except some improvements hereafter exposed.

As figured in Figure 2, each beamline will have its own Vacuum PLC and Interlock PLC coupled with their own touch panel (local HMI). DESIR PLCs will be localized in a control room far from equipment and will communicate via the Profinet network with distributed Input/Output (I/O) modules (ET200S) deployed in the racks along beamlines. When ET200S are needed on high voltage platforms like the GPIB or PIPERADE, “classical” Ethernet fibber optics are used.

According to the SPIRAL2-Phase1 standard (LINAC, NFS and S3), a “vacuum” PLC unit manages all pumping groups (Pumps, Gauges and Valves) and gas systems (like mass-flow controllers) for a beamline sector. In parallel, Profibus fieldbus allow to collect “live” information from turbo-molecular pumps like the rotation speed or detailed status or fault words.

In addition to the vacuum PLC, a dedicated “interlock” PLC is also affected to each beamline. It interlocks the equipment according to the safety conditions like veto on the high voltage power supplies but also controls all beamline insertion devices like electro-pneumatic translators to put diagnostics IN or OUT the beam axis.

Modbus-TCP servers are implemented in PLCs to manage the communication with dedicated IOCs. The vacuum Modbus table is made of read-only Registers. On EPICS side, only the valves status and pressure values are exchanged and displayed on operator interfaces. Actions on vacuum devices are only authorized using PLCs touch panels, even in remote mode with VNC Clients. WinCC client software will be used at GANIL to develop centralized vacuum interfaces.

### New PLC Based Controlled Beamline Equipment

DESIR Interlock PLCs are driving two other kind of equipment: Faraday cups (FCup) and motors.

DESIR beamline FCups are used with “PicoLIN” transimpedance amplifiers [14] developed at GANIL for CW low intensity beam measurement: 8 ranges from 10 $\mu$ A/V down to 1pA/V are selectable. This amplifier is directly controlled in remote mode with the Interlock PLC ET200S Digital I/O and the output signal is sampled and digitized with a 16bit ADC from the same ET200S. This solution used for the HRS tests and commissioning since 2017 is adopted for all DESIR FCups.

The other “new” equipment controlled by PLCs are motors used for the HRS Slits positioning (20 motors), and will be used for six electrostatic 90° beamline deflectors to place or remove them from beam axis. Brushless motors have been selected (Siemens ref 1FK7015) and equipped with a brake to maintain the position when the motor power is switched off (after 1 minute timeout). Classical position encoders with optical disk are not radiation hardened. This is the reason why we preferred these motors with multipole resolvers. Each motor is driven with a Siemens CU-310 one axis control unit and a Siemens PM340 power module. The communication with the Interlock PLC is based on Profinet fieldbus.

## SPECIFIC SOLUTIONS FOR DESIR EQUIPMENT

### “Heavy” Client’s Developments

The EPICS CA protocol makes it possible to monitor and control any beam line equipment through PV calls in many programming languages.

Using EPICS features, a Python program is under development to operate the PIPERADE traps, i.e. scan the different trapping and excitation parameters, define the time sequence and treat on-line measurements. It is inspired by the PyMassScanner program developed by the JYFLTRAP group (Jyväskylä University, Finland) [15] part of our collaboration.

Other Python software tools have been developed at CENBG to answer tests and commissioning needs for the GPIB and PIPERADE. The first example is “Plotpot” which displays the electric field seen by ions in Paul or Penning traps with respect to voltages applied on the electrodes. A second example is the automatic beam injection with a multiparameter algorithm based on a simplex optimization method.

“CorrAb” is another tuning application under development at CENBG for the HRS optimization. It will be used to estimate the separator aberrations using a dedicated emittance meter and then apply the computed voltages to the 48 poles of the HRS multipole to correct as much as possible the separator aberrations. The goal is to reach a resolution of 20000 for isobaric separation using this software.

### High Voltage Power Supplies (HV-PS)

Most of the DESIR beam-lines and setups are composed of electrostatic optics: Quadrupoles, Hexapoles, Benders and Steerers.

In order to meet the High Voltage-Power Supplies (HV-PS) requirements (optics and diagnostics), ISEG multichannel crates provide all DC voltages (see Fig. 3).

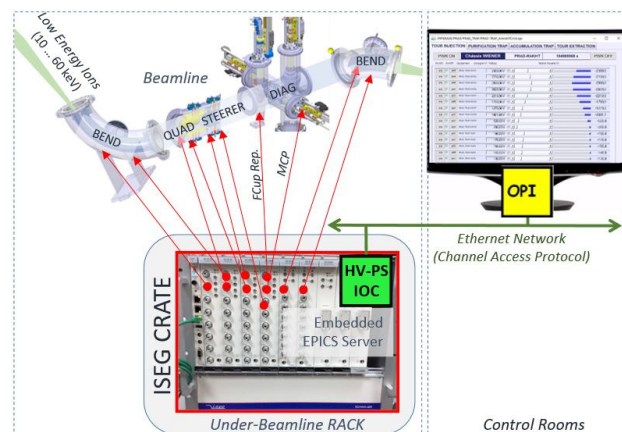

Figure 3: Hundreds of high voltage power supplies (HV-PS) will be deployed under DESIR beamlines and setups. Each multichannel ISEG crates will concentrate a large number of HV-PS and its CC24 controller will run the embedded EPICS server making this solution very “light” and easy to maintain. CSS Operator interfaces are already used to control sets of HV-PS to tune DC electrical fields.

Since 2017, more than 200 HV-PS channels are used at CENBG for the HRS, GPIB and PIPERADE.

### Pulse Pattern Generator (PPG)

Ion traps such as PIPERADE need a configurable real-time “conductor”. This sequencer also called PPG has been developed for GSI-SHIPTRAP and CERN-ISOLTRAP [16] on RIO FPGA, Real-Time PCI boards with LabVIEW software. We developed seven years ago a PPG for PIPERADE reusing the same LabVIEW FPGA State-Machine on a CompactRIO (NI-7410) to generate time sequences over 32 digital outputs with 10 ns time resolution. High speed LVTTL modules (NI-9402) trigger Agilent function generators (Traps RF excitations) and gate home-made high-speed and high voltage switches (ions injection – transfer - extraction).

The PPG IOC is running on the remote Linux PC to benefit from a “real” EPICS server with full functionalities compared to the uncomplete LabVIEW EPICS Server.

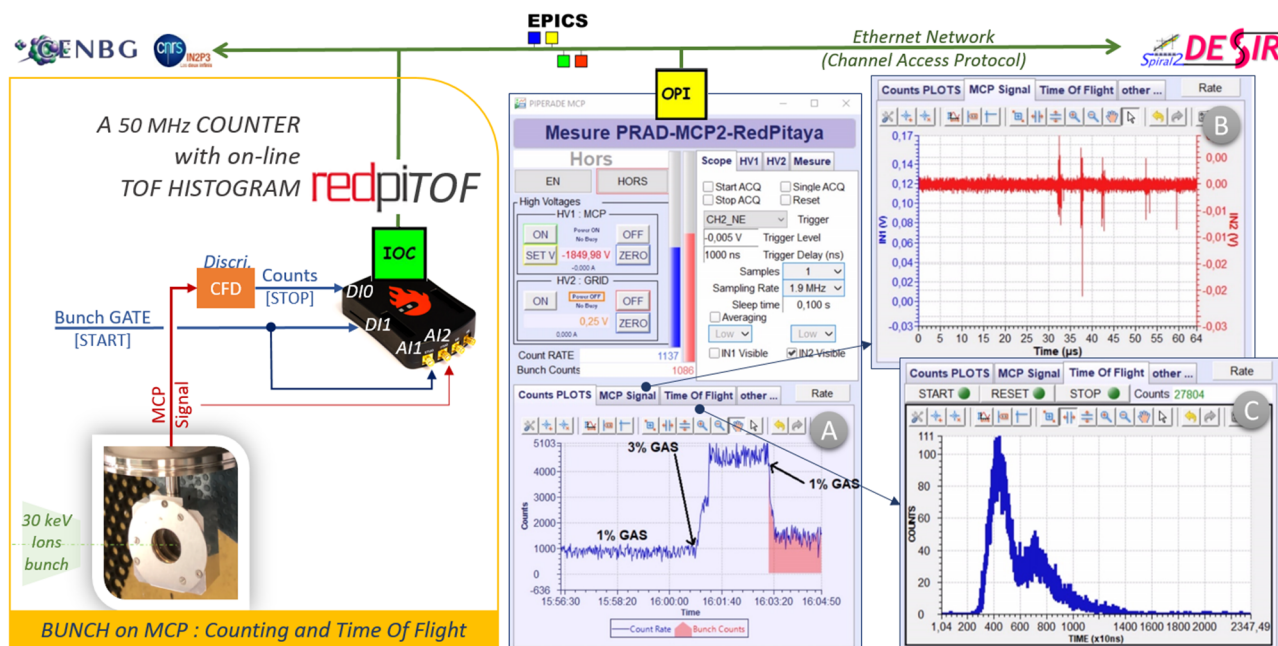

Figure 4: Illustration of our RedpitoF device developed on a Redpitaya board to count ions detected by a micro-channel-plate (MCP) and measure the Time Of Flight (TOF) with 10 ns time resolution. The TOF histogram (C tab) is constructed on-board and the embedded EPICS IOC allows EPICS Clients to control it. Counting rates (see “A” tab on figure), MCP analogue signal (see “B” tab) and TOF histogram (see “C” tab) are monitored online on the RedpitoF CSS Operator Interface.

A LabVIEW EPICS Client is running in the CRIO and “feed” the IOC to control the PPG (time sequence definition and start/stop controls) and update the current PPG status with configuration read-back values.

The same PPG device has been cloned to control via five HV fast switches the GPIB buncher time sequence and define the bunch time structure.

### Redpitaya for Beam Diagnostics

**Bunch intensity on FCup** Bunched ion beams produced by the GPIB RFQ-Cooler-Buncher have to be characterised. Hardware solutions are needed to measure the time dispersion, longitudinal emittance and energy dispersion of these microseconds length bunches produced with a slow repetition rate (few bunches per second).

In mid-2019 we chose the cost efficient Redpitaya (RP) board (STeMLab 125-14) to monitor high intensity ion bunches. This choice was motivated by:

- The High performance “dual channel scope” (125 MSamples/s; 14 bits ADC on  $\pm 1$  V input signal).
- The board size and SMA connectivity: Easy integration close to beam diagnostics without any hardware development.
- Its Digital Inputs/Outputs usable to drive an amplifier and check its status
- Its Linux operating system (Ubuntu) with the embedded EPICS IOC already developed by the Australian Synchrotron [17].
- The relative low-cost of this complete solution.

A high-speed transimpedance Femto amplifier (DHPCA) amplifies and converts the collected charges of

a FCup into a voltage signal. This amplified signal is then injected in one of the two RP SMA analogue input and an operator interface is able to monitor the acquired high-speed signal from the waveform process variable generated in the embedded IOC. The amplifier range is remotely selected using some digital I/O also used to read the amplifier status.

**Counting and timing with RedpitoF** Ion counting and TOF measurements using a Micro Channel Plate (MCP) detector are required for PIPERADE trap measurements and GPIB commissioning. Although counting and coincidence solutions have already been developed on RP boards [18, 19], we started the RedpitoF development in end-2019 (see Fig. 4).

In addition to the RP scope and wave generator IP, new counting and TOF functionalities using two 100 MHz digital inputs (DI) have been implemented on the Xilinx FPGA and dual core ARM (see Fig. 5). This new “device” is based on a 50 MHz counters (100 MHz clock) and a real-time TDC with 10 ns time resolution implementation.

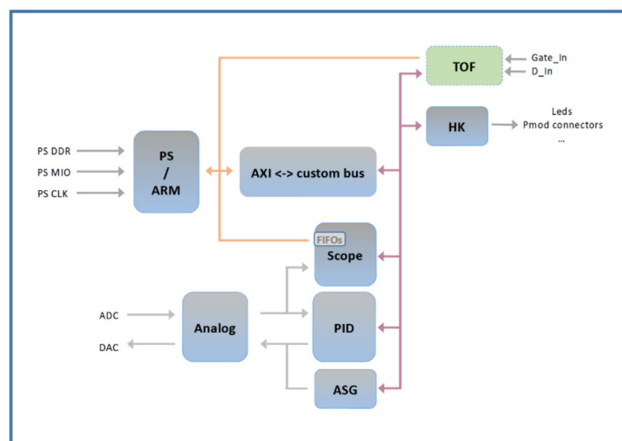

Figure 5: Overview of the firmware architecture. It illustrates how the new TOF function (in green) is interfaced with the original system (in blue).

The first DI is used as a “Gate” signal. The TDC “starts” on a rising edge, while the second DI is “reading” ion signals and act as the TDC “Stop” on rising-edge signal coming from the detector (MCP) discriminated output.

This development has been completed last year with the on-board 16k channels TOF histogram construction, controls (start, stop and reset) and bin size selection (10 ns to 80 ns) to permit TOF dynamic up to 1.3 ms (see Fig. 6).

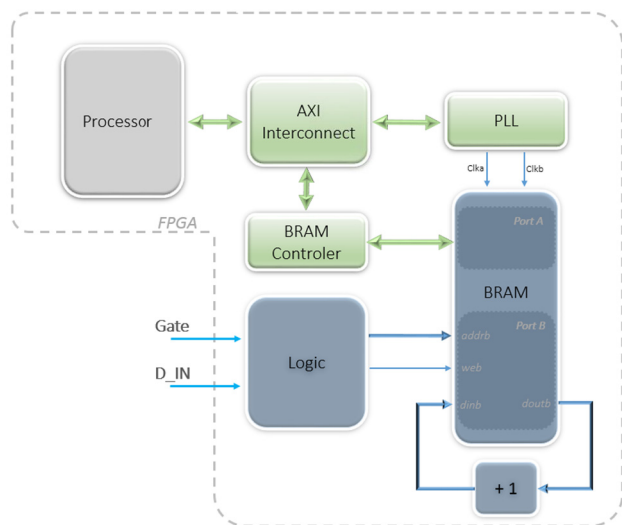

Figure 6: Here is the architecture of the RedpiTOF FPGA implementation. Histogram construction is based on the use of a dual Port RAM. The two digital inputs are processed into the logical module (Logic) to address the first RAM port and increment the value of the selected memory register (Memory address = TOF channel number). The second port is used by the processor to read the histogram over AXI bus with the EPICS driver.

Since January 2021, two RedpiTOF boards are daily used: one for the GPIB bunch characterisation and the other for PIPERADE penning traps.

## CONCLUSION

The Control System (CS) developments we made at CENBG are already used to test and commission the HRS separator, the GPIB RFQ-Cooler-Buncher and PIPERADE penning traps. These slow control CS developments have to be extended to the LS, LT, LHR and LHD DESIR beam-lines composed with the same electrostatic devices and diagnostics.

Some CS solutions have to be improved in the following years, in particular for beam diagnostics like low intensity current measurement systems needed for bunched beams and an emittancemeter.

We are also preparing the migration on Phoebe to develop most of the operator interfaces and we will use our institute Gitlab IN2P3 for all of our software developments, up to now using a Subversion repository.

The collaborative work with the GANIL CS team is continuing to prepare as much as possible the DESIR beam-lines commissioning at GANIL programmed in 2024.

## ACKNOWLEDGEMENTS

This work has also been performed with the helpful contribution of PIPERADE and HRS teams, thanks for their feedback and advice as users of these developments.

The authors would like to thank the JYFLTRAP team, in particular T. Eronen, for providing the PyMassScanner program and advice. The authors also thank GANIL CS & Automation group, more particularly C. Haquin, C.H. Patard and Q. Tura who are more and more available for this collaborative work. Funds to the DESIR-EQUIPEX were allocated by the French Ministry of Higher Education and Research.

# LASER MEGAJOULE FACILITY OPERATING SOFTWARE OVERVIEW

J.-P. Airiau, V. Denis, H. Durandeau, P. Fourtillan, N. Loustalet, P. Torrent  
CEA, Le Barp, France

## Abstract

The Laser MegaJoule (LMJ), the French 176-beam laser facility, is located at the CEA CESTA Laboratory near Bordeaux (France). It is designed to deliver about 1.4 MJ of energy on targets, for high energy density physics experiments, including fusion experiments. The first bundle of 8-beams was commissioned in October 2014. By the end of 2021, ten bundles of 8-beams are expected to be fully operational.

Operating software are used to automate, secure and optimize the operations on the LMJ facility. They contribute to the smooth running of the experiment process (from the setup to the results). They are integrated in the maintenance process (from the supply chain to the asset management). They are linked together in order to exchange data and they interact with the control command system. This paper gives an overview of the existing operating software and the lessons learned. It finally explains the incoming works to automate the lifecycle management of elements included in the final optic assembly (replacement, repair, etc.).

## INTRODUCTION

The LMJ facility is still in construction. We are currently mixing assembly, operating and maintenance activities at the same time. The progressive increase of operating activities concerns the laser bundles (10 of 22 expected) and the target chamber diagnostics (14 of 33 expected) (see Fig. 1).

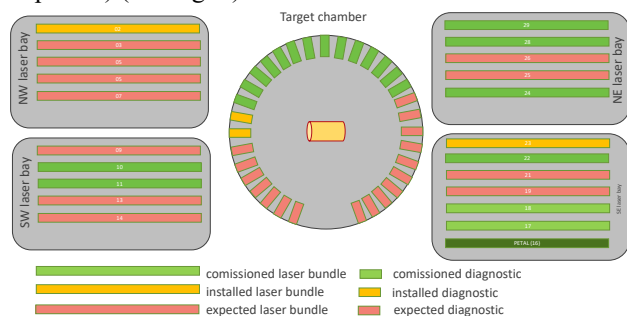

Figure 1: Laser bundles and target diagnostics status.

Laser bundles assembly started in early 2013; the first physics experiment on the facility has been done at the end of 2014 with one laser bundle and two target chamber diagnostics. The end of laser bundle assembly operations is expected for 2025. The full set of target chamber diagnostics is expected later.

Operating software are used to automate, secure and optimize the operations on the LMJ facility. They contribute to the smooth running of the experiment process (from the setup to the results). They are integrated in the maintenance process (from the supply chain to the asset management).

## OPERATIONS VS MAINTENANCE

Operating the facility must be still possible while doing assembly and maintenance activities avoiding coactivity issues. These activities must respect safety and security instructions.

Operating such a facility needs to manage many different technical skills (mechanics, electronics, automation, computing and physics). The LMJ is composed of many components. Some of them could be « on the shelves » parts (ex.: pump or motor), others could be specifically designed for the facility and be made of innovative technologies in order to meet the extreme requirements (temperature, pressure and radiation). The supply chain could be very complex for some parts (exclusive know-how, small manufacturing capacity).

The main goal is to fully operate the facility with all the laser bundles and target diagnostic available. But like all complex system, there is sometimes issues on the components (failure, malfunction, etc.). The impact of these issues could be transparent (fault tolerance managed by redundancy), moderated (fault could be bypassed), serious (one laser bundle or one target diagnostic is unavailable) or critical (experiment failure/facility shutdown).

Everything is done to avoid a critical failure and optimize the operation availability. This availability is measure with a Key Performance Indicator (KPI). For example, an availability of 75 % means that quarter of the time the facility could not operate in a nominal way. The time wasted in unplanned maintenance (replacement of faulty parts) downgrade the availability. This KPI is used to measure the technical management of the facility and the ability to anticipate the failures. It is also used for long and mid-term planning.

In order to maximize the availability, it is important to identify all the parts with a Mean Time To Failure (MTTF) lower that the facility's operating life time. It is important to characterize some indicators used to check the "health" status of these parts. By monitoring these indicators, you can anticipate the replacements before the

occurrence of failures. The stock management is based on the MTTF in order to plan the supply of spare parts.

Some of the issues related to the human factor cannot be predicted. It is possible to limit these issues by constantly updating the operating procedure with the feedback (to avoid doing the same error twice). However, it is hard to eliminate totally these kinds of issues.

Despite substantial efforts to reduce unplanned event, you have to deal with operations and maintenance activities. In order to ensure the highest availability KPI, these two activities must be closely linked and complementary. You can't oppose them: operating the facility need maintenance to run and maintenance is useful only if the facility is running (see Fig. 2).

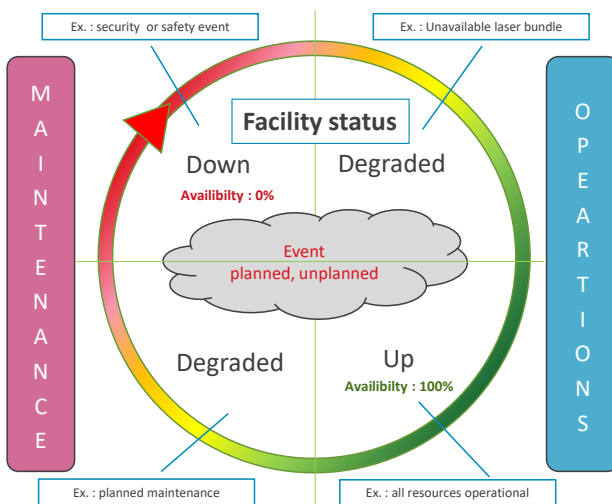

Figure 2: Operations and maintenance duality.

A set of operating software are used for each activity and interfaces between them provide the link.

## OPERATING SOFTWARE

Operating software tools are used to control and automate operation and maintenance. These high level tools manage process made of complex tasks in order to reduce the processing time and avoid risk linked to the human factor. Human actions are limited to control critical step in the process (monitoring). The control is made by an operator (technician, contactor) and can be helped by an expert (engineer) if necessary. The idea is to avoid wasting time in low value-added actions and save resources. The tools are used to build dedicated reports to ease the analysis of an issue. The results of the analysis can be re-integrated in the tools and be used to identify a known degraded behavior.

Operating software are used for experiment and maintenance processes.

## Operating Software for Experiment

The operating software are developed internally, they are linked with the command control system (see Fig. 3). The shot manager tools (GTIR) is the input and output point of an experiment. The experiment setup is described in GTIR. The results are stored and displayed in this tool. Computing tools are used to:

- predict the control command setup (PARC),
- compute the results and check security and performance during the different step of the shot sequence (rod shot, power shot, etc.),
- calibrate equipment and CC setup with calibration sequence,
- validate experiment results for laser bundles and target diagnostics (PARC + OVID).
- Equipment setup and characteristics are stored in the command control configuration tool (GCI).

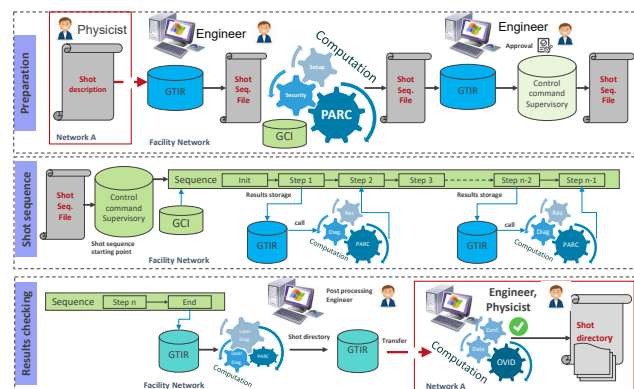

Figure 3: Operating software for experiment.

## Operating Software for Maintenance

The facility is composed of more than 200 000 mounting points (registered in the Enterprise Asset Management (EAM) tool). Each mounting point could have an equipment mounted on it. The equipment can be composed of sub parts. Most of the times you have spare parts in the stock. It represents a huge quantity of part and is not humanly possible to identify, check and follow-up the status of every ones. Like for experiment, a set of tools are used for the maintenance activities.

The main tool called GMAO is based on Infor EAM software. It provides a parametrable asset management environment. Every work order is registered in the software in order to follow the facility configuration set-up. Each equipment is identified by a barcode number.

The Electronic Document Management (EDM) called SIROCO is based on Dassault Systems ENOVIA software. Every information related to the lifecycle of equipment (manufacturing, control file, characteristics, etc.) is registered in SIROCO.

The command control configuration tool (GCI) manages the current setup and characteristics used to conduct an experiment.

The software used to manage the lifecycle of equipment are described on Figure 4. Each new mounting or replacement of equipment is initiated in GMAO as a work order. The planification and the authorization workflow are managed by other operating tools. Once the work permit is authorized and planned, the equipment replacement can be done by an operator helped with the procedure extracted from SIROCO. GMAO and GCI are notified of the part replacement (part with barcode xxx has been replaced with part with barcode yyy). In the case of complex equipment composed of subparts, all the replaceable sub parts are updated in each tool.

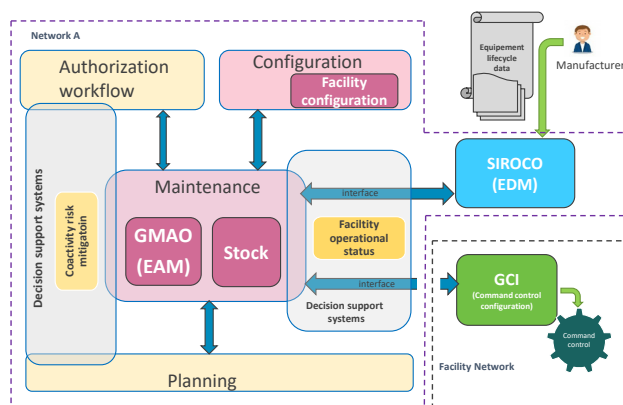

Figure 4: Operating software for maintenance.

A closed link between these three operating software (GMAO/SIROCO/GCI) is necessary.

### Interface Between Experiment and Maintenance Software

Characteristics of equipment are supplied by the manufacturer and manage by the EDM tool SIROCO. The facility installed configuration set-up is managed by the EAM tool: GMAO (i.e.: the equipment identified with its barcode is installed and operational). The command control configuration tool GCI registers all the information of all equipment driven by the command control (setup values, characteristics and lifecycle attributes).

The consistency between these 3 tools is critical for two reasons:

- Characteristics from GCI are used for simulation computation (ex. Optics transmission) and equipment calibration (sensibility for an energy sensor). If there is a mismatch in the characteristics associated to equipment (wrong barcode number), you can have biased simulation computation and an important variance on diagnostic results.
- The lifecycle attributes are used to monitor the behavior of equipment during its life in the facility environment and stored in the GCI. These indicators are set by the command control (ex. working time of a pump in hour) or by operating software like PARC [1] and SCIBORG [2] (ex. cumulated energy seen by

optics). They are returned to the manufacturer (via SIROCO) when the equipment is down to provide feedback analysis. If there is a mismatch in the indicator associated to equipment, data returned to the manufacturer can be wrong and might bias the results of analysis.

A consistency rule has been specified between tools and software interfaces has been developed to manage the consistency.

## LESSONS LEARNED

### Network Issues

Maintenance and experiment operating tools are deployed on two physically separated networks. For cybersecurity reasons, the software link is not possible between GMAO/SIROCO and GCI (see Fig. 4). The interface cannot use a synchronous and dedicated protocol to exchange data. The link is done by file exchange between the two networks; each application can load the file in a shared directory and interpret the content.

This one way asynchronous exchange may break the consistency rule. A late update of GMAO data (data transfer issue) can lead to wrong notification of GCI.

The project to move GMAO and SIROCO applications on a network with less cybersecurity constraint has started. The main goal is to update the interface in order to communicate in a synchronous way with web services.

### Complex Consistency Rule

The old consistency rule between GMAO and GCI was based on the mounting point key. Equipment and its sub parts (structured as a tree) are referenced in GMAO and geographically positioned with the mounting information. This same information is reported in GCI when the work order to replace the equipment is done. The consistency rule (GMAO vs GCI) works for the equipment only if the tree structure of the equipment and its sub parts are the same in both of the tools.

This hypothesis is not always respected and creates some consistency error.

A new simple consistency rule has been introduced. GCI structure tree uses a Functional Code Number (FCN) as a unique identifier of an element in the tree structure. The FCN information will be added in GMAO and updated after the replacement of the equipment by notification. This rule covers all the use cases.

### Identifying Parts on the Facility

Field inventories are conducted to control the “real” consistency between what is mounted (barcode read on the part by the operator) and the information of GMAO. Sometimes errors are found during these inventories.

The main reason of these errors is due to the difficulty of identifying the right part. The same equipment or part may be found at many places in the laser bay (ex.: autom-

aton). We have optical scanner to identify the part with its barcode but these scanners are not yet connected on mobile devices and the GMAO is not connected to these devices.

A project of deploying local WIFI network in the facility has been initiated. The mobile Infor EAM application will be installed on these devices and provides a direct link to the information of the work order by scanning the bar code.

### Spare Parts Inventory

Some parts needs to be replaced or maintained regularly (ex.: pump). After a few year of use, some equipment can be deprecated and the new production series is not compatible with the current setup (ex.: control command hardware). The know-how of a manufacturer can disappear because the product has no more customer (ex.: neodymium doped laser glass for amplifier) so you need to manage a strategical stock for the lifetime of the facility.

The spare parts inventory is about to be completed. For each part, it is important to evaluate the stock size, the maintenance frequency and the maintenance procedure (resources, tools and time expected).

### Health Indicators

Some equipment had sensors to monitor their status or performance. These data are processed and stored by the control command supervisory system. Operating tools like PARC [3] manage high level indicator related to laser, alignment and synchronization performances. These health indicators are used to detect degraded operating mode and anticipate maintenance before breakdown.

An exhaustive survey of health indicators is about to start. The main goal is to identify the missing health indicators and the way to implement them.

### Global Monitoring System

Each field of activity in the facility has a monitoring system (control command hardware, computing hardware, network, supervision system, software). This could be legacy software (ex. Nagios), logging system or specific software. The monitoring is limited to a specific perimeter and you can't do cross perimeter analysis. In an issue is detected on one of this system, you can't know the impact on the parent systems. Conversely, if you can't run a root causes analysis to find an issue on the child systems.

The project to deploy a global monitoring system on the facility (LMJ Dr.) has been initiated. This system will extract, load and transform data from the different existing monitoring subsystem including health indicators. The data will be stored in a standardized format (data + metadata) as time series.

The primary goal of this system is to be able to manage multipurpose monitoring. For example, it will be possible to correlate the malfunction of a diagnostics with the loss of a network link between this diagnostic and the associated computer.

The secondary goal is to use the time series to detect health indicator decrease and/or predict equipment failure (AI tools based on knowledge database).

## USE CASE (FINAL OPTIC ASSEMBLY LIFE CYCLE)

To illustrate how closed is the link between operating tools mentioned before, this use case (see Fig. 5) shows the different steps to manage the lifecycle of an element (vacuum window) of the final optic assembly

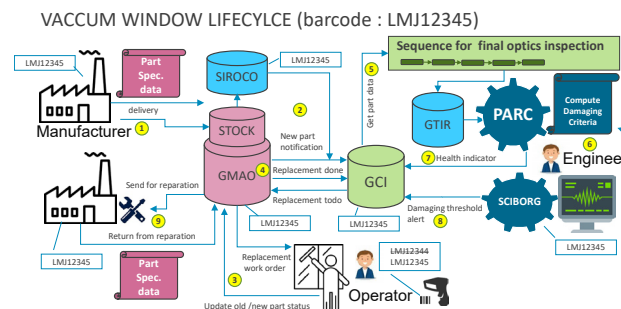

Figure 5: Vacuum window use case.

## CONCLUSION

To perform ignition experiments on the facility, the energy expected on target chamber will be very high. The vacuum windows damaging will be important and this part will need to be replaced and repaired several times. The rate of maintenance on this particular optic element will be intensive. The operating software used for experiment and maintenance activities must be perfectly coordinated to ensure this rate of replacement. All the improvements based on the lesson learned needs to be deployed in order to achieve these ambitious goals.

# TOWARDS A NEW CONTROL SYSTEM FOR PETRA IV

R. Bacher, T. Delfs, D. Mathes, T. Tempel, T. Wilksen  
Deutsches Elektronen-Synchrotron DESY, Hamburg, Germany

## Abstract

At DESY, an upgrade of the PETRA III synchrotron light source towards a fourth-generation, low emittance machine PETRA IV is currently being actively pursued. The basic concept of the control system of PETRA IV is to exploit synergies between all accelerator facilities operated by DESY. The key figures of PETRA IV's new accelerator control system include the DOOCS control system framework, high-end MTCA.4 technology compliant hardware interfaces for triggered, high-performance applications and hardware interfaces for conventional slow-control applications compliant with industrial process control standards such as OPC UA, and enhanced data acquisition and data storage capabilities. In addition, the suitability of standards for graphical user interfaces based on novel Web application technologies will be investigated. Finally, there is a general focus on improving quality management and quality assurance measures, including proper configuration management, requirements management, bug tracking, software development, and software lifetime management. The paper will report on the current state of development.

## INTRODUCTION

With PETRA III, DESY operates one of the best storage ring X-ray radiation sources in the world. PETRA III is a 2300-metre-long storage ring feeding 24 user beamlines. It is operated either in brightness mode (480 equally distributed bunches, 120 mA stored beam) or in timing mode (40 equally distributed bunches, 100 mA stored beam). Research groups from all over the world use the particularly brilliant, intense X-ray light for a variety of experiments - from medical to materials research.

DESY plans to expand it into a high-resolution 3D X-ray microscope for chemical and physical processes. PETRA IV [1] will extend the X-ray view to all length scales, from the atom to millimetres. Researchers can thus analyse processes inside a catalyst, a battery or a microchip under realistic operating conditions and specifically tailor materials with nanostructures. PETRA IV also offers outstanding possibilities and optimal experimental conditions for industry.

PETRA IV will replace the PETRA III facility and will be housed by the existing PETRA III buildings. An additional experimental hall will provide space for additional 18 user beamlines. In addition, a new synchrotron (DESY IV) will serve as booster between the existing electron source LINAC II and PETRA IV.

In 2020, a preparatory phase for the future project PETRA IV was initiated with the aim of submitting a Technical Design Report by mid-2023. Construction work is

scheduled to begin in early 2026, followed by a commissioning phase in 2028.

The following chapter will describe the baseline of the accelerator control system of the future PETRA IV facility.

## CONTROL SYSTEM DESIGN BASELINE

The development and implementation of the future PETRA IV accelerator control system will be embedded in a long-term process to consolidate the whole accelerator control system landscape at DESY and to take advantage of synergies between the accelerator facilities operated by DESY. The accelerator control system of PETRA IV will closely follow the control system concept implemented at the European XFEL. Consequently, support and maintenance of the existing control system framework used at PETRA III will not be continued beyond its expected lifetime.

### Control System Framework

The Distributed Object-Oriented Control System (DOOCS) [2] will form the basis of the future control system of PETRA IV. DOOCS is the established control system framework at FLASH, European XFEL and other conventional accelerator facilities operated by DESY, as well as advanced accelerator projects based on plasma wake field acceleration.

DOOCS is based on a distributed client-server architecture combined with a device-oriented view. Each control system parameter is made accessible via network calls through a device application. Its transportation layer is based on the standardized, industrial RPC protocol. The DOOCS framework is written in C++ and supports a variety of fieldbus and hardware interfaces via device classes. These are accessible through additional libraries which can be linked as needed individually to the server core library. Libraries for creating client applications in C++, Java, Python or MATLAB are available either as a separate implementation or as C-bindings. Through the client API DOOCS provides access to multiple popular control system such as EPICS and TANGO. At DESY, EPICS is used for facility control (electrical power and water distribution, ventilation and air conditioning) and control of the cryogenic systems, while TANGO is the standard control system for operating the beam line components and the experimental equipment.

The initial development of DOOCS dates back to 1993. Since that time, it has steadily developed into a powerful, reliable and versatile control system. Recently, a roadmap was established to meet the increasing user demands over the next decade and to continue to keep pace with the rapid developments in IT technologies.

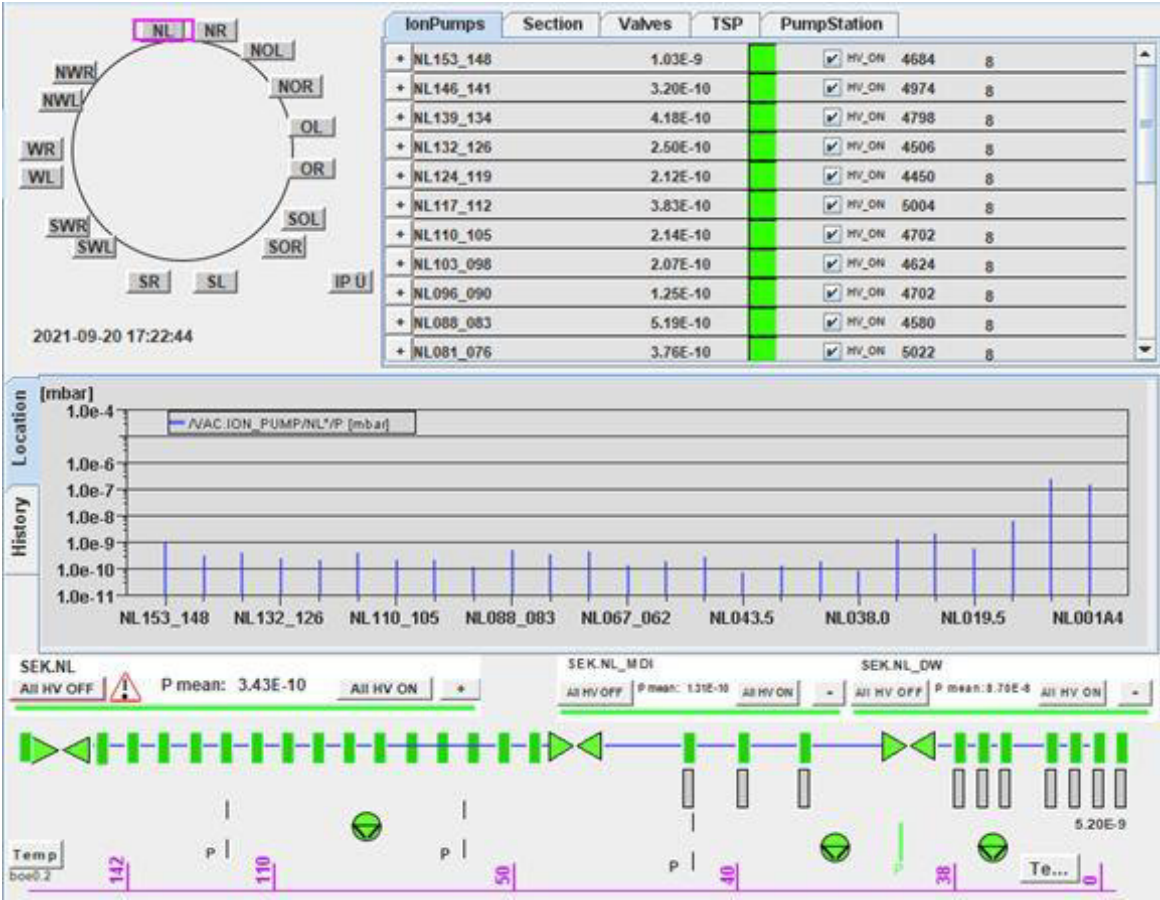

Figure 1: Sample JDDD display.

Graphical User Interfaces

The proven Java DOOCS Data Display (JDDD) [3] is chosen as standard user interface. JDDD is a Java application and follows a thin-client approach with a functional and rich set of widgets. Individual UI components can be easily created through a versatile editor IDE without the knowledge of any programming language (Fig. 1).

While JDDD is the tool of choice for the standard beam operation as well as operating technical accelerator devices and systems, Python is increasingly becoming the preferred programming language for rapid prototyping and visualization of scientific procedures and data.

Even if JDDD also provides a secure, HTML5-based Web interface, with the advent of modern Web standards such as Progressive Web Apps (PWA) other promising alternatives to design graphical user applications seem to be available. PWA are multi-platform, browser-based applications with a look-and-feel of versatile classical desktop applications. The potential of graphical user applications based on the React [4] JavaScript framework is currently investigated.

Hardware Interfaces

In general, the hardware interfaces for triggered, high-performance applications (e.g. beam diagnostics, injection / ejection system, feedback systems, timing / synchronization system, machine protection system, RF control) will

be compliant with the high-end MTCA.4 technology [5]. MTCA.4 is the accepted long-term standard for the DESY accelerators and is enjoying growing popularity within the accelerator community and the related industry. The operating system for server hosts running within the MTCA.4 platform will be Linux.

The base configuration of a MTCA system includes a power-supply, a Management-Controller Hub (MCH), a CPU as an Advanced Mezzanine Card (AMC), a Timing System AMC, and optionally a Timing System Rear Transition Module (RTM) if required.

Based on the existing MTCA.4 timing module used at the European XFEL, a successor model is currently being developed at DESY. This module will function either as a transmitter or as a receiver. The module will distribute the RF reference signal, provide low-jitter clocks and trigger signals as well as beam-synchronous data such as a timestamp, revolution counters, beam modes, bunch pattern and bunch current via a dedicated optical fibre network. Storage ring, booster and linac will each be equipped with central timing system components, synchronized across the overall facility. Beamline experiments can make use of the same MTCA-based timing system hardware to exploit all accelerator-provided timing system information.

Dependent on the location in the accelerator, the MTCA systems will be equipped with additional digital I/O AMC modules for specific read-out, measurement and control tasks, e.g. interface boards to the beam position monitor

Any distribution of this work must maintain attribution to the author(s), title of the work, publisher, and DOI

front-end electronics or feedback controllers as well as ADC boards to acquire measured bunch current pulses or HV-pulses generated by the injection and ejection elements.

All of these modules can be managed remotely via Intelligent Platform Management Interface (IPMI) interfaces and the MCH. Linux drivers with hot-swap support allow for PCIe access of the various AMC and RTM modules from applications running on the CPU AMC.

Likewise, the hardware interfaces for conventional slow-control applications (e.g. magnet power supplies, vacuum system) will be compliant with industrial process control standards preferably providing a well-established and widely-used industrial API.

Special emphasis will be put on the OPC UA interface technology [6]. All power converters for magnets as well as power supplies for getter pumps of the vacuum system will implement an OPC UA server. DOOCS provides a generic bridge server, which seamlessly integrates OPC UA devices into the accelerator control system.

Front-end hardware systems based on the Beckhoff controller technology (EtherCAT / OPC UA) will also be used in many cases, e.g. to control the motors of the insertion devices or of the movable girders supporting all accelerator components. In addition, classical PLC system have to be interfaced. In both cases, generic bridge servers to the accelerator control system are available.

### *Data Acquisition and Archiving*

Systems and tools for data acquisition, data archiving and data providing will be implemented with domain-specific interface standards and technologies. Both, time series data as well as snapshot data have to be considered.

Time series data include data from fast data streams in synchronism with the beam revolution frequency (130 kHz) such as single-turn orbit data, and data from slow data stream updated asynchronously with less than 100 Hz. These include e.g. multi-turn orbit data or magnet currents.

Snapshots are measured and stored once and are triggered either by a value change (e.g. in case of a device error), by a specific event (e.g. at beam injection), or by an operator request (e.g. while performing a study).

For both cases, versatile visualization and analysis tools have to be provided. Particular emphasis will be placed on the capability to support data science applications operated in either online (e.g. learning feedbacks, learning tuning procedures) or offline (e.g. failure prediction, predictive maintenance forecast) mode.

### *High-Level Control Applications*

A team of controls experts and accelerator physicists has been already established to interface specific needs of beam commissioning and operations and implement corresponding tools and applications.

The well proven MATLAB Middle Layer library suite [7] supplemented by procedures developed for PETRA III operation will be adapted for further use at PETRA IV. In addition, novel control concepts based on advanced machine learning algorithms are being developed and tested

at PETRA III. Resulting applications to be intended afterwards for regular standard operations will be transformed to well-behaved operator panels or server applications.

Similar to the so-called Virtual European XFEL Accelerator [8] a Virtual PETRA Accelerator infrastructure is being set-up. It will be used to test new concepts, enhancements or just modified and improved applications before they will be put into the field which can potentially save significantly commissioning and machine studies time.

### *Quality Assurance*

High availability is a key parameter of modern synchrotron light sources. This must also be reflected in the availability and quality of the software and hardware components of the control system.

Various quality assurance measures are being set-up. These include a revision of the issue and bug tracking workflow and a proper management of requirements for the control system during the preparatory, construction, commissioning and operating phase of PETRA IV. A template has been worked out to document the requirements for the control system which will be regularly reviewed and adapted if needed. Training courses for application developers covering various topics, e.g. application software development, graphical user interface design, software testing etc., are being organized.

The control system of PETRA IV will consist of a huge number of software artefacts. In contrast to PETRA III, also the number of hardware components is significantly larger. A comprehensive configuration management of software and hardware components has to be provided during all stages of the PETRA IV life cycle, e.g. by maintaining a configuration management data base or by well-defined workflows and processes for change and release management.

## **ACKNOWLEDGEMENTS**

The authors thank the PETRA IV project team at DESY for constructive discussions and the Helmholtz Association of German Research Centers and the Federal Ministry for Education and Research for supporting the preparatory phase for the future project PETRA IV.

# THE NEW SMALL WHEEL LOW VOLTAGE POWER SUPPLY DCS FOR THE ATLAS EXPERIMENT

Christos Paraskevopoulos<sup>1,2</sup>

<sup>1</sup>National Technical University of Athens, Zografou, Greece

<sup>2</sup>Brookhaven National Laboratory, Upton, NY, U.S.A

## Abstract

A series of upgrades are planned for the LHC accelerator to increase its instantaneous luminosity to  $7.5 \times 10^{34} \text{ cm}^{-2}\text{s}^{-1}$ . The luminosity increase drastically impacts the ATLAS trigger and readout data rates. The present ATLAS Small Wheel Muon (SW), will be replaced with a New Small Wheel which is expected to be installed in the ATLAS underground cavern by the end of the Long Shutdown 2 of the LHC. Due to its complexity and expected long-term operation, the New Small Wheel (NSW) requires the development of a sophisticated Detector Control System (DCS). The use of such a system is necessary to allow the detector to function consistently and safely and have a seamless interface to all sub-detectors and the technical infrastructure of the experiment. The central system handles the transition between the probe's possible operating states while ensuring continuous monitoring and archiving of the system's operating parameters. Any abnormality in any subsystem of the detector triggers a signal or alert (alarm), which notifies the user and either defaults to automatic processes or allows manual actions to reset the system to function properly. The part that will be described is the modular system of Low Voltage (LV). Among its core features are remote control, split of radiation sensitive parts from parts that can be housed in a hostile area and compatibility with operation in the radiation and magnetic field as in the ATLAS cavern. The new Low Voltage Intermediate Control Station (ICS) will be used to power the Low Voltage Distributor (LVDB) boards of the NSW and through them, the readout and trigger boards of the system providing data and functioning safely.

## ATLAS NEW SMALL WHEEL

ATLAS [1] is the largest high-energy physics detector ever built by man. The LHC delivers millions of collisions each second, that take place in the heart of ATLAS. These collisions though, create a dangerous radiation environment, which the detector has to endure. To efficiently handle the increased luminosity of the High-Luminosity LHC (HL-LHC), the Small Wheel (SW) which is the first station of the ATLAS muon spectrometer end-cap system, will be replaced. The New Small Wheel (NSW) [2] will have to operate in a high background radiation region (up to  $22 \text{ kHz/cm}^2$ ) while reconstructing muon tracks with high precision as well as providing information for the Level-1 trigger. The New Small Wheel consists of two detector technologies of gaseous detectors, the first is called small-strip Thin Gap Chambers (sTGCs), and the second comes from the category of micro-pattern gaseous detectors and is named Mi-

cromegas (MMG) [3]. The NSW apart from the two new detector technologies is a platform presenting new Custom ASICs and electronic boards. The readout system is based on Front End Link eXchange (FELIX) housing 2.5 Million readout channels, common configuration, calibration & Detector Control System (DCS) path and new power supply system.

## THE NEW SMALL WHEEL DETECTOR CONTROL SYSTEM

In order to monitor and control the operation of the detector, a framework has been devised, which allows for remote supervision and intervention in the detector and its sub-systems: The Detector Control System (DCS) [4]. The DCS is simply a Supervisory Control And Data Acquisition (SCADA) system equipped with User Interfaces (UIs), automated scripts and control/monitor functionality. This control scheme is used daily, in the ATLAS Control Room. It is also used by the subdetector experts to guarantee a safe and efficient physics run. The main task of the DCS is to enable the coherent and safe operation of the full detector by continuously monitoring its operational parameters and its overall state.

### Finite State Machine Hierarchy

The chosen software used for the back-end system is called WinCCOA [5]. WinCCOA is a highly modular, device oriented product also with event driven architecture. The back-end system, used by all the four LHC experiments, is implemented using this commercial SCADA package. On top of the SCADA package, the Joint Controls Project (JCOP) framework [6] provides a set of software tools and guidelines and assures the back-end homogeneity over the different sub-systems, sub-detectors and LHC experiments. The projects are mapped onto a hierarchy of Finite State Machine (FSM) elements using the JCOP FSM toolkit. The FSM is conceived as an abstract machine that is able to be in only one of a finite number of states at a time. The state can change when initiated by a triggering event or condition (transition state).

### System Architecture

The NSW DCS projects closely follow the existing look, feel and command structure of MUON DCS, to facilitate the shifter and expert operations. The top node of both MMG and sTGC will propagate its state and receive commands from the ATLAS overall DCS. Shifters will mainly use the

Figure 2: The DCS Overview panel and the Alarm Screen.

Overview DCS FSM panels and DCS Alarm Screen (Fig. 2).

## THE LOW VOLTAGE PROJECT

### Power Supply

Low voltages for MMG and sTGC are supplied by the widely used CAEN system [7], which is developed for the LHC experiments. Among its core features are:

- Remote control
- Split of radiation sensitive parts from parts that can be housed in a hostile area
- Compatibility with operation under radiation and magnetic fields as in the ATLAS cavern

All the devices are reachable only via the ATLAS Point 1 network. Communication with the control machines is achieved through OPC UA server-client connection. The NSW will be installed at both Side A and C ATLAS End Caps.

The LV CAEN OPC UA servers are also partitioned into Side A and C and deployed on the equivalent host servers. The OPC UA clients, running on the same machines, gather the address space of the individual channel parameters and transmit them to the projects. The two CAEN mainframes of type SY4527 that control the NSW LV also also follow the side architecture of the OPC UA servers and host servers. The mainframes are installed in the ATLAS Service area (USA15). Each mainframe houses 8 branch Controllers.

MOPV006

Figure 3: An overview of the installed hardware that is connected to each NSW Endcap.

Figure 4: Power supply Control and FSM monitoring panels.

These specifically designed for the NSW branch controllers are connected to the Low Voltage Intermediate Conversion Stage (ICS) modules. ICS will be the provider of the Low Voltage for the readout cards. ICS will be in the hostile environment of the system near to the chambers that are mounted on the NSW.

Each LV controller is connected with two ICS crates, 16 in total for each side. The ICS crates power two adjacent sectors of each sub-detector technology, providing the low voltage for the readout cards. Also two extra ICS are needed for powering the trigger electronics of sTGC detectors. Each Crate hosts 4 modules while every module has 8 output channels, adjusted output channel voltage is 9–11 V and output current 0–17 A. There is also one “virtual” internal channel for general board settings. The LV ICS crates are powered from primary generators called NGPS-30300 with adjustable voltage output. These primary generators are also constructed by CAEN and are located in another service area of the ATLAS experimental cavern (US15). The 34 NGPS primary generators are housed in the allocated NSW racks in US15. The project and CAEN OPC UA server connected to NGPS devices is hosted in a dedicated MUON machine. All the NSW equipment parts were tested and validated by the author with specific automated power cycling and control tests.

### Low Voltage FSM

The FSM is based on a strict hierarchical structure with parent-children relations. In this tree-like structure commands propagate from the parents down to the children whereas the states propagate from the children up to the parent on a “most-severe” priority. In this way, when an action is required on all children it is sufficient to give the command to the very top node and correspondingly, the state of the top node summarises the state of all children nodes of

Figure 5: The LV channel node and the ICS Controller accommodating the control panels.

any generation. Three different FSM structures and designs were needed in the case of the NSW LV DCS: the Low Voltage General, NSW NGPS Controller and The ICS module Controller. These three FSM structures are also interfacing through their common hardware parts. The Device Unit (DU) is the base of the FSM and the nodes of this type usually correspond to a device instance and are used to interface to this device. Commands coming from their parents are translated to values, settings of the devices parameters and accordingly, the parameter's values define the node's state which propagates to the highest nodes. A Device Unit node of course cannot contain any children. In the case of the Low Voltage General FSM the DU is a NSW LV individual channel. Each individual channel can be controlled separately while value, status and alarm monitoring is available on the panel. The state and Status of the DU depends on the status data point element of each ICS channel and the communication validity of the OPC UA server.

The design of the ICS Controller FSM DU is based on the channel DU and it is adjusted to accommodate the "virtual" channel error bits. However, the NGPS FSM follows a different design. Each NGPS generator is a DU. This device has different characteristics, functionalities and errors compared to the ICS channel controller. These are seemingly integrated to the control scripts of it.

The projects were validated through daily usage from shifters at the commissioning site as a first stage and then through the NSW control in ATLAS Control room. Except for the FSM design the mapping of channels to detector layers and crates to Sectors was validated. Then the communication with the device setup in ATLAS cavern was established and validated too, The LV FSM operates as expected and is well integrated with the setup in everyday operation.

### Interfacing NSW Projects

The NSW LV project will have to interface with the rest of the projects while all are being monitored by the Supervisory Control System. The most important interfacing are the electronics and the temperature monitoring projects. NSW separate configuration/monitor, readout and trigger path consists of 2.4 million readout channels that result in 100 000 DCS parameters. NSW on-detector and cooling temperature monitoring relies on 64 MDT Device Modules (MDM) [8], 32 on each wheel. These devices will monitor the detector

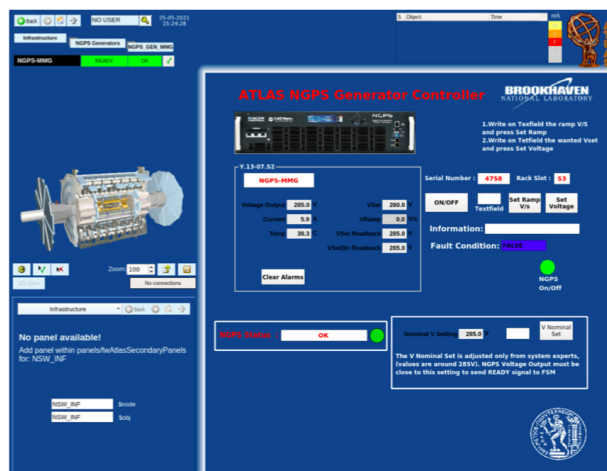

Figure 6: Among others the NGPS DU panel includes: On/Off button, Control of Ramp and Set voltage, Clear Alarms function, Slot and Serial number indications, Vnominal set. Alarms are developed and included to all the aforementioned FSMs.

temperatures and magnetic field. The electronics powering and then the temperature values are directly connected with the LV FSM. In case of alarms incoming from raised temperature value flags, the LV FSM will have to automatically power off the connected devices to avoid failures within the system.

## ACKNOWLEDGMENTS

We acknowledge support of this work by the project "DeTANet: Detector Development and Technologies for High Energy Physics" (MIS 5029538) which is implemented under the action "Reinforcement of the Research and Innovation Infrastructure" funded by the Operational Programme "Competitiveness, Entrepreneurship and Innovation" (NSRF 2014-2020) and co-financed by Greece and the European Union (European Regional Development Fund). This work was funded in part by the U. S. Department of Energy, Office of Science, High Energy Physics under Contracts DE-SC0012704, DE-SC0009920.

# THE HV DCS SYSTEM FOR THE NEW SMALL WHEEL UPGRADE OF THE ATLAS EXPERIMENT

E. Karentzos\* on behalf of ATLAS Collaboration,  
Albert-Ludwigs-University Freiburg

## Abstract

The background radiation at the HL-LHC is expected to exceed the one designed for the ATLAS muon spectrometer. In order to cope with the foreseen limitations, the collaboration decided to replace the Small Wheel (SW) with a New SW (NSW) by combining two prototype detectors, the small-strip Thin Gap Chambers or sTGC (STG) & and resistive Micromegas (MMG). Both detector technologies are “aligned” to the ATLAS general baselines for the NSW upgrade project [1], maintaining in such way the excellent performance of the system beyond Run-3. Complementary to the R&D of these detectors, an intuitive control system was of vital importance. The Detector Control System (DCS) for both the MMG and the STG High Voltage (HV), have been developed, following the existing look, feel and command architecture of the other sub-systems. The principal task of the DCS is to enable the coherent and safe operation of the detector by continuously monitoring its operational parameters and its overall state. Both technologies will be installed in ATLAS and will be readout and monitored through the common infrastructure. Aim of this work is the description of the development and implementation of a DCS for the HV system of both technologies.

## OVERALL VIEW OF THE NSW HV DCS SYSTEM

Figure 1 illustrates a simplified sketch of the New Small Wheel. The wheel consists of 16 sectors equally divided into large and small sectors. However, the detector geometry is different for each sector type. The numbering of the sectors begins at the left large sector with number 1 and continues clockwise, similarly to the realization in DCS. All large sectors have odd numbers (1,3,5,7,9,11,13,15) while the small ones have even numbers (2,4,6,8,10,12,14,16). Each sector is equipped with the so-called quadruplets of both detector technologies. One quadruplet consists of four layers of a certain detector type.

### MMG Scheme

The Micromegas sectors are divided into two quadruplets in radial direction. The quadruplets close to the beam axis defined as xM1, and the outer ones with xM2. Small and large quadruplets just differ in dimension, while similar size layers (xM1, xM2) differs in the number of Printed Circuit Boards (PCB). The larger ones consist of five single readout PCB's which are mounted together to form a detector layer

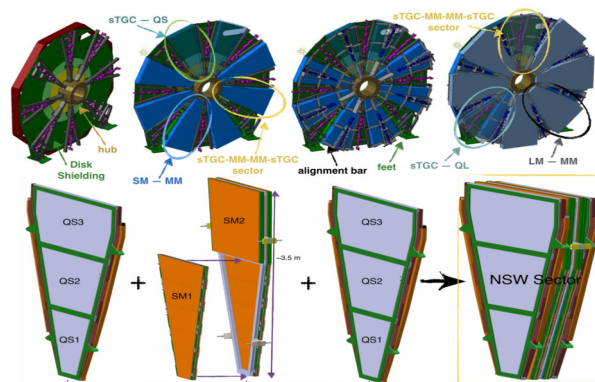

Figure 1: Representation of the NSW (top) with the relevant positions of the NSW sectors, (sTGC and MMG, Small & Large). The different sTGC and MMG modules composing a small sector of the NSW (bottom).

of a quadruplet. On top of the PCB the readout lines are located.

**HV Modules Requirements:** For both MM quadruplet types a nominal voltage of 570 V/128  $\mu$ m for the readout is foreseen. The drift boards are supplied by a voltage of 300 V. The current is expected to be less than 1  $\mu$ A for a readout HV channel. One channel serves one PCB, while the number of channels of all modules sum up to 1024.

### sTGC Scheme

The sTGC detectors are divided into 3 quadruplets in the radial direction. The quadruplets naming in radial direction uses the partition definition of inner, middle and outer. A special characteristic is that the innermost quadruplet of the sTGC is divided into two HV sectors in radial direction, due to higher particle flux close at the beam pipe.

**HV Modules Requirements:** The sTGC quadruplets are operated only with one voltage of around 2.8 kV. There is no aggregation of channels planned, as the number of channels of all modules sum up to 1024. The chosen limits are 1 mA for the innermost HV sector of the inner quadruplets and 0.5 mA for the remaining ones.

### Overview of the DCS Internal Structure

In order to incorporate the hardware information into the DCS, several components have been used or developed within the scope of the JCOP Framework [2]. Datapoint Types (DPT) have defined for each hardware component, device and detector segment. Their instances, namely the

\* efstathios.karentzos@cern.ch

©2021 CERN for the benefit of the ATLAS Collaboration. CC-BY-4.0 license.

datapoints (DP), contain all the information (DP Elements) needed in order to describe all the parameters (configs). Additionally, a DP generator developed and programmed to map and set up all the necessary DPs to their associated HV channels., which will be used as the base of the system. In order to translate this structure, to something more meaningful and user friendly, a set of panels has been developed, for the control, monitoring and configuration of the HV system. Finally, a control manager is under development, in order to adjust the high voltage as a function of the pressure and the temperature.

## ARCHITECTURE AND HARDWARE REQUIREMENTS

The detailed architecture of the local DCS relies on the structure of the general DCS system of the ATLAS experiment and on the electronics architecture. Each sub-detector is implemented and organized in a unique way but it must also conform to the guidelines defined by the ATLAS central DCS [3, 4]. When special requirements need to be handled by the detector then tailored solutions must be applied.

### Architecture

The system architecture consists of several components based on the sub-detector needs and it is supplied by the Universal multichannel CAEN system. The hardware architectures of each sub-system are depicted in Figs. 2 and 3. The MMG chain, the simplest one, consists of 3 SY4527 mainframes [5] that host, supply and control 2 different type of HV boards, A7038ST(P/N, x10 in total) & A7038AP (x16).

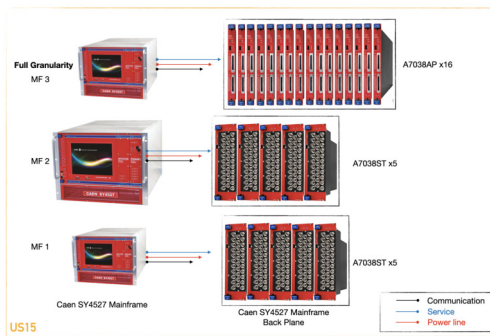

Figure 2: The hardware chain of the MMG as has been installed at ATLAS P1.

The STG chain consists of 2 A1676 branch controllers [6] installed on a SY4527 mainframe, controlling 4 Easy3000s crates [7], hosting 6 HV boards (x3 A3535AP & x3 A3540AP).

Both the easycrates and the easyboards are supplied by two external DC power of 48V generated by separate AC/DC converters. The first generator of type A3485, provides the Service power, needed to control the devices, while the second one of type A3486, is used to supply the line with power. Each generator is controlled by a dedicated branch controller.

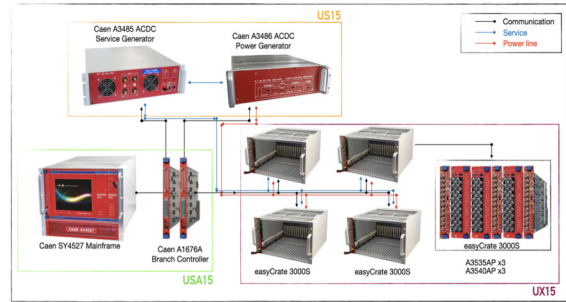

Figure 3: The hardware chain of the STG as has been installed at ATLAS P1.

The communication between the hardware and the DCS is achieved via the OPC UA server-client pairing [8]. Both are deployed on the host servers with the OPC UA clients gathering the address space of the individual channel parameters, transmitting them to the main control stations. The graphical user interface (GUI) of the generators is depicted in Fig. 4, while for the mainframe's monitor and control a dedicated panel is shown in Fig. 5.

Figure 4: Service projects for the monitoring of the 48V ACDC Generators.

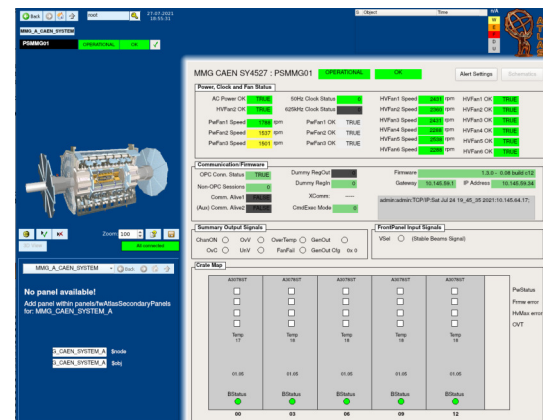

Figure 5: Service projects for the monitoring of the SY4527 mainframes.

## Requirements

The DCS is responsible for the safe and coherent operation of the detector. All ATLAS sub-detectors have their own local DCS, controlling and monitoring the sub-detector and its equipment. Among its core requirements are:

- Remote control, monitoring and configuration of a wide variety of parameters, like voltage and current set/read-back, state and status values along with error flags.
- Active archiving with smoothing and on-the-flight storage in the DCS database [9].
- Data exchange with other sub-systems.
- Discrimination between radiation sensitive and hard parts,
- Compatibility with operation under radiation and magnetic field as in the ATLAS cavern.
- Automated mechanisms, such as the safety Interlock, the Reset Trip, the HV transition when the Beam for Physics is expected or not, etc.
- Communication is established via the OPC UA server-client pairing.

## FSM HIERARCHY AND LOGIC

As a detector oriented hierarchy the control system is represented by an homonymous Finite State Machine (FSM) [4] node (MMG/STG). The top node defined as the main control unit, and from there commands are propagated downwards into the device or logical elements. Such units, groups and geographical detector segments are represented by device-oriented (SMI) FSM objects. The current condition of each object is determined by a set of states alongside with their transitions. A state transition is triggered either by a condition change or by a dedicated action. Figure 6 depicts the device and logical state diagrams. It allows a device to change from its ground state OFF to its operational state ON via optional stages, while for logical objects, the mandatory states are READY or NOT\_READY, reflecting conditions for which data taking is possible or not. The state UNKNOWN is used when the condition cannot be verified for both cases.

Figure 7 shows an instance of the MMG FSM tree along with each commands. The actual state is determined by the states of the associated children via state rules implemented using SML and they propagate upwards. Custom-made actions can be defined easily via the read control scripts, i.e. interlocking or resetting the flag of a channel, complementing the system.

## OPERATION PANELS

Both projects have been developed, following the existing look, feel and command architecture of the other Muon sub-systems, in order to facilitate the shifter/expert operations.

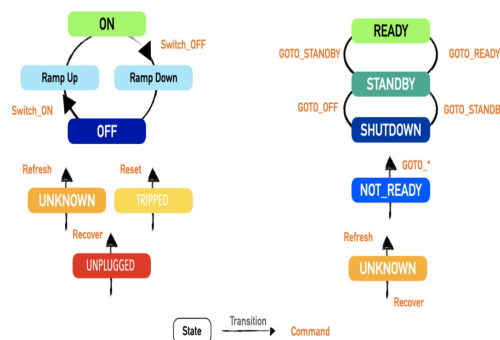

Figure 6: Device (left) and Logical (right) object state model.

Figure 7: MMG FSM Tree instance at chamber level.

For each individual layer, a main panel has been developed, providing the user with useful information, reflecting the state and status of the detector. All the vitals of each layer can be displayed in trend-plots or/and tables; while a secondary panel provides supplementary to the main panel details.

A general review of the graphical user interface of the top FSM nodes and their constituents are shown in the Figs. 8–13. To facilitate the experts' work also advanced panels and colormaps of the system have been developed. A typical example of a colormap, used by the MMG, is shown in Fig. 13.

## Side View

The shifter/expert in the Atlas Control Room usually will have an overview of the sub-system. The typical view for the MMG technology is shown in Fig. 8, where 10 wheels are displayed. As the number of HV sectors within the MMG quadruplets is identical to the partitioning of the quadruplets, their representation in the panel can be retained. The sTGC sectors, seen in Fig. 9, have 3 quadruplets, but 4 HV sectors in radial direction. Therefore, 4 indicators are shown for each sector of the sTGC. Each wheel represents the quadruplets, either close to the IP or HO side. The color indication of the trapezoidal and its accompanied circle refer to the FSM State and Status of the complete quadruplet., respectively. Furthermore, both shapes feature different actions depending on left-, right- or double-clicking [10, 11].

## Sector View

The dedicated to the sector panel is shown in Fig. 10. On the top the chosen sector is indicated in a text field. A table is displayed, where all the key parameters for each layer of the quadruplets of the chosen sector are shown. These are the name and location of the connected HV board and channel

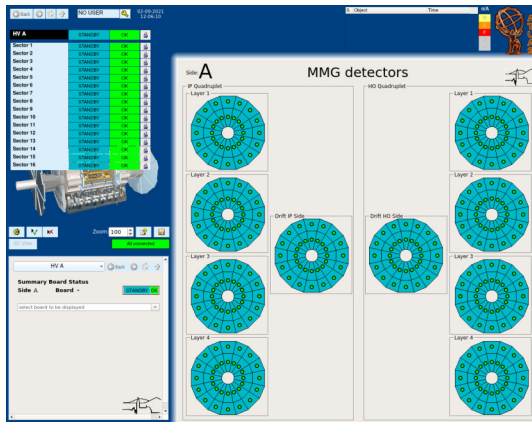

Figure 8: Operational Panels for the MMG sub-system.

Figure 9: Operational Panels for the STG sub-system.

as well as the actual values of voltage and current, accompanied by their error flags. Below the table the connected HV modules are shown, together with additional information of the type, the connection pattern, the temperature, the serial number and the error flags. Complementary to that, a manipulation section on the configuration has been added for convenience during the commissioning at P1 [10, 11].

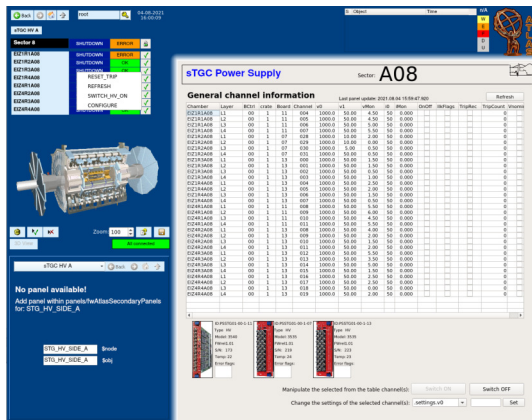

Figure 10: Operational Panels for both MMG and STG sub-systems.

## Chamber View

In case that a more detailed view of a quadruplet is desired, the panels in Figs. 11 and 12 can be called. In the top the name of the quadruplet is given. Below the name of the quadruplet the names of the connected HV modules are displayed, including their periphery of mainframes, branch controllers, etc. On the right side of the names there are buttons which allow the user to navigate to the corresponding panel, which holds the information about the selected module. Below the fields for the HV modules a table shows more details about the connected channels, their set and monitored voltage or current. The last column of the table shows the errors and has a color-changing indication for fast reading. On each cell of the table, the right-click functionality is enabled. This triggers the instantiation of a trend plot which pops below the table. The trend plot is automatically updated if a change in the values occur. In contrast to this, the table is only updated if the “refresh” button is used. Furthermore, a so called “expert mode” is implemented, followed by the chamber overview panel. This allows shift experts to modify the values of voltage or current of the displayed channels [10, 11].

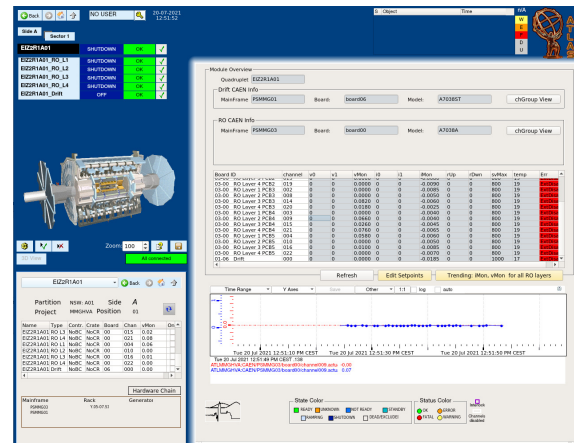

Figure 11: Operational Panels for both MMG and STG sub-systems.

## Layer View

User can navigate lower to the hierarchy, to the so-called Layer View. Here is the main difference between the p2 projects. For the MMG project, the layer belongs to the family of the LUs while for the STG belong to the DUs. Thus, it will be presented at the next subsection. Figure 12 depicts the layer view of the MMG. There the overview picture can be taken for the all the layer’s PCBs, along with its connected high voltage channels. On the right, the key parameters of the layer’s operation is given, along with their associated hardware components.

## Channel View

The lowest layer of the FSM hierarchy is the so called, Channel or Layer View, depicted in Fig. 13, for the MMG

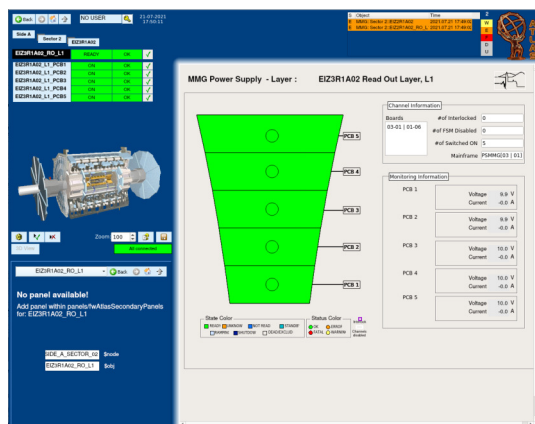

Figure 12: Operational Panels for both MMG and STG sub-systems.

and the STG, respectively. There the connected high voltage channel and its model name is displayed in the top. The table contains the key parameters of operation and offers the same functionality as for the quadruplet module view; a trend plot of a variable is called by a right-click in the corresponding cell [10, 11].

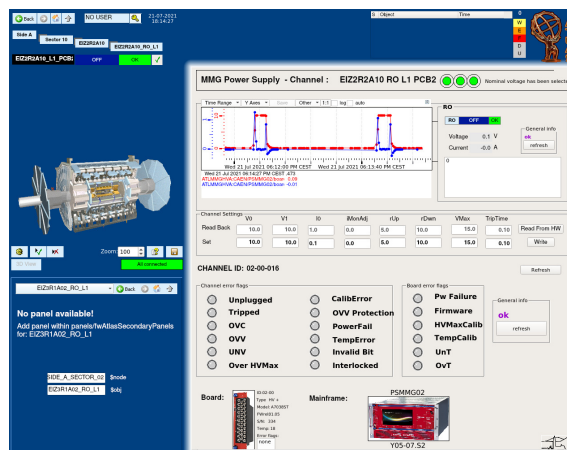

Figure 13: Operational Panels for both MMG and STG sub-systems.

## Expert Panels

A variety of expert panels (archiving and alarm handling, configuration and check of the periphery address, overall system review, database status, and more) has been developed for both projects, to accommodate all the needs for all type of users (shifter, developer, maintainer, expert) but mainly to facilitate the work of the expert during intervention or debugging and troubleshooting. A typical example of an expert panel, is the colormap, as can be seen in Fig. 14 [10, 11]. This panel is developed to provide the controllers a quick overview on the full detector by using color indication. Therefore, 2 wheels are displayed to represent the drift lines for both HO and IP sides. The readout channel are displayed in a colormap matrix (row: sector number, column: pcb num-

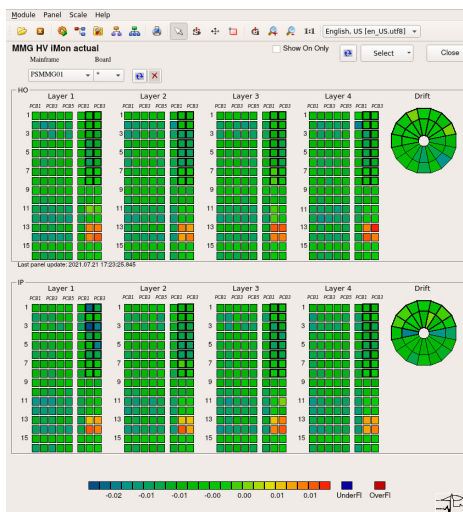

Figure 14: Operational Panels for both MMG and STG sub-systems.

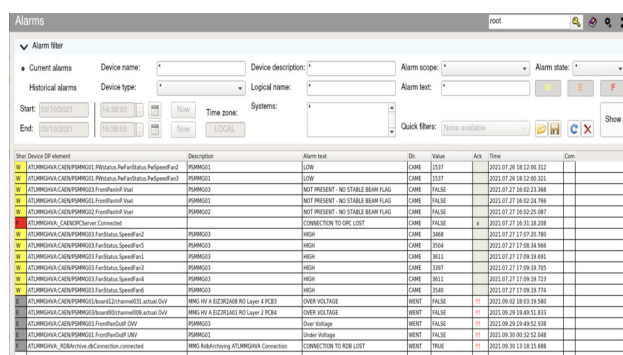

Figure 15: The Alarm Screen.

ber) as colorboxes. Via the drop-down menu it is possible to select the layer and the parameter, which should be displayed. These can be parameters of the HV channels as the monitored or set voltages, currents or the environmental parameters of the quadruplets. The color palette is adjusted automatically to the lowest (blue) and highest (red) value, but also can be set by the operator. This allows the operator to determine a layer which is out of the desired range. By hovering the mouse over a layer a tool tip with the numeric value of this layer is displayed. Additionally, by left-clicking on a rectangle a summary of all of its basic parameters is displayed.

## ALARM SCHEME

A powerful alert system (Fig. 15) notifies the operators about detected anomalies/malfunctions of the system during detector operation; providing higher (FSM) and lower (device) level error signalization. Error signalization within the FSM hierarchy is performed using a parallel tree of “Status” objects. For each FSM object, a dedicated Status instance is assigned with the states OK, WARNING, ERROR, and FATAL, signaling a problem in the corresponding part of the detector attributed to one of the following severity: Warn-

ing, Error, Fatal. An embedded help system also provides instructions required for recovery.

# WORKING UNDER PANDEMIC CONDITIONS: CONTACT TRACING MEETS TECHNOLOGY

E. Blanco Viñuela\*, T. Previero, E. Matli, B. Copy, S. Danzeca,  
R. Sierra, R. Losito, Ch. Delamare, A. Masi  
CERN, Geneva, Switzerland

## Abstract

COVID-19 has dramatically transformed our working practices with a big change to a teleworking model for many people. There are however many essential activities requiring personnel on site. In order to minimise the risks for its personnel CERN decided to take every measure possible, including internal contact tracing by the CERN medical service. They performed manual procedures which relied on people's ability to remember past encounters. To improve this situation and minimise the number of employees who would need to be quarantined, CERN approved the design of a specific device: the Proximeter. The project goal was to design a wearable device, built in a partnership with industry (*Terabee* and CERN), fulfilling the contact tracing needs of the CERN medical service. The proximeter records other devices in close proximity and reports the encounters to a cloud-based system. The service came to operation early 2021 and more than 8000 devices were distributed to CERN members of personnel. This publication reports on the service offered, with emphasis on the overall workflow of the project under exceptional conditions and the implications data privacy imposed on the design of the software application.

## INTRODUCTION

COVID-19 has dramatically modified working conditions hence affected largely to global economies and enterprise businesses. However, during the pandemic situation essential activities still required personnel on site. In order to keep production stability but ensuring workers safety there was an increased focus on finding solutions to comply with COVID-19 social distancing recommendations [1].

Initially, most of CERN activities adapted and were executed remotely (teleworking), but still some critical activities required work on site. The Health, Safety and Environmental (HSE) unit at CERN introduced a series of measures following the recommendations issued by the Host States. Social distancing and contact tracing have been some of the measures implemented. Contact tracing is defined as the capability of identifying persons who have been in the vicinity of an infected person so their isolation would avoid the spread of the virus. This tracing process was manually conducted by the medical service and required a large effort to keep up with the rate of infection. The process was mostly relying on memories of the infected individuals who should

remember with whom they may be in close contact hence does not guarantee perfect traceability.

Two main challenges appeared: (1) help individuals in keeping a **social distance** and (2) timely **identify individuals** who were in close contact with an infected person, the so-called contact tracing.

To tackle the mentioned challenges CERN approved the design of a specific device: the proximeter. The overall project goal was to design a wearable device able to record other devices in close proximity. Additionally an application provides only the close contacts under the request of the medical service.

This publication reports on the service offered, with emphasis on the overall workflow of the project under exceptional conditions and the implications data privacy imposed on the design of the overall service.

## THE PROXIMETER

First of all, the definition of two essential terms representing key events widely used during this publication is introduced here: **encounter** as the event of two individuals being within 2 meters distance for more than 30 seconds and **close contact** as the event of an encounter lasting more than 15 minutes which must be traced if required by the medical service.

The device was created with two main objectives: (1) **warning**: so the users are warned once they are not keeping the expected social distancing (2) **contact tracing**: timely provide potential close contacts in case of a positive appears.

Several similar devices with these characteristics were available on the market, but none presenting at the same time the desired precision, scalability to 10000 and more devices, timely data availability and more importantly adaptability in order to protect the sensible data collected at all moments of use and transfer. CERN decided then to issue a competitive tender with those specific requirements.

The company that was awarded the contract, *Terabee* [2], adapted one of its products, the *Terabee mobile robotics positioning system*, to comply with the specifications. In particular, for the connection to the CERN infrastructure *Terabee* implemented the CERN's *miniIoT* (Internet of Things) technology, under licence from CERN, while using its own technology for the encounters tracking based on the accurate Ultra Wide Band (UWB) radiofrequency.

Then, *Terabee* engineered a device that CERN called the **proximeter** (Fig. 1) which become a commercialised wearable product in *Terabee's* portfolio [3].

\* Enrique.Blanco@cern.ch

Figure 1: The proximeter device.

Some of the key requirements of the product and the solutions provided are shown in Table 1.

Table 1: Main Requirements and Solutions Given

Requirements	Solutions
Precise detection	UWB technology
Warning features	Buzzer and visual LEDs
Easy to use	Wearable device
Autonomy	Large capacity battery
Encounters accessibility	IoT networking: LoRaWAN®
Privacy	Encryption and no geotagging

The proximeter only knows where it is with respect to other proximeters. It does, however, know that specific information to an accuracy far better than that of mobile-phone-based apps, which makes it very good at telling its holders when they are getting too close, while keeping their whereabouts confidential.

The proximeter device [4] is a twofold design (Fig. 1): it is composed of a mainboard and a sensor-board. The sensor-board hosts a Ultra Wide Band (UWB) sensor. The sensor-board communicates with the mainboard via an SPI bus, that is shared with the LoRa® transceiver. The board is powered by a rechargeable Li-Ion battery rated at 3350mAh. The device also provides a red LED, which is used to assess the charging state, an RGB status LED, and a vibrator motor, which warns the user in case of an encounter is detected.

When the device is powered on, it joins the LoRaWAN® network and sends encounters that were not transmitted, if present. At the end of each encounter, the recorded information is saved in a flash memory and is used to compose the LoRaWAN® packets to be transmitted. Every 15 minutes, the device checks the encounters that have not yet been sent and empties the queue via LoRaWAN®. The communication between the device and the LoRaWAN® network is encrypted via AES-128.

## THE IoT INFRASTRUCTURE

As already introduced the device uses LoRaWAN® to exchange the encounters. The LoRaWAN® specification [5] is a Low Power, Wide Area (LPWA) networking protocol

designed to wirelessly connect battery operated ‘things’ to local or global networks, and targets key Internet of Things (IoT) requirements.

LoRaWAN® is the default IoT protocol for CERN [6] and it has been used in other projects in the last years. The choice of the proximeter for using this network was made in base of the experience already acquired with other devices, the existence of the *miniIoT* platform developed at CERN and the important requirements of coverage, power consumption and confidentiality. The network offers extremely **long-range data** links which allows to exchange data all around the campus (around 60 km<sup>2</sup>) with minimal deployment. The proximeters are battery-powered and LoRa has a reduction in **power consumption** by a factor of 10 compared to Wi-Fi. LoRaWAN® parameters are only known by the LoRaWAN® network administrators, not even the owner of the device knows them, and all communications are **encrypted** from the device up to the application.

The CERN IT department offers the infrastructure of the network together with a complete architecture which allows to host the device transmitted data.

## THE SERVICE

CERN imposed the use of the proximeters as part of the efforts to respond to the challenges posed by COVID-19. To date, more than 8000 people received the wearable device with a goal to minimize potentially harmful encounters and provide contact tracing information in case of need.

Setting up such global service was a non trivial task as the service must take care of different aspects as distribution, asset management, support, data collection and, finally, provide the relevant close contacts to the medical service. All these must be done under strong requirements on personnel safety and privacy. To succeed in this task a diverse team of people in different technical and organisational fields was assembled.

### Distribution

Distributing such amount of devices as fast as possible during the pandemic situation constituted the first challenge. Put in practice this demand required a fast and organised distribution mechanism which guaranteed the users safety as crowds had to be avoided.

A dedicated web-based appointment mechanism was set up. Users could reserve a slot to pick up their proximeters at their convenience (location and time). This ensured the safety for the team delivering the devices and the users themselves.

The response of the CERN personnel collecting the devices was extremely good (Fig. 2) considering that the majority of them were teleworking from their homes. This mechanism gave additional trust which indeed allowed a general recall campaign to deal with the release of a newer firmware version (mid February 2021) improving safety features deployed on the first firmware version. The distribution started with a pilot of 950 devices in December 2020 which

confirmed their effectiveness, successfully reporting violations of the two-metre rule with an accuracy of up to 90%. The full scale roll out officially started early 2021 and the use of the proximeter became mandatory from 1st of March 2021 when the number of 5000 devices distributed was successfully reached.

Figure 2: Distribution of the proximeters.

The distribution of the devices was executed by the registration service initially in different sites (e.g. experimental areas, restaurants...) and then centralised in a single location. Additional staff was required to deliver such amount of devices in parallel.

## Asset Management

This activity started with the procurement of the devices themselves which were configured with the required encounter parameters (distance: 2 meters and time: 30 seconds) at the factory (*Terabee*). The CERN procurement and supply chain teams worked together to handle the equipment providing them to the distribution point.

All the devices were registered in the computerised maintenance system available at CERN: *InforEAM*<sup>®</sup>. This allowed proper asset management to cope with the administration of spares and to handle the dysfunctional or lost devices while also playing an essential role on the data protection as will be explained later. The support of this activity was done by the asset and maintenance management team.

## Proximeters Support

The success of the project resided on the adoption of the wearable device by the users.

The device is not complex to use as it only requires to switch it on. However users need, both, to understand the different status modes and, more importantly, what and how the personal data shared is exploited. To cope with the first need, a complete user manual was created, distributed with the device and also made available online. To respond to the second need, a comprehensive online training course was created on the learning hub at CERN. This became essential in explaining the goals of the project and showing the kind of data collected together with their potential use by the

medical service providing total transparency on personal data use. Moreover the information about the proximeter project was regularly reported to the CERN personnel.

The support of the users was made by a team of experts on different domains (e.g. electronics, software, architecture, data protection...). All support was centralised in the CERN ticketing support service: *ServiceNow*<sup>®</sup> where a functional element was created to provide the CERN-wide support for the proximeter device. Diverse technical teams were involved in this support. The proximeter functional element provided a central point of support with links to a comprehensive set of the project information, online courses, frequently asked questions, manuals and the privacy notice.

During the current year (project activity) and until mid-September, there have been 216 incident requests and 131 general requests. These figures are considered to be low with respect to the number of deployed proximeters and they corroborate the quality and the ability of the device to be operational.

## Data Collection

The proximeter stores the encounters locally with the following data (see example of Table 2): Peer device (*RefTag ID*), own device (*myTag ID*) starting time of the encounter (*Date*) and duration (*NUM*). The last representing the total number of 30 seconds slots of the whole duration of the encounter. Data is regularly sent via the LoRaWAN<sup>®</sup> network and then stored in a database as records.

Table 2: Data Records Transmitted and Archived

RefTag ID	myTag ID	NUM	Date
24500	12893	32	01-MAR-21 10:26:00
22382	12893	3	01-MAR-21 10:51:00
53019	12893	7	01-MAR-21 10:58:00

The data is kept for a maximum of 14 days which is the time window when the tracing of close contacts may be of interest, then it is deleted. The IDs serve to identify the proximeter involved in the encounter. By design, the proximeters can not register the *geolocation* of the devices, so user's whereabouts remain confidential.

## Tracing Exercise

The ultimate phase is the ability of the medical service to trace people in close contact with a tested positive case or a person showing disease symptoms. The medical service is the only service allowed to perform this activity.

A complete software suite, the *proximeter portal* was designed. It allowed the medical service to query the records with the name of a person and to get back the close contacts list. This software suite represents the core of the service as it provides not only this feature but also handles the distribution and management of the devices by the registration service. Figure 3 shows the functionality given when tracing people. The example shows the identification of a close contact with

Figure 3: Close contacts from a contact tracing request.

two encounters of 30 seconds and 15 minutes and 30 seconds respectively.

The software suite will be technically introduced later but its functionality appears along this publication in many aspects: e.g. distribution, data privacy, and user interface allowing CERN personnel to consult their own generated data.

## THE DATA PRIVACY

CERN collects and uses **Personal Data** related to people who interact with the organisation in carrying out the mission. CERN is committed to respecting the security and confidentiality of the Personal Data for which it is responsible, in accordance with its Data Privacy Protection Policy<sup>1</sup>. CERN processes only such Personal Data as is required for the proper functioning of the Organization. A privacy notice for the proximeter device was created.

Data privacy has been the central concern on the proximeter project, therefore the design of the service including the tools, architecture and the software providing the main functionalities (i.e. assignation, asset management and tracing) have followed strong principles to protect the users privacy.

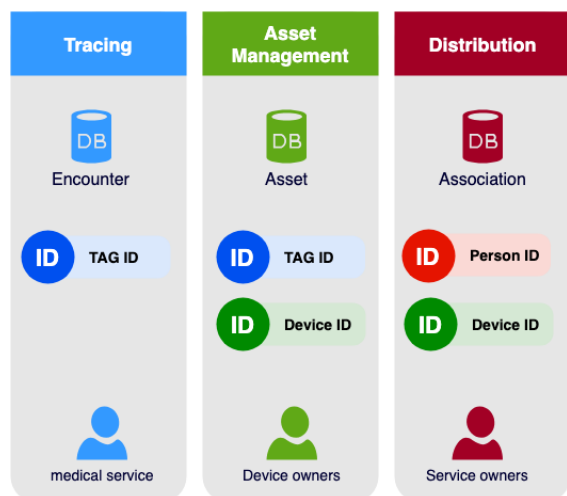

Figure 4: Global architecture based on scattered databases.

Three distinct databases were designed and deployed for that purpose: (1) Encounter, (2) Asset and (3) Association. Figure 4 shows the databases, the team having access and

<sup>1</sup> The Processing of Personal Data at CERN (OC11)

their main function. Access to the databases is only granted to specific teams with a clear purpose: e.g. medical service only has access to the Encounter DB, device owners only has access to the Asset DB and the registration service only has access to the Association DB.

An access to an individual database is not enough to relate the identity of a person and his/hers assigned proximeter guaranteeing anonymity. Also it shows the main identifiers (IDs) allowing a data pseudonymization which permits the data records be less identifiable while remaining suitable for the traceability (Table 3).

Table 3: Data Pseudonymization with Identifiers (IDs)

ID	Function
Person ID	CERN person identification number
Device ID	Proximeter visible identification number
TAG ID	Proximeter internal identification number

The CERN office of data protection (ODP) played a central role in the validation of the choices made. It particularly advised about the final solution providing users with the ability to consult their personal data kept at all times. To comply with this requirement the software suite added a new functionality called *self-service* to allow people to see their encounters. Obviously the data provided to the users listed the encounters of the person without the identification of the peers to ensure their anonymity.

Another aspect which was also looked at carefully was the security. The software suite together with the infrastructure was provided to the IT security team who run a complete audit to identify the robustness of the solution with respect to any possible data leak.

## THE PROXIMETER PORTAL

The design of the software application was driven by the requirements of the contact tracing but also with the idea of minimising resources by employing services already provided by CERN. The data scattered in different databases imposed several constraints on the design of the software increasing the complexity and making difficult the diagnostics in case of any technical issue. A second concern was to make a software suite in the shortest possible period of time to provide the application to the medical service as soon as possible.

The software suite ensures functionality to manage the proximeters by the registration service: i.e. assignment, lost&found and relinquish (REGISTRATION, STATUS and FOUND), the self-service (MY DATA) allowing all users to consult the personal data retained (encounters) and the tracing (TRACKING) of close contacts for the use of the medical service (Fig. 5).

The portal application is based on web technologies and split in a front-end and a back-end. The web application back-end is based on *Java™ 11*, *Maven™* and *Spring®*

Figure 5: Proximeter portal main interface.

*Boot* and exposes data via a REST APIs and serves the static files of the front-end, built with *Vue.js*.

The code is hosted on CERN's *GitLab* and the build of the project, the publishing of the artifacts and the actual deploy of the application is managed through *GitLab*'s pipelines. The final artifact resulting from the build process is a Docker image containing the layered *fat JAR* representing the application which is pushed to the project's *GitLab* Container Registry. The image is then deployed on CERN's PaaS (Platform as a Service - *OpenShift*<sup>®</sup>). The project is completed with metrics collection (*Prometheus*) and visualization (*Grafana*).

In order to provide the web application functionalities, many already existing CERN's resources has been leveraged. CERN's SSO (*Keycloak*) together with its integration with e-groups granted us the possibility to create group of users and give them different roles.

## THE STATISTICS

The proximeter portal has been used since early 2021. The distribution of the proximeters reached a notable number of 5000 right before being mandatory at CERN and passed 8000 in September 2021. The only available figure of their real use is the number of those which produce encounters, otherwise the number of proximeters in use is unknown as we intentionally do not check on the proximeters when they connect to the network at their arrival at CERN.

Figure 6: Active proximeters and number of encounters (per day).

During the initial period of the proximeter use (March 2021), the number of unique active proximeters was about 2000 and the number of encounters per working day was approximately of 14500 as average (Fig. 6), note the Easter

holidays and week-ends with far fewer encounters. The number of close contacts (encounters with more than 15 minutes) was estimated of approximately 550 per day in average. Note the period shown had a high rate of personnel working from home (teleworking) so a limited number of CERN personnel working on site.

During 2021 the number of positive cases was up to 17 per week (5 per week in average), but the medical service checked on possible close contacts of personnel with compatible disease symptoms. As a reference, in the last weeks of September, the medical service executed approximately 10 extractions per week to find close contacts.

## CONCLUSION

CERN invested in performing a rigorous contact tracing as a way to break the chain of infection. The key factor relied on improving the manual tracing executed by the medical service and provided an **immediate report** of close contacts for the medical service. This would minimise the number of employees who would need to be quarantined. The proximeter service revealed itself essential to allow a more precise contact tracing.

The success of this project, allowed by a notable internal cooperation among diverse teams at CERN, was not only based on the device itself but also on providing a service permitting the medical service to fulfil its needs of tracing. The service came to operation early 2021 and more than 8000 devices were distributed to CERN members of personnel who received the device as a protection measure while respecting the personnel privacy.

The software suite handling the proximeters and enabling the contact tracing was designed and engineered reusing all possible resources already available, therefore minimising cost and impact of CERN infrastructure and resources and, always, with the main concern of data privacy. This project indeed reflects well the concept of **privacy by design**.

# THE INCLUSION OF WHITE RABBIT INTO THE GLOBAL INDUSTRY STANDARD IEEE 1588

M. Lipiński\*, CERN, 1211 Geneva 23, Switzerland

## Abstract

White Rabbit (WR) is the first CERN-born technology that has been incorporated into a global industry standard governed by the Institute of Electrical and Electronics Engineers (IEEE), the IEEE 1588 Precision Time Protocol (PTP). This showcase of technology transfer has been beneficial to both the standard and to WR technology. For the standard, it has allowed the PTP synchronisation performance to be increased by several orders of magnitude, opening new markets and opportunities for PTP implementers. While for WR technology, the review during its standardisation and its adoption by industry makes it future-proof and drives down prices of the WR hardware that is widely used in scientific installations. This article provides an insight into the 7-year-long WR standardisation process, describing its motivation, benefits, costs and the final result. After a short introduction to WR, it describes the process of reviewing, generalising and translating it into an IEEE standard. Finally, it retrospectively evaluates this process in terms of efforts and benefits to conclude that basing new technologies on standards and extending them bears short-term costs that bring long-term benefits.

## INTRODUCTION

### White Rabbit

White Rabbit (WR, [1]) is an open-source [2] technology developed to provide the Large Hadron Collider (LHC) accelerator chain with deterministic data transfer, synchronisation with sub-nanosecond accuracy and a precision of a few picoseconds. First used in 2012, the technology has since then expanded its applications [3] outside the field of particle physics and is now deployed in numerous scientific infrastructures worldwide. Moreover, it has shown its innovative potential by being commercialised and introduced into different industries, including telecommunications, financial markets, smart grids, the space industry and quantum computing. On 16 June 2020, the WR synchronisation method was recognised by being included in the worldwide industry IEEE 1588 standard called Precision Time Protocol (PTP, [4]), governed by the Institute of Electrical and Electronics Engineers (IEEE, [5]), the world's largest technical professional organisation dedicated to advancing technology.

WR's wide-spread use in scientific installations and its adoption into industry can be attributed to 3 factors:

1. The open-source and commercial nature.
2. The collaborative and welcoming community.
3. Basing it on standards, extending them if needed.

This article focuses on the third factor to the success of WR.

## Standards and Standard-Defining Organisations

A technical standard is usually a formal document that establishes uniform engineering or technical criteria for externally visible operational aspects of a technology. While independently developed products (e.g. devices, software) that follow the same standard are meant to inter-operate, innovation is made possible in the internal implementation of these standard-based solutions.

Technical standards are prepared by groups that gather expert representatives of industry and academia specialised in a given domain. These groups are referred to as standard-defining organisations (SDOs) and can be organised as international organisations, unions, associations or consortia. Examples of SDOs relevant to this article:

1. International Telecommunication Union (ITU): a specialised agency of the United Nations responsible for information and communication technologies.
2. Institute of Electrical and Electronics Engineers (IEEE): a professional association for electronic engineering and electrical engineering (and associated disciplines).

Our everyday life is heavily dependent on standards prepared by IEEE and ITU. The ITU standards govern the operation of mobile networks. Commonly used means of communication, such as Ethernet, Local Area Networks and WiFi are all defined in IEEE standards.

## IEEE1588 Standard

The IEEE 1588 standard defines the Precision Time Protocol (PTP) that provides precise synchronisation of clocks in packet-based networked systems. The standard is commonly used to synchronise devices (e.g. sensors, actuators) in factories, power plants, distributed measurement systems as well as in finance, audio-video and telecommunication. First published in 2002, it was updated in 2008 and 2019.

The operation of PTP is divided into two main actions: establishment of a synchronisation hierarchy in the network and synchronisation of network devices following the established hierarchy. The IEEE 1588 standard is actually a "generic framework" that defines the above-mentioned mechanisms, as well as numerous options and parameters to enhance and fine tune its operation. The configuration of this "generic framework" is called a "PTP Profile". The framework cannot be used without a profile, thus the IEEE 1588 standard includes generic-purpose profiles, called Default PTP Profiles. Many industries define PTP Profiles adjusted to their particular requirements [6]. For example ITU-T defines PTP Telecom Profiles (e.g. G.8265.1) and the IEEE defines PTP Profiles for Power (C37.238) as well as Audio/Video, Automation and Automotive (802.1AS).

Notably, the IEEE 1588 standard purposely does not define requirements with respect to synchronisation perfor-

mance or hardware. These requirements can be defined in the PTP Profiles. As such, synchronisation performance of PTP devices depends on their implementation and the PTP Profile used. Typically PTP devices provide synchronisation at the microsecond level.

## WR AND ITS MOTIVATION FOR USING AND EXTENDING STANDARDS

The WR project was launched to renovate CERN's General Machine Timing (GMT), a system that orchestrates and synchronises operation of all the CERN accelerators. The GMT was created over two decades ago as a custom-made system based on the RS-422 standard. As such, it requires costly in-house support and tailor-made spare parts, resulting in maintenance challenges.

Apart from the technical requirements [7], the goal of the WR project was to create a technology with decades-long support from industry to minimise the cost of spare parts and maintenance. Achieving this goal was based on 3 pillars which are complementary: (1) open-source and commercial nature of WR, (2) collaborative and welcoming WR community, and (3) choice of well-established standards as the basis of WR. The public availability of design sources allows enhancement and reuse, as well as commercialisation by multiple companies. The more applications and users, the more attractive commercialisation is for companies while preventing vendor lock-in. The more companies sell WR devices, the more competitive is the price of WR gear, encouraging new users. Both companies and users favour investing in standard-based solutions for a number of reasons, such as stability and maturity, availability of existing products and tools, and interoperability of products from different vendors.

As even standard technologies become obsolete (e.g. RS-422) the choice of the base standard(s) is important. WR is based on the family of well-established IEEE 802 networking standards (IEEE 802.1Q and IEEE 802.3) and IEEE 1588, with good provisions for evolution and long-term support.

While the chosen base standards provided the functionalities (data transfer, synchronisation) required from WR, CERN's requirements exceeded their performance capabilities. At that time it was decided that any enhancements to improve the performance should be made compatible with the base standards for the following reasons:

1. Off-the-shelf standard gear can be used to minimise costs where high performance is not needed.
2. Off-the-shelf standard existing tools can be used.
3. The improvements are more likely to be implemented by companies.
4. The improvements can evolve with the standard allowing long-term support.
5. The improvements might make it into the base standard.

The above reasoning shaped the way in which the WR synchronisation method was specified, i.e. a WR extension to the IEEE 1588 standard.

## WR EXTENSION TO IEEE 1588

CERN's requirement for the WR technology specified synchronisation at the sub-nanosecond level, which was well beyond the performance achievable by IEEE 1588 devices at the time of WR's conception. Within the WR project, the standard's shortcomings were identified and solutions proposed to overcome them:

1. Clock synchronisation over the physical layer.
2. Enhancement of timestamps through phase detection.
3. Automatic evaluation and calibration of asymmetries.

While initially, it was considered to specify the above PTP enhancements as an independent protocol around the operation of the Default PTP Profile, the flexibility of PTP's "generic framework" allowed to use its built-in extensions mechanisms to accommodate the proposed solutions. And thus, the WR synchronisation method is described in the *White Rabbit Specification - draft for comments* [8] as an extension of the IEEE 1588-2008 standard in the form of a White Rabbit PTP Profile (WR PTP Profile). After substantial efforts and consultations with the author of IEEE 1588, this profile was defined such that it is compatible with the Default PTP Profile and it looks as any other PTP Profile. The WR PTP Profile specified in [8] includes:

1. Theoretical background for the extensions.
2. Hardware requirements to implement the extensions.
3. Protocol additions/changes to support the extensions.
4. Formal definition of the WR PTP Profile.

Such a definition of the WR synchronisation method meant that in a distant future the WR PTP Profile could be standardised on its own or it could be incorporated into the base standard - an ambitious task that CERN decided to undertake.

## PATHS FOR WR STANDARDISATION

There is no crash-course at CERN on how to standardise new technologies. All had to be learned from scratch on a trial and error basis. The WR standardisation effort was started by setting up a project [9] with the goal "*of standardising the White Rabbit extension to the IEEE1588-2008 standard*" and gathering a Study Group [10] to advise on how to do so.

First, potential WR standardisation paths were identified:

1. Standardisation in ITU-T:
  - (a) within an existing Telecom PTP Profile,
  - (b) as a new Telecom PTP Profile.
2. Standardisation in IEEE:
  - (a) as a new PTP Profile included in IEEE 1588,
  - (b) as part of AVB Gen2<sup>1</sup> in the 802.1AS PTP Profile.
3. Standardisation by a WR consortium acting as an SDO.

Second, each of the paths was studied in terms of cost, effort and prospects of success. As such, WR was presented at relevant ITU-T and IEEE meetings to the respective communities. Attendance in these meetings allowed to evaluate the operational procedures and dynamics of the groups, as

<sup>1</sup> Now known as Time Sensitive Networks.

well as the level of interest in the extensions proposed by WR, and synergies with ongoing projects. The observations and conclusions from this phase were as follows:

1. The level of performance provided by WR exceeded the needs of industry at that time, thus companies would find it hard to justify efforts into WR standardisation.
2. The ITU-T path was considered infeasible.
3. Creating a WR Consortium was too costly and risky.
4. Many synergies were found between WR solutions and the AVB Gen2, which was encouraging.
5. WR inclusion into IEEE1588 was identified as the best and most feasible WR standardisation path.

At that time, WR was presented at important events such as the IEEE Plenary [11], as well as meetings of dedicated SDO working groups. The presentations were made by CERN and industry representatives and demonstrated applications outside of CERN, thanks to the open-source and collaborative nature of WR and its community. As a result of these efforts, WR became recognised in the industrial timing community. This, in turn, made it possible to consider WR for inclusion into the base standard - the best possible scenario.

## WR STANDARDISATION IN IEEE 1588

### IEEE Standard Lifecycle

Each IEEE standard must obey the *Standards Development Lifecycle* presented in Fig. 1 which for existing standards ensures that a new revision is published every 10 years. Luckily, step 1 in the lifecycle of IEEE 1588 was triggered in 2012 when WR standardisation paths were evaluated.

Figure 1: Standards Development Lifecycle, indicating times for the IEEE1588-2019 revision.

In the first step in Fig. 1, the scope of the project is defined in the Project Authorisation Request (PAR) which is submitted to IEEE for approval. For existing standards, the scope can be limited to a simple erratum or it can add new features. For the IEEE 1588, a Special Session at the ISPCS 2012<sup>2</sup> conference was held to evaluate the needs of the community. Among many contributions, it was proposed to include WR into the revised IEEE 1588 [12]. The feedback indicated that a major revision of the standard was needed, therefore a Study Group was formed to prepare the PAR which stated:

<sup>2</sup> The International IEEE Symposium on Precision Clock Synchronization for Measurement, Control, & Communication.

“The protocol enhances support for synchronization to better than 1 nanosecond”. This sentence reflected group’s enthusiasm to include WR into the standard, yet with no guarantees.

### P1588 Working Group

In the second step in Fig. 1, a P1588 Working Group (P1588 WG, [13]) was mobilised to work on the new revision of IEEE 1588. Over 180 representatives from industry and academia joined the group, though only around 40 actively participated. The P1588 WG was divided into 5 subcommittees (SC) to work on different aspects of the revision, namely Maintenance, Management, Architecture, Security and High Accuracy SCs were formed. The latter, was dedicated to including WR into the standard. Each SC met online twice a month and reported its progress monthly on an online Plenary of the entire P1588 WG. Two to three times a year, P1588 WG face-to-face (F2F) meetings were organised in different locations; one was held at CERN. The proposals prepared by SCs were reviewed by the entire P1588 WG.

### P1588 High Accuracy Subcommittee

The High Accuracy SC was lead by CERN and included around 20 active representatives from such institutes and companies as NIST, Huawei, National Instruments, ADVA Optical Networking, Microsemi, Intel, Boeing, Ericsson, Meinberg and Cisco. The SC started step 3 in Fig. 1 by studying and understanding the WR PTP Profile [8]. This was important before deciding how to include WR into the standard. The study revealed a number of challenges:

1. There was no immediate need for the performance provided by WR which required hardware modifications. The interest was rather in using WR methods for improving performance of existing hardware.
  2. WR is specified for a particular type of medium (1 Gbps Ethernet over single mode bidirectional fibre) while the standard is generic.
  3. WR requires a particular hardware implementation while IEEE 1588 is purposely silent in these regards.
- As a result, the WR PTP Profile could not be included into the IEEE 1588 standard in a straightforward way and the efforts for WR inclusion were questioned numerous times.

Eventually, a consensus was reached which proposed a method of including WR in the standard that encouraged contributions from the SC members. As described in Fig. 2:

1. WR was divided into a number of optional features that could be useful on their own for different industries, i.e. Layer 1 Syntonisation Enhancements (L1 Sync), Configurable correction of timestamps, Calculation of the delayAsymmetry, mechanism for external configuration and masterOnly mode.
2. These optional features were made generic and extended to accommodate the needs of some members [14]. Methods known to work for WR became a particle configuration of the generic feature and were presented as examples.

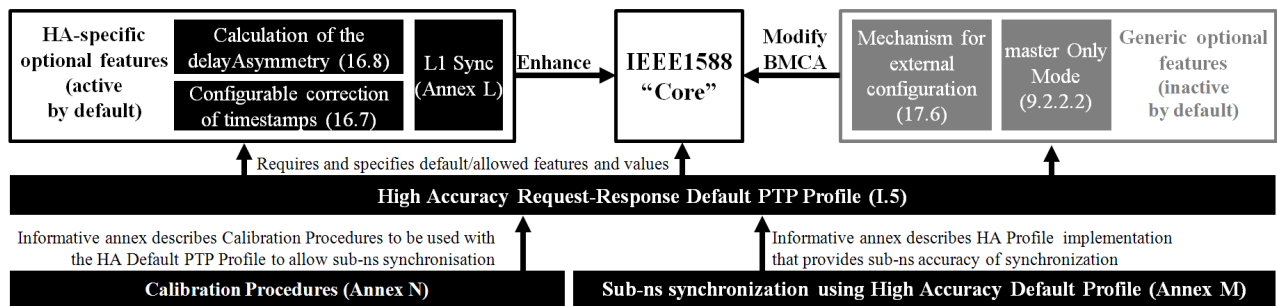

Figure 2: WR incorporation into IEEE1588-2019.

3. A new High-Accuracy Default PTP Profile (HA PTP Profile) was defined that makes use of the new optional features and specifies how a WR implementation should configure them.
4. While the WR methods included into the normative parts of the standard define only protocol aspects (no requirements on performance or hardware), the implementation details that allow achieving sub-ns accuracy of synchronisation were described in an informative annex, as an example implementation of the HA PTP Profile. Additionally, the WR calibration procedures [15] could be also included as an informative annex.

With the above compromise methodology, all aspects of the WR PTP Profile [8] and WR Calibration [15] could be included into the IEEE 1588 standard. WR was translated into three new annexes (L, M and N) and a number of additional clauses (e.g. 16.7, 16.8, 17.6, I.5) constituting a total of over 55 pages. Additionally, the core text of the standard (PTP “generic framework”) had to be enhanced with more precise definitions (e.g. clock, clock signal, Direct PTP Link), as well as an improved specification of timestamp generation and medium asymmetry, see [16] for details.

This compromise means that the WR PTP Profile and the HA PTP Profile are not compatible at the protocol level. While the existing WR hardware can be used to implement the new profile, the software WR implementation of the PTP stack [17] had to be updated. Before submitting the final text for the HA features and PTP Profile to the P1588 WG, the updated protocol was prototyped and compliance tests were developed independently to ensure its high quality [18].

With the new text ready and the solutions thoroughly tested, the High Accuracy SC submitted the text to the P1588 WG, where it joined that of the other SCs - the draft of the entire new standard (which grew from 289 to 499 pages) was ready for balloting.

## Balloting

Balloting is a voting and review process of IEEE standards in which each reviewer votes to either reject or approve the text. The approval can be made conditional on implementing voter’s comments. Each comment must be precise, explain the problem, and suggest new text that solves it. All comments are reviewed by a dedicated committee and each comment must be addressed. An updated text of the stan-

dard is submitted for re-circulation. In re-circulation, the reviewers vote with the same rules as before, but comments can be made only to the text that changed. In this way, after a limited number of re-circulations, the voting converges.

For the revised version of IEEE 1588, there were three ballots internal to the P1588 WG, which are still step 3 in Fig. 1. In these WG ballots, 3352 comments were submitted in the first one, 1504 in the second one and 749 in the third one. It took 18 months to go through this step and have the draft ready for the next step, i.e. Sponsor Ballot.

The Sponsor Ballot, step 4 in Fig. 1, is the IEEE Standards Association Public Review process in which anyone in the world can take part and vote submitting comments. A group of 127 registered balloters submitted a total of 358 comments which took 2 re-circulations and a total of 16 months to resolve before getting the required number of affirmative votes.

## Final Approval and Publication

The balloted draft was then approved by the IEEE Standards Review Committee and Standards Board in November 2019. At this point the new revision of the IEEE 1588 standard, IEEE1588-2019, superseded the previous IEEE1588-2008. However, the standard was not yet publicly available. It was passed to the IEEE Editor. The editing process took around 6 months and the new edition of the IEEE 1588 standard, WR included, was published on 16 June 2020.

## COSTS, BENEFITS AND LESSONS LEARNED

On behalf of CERN, the author was heavily involved in each step of the IEEE *Standards Development Lifecycle* described in the previous section. His involvement included leading the High Accuracy SC, contributing to the work of the Architecture, Management and Maintenance SCs, as well as substantially helping in the ballot comments resolution and working with the IEEE Editor in the final stage.

The indicative costs of CERN’s involvement in the work of the P1588 WG in order to standardise WR amounts to an estimated 2.25 person-years and 26 kCHF spread over 7 years. It includes participation in online and F2F meetings, preparation and review of documents and organisation of a F2F meeting at CERN; it excludes implementation of the HA PTP Profile and its compliance tests.

The motivation for standardising WR was to achieve long-term benefits, such as wide adoption and support from industry to minimise costs for CERN installations. Although these benefits cannot yet be unequivocally claimed only 1 year after IEEE 1588-2019 publication, some clear initial indications can be observed. Moreover other benefits of WR standardisation are apparent.

WR technology has benefited technically from the transformation into the HA options and PTP Profile. Not only has a number of known shortcomings of WR been fixed but WR technology has also become a more generic and flexible solution – see [14].

Even before the WR standardisation was completed, many companies had enthusiastically acted on the premise that WR would become an integral part of IEEE 1588. This included companies already familiar with WR and newcomers. The prospective WR standardisation clearly motivated these companies to invest time and resources into WR technology, which was tested for future applications in telecommunication networks on this premise [19]. The increasing number of applications and companies producing and supporting WR devices is essential for healthy competition and technology evolution, e.g. commercial long-distance WR-based time transfer [20].

The IEEE 1588 standard benefited from CERN's contributions and expertise. The constantly growing number of WR users increases the popularity of the standard. The enhanced level of accuracy achievable by the IEEE 1588-2019 meets the increasing needs of the industry. While the accuracy required from IEEE 1588 devices by industry in 2012 was at sub- $\mu$ s level, it has now increased to 4 ns [21] and will surely increase further. IEEE 1588-2019 is prepared to meet these requirements.

Finally, WR standardisation is a technology transfer that fulfils CERN's mission to *push the frontiers of science and technology, for the benefit of all* [22]. CERN has become a recognised player in the timing industry and continues its mission as the key driving force for innovation in the P1588 WG that continues to oversee the evolution of the IEEE1588 standard. As such CERN now leads the *P1588 New Features SC* mandated to add new features to IEEE1588, some of them inspired by new developments in the WR community.

## WR AFTER STANDARDISATION

WR technology provides deterministic data transfer and accurate time transfer over an Ethernet Bridged Local Area Network using an extension to IEEE 1588. Initially this extension was the WR PTP Profile of IEEE1588-2008. After the WR standardisation described in this article, it will be the HA PTP Profile of IEEE1588-2019. This update requires only upgrade of the software implementation of the PTP used in WR devices, i.e. PPSi [17]. Currently the beta version of the HA PTP Profile is available, yet official releases of WR firmware still use the WR PTP Profile.

The migration of WR devices to use the HA PTP Profile is foreseen in the coming years and it is intended to be

transparent for the WR users. WR Switches will support both PTP Profiles, WR and HA. The WR Nodes will use a profile of their choice, yet their support for the WR PTP Profile is meant to be deprecated at some point. On the other hand, the WR Switch is meant to support both profiles in the long-term. When connecting a WR device (switch or node) to a WR Switch, it will attempt to run the HA PTP Profile by default. If the HA PTP Profile is not detected on the adjacent WR device, the WR PTP Profile will be attempted. Thus, a WR Network can effectively use both profiles, WR and HA, in a manner transparent to the user.

The compliance of WR devices with the WR PTP Profile and the HA PTP Profile is ensured through extensive compliance tests developed using the VeriX ATTEST framework. While the framework is proprietary, the compliance tests are open-source [18]. The WR PTP Profile tests were purposely developed to ensure compliance of new WR firmware releases with the legacy devices/release. The HA PTP Profile tests were developed to verify the new profile during its development, and are meant to verify compliance with the HA PTP Profile of its implementations by CERN and the industry.

Notably, WR technology is a particular implementation of the HA PTP Profile that guarantees sub-ns accuracy of synchronisation. There might be other implementations of that profile without such guarantee.

## CONCLUSION

Standardisation of a new technology is a long process which requires not only an excellent technical solution but also patience and an open-minded attitude which allows to reach consensus. The duration and dynamics of the standardisation process depend on the SDO, the particular standard and the group that works on it, thus each potential standardisation effort must be considered individually.

The author is convinced that for technologies which are meant to last for decades and be deployed in thousands of units, the benefits of standardisation clearly out-weigh the efforts. A decrease of price by a hypothetical 50 CHF for a single WR device, costing hundreds or thousands CHF, due to competition encouraged by the WR standardisation compensates the monetary cost of this standardisation as soon as 500 units are purchased. The 2.25 person-years spent during 7 years on WR standardisation are more than compensated by 20 experts from industry scrutinising the technology ensuring its longevity and making it future-proof, while learning how to implement it in their companies.

Of course, standardisation is an investment which, by nature, brings profits with time and it is only in a decade or so that a true evaluation of the benefits of WR standardisation will be possible.

## ACKNOWLEDGEMENTS

WR would not have made it into the IEEE 1588 standard without the strong support and invaluable help of John Eidson, called in the community “the father” of IEEE1588.

# THE ESRF-EBS SIMULATOR: A COMMISSIONING BOOSTER

S. Liuzzo\*, L.R. Carver, J.M. Chaize, L. Farvacque, A. Götz, D. Lacoste,  
N. Leclercq, F. Poncet, E. Taurel†, S. White  
ESRF, Grenoble, France

## Abstract

The ESRF-Extremely Brilliant Source (ESRF-EBS) [1] is the first-of-a-kind fourth-generation high-energy synchrotron. After only a 20-month shutdown, scientific users were back to carry out experiments with the new source. The EBS Simulator (EBSS) played a major role in the success of the commissioning of the new storage ring. Acting as a development, sandbox and training platform, the machine simulator allowed control room applications and tools to be up and ready from day one. The EBSS can also be seen as the initial block of a storage ring digital twin. The present article provides an overview of the current status of the EBS Simulator and presents the current roadmap foreseen for its future.

## INTRODUCTION

The ESRF storage ring was upgraded in 2019 to provide 100 times brighter X-rays [1]. The strong demand for experiments at ESRF imposed a very tight schedule for dismantling, installation and commissioning of the new storage ring. Overall, 20 months of dark time for external users were necessary [2]. Only three of these months were dedicated to Storage Ring commissioning. In order to cope with this schedule, the design and update of the whole software infrastructure had to be brought forward as much as possible. This is particularly true for the high-level applications needed on the first day of commissioning, such as the new magnets control. In addition, several applications specific to the commissioning such as beam threading algorithms [3] had to be prepared and tested to be used effectively, with minimal debug time.

For this purpose a full test of the software from high-level applications to power-supplies level (current input, not hardware level) was realized via an EBS control system simulator (EBSS). This control system simulator was strongly focused on the new EBS magnets control system that needed to be completely redesigned, but included as well all the frequently used diagnostic devices (beam position monitor (BPMs), tunes, emittances, etc..) needed for the development of the tools used for the commissioning. The output values of the simulated diagnostic devices are generated from a given lattice optics model that is updated upon a magnetic strength or RF frequency variations in the simulated control system - as depicted in Fig. 1.

From the user's point of view, the simulator is identical to the "physical" control system. The devices providing the information on the beam position have identical names for

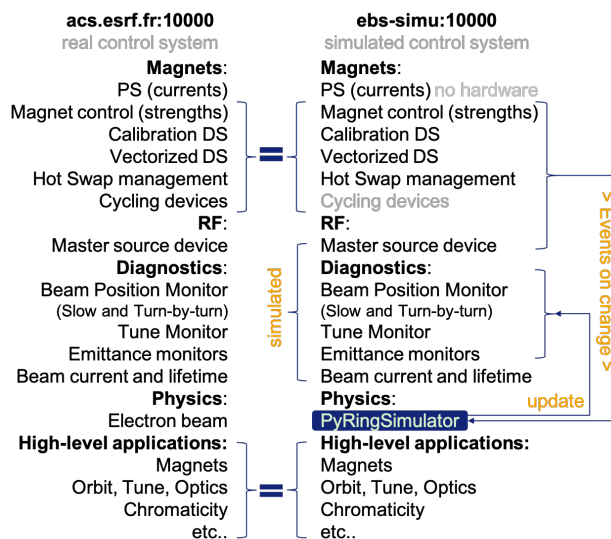

Figure 1: Real control system vs EBS simulator.

attributes and properties as their physical counterparts. This allows to port the applications from the simulator environment to the real machine by simply changing the environment variable pointing to the TANGO [4] database.

EBSS is a clone of a subset of the EBS control system that allows to interact with a simulated beam and to visualize the expected behaviour of most of the relevant electron beam and lattice observables: orbit, tunes, emittances, optics and coupling.

In the past, the ability to run off-line control room applications was already available, for example via toolkits such as the Matlab-Middle-Layer [5], used in many 3rd generation light sources or specific solutions - like the one on which the Virtual XFEL [6] relies.

For storage-rings, Matlab-Middle-Layer provides a high level switch from simulations to real beam experiments. This limits the development to anything above the matlab-middle-layer software infrastructure. The EBSS instead acts at a lower level, replacing directly the beam, thus giving access to all control levels. It notably enables real-time tests of features (1-2s/loop) not only for beam dynamics experts but also for control system engineers.

## STRUCTURE OF THE SIMULATOR

The core of an EBSS instance [7] is composed of more than ~ 4000 Tango devices compared to ~ 25000 in the physical accelerator complex (including the 3 accelerators - linac, booster + storage ring). Each EBSS instance runs on its own Tango control system - the associated Tango database

\* simone.liuzzo@esrf.fr

† taurel@esrf.fr

Figure 2: View of the 86 Tango device servers running within a docker.

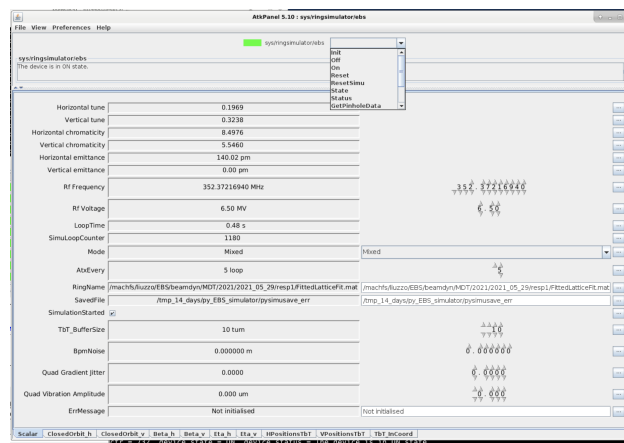

Figure 3: PyRingSimulator ATK panel view.

being isolated in a Docker container. This allows multiple EBSS to run simultaneously and independently on the same host. The device servers architecture is depicted in Fig. 2. Presently three EBSS instances are deployed at the ESRF - each one consuming about 25-30% of the CPU resources and 18-20% of the memory of a 16-CPU/64-Gb host.

### Tango Device Servers

Each EBSS Tango device exposes the exact same interface as its production counterpart. This ensures a total transparency to its clients and guarantees a smooth transition from simulation to production. At the lowest level of the control system, most of the devices are written in C++ and support a compilation flag providing a way to specify the target platform - i.e., simulation or production. For instance, the BPMs read the beam position from the dedicated hardware when running in production mode, whereas they obtain it from the ring simulator while running in the context of an EBSS instance. The behaviour of some devices has also been modified in order to broadcast or specifically notify (upon change) the EBSS environment - e.g., a strength modification on a magnet will trigger a modification of the EBS storage ring magnetic model and a consequent update of the relevant beam parameters. These asynchronous notifications rely only on the Tango events mechanism. A total of ~ 100 Device Classes and ~ 500 Device Servers are configured to run the EBSS.

**Physics Core: PyRingSimulator** The PyRingSimulator device server (see Fig. 3, and Fig. 2 level 1) runs high energy electron beam dynamics simulations [8]. It was initially developed in Matlab [9] and C++ [10], and has recently been ported to Python 3 [11].

The PyRingSimulator DS runs a dedicated process at startup (`ebss_simu.py`) that continuously<sup>1</sup> computes the optics using python Accelerator Toolbox (pyAT) [12]. For each EBSS instance, one CPU core is then fully dedicated to

this process. This structure allows to better exploit the CPU resources and provides a clear separation among the issues and workload related to control and those related purely to beam dynamics. Moreover, this separation allows for future extensions of the beam dynamic simulations to exploit more CPU resources, GPUs or the ESRF computing cluster, keeping the pyTANGO DS unchanged.

The simulated diagnostic DS continuously reads/monitors the updated parameters in PyRingSimulator instead of measuring real beam properties. From the user's point of view, the devices providing orbit, tune, chromaticity, etc, behave as the physical ones available in the control room. Figure 1 depicts the structure of the Tango devices layers: the PyRingSimulator device is the only one not existing in the real control system: it actually replaces the electron beam.

The electron beam magnetic lattice (optics model) used by PyRingSimulator can be the same as the one used for operation, a measured one or a different one (yet, an EBS optics model). It is defined by three individual lattice files: a reference optics with no errors nor corrections, a lattice including errors (on any magnet or BPM, potentially unstable) and a lattice including the same errors as in the previous one and the corresponding corrections. This structure allows to hide the lattice errors (any error that is possible to specify with pyAT) to the user, just as in real life. On the other hand, these three models can be identical if needed to give full freedom in the conditions of the machine to mimic. For example, to simulate the first turns steering, the lattice with errors and corrections has all the corrections set to zero, and it is thus identical to the one with errors only. An unstable lattice is simulated and as the correctors strengths are set to progress in the first turns steering, the simulations are updated to display the trajectory signal at more and more BPMs, finally leading to a stable machine (see [3]).

In order to make the EBSS even closer to the physical storage ring a few stochastic effects are also included: BPM noise, magnets vibrations (quadrupole), and field gradient jitter.

The optics computations can be selected (for speed reasons) among the following options:

<sup>1</sup> the loop runs continuously and not only upon changes to allow the introduction of stochastic errors, see later.

1. *Emittance* mode ( $> \sim 1.6$  s/loop), computing all linear optics, including emittances but excluding Turn-by-turn data;
2. *LinearOptics* mode, as the *Emittance* mode but without the lengthy natural emittance computation ( $> 0.8$  s/loop),
3. *Mixed*, iterates one loop *Emittance* and few loops *LinearOptics*,
4. *Turn-by-turn* mode (0.02 s/loop/turn (not linear, 0.4 s for 1 turn, 2 s for 100 turns), only computes the T-b-T buffer for the required number of turns and with the specified injection coordinates.

The actual loop speed of the EBSS depends on the number of magnets (or RF) that are modified before the required computations. The times are approximately doubled when using radiation for all computations (rarely used case). A computation loop counter is used at the Tango device level as a trigger signal for new data.

The PyRingSimulator has the ability to set the strengths of the magnets from the optics model (with errors and corrections) to the magnets of the EBSS. This feature was introduced to be able to reset the initial conditions of the simulations and proved to be extremely useful.

Moreover it is possible to save a lattice to pyAT format at any moment for further studies or to debug the EBSS itself.

**Simulated Lifetime/Current Decay** The lifetime/current device is a standalone device implementing an exponential decay starting from a given current, with a given lifetime. Simulations of beam (Touschek) lifetime are impractically long (hours on a single core, minutes on a computing cluster), and are not crucial for the purpose of the EBSS.

## DS AND APPLICATIONS DEVELOPED FOR EBSS

Before the commissioning of the EBS storage ring, the EBSS proved to be extremely useful. Several high level applications needed complete refurbishment, including some major ones such as the magnet control applications.

### Magnets Control

Having to develop a completely new control of the magnets - starting from low level device servers to a user-friendly and intuitive graphical interface - was the occasion to also include new features. This is a risky action when it is not possible to test the new features. For EBS, the EBSS was the key to progress in this development, allowing to debug offline in a pure virtual/simulated environment. The new features included in the magnet control were:

- individual control of (more than 1000) power-supplies,
- control of magnets organized by arrays or family,
- magnet set points expressed in “strength” (calibration curves integrated in the control system, including combined function sextupoles with 5 current channels to pilot 4 strengths),

Figure 4: Application for the control of the individual magnets in strengths. Top, the main panel with family tuning, bottom, a view of the sextupole magnets.

- definition of new cycling and ON sequences that avoid the peak power consumption to run out of limits,
- ability to *freeze* magnets (inhibit any user modification of a specific magnet),
- integrate the hot-swap features [13]
- tuning of electron beam resonance knobs,
- save and load of currents (primary) and strengths (utility) of the storage ring magnets configuration files.
- a completely new user interface.

All these features were introduced and tested within the EBSS, leaving for the commissioning only a few issues and some unforeseen developments. A-posteriori, even more applications of the EBSS would have been beneficial before the commissioning - for example, to identify calibration issues.

The final look and feel of the EBS magnets control application is shown in Fig. 4. From the user's point of view, it is impossible to distinguish an instance of the application running in the context of the simulator from an other attached to the physical machine. All actions are fully functional.

### First Turns Steering

An other key feature to a successful commissioning was the ability to automate the first turns trajectory steering. For this purpose basic scripts were designed and tested in the EBSS again solving bugs, giving confidence in the use of the tools and leaving only a few developments to be tested with real beam. The successful use of the EBSS was here also enhanced by the test of applications designed for EBS but tested in the old ESRF storage ring. More details are available in Ref. [3].

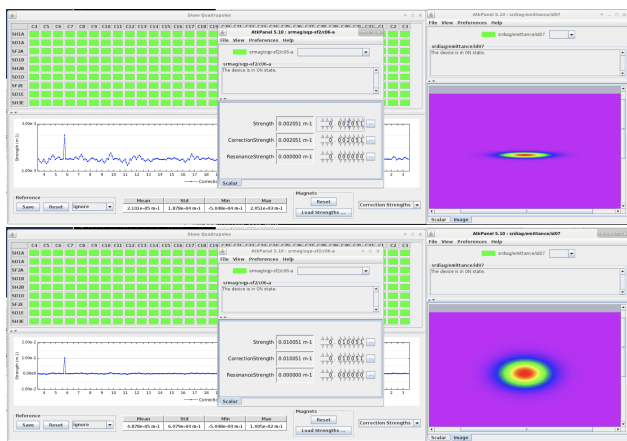

Figure 5: One skew quadrupole is powered (top, low field, bottom, large field) in the EBSS to show the effect on one of the simulated emittance diagnostics.

### Tune Correction

A new tune correction application was also deployed. The multiplication of the available knobs allowed to generalize the tune correction to any vector of quadrupole magnets, rather than simply two families. This new feature was tested in the EBSS and in the old ESRF storage ring and did not require any further tuning with real beam.

### Optics and Coupling Correction

Some of the applications used during the operation of the previous ESRF storage ring could not be updated before commissioning because of the lack of time. Some were deliberately postponed with no detrimental impact on the commissioning schedule. An example is the optics and coupling correction application. This was completely redesigned and updated during the beamline commissioning time, making extensive use of the EBSS simulator to test all steps, from the response matrix measurement to the fit of the lattice errors and the application of quadrupole correction. An example of beam emittance display with a skew quadrupole mistuned on purpose is displayed in Fig. 5.

### Slow and Fast Orbit Correction Interaction

The EBSS simulator has nevertheless a limitation, that is the speed of the computation loop. All fast systems such as fast orbit and emittance feedbacks are not available in the EBSS. Nevertheless, tests of the correct simultaneous use of Fast Orbit Feedback, Slow orbit correction, and setting of closed orbit bumps, were possible and allowed to exploit the EBSS to redesign the orbit correction logic for EBS in parallel to the User Service Mode operation (USM).

### More Applications Developed for Commissioning

The EBS simulator also allowed the development and test of: beam based alignment functions, chromaticity measurement and correction, a Tango DS for the computation of optics at any given longitudinal coordinate, a procedure of

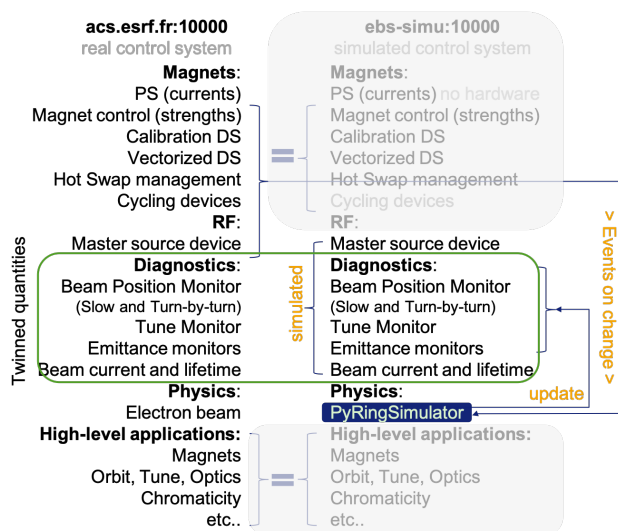

Figure 6: Digital twin configuration using the existing EBS Simulator.

measurement to evaluate the beam energy, the procedure to load new SR optics, and many more.

EBSS allows to perform realistic, real-time virtual Machine Dedicated Time (MDT). During real MDTs if a problem occurs, the solution can be looked for in parallel with the EBSS, while other MDT activities continue to take place.

## TOWARDS A DIGITAL TWIN

The EBSS infrastructure is a first step towards a Digital Twin [14] of the Storage Ring. In fact, a complete digital twin continuously monitors the real machine settings and updates the expected output accordingly. Today it is manually possible to use a measured lattice to trigger the simulator computations and to set the strengths so that EBSS matches the real machine configuration. In order to move towards a digital-twin, this action would need to be automated. An instance of the PyRingSimulator device could then run in the real control system sourcing the currently loaded optics as a model - a trivial action requiring a simple modification of a Tango property - and use the real magnets settings - that are already expressed in strengths! - to update the optics model (see Fig. 6). This would allow to have constantly (at the speed of the simulator loop) an estimate of the expected orbit, tunes, dispersion and optics of the SR. The absolute comparison being far from easy to obtain with the existing lattice model at the ESRF, relative variations monitoring should be possible without major issues. A further improvement would be to include ID gaps models, such that it would be possible to monitor for example the optics modulations induced by ID gaps during USM.

Both improvements on the lattice modelling and on the control infrastructure are needed, since the magnet device servers are presently designed to work either on the real control system or in the EBSS. Regarding the control aspects of this problem, the idea would be to implement a bridge between the physical control system and its virtual counter-

part. The ability to access Tango devices across separated control systems makes such a task quite straightforward.

Another step towards a real digital twin is to connect the control device to either the real live devices or the archive database to display live or historical values as readings. This step would be useful for debugging applications, new algorithms and or using the digital twin as a time machine able to go back in time. Connecting the digital twin to the beamline control system simulator is another area to be explored. This would allow beamlines to test developments with a simulated copy of the accelerator i.e. the EBSS.

## PORTING EBSS

There are a number of new projects started or planned to replace the current 3rd generation storage rings with a 4th generation one. For those projects which are using Tango for the accelerator controls or are interested in trying it out with a simulator, the EBSS offers a powerful solution. However there is a certain amount of work required to port the EBSS to a new storage ring.

To port the EBSS to another storage ring the following would need to be carried out:

- Define the devices according to the naming scheme of the new storage ring
- Implement simulation devices for each of the device classes. One option is to start off with a generic device simulator e.g. using the tango-simlib [15]
- Populate the Tango database with the simulated devices
- Define the optics of the new storage ring for pyAT
- Start the docker containers with the new simulators

## CONCLUSIONS

The EBSS proved to be an extremely powerful tool for the preparation of the ESRF-EBS storage ring commissioning. It allowed to eradicate most of the coarse bugs and to include several additional features without any delay on the initial schedule. The EBSS was used with large profit also after the EBS storage ring commissioning and is presently used for the continuous development and upgrade of all the softwares for which a direct impact on the electron beam is expected.

The infrastructure that was set in place to realize the EBSS is such that future developments towards a Digital Twin are simplified. The final objective will be to continuously monitor the expected (simulated) beam properties from the storage ring control room, such as optics and response to magnetic fields variations. Such a development will also allow to implement Artificial Intelligence and Machine Learning algorithm that will constantly compare model vs measurement enabling: 1) early detection of faults, 2) slow drifts of parameters potentially linked to hardware failures, 3) continuous lattice optics model update, and 4) many other features.

The extension to other accelerators is presently not trivial, due to the intrinsic peculiarity of each control system. Nevertheless the strategy is set and at least the PyRingSimulator DS would require few modifications (the specific name of

the devices) to be used for other storage rings, or high energy electron transfer lines. Specific developments will be needed instead to extend the use of the simulator to linacs, energy ramped accelerators and hadron accelerators.

The several aspects mentioned above will be addressed in the near future and are presently part of a proposal for a future EU collaboration project [16].

# A DYNAMIC BEAM SCHEDULING SYSTEM FOR THE FAIR ACCELERATOR FACILITY

S. Krepp\*, J. Fitzek, H. Hüther, R. Mueller, A. Schaller, A. Walter  
GSI Helmholtz Centre for Heavy Ion Research, Darmstadt, Germany

## Abstract

The new Accelerator Control System for GSI/FAIR is now being used productively for the GSI accelerator facility. As the central component for online beam orchestration, the Beam Scheduling System (BSS) is situated between the FAIR Settings Management System and the FAIR Timing System. Besides device settings, the Settings Management System provides timing schedules for beam production. The primary purpose of BSS is to define which of the beam schedules are executed by the Timing System, how often and in which order. To provide runtime decisions in pre-planned execution options (e.g. skipping of a particular beam), it processes external signals like user input, experiment requests or beam prohibits provided by the interlock system. More recently, advanced features have been added that allow for dynamic execution control required by Storage Ring Mode features such as breakpoints, repetitions, skipping and manipulations. This contribution gives an overview of the Beam Scheduling System including its interfaces.

## INTRODUCTION

One of the major building blocks of the new Accelerator Control System for GSI/FAIR is the Beam Scheduling System (BSS). Residing in the middle tier of the FAIR Control System, its core functionality is the orchestration of beams based on user requests. Figure 1 shows how BSS is embedded into the overall Control System architecture.

In the FAIR Settings Management System LSA, beams are represented as Beam Production Chains and are put together to Patterns for defining an execution sequence. This includes both, settings for hardware devices, as well as an execution schedule defining which Timing Events are to be sent to which parts of the facility. Additionally, by assigning Patterns to Pattern Groups, LSA defines which Patterns must be executed sequentially and which Patterns may run in parallel. The schedule for each Pattern and the information about Pattern Groups is provided to the BSS system, which creates an overall schedule for the accelerator facility and sends it to the Timing System's Generator component. The Generator then translates this schedule to the low-level programming of the Data Master.

Operators and experimenters define, which beams they would like to have produced using applications and services, that in turn send these requests to BSS. At the same time, the Master Accelerator Status Processor (MASP) determines whether a certain Pattern can be executed, by collecting status and interlocks of all required devices and services. BSS then combines both of these inputs and sends commands to

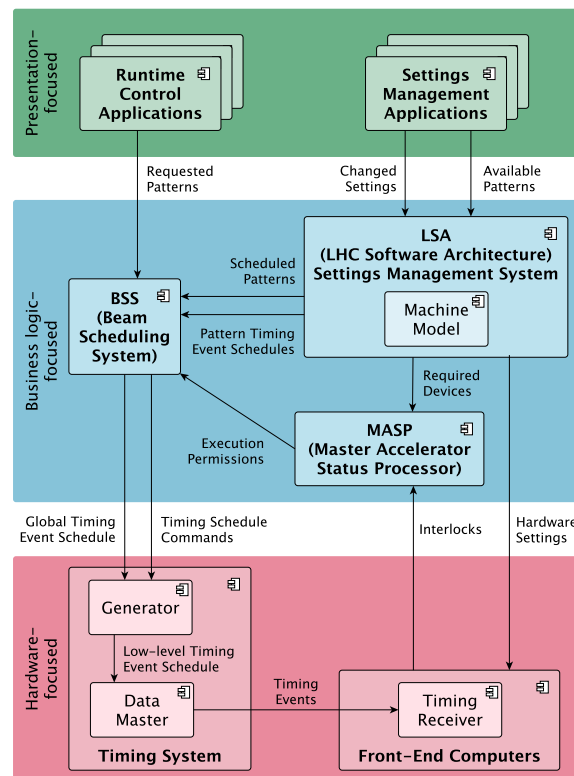

Figure 1: BSS in the FAIR Control System.

the Generator, that dynamically modifies the overall schedule accordingly. At runtime, the Data Master sends out timing events via the White Rabbit-based timing network. Those events lead to synchronous execution of settings in devices as calculated and provided by LSA.

As shown, BSS is the central instance that decides which of the preconfigured schedules are executed. This contribution presents technical details of the BSS system and its interfaces to give an insight, of how beam orchestration is realized within the GSI/FAIR Accelerator Control System.

## SCHEDULE REPRESENTATION

Schedules within BSS are represented as schedule graphs that can be executed by the Timing System [1]. The graph itself is represented in the .dot format [2]. The vertices in this directed graph can roughly be interpreted as executable units linked together by a set of edges. Once started, a control thread walks over those vertices one after another in order to execute them. The actual sequence of vertices is defined by a set of edges marked as default destinations. Alternative routes through the schedule are defined by a set of alternative destinations.

\* s.krepp@gsi.de

To allow for dynamic schedule changes, the Timing System supports switching of default destinations in the schedule graph, thus allowing the beam schedule to be altered at runtime by changing the default path through the schedule graph. BSS is responsible for managing the configuration of the Timing System by providing beam schedules and for altering those schedules on the fly based on user requests.

## SCHEDULE CONFIGURATION

As described, LSA supplies BSS with individual schedules per Pattern and it is up to BSS to integrate them into a global timing schedule. Doing so, the schedules are not just merged, but extended to later gain flexibility at runtime. Conceptionally, the resulting schedule is driven by three major requirements. Firstly, Patterns specified in one Pattern Group must be scheduled sequentially respecting their specified execution order, while Patterns in different Pattern Groups shall run in parallel. Secondly, BSS must be able to permanently enable and disable each individual Pattern schedule's execution to allow for beam prohibits and user requests. Thirdly, BSS must be able to schedule individual Patterns for being executed exactly once.

The first requirement is met, as BSS manages Pattern Schedules on a per Pattern Group basis. It combines the individual Pattern schedules to a circular Pattern Group schedule graph. Different Pattern Groups result in different Pattern Group schedule graphs and can be executed in parallel.

An example Pattern Group schedule graph is shown in Fig. 2. Each individual Pattern schedule has one explicit entry and exit node, e.g. A\_ENTRY and A\_EXIT. The Pattern schedule for Pattern A is shown here only as one node A for the sake of simplicity. However, in the real schedule graph, node A actually consists of many vertices and edges that represent the actual behaviour of the machine, e.g. the timing events for this Pattern. The currently active loop through the graph is drawn with solid edges, alternative paths through the graph are drawn with dotted edges.

To meet the second requirement, and to be able to switch the execution of one Pattern on and off, BSS adds an alternative path directly from ENTRY to EXIT, i.e. the edge from A\_ENTRY to A\_EXIT. To prevent Patterns from being executed right away, once they are provided to the Timing System's Generator and execution is started, the edge that skips Pattern execution is in fact set as the default one. Consequently, it is drawn as a solid edge in the figure. The edge used for actually executing Pattern A is represented by a dotted line, as it must be explicitly switched on later by BSS.

In addition to the Pattern schedules provided by LSA, BSS adds a so-called Default Pattern schedule to the Pattern Group schedule graph. It is used for idle operation, i.e. when no beam is requested. Finally, each Pattern's exit node is extended with outgoing edges to each available Pattern's entry node which gives BSS the ability to build arbitrary loops of Pattern schedules.

To meet the third requirement of being able to execute a Pattern only once, it was necessary to keep the entry nodes

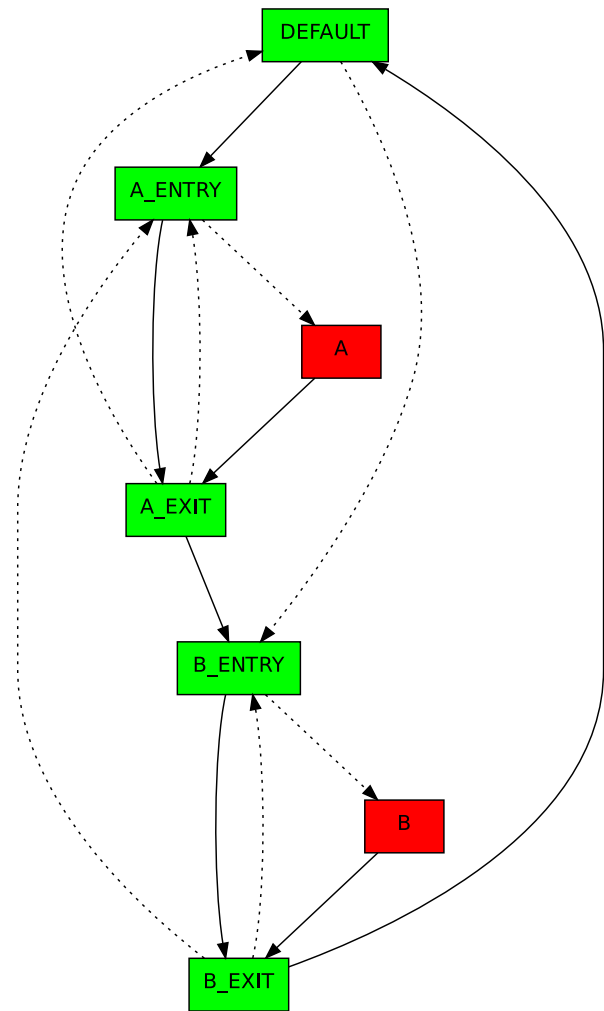

Figure 2: Pattern Group schedule with only the Default Pattern being active.

in the active loop for each Pattern also in the case, that this Pattern is not being requested at the moment. This is why in case no Pattern is requested, the Pattern Group schedule graph's active loop does not only consist of the Default Pattern pointing to itself, but contains all the entry and exit nodes as shown. The single shot request is described in more detail in section NON-PERMANENT OR SINGLE SHOT REQUESTS.

After the Pattern Group schedule has been prepared by BSS, it is added to the Timing System's global schedule. The Timing System supports multithreading by assigning parts of the global timing schedule to a certain thread. In order to support parallel execution of independent Patterns, each Pattern Group schedule is executed in its own thread. With a start command sent to the Generator, the execution begins right away. When the graph from Fig. 2 is executed, the Timing System loops over the nodes that are coloured green: a sequence containing the Default Pattern schedule and the nodes A\_ENTRY, A\_EXIT, B\_ENTRY, B\_EXIT. However, the Patterns A and B are not executed since their internal schedule subgraphs A and B are skipped.

Whenever the Pattern Group gets changed, e.g. a Pattern is added or removed, BSS stops the corresponding thread and replaces the old Pattern Group schedule with the new one.

As shown, the overall timing schedule at FAIR includes schedules for multiple Pattern Groups, which itself integrate multiple Pattern schedules. The following sections describe how BSS interacts with the Timing Schedule and how this is triggered by external requests.

## SIGNAL-BASED RUNTIME DECISIONS

The primary input for runtime decisions concerning which parts of the global schedule should be executed are dedicated binary signals, with valid values being either enabled or disabled. Signal states are exclusively managed by BSS, however it exposes a client API for reading and writing signal states. BSS defines various signal types which can be used for different use cases as well as for access control. Signals of type DISABLED\_BY\_LSA for instance, can only be set by the Settings Management System itself and not be overridden by client applications.

Basically, BSS performs two categories of runtime decisions. The first one are decisions on Pattern Group level, i.e. which Pattern should be running, which will be described in the next section. The second category are decisions on Pattern level where decisions on alternative paths within a Pattern schedule are made (see section STORAGE RING CONTROL).

## PATTERN SCHEDULE EXECUTION CONDITIONS

In order to decide which Pattern schedules to execute, each schedule is bound to an execution condition. Each execution condition is expressed as a propositional formula using signals as statements and logical operators (AND, OR, NOT). Because of their binary nature, signals can be directly mapped to boolean variables. This way, complex execution conditions can be easily built as the following example illustrates:

$$(SIGNAL\_A \vee SIGNAL\_B) \wedge \neg SIGNAL\_C \quad (1)$$

If a Pattern schedule is bound to the above condition, it is scheduled for execution if at least one of SIGNAL\_A or SIGNAL\_B is enabled and Signal\_C is disabled.

Signals used in execution conditions are either predefined signals that are independent from current scheduling-related settings in the facility (static signals) or signals defined by the Settings Management System (dynamic signals). Static signals for instance, are typically used for requesting beam, also from custom experiment control systems. It is up to the Settings Management System to supply BSS with execution conditions and dynamic signal definitions.

## PERMANENT REQUESTS

With signals being used in execution conditions and BSS providing a simple API for changing signal states, users can enable and disable Pattern executions by simply sending permanent signal change requests. Signal state changes are persisted in a database. Afterwards BSS executes relevant execution conditions and determines which Patterns to enable or disable in the global timing schedule. Finally, it sends commands to the Timing System that switch schedule edges accordingly.

In order to permanently enable an actual Pattern for execution, the default destination from the Pattern's entry node is simply switched from the exit node to its actual timing schedule content (as represented by A in Fig. 3).

Figure 3: Part of a Pattern Group schedule with Pattern A being enabled.

## NON-PERMANENT OR SINGLE SHOT REQUESTS

As described above, permanent signal requests lead to schedules being executed periodically since the resulting default execution path is always a circular subgraph. Therefore, those requests are not adequate for experiments requiring precisely a single shot or any other fixed number of Pattern executions. This is especially true for schedules of short duration, as reaction times of operators (and even automated systems) are threshold-bound and not arbitrarily short. It cannot be expected that an operator waits for a single execution of a Pattern and is able then to disable it before the next execution starts.

To allow for single shots, BSS provides so called non-permanent requests. Whenever a non-permanent request arrives, BSS does not apply the requested signal changes permanently, but builds a signal state snapshot from all existing signal states and applies the non-permanent changes to it. Afterwards, execution conditions of all schedules are evaluated against these snapshots. Schedules being enabled

by this evaluation are scheduled to be executed exactly once (Fig. 4).

Figure 4: Queued Flow command in A\_ENTRY leading to an exactly once execution of A when consumed.

To make this work, the BSS utilizes the ability of the Timing System to define command queues for schedule nodes. To prepare the schedule for non-permanent requests, a command queue is defined for each Pattern's entry node. Whenever a Pattern schedule should be executed exactly once, BSS writes a non-permanent flow command to the corresponding command queue specifying a temporary successor. When the Timing System executes this node, it will consume the command and will not go down the default execution path, but instead to the one specified in the command. Since the queued command is consumed, the prior default path is used again for the next execution.

## STORAGE RING CONTROL

In addition to enabling and disabling whole Patterns, BSS also allows for a more fine-grained schedule control, that is extensively used for the Storage Ring Mode features breakpoints, skipping, repetition and manipulation for ESR and CRYRING [3]. To support these features, beam schedules for FAIR can contain sub-schedules with elements/edges that can be directly controlled by users utilizing BSS's signals. The mechanism is simple and is again based on switchable schedule edges which are based on the state of certain dynamic signals. A set of signal types has been added, that allows the definition of signals, from which BSS can directly infer which edges to switch.

To allow for breakpoints, where Pattern execution stops at defined points, the signal type `BREAK_ENABLED` is connected with a pre-defined break loop in the schedule graph. Setting the corresponding signal allows BSS to enable or disable the breakpoint. The name of the specific breakpoint is encoded in the signal's name, thus allowing for several breakpoints in the same schedule. Knowing the structure of

Figure 5: Part of Pattern schedule with an enabled breakpoint.

a breakpoint sub-graph, BSS can switch the edges accordingly. This is demonstrated in Fig. 5. If BSS receives a signal with type `BREAK_ENABLED` and value==`ENABLED`, BSS firstly decodes the breakpoint Subchain from the signal's name. Afterwards it sets the default execution path from `BREAK_ENTRY` to `BREAK_BLOCK_ENTRY`. If the same signal is received with value==`DISABLED`, it sets `BREAK_EXIT` as the successor of `BREAK_ENTRY`, which means that the break loop is no longer executed.

Skipping of Subchains has been realized using the signal type `SKIP_SUBCHAIN`. Similarly to skipping whole Patterns as described above, signals of this type are associated with edges that allow circumventing optional Subchains. As all of these features make use of dynamic signals whose initial value is set to be `FALSE`, the Subchain will be executed and not skipped by default.

Another basic feature of Storage Ring Mode is supporting Subchain repetitions, e.g. for performing a measurement for a defined number of times. With the beginning of Subchain execution in the Timing System, a command queue at an dedicated repetition node is filled with a command that defines the number of repetitions for this Subchain. BSS is responsible for cancelling these repetitions upon user request. This is done by flushing the corresponding queue using the Generator's command interface.

The most distinguished Storage Ring Mode feature is trimming (i.e. manipulation of settings) while a Pattern is running. This manipulation is realized as a loop in the graph that is connected with an exit signal that can be triggered by the user through BSS. While executing the same Subchain over and over again, the user can apply small setting changes to the devices.

For more information about these Storage Ring Mode features, please refer to [3].

# BEAM SCHEDULING VS. MACHINE PROTECTION

The Beam Scheduling System is not part of the Machine Protection System of the FAIR facility as it operates on a different time scale than fast hardware protection systems. However, if something goes wrong in the machine, BSS is responsible for preventing Pattern schedules from being executed on a software level. To do so, it continuously processes status messages from the Master Accelerator Status Processor (MASP), which in turn monitors relevant devices and services. Whenever BSS detects, that a Pattern must no longer be executed, BSS disables the associated schedule in the global timing graph. In contrast to Patterns that are just disabled by user requests, for prohibited Patterns, even their entry and exit nodes are excluded from the schedule loop (see Fig. 6). This ensures, that parts of the global schedule which have been prohibited by interlocks, can no longer be enabled by user requests, as long as the causing interlocks remain active. In this regard, interlocks act as an overruling of the signal based execution conditions.

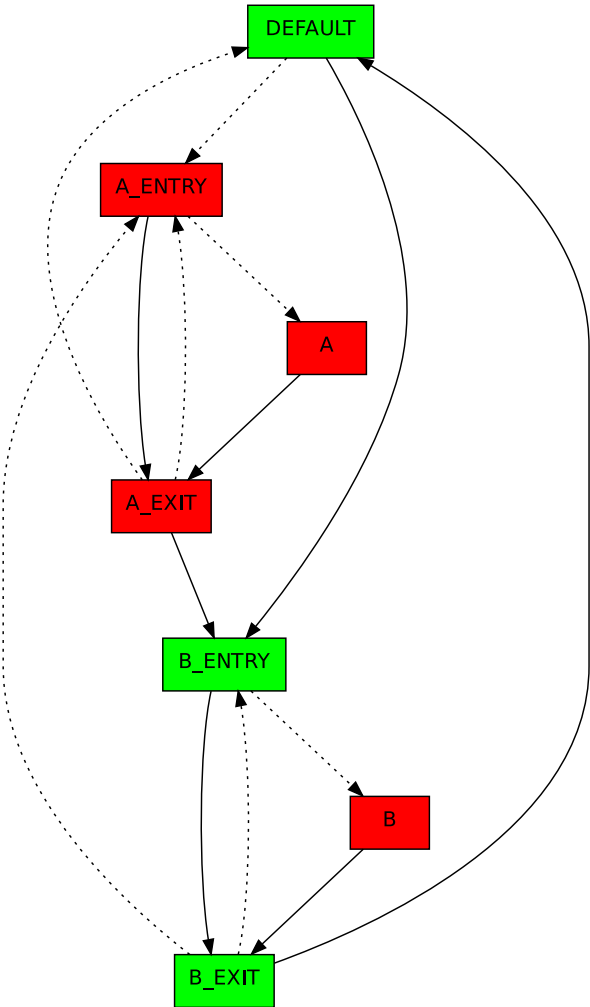

Figure 6: A Pattern Group schedule with Pattern A disabled by the Machine Protection System.

# SUMMARY AND OUTLOOK

The Beam Scheduling System, as described in this contribution, has been used productively in several beamtimes. Newer features, like those for Storage Ring Mode operation have been added and it has proven to be a reliable and important building block of the FAIR Control System. Complete integration into the settings management system’s data supply process, has allowed for an integrated solution, that makes LSA not only the place for calculating settings for devices, but also the place for schedule planning. BSS on the other hand, creates the global execution schedule and brings it together with runtime information, like user and experiment requests and beam prohibits, which makes it the central instance to decide, which of the preconfigured schedules are to be executed by the Timing System.

Next BSS developments will target requirements coming from the Injector Controls Upgrade project, which will bring the existing UNILAC into the new Accelerator Control System. Challenges are expected to arise from its 50Hz operation and a large number of pre-planned schedules.

### Abstract

A new dedicated electron injector linear accelerator (linac) was constructed for the soft X-ray synchrotron radiation facility, NewSUBARU. The SPring-8 linac was used as the injector at the facility since its operation started. However, the new linac enabled NewSUBARU to operate independently from the SPring-8. The control system of the new linac and the existing storage ring must be constructed as a unified system for seamless operation. The control framework already used for the SACLA/SPring-8 was also used for the NewSUBARU. MicroTCA.4 (MTCA.4), EtherCAT, and GigE vision camera were used for the new linac control. For the storage ring control, the existing VMEbus system (VME) was used with virtually no changes. The open source version of Qt5 was selected to create a graphical user interface program (GUI). Additionally, the design of the new linac is planned to be used in the 3 GeV synchrotron radiation facility project currently under construction in eastern Japan. Similar kind of hardware and control framework will be utilized for the project.

### INTRODUCTION

NewSUBARU is a soft X-ray synchrotron radiation facility with a 1.5 GeV electron storage ring having a circumference of 118 m [1]. It was built at the SPring-8 site and shared a linac of SPring-8 as an injector. The NewSUBARU started user experiments in January 2000. SPring-8 is a hard X-ray synchrotron radiation facility with an 8 GeV electron storage ring having a circumference of 1,436 m. It has a 140 m-long 1 GeV linac and an 8 GeV booster synchrotron having a circumference of 396 m as injectors and has been in service for user experiments since October 1997. SACLA is an X-ray free electron laser facility with a 400 m-long 8 GeV linac that was constructed at the SPring-8 site. The SACLA has been in service since March 2012.

In the SPring-8 upgrade project (SPring-8-II), a method for realizing an ultra-low emittance ring was studied. The plan consisted of drastically modifying the SPring-8 storage ring and injecting a low emittance beam of SACLA directly into the ring. This required the existing injectors, the linac, and the booster synchrotron of SPring-8, to be shut down. However, this would further show that NewSUBARU would no longer be operational. Therefore, a new 1 GeV linac had to be built exclusively for NewSUBARU. As it had to be installed in the existing beam transport tunnel, the linac was designed to be compact with a total length of 70 m and used C-band accelerating structures developed at the SACLA [2]. In July 2020, a beam injection from the SPring-8 linac to the NewSUBARU was completed and the installation of the new linac was started. The

commissioning of the linac started in February 2021, and two months later, in April, the user experiments at NewSUBARU were resumed. Figure 1 shows the layout before and after the new linac was installed at the NewSUBARU. A picture showing the NewSUBARU building and the new annex building for the new linac is illustrated in Figure 2.

Figure 1: Layout of the NewSUBARU before and after installation of the new linac.

Figure 2: NewSUBARU building and new annex building for the new linac.

Since 1995, MADOCA control framework has been developed and used for the SPring-8 and the SACLA [3]. In 2018, the MADOCA was upgraded for integrated operation of the SACLA and SPring-8 as part of the SPring-8-II [4-6]. Using this new control system, beam injection from the SACLA to the SPring-8 storage ring was started in 2020.

The NewSUBARU has adopted MADOCA as its control system since its introduction. With the construction of the new linac, it was natural to completely shift from the first MADOCA to the upgraded one. To operate the new linac and the existing storage ring together, a file server, the database servers, and the computer networks required further upgrading.

When upgrading an existing facility, the shutdown period must be as brief as possible. To achieve this, advance

<sup>†</sup> hosoda@spring8.or.jp

careful preparation and an efficient work plan for the shut-down period are vital. It was expected that changing the VME of the storage ring would require tremendous work, such as, checking the I/O of the equipment. Hence, it was decided to leave the VME mostly unchanged. In contrast, all the servers, networks, and software were upgraded.

This paper reports the upgraded NewSUBARU control system.

## EQUIPMENT CONTROL OF THE NEW LINAC

### MTCA.4

The RF system of the new linac consists of a gridded RF thermionic gun, a 238 MHz RF cavity, a 476 MHz sub-harmonic buncher, an S-band accelerating structure, and 16 high-gradient C-band accelerating structures. The low-level RF (LLRF) system of the SPring-8 storage ring was updated from conventional analog circuits to digital circuits using the MTCA.4 in 2016. From then on, the MTCA.4 has been operating for the LLRF system [7, 8]. Additionally, the MTCA.4 was selected for the LLRF system of the new linac.

As a high-speed AD/DA board for IQ modulation and demodulation of the RF signals, the Struck SIS8325 AMC board was utilized. This board had 10-channels of 250 Ms/s 16-bit ADCs, 2-channels 250 Ms/s 16-bit DACs, and an FPGA. For the FPGA logic, the following additional features were implemented along with the original logic: converting the data detected by the ADCs to the IQ signals; collecting the data at a fixed delay time from a master trigger signal of the linac; storing the waveforms in memory banks; and reading them out using a DMA transfer.

For the Rear Transition Modules (RTMs), which are responsible for the RF signal I/O and level adjustment, a newly manufactured Cadox 72DSR238A01 direct sampling board was used for 238 MHz and Struck DWC8VM1 down-conversion boards were used for other frequencies.

In 2018, a test bench of a gridded RF thermionic gun, a 238 MHz RF cavity, and a 476 MHz sub-harmonic buncher for the linac was constructed and the operation of the MTCA.4 was tested for them.

The C-band accelerating structure system for the linac was tested in May 2020 to evaluate its performance, including the LLRF system using an MTCA.4. The device control software running on the MTCA.4 CPU was developed in conjunction with the test.

The same SIS8325 AMC boards were used for the readout of the nine beam position monitors (BPMs) and five beam current transformers (CTs).

A newly developed MDT MMETRG01B AMC board was used to transmit a trigger signal. This AMC board had five SFP transceivers (one input and four outputs) on the front panel and was connected to the other boards via optical fibers. A high-speed serial signal with a bit rate of 1 Gbps and 8B/10B encoding was used to transmit the event code that defines when the trigger signals should be output. The delay time of the trigger signal could be set using a 24-bit coarse delay counter with a 238 MHz clock

and a 5-bit fine delay counter with 78 ps resolution. The board could handle 16 inputs and 16 outputs with a dedicated level converter connected via a connector mounted on the front panel. Furthermore, eight M-LVDS lines of the MTCA.4 backplane could be used for input and output, and the trigger signals were transmitted to the SIS8325s installed in the same chassis without any additional wiring.

The MMETRG01B was installed in the LLRF section of the storage ring to generate and transmit a master trigger signal. Four MMETRG01Bs were installed in the LLRF sections of the annex building for the new linac to receive the master trigger signal. They were connected using phase-stabilized optical fibers to avoid any temperature drift effects. Table 1 summarizes the AMC modules used in the five MTCA.4.

Table 1: AMC Modules Used in the Five MTCA.4

Host	Target equipment	AMC modules
1	linac master trigger, storage ring injection magnets/monitors trigger	MMETRG01B $\times$ 1
2	linac LLRF/HPRF/vacuum of gun, 238, 476	MMETRG01B $\times$ 1, AdXMC1573 $\times$ 1, SIS8325 $\times$ 3
3	linac LLRF/HPRF/vacuum of S-band, BPM $\times$ 3, CT $\times$ 4	MMETRG01B $\times$ 1, AdXMC1573 $\times$ 1, SIS8325 $\times$ 3
4	linac LLRF/HPRF/vacuum of C-band1, C-band2, BPM $\times$ 2	MMETRG01B $\times$ 1, AdXMC1573 $\times$ 1, SIS8325 $\times$ 5
5	linac LLRF/HPRF/vacuum of C-band3, C-band4, BPM $\times$ 4, CT $\times$ 1	MMETRG01B $\times$ 1, AdXMC1573 $\times$ 1, SIS8325 $\times$ 6

The MicroTCA Carrier Hub (MCH) and CPU board used were from N.A.T., and the operating system (OS) was the Ubuntu 16.04 LTS low latency kernel. The MCH had an intelligent platform management interface (IPMI) to monitor the status of each AMC board, air-cooling fan, power supply, and so on, from other servers via a network. We are testing to monitor those monitor values from a Zabbix server.

### EtherCAT

The MTCA.4 was used for the devices to treat high-speed wide-bandwidth data, whereas, the EtherCAT was used for relatively slow-speed devices [9].

PLCs were used in high-power RF (HPRF), such as, klystron power supplies and vacuum controllers. The PLCs were controlled using EtherCAT. The Advanet AdXMC1573 XMC EtherCAT master board was mounted on a Vadatech AMC105 PMC/XMC carrier and installed in each MTCA.4 chassis.

Additionally, EtherCAT was also used for magnet power supply control. To reduce the construction cost, a few magnet power supplies were reused that were no longer required at other accelerator in our site. These power supplies had optical remote I/O to connect to an OPT-CC VME board developed at SPring-8 as a field bus in the past. A gateway was prepared for EtherCAT and OPT-CC to accept

them. All the magnet power supplies were controlled using a PC server with an Advantec AdEXP5712 PCI Express EtherCAT master board.

Eight beam profile monitors were present for adjusting the beam position and shape by watching the screens. Stepper motors were driven to move the screens and adjust their focus. Moreover, the stepper motors were used to move the collimator to adjust the electron beam charge. Their positions were read by resolver counters. A second PC server with an EtherCAT master board was prepared to control the motor controllers and the resolvers.

The number of slaves for six EtherCAT masters is listed in Table 2.

Table 2: The Number of Slaves for Six EtherCAT Masters

Host	Target equipment	Number of slaves
1	linac gun PLC, 238 PLC, 476 PLC, vacuum PLC	4
2	linac S-band PLC, vacuum PLC × 2	3
3	linac C-band1 PLC, C-band2 PLC	2
4	linac C-band3 PLC, C-band4 PLC, vacuum PLC	3
5	linac magnet power supplies	65
6	linac beam profile monitor × 8, collimator, resolver counter	13

### GigE Vision Camera

To watch the beam image on the screen of a beam profile monitor, a GigE vision-enabled JAI GO-2400M camera was selected [10]. A PC server was set up and two Neousys Tech PCIe-PoE354at PoE-type network interface boards and a K. K. Rocky RCB-LVDS-TRIG8 trigger input counter board were installed. Eight cameras were directly connected to each port of the PCIe-PoE354at with Ethernet cables. Power supply control via Power-over-Ethernet was also performed. The RCB-LVDS-TRIG8 received the trigger signal and distributed the LVDS standard signal to the eight cameras using an Ethernet cable. Next, the TTL standard signal was input to the camera through the LVDS-TTL translator (RCB-LVDS2TTL).

The Aravis open source library was used for camera control and to read out the image data. The collected image data were stored on an NFS server in the HDF5 format with the associated meta-information such as camera gain and shutter speed.

## EQUIPMENT CONTROL OF THE EXISTING STORAGE RING

### VME

The storage ring control system consisted of subsystems of RF, magnet, vacuum, monitor, utility, and safety. Each subsystem was controlled using a VME equipped with Solaris 10 OS. As the control equipment for the storage ring was practically unchanged, the same CPU board, I/O board, and chassis were utilized.

A test bench for the RF control was constructed after the shutdown of the NewSUBARU in July 2020. The test bench was prepared to identify the libraries required to transition to a new control system, such as, the gcc4. It was confirmed that the updated equipment control software would work without any challenges. The RF control was chosen for the test because it had the largest number of I/O boards to handle, and only some of them were used in the NewSUBARU.

In the MADOCA framework, the executable files, and the configuration files for the equipment control software running on the VME CPU were placed on a file server. In December 2020, a dedicated file server for the NewSUBARU was installed, and the old mount point was changed to a new one. This allowed easy transfer to the new control system.

For the electron charge measurement system, an interrupt register board was added to collect the data synchronized with the injection trigger signal. The synchronized data acquisition software was prepared using the basic functions of the new control system.

## CONTROL FRAMEWORK

The new control framework of the NewSUBARU is the same as the one already in use at the SACLA/SPring-8.

In the framework, a system called the MDAQ is provided as the data acquisition software. MDAQ\_POL collects data at fixed time intervals of 1 to 10 s; MDAQ\_SYNC collects data synchronized with external triggers of 1 to 20 Hz; MDAQ\_IMG collects image data when requested with a maximum repetition rate of 1 Hz; and MDAQ\_WFM collects waveform data when requested with a maximum repetition rate of 20 Hz. The data collected by MDAQ\_POL and MDAQ\_SYNC were saved to an online database using the Cassandra database management system for storage. The image data collected by MDAQ\_IMG and the waveform data collected by MDAQ\_WFM were saved in a file server with an NFS mount, and their meta-information was saved in the online database. The number of registered signals collected by MDAQ\_POL, MDAQ\_SYNC, MDAQ\_IMG, and MDAQ\_WFM were 3,616, 729, 8, and 352, respectively.

To ensure that the NewSUBARU control system was completely independent of the SACLA/SPring-8 control system, a new file server, database servers, and a message server (MQTT broker) were installed in designated areas of the NewSUBARU building.

Moreover, the computer networks that connect the NewSUBARU building and the annex building of the linac were newly prepared.

## OPERATION GUI

As the new linac was inaugurated, the NewSUBARU control room was fully operational when compared to the previous setup where the SPring-8 linac operation was separate in the central SPring-8 control room. In the new layout of the control room, the number of operator consoles

was increased from two to six. The OS of the consoles was the SUSE Linux enterprise server 15.

Operational applications such as, accessing the log database and handling control messages are essential for maintaining the operational logic and/or sequence. They are usually in the GUI form. The open source version of the Qt5 was selected to create GUIs. The Qt plug-ins and function libraries were prepared in advance, for instance, message exchanges with child processes, forms, graph platforms, basic figure placement plug-ins, and thread-safe programming samples. For the linac, all the GUIs were newly built. For the storage ring, the old GUIs were all transferred to the Qt-based GUIs. The RF control GUI for the C-band is shown in Figure 3.

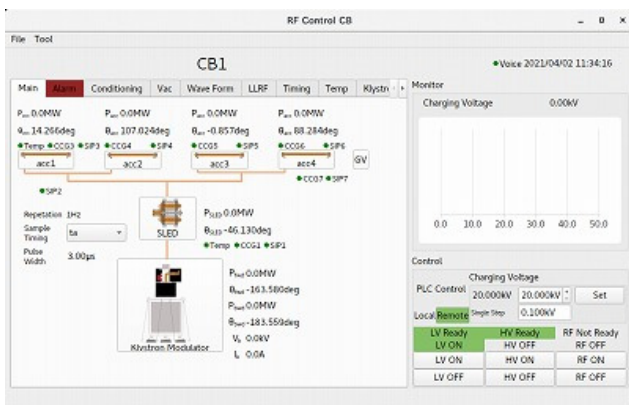

Figure 3: RF control GUI for the C-band.

## CONCLUSION

The high-performance dedicated new injector linac has started its operation at the NewSUBARU. This has facilitated the continuation of user experiments after the shutdown of the SPring-8 linac. In addition, the operational flexibility of the NewSUBARU was improved.

To construct the linac, five MTCA.4s were prepared for the RF and monitor, and three PC servers for the magnet power supply and beam profile monitor. Six VMEs of the storage ring were retained with virtually no changes. The maintenance of the VMEs and its replacement may pose a challenge in the future. All the operational GUIs were created using the Qt5. Updating the control system has significantly improved the operation of the NewSUBARU.

Further, the design of the new linac is planned to be used in the 3 GeV synchrotron radiation facility project currently under construction at the Tohoku University campus in eastern Japan [11]. The project plan includes utilizing the same equipment control hardware comprising the MTCA.4, EtherCAT, and GigE camera as well as the same control framework. The project is scheduled to observe its first light in the first half of 2023.

### Abstract

The RIKEN linear accelerator (RILAC), an injector of the Radioactive Isotope Beam Factory (RIBF) project, was upgraded by installing a superconducting RIKEN linear accelerator (SRILAC) and a 28-GHz ECR ion source (SRILAC project). In addition to controlling these two new apparatuses, the control system of the updated RILAC requires various improvements to the shortcomings of the previous RILAC control system, for example, control methods for electromagnet power supplies using GPIB, a low-performance machine protection system. Moreover, there were issues regarding the integration of small LabVIEW-based systems into the main part of the control system. For efficient operation in the SRILAC project, a distributed control system utilizing the Experimental Physics and Industrial Control System (EPICS) should be adopted in the other parts of RIBF. A higher-level application protocol needs to be integrated into the EPICS channel access protocol. We developed new systems to solve the issues mentioned above and introduced systems that have been proven in other facilities, such as Archiver Appliance as a data archive system. The control system was successfully upgraded and used in the SRILAC beam commissioning completed in 2020. The new control system is currently in its operational phase.

### INTRODUCTION

The RIKEN Radioactive Isotope Beam Factory (RIBF) accelerator facility comprises five cyclotrons and two linear accelerators. One of the linear accelerators, the RIKEN linear accelerator (RILAC) [1], has been utilized not only as an injector for cyclotrons but also for stand-alone experiments such as the synthesis of superheavy elements. As an upgrade project, to perform search experiments for superheavy elements with atomic numbers of 119 and higher [2], the superconducting RIKEN linear accelerator (SRILAC) has been introduced downstream of RILAC to enhance beam energy, and a 28-GHz superconducting electron cyclotron resonance ion source (28-GHz SC-ECRIS), similar to the existing RIKEN 28-GHz ECRIS[3], has been introduced at the frontend of RILAC to increase beam intensity [3].

The RIBF control system was constructed using a distributed control system based on the Experimental Physics

and Industrial Control System (EPICS) [4]. The new control system for the RILAC upgrade project should be constructed using the EPICS-based control system, and it should be integrated into the existing RIBF control system. The RILAC upgrade project includes various types of hardware such as a 28-GHz SC-ECRIS, beam energy position monitors (BEPM) [5], N<sub>2</sub> gas-jet curtain systems [6], and superconducting cavities [7]. Furthermore, the new control system requires improvements to the existing RILAC control system, such as a control method for electromagnet power supplies, a machine protection system, and a data archive system. The protocol for a higher-level application environment should be unified with the EPICS channel access (CA) protocol to enhance operational efficiency. We decided to mainly adopt programmable logic controllers (PLCs) to construct the system and utilize other methods for areas where application of PLCs is difficult considering our limited manpower and resources.

### RIKEN 28-GHZ SC-ECRIS CONTROL

The 28-GHz SC-ECRIS was commissioned in advance of the commissioning of other apparatuses. The control system comprises the following: control of ion-source-specific devices (e.g., gas flow controllers, an insertion device of material rods, a high-voltage power supply, and a gyrotron), control of superconducting electromagnet power supplies, and vacuum control [8]. The superconducting electromagnet power supplies embedded MELSEC-Q series as a PLC are connected via NetDev[9], which is an EPICS device support, and controlled by a PC-based EPICS input/output controller (IOC). On the contrary, the control of the ion-source-specific devices and the vacuum control mainly comprised FA-M3 PLCs manufactured by Yokogawa Electric Corporation. These systems have a multi-CPU configuration, a sequence CPU (F3SP71), and a Linux CPU (F3RP61-2L)[10]. Mainly, interlock logic is implemented on the sequence CPU, and EPICS required for higher-level applications is implemented on the Linux CPU.

In contrast to other control systems, some control stations with digital and analog modules need to be installed on the high-voltage stage with several tens of kilovolts. Therefore, the connection is insulated between the devices in the high-voltage stage and some devices on the ground level. The control system of the existing 28-GHz SC-ECRIS uses TCP/IP to exchange interlock signals between

<sup>†</sup> a-uchi@riken.jp

the safety system and the control stations in the high-voltage stage. To enhance reliability, the new control system uses two different types of CPUs in the main PLC station, which are connected to five PLC substations with star-topology field bus communication using optical fiber [11]. As a result, the interlock signal also exchanges to the control station on the high-voltage stage through field-bus communication using the optical fiber, and the system reliability was improved compared with the system using the TCP/IP-based interlock signal.

## MAGNET POWER SUPPLY CONTROL

The introduction of the 28-GHz ECRIS causes a layout change in the low-energy beam transport (LEBT) system, where new power supplies have been introduced to the electromagnets used. In contrast, several old electromagnet power supplies are used for the electromagnets used in medium-energy beam transport (MEBT) systems. The electromagnet power supplies for MEBT use GPIB as the communication protocol for the control system, and their performance is low compared with recent methods such as IP network-based systems. Therefore, we upgraded the control method of power supplies by replacing the GPIB communication with the VME-based method, which is the standard method of the RIBF control system.

In the VME-based method, electromagnet power supplies are controlled by NIO (NIO) system, as in the case of SPring-8 [12]. The NIO system comprises a master board (NIO-C) and a slave board (NIO-S). Optical fibers connect NIO-Ss to an NIO-C inserted in the VME chassis via a branch board. The EPICS IOC installed in VxWorks controls the object by accessing the shared RAM of the NIO-C, and a maximum of 43 NIO-S can be connected to each NIO-C.

For a high-energy beam transport (HEBT) system, old electromagnet power supplies are also used in the new system. Six of these electromagnet power supplies were remotely controlled by GPIB communication, similar to the MEBT system, and no interlock outputs were implemented for the machine protection system described later. As these power supplies were manufactured more than 20 years ago, converting them to the NIO method, as well as the MEBT electromagnet power supplies, has many limitations and is expensive. Therefore, the GPIB communication boards were removed from the MEBT magnet power supplies and the GPIB communication was modified with an easy-to-handle transistor-transistor-logic (TTL) communication by controlling the IO directly with PLC DI/DO.

The controller utilizes a two-CPU module configuration of F3SP71-4S and F3RP71-2L (see Fig. 1). The sequence CPU implements the core of hardware control, such as BIT output, to an electronic substrate, and a strobe signal timing. The Linux CPU module becomes the EPICS IOC and communicates with the man-machine interface to set the current value and provide the status of the electromagnet power supply. In the beam commissioning, approximately 30 modified electromagnet power supplies were controlled via the EPICS CA protocol without GPIB communication.

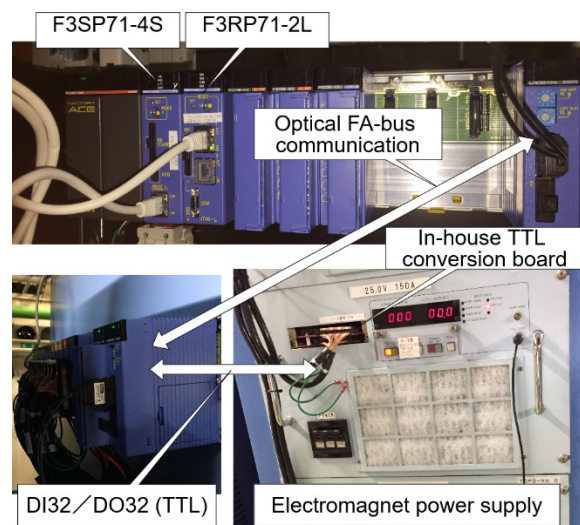

Figure 1: Example of a power supply updated from GPIB to TTL using FA-M3 PLC.

## MACHINE PROTECTION SYSTEM

### Motivation

In increasing the beam intensity and energy by this upgrade, hardware damage caused by failures of the accelerator components; for example, damage caused by unintended beam orbit changes, will be more serious. As a result, it may cause problems for the beamline components of the HEBT and experimental equipment. In addition, we must prevent problems occurring at the superconducting cavities of SRILAC, such as quenching due to vacuum deterioration caused by beam loss. Therefore, the machine protection system, which is a mechanism to protect the hardware from high-power beams, needs to have a higher performance than before. Before the SRILAC project, the interlock system used in RILAC was realized only via hardware combined with mechanical relays. As a result, the versatility of conventional systems is not high, and hardware circuit modification is required when the input signals are increased, or the logic is changed.

The above-mentioned machine protection system aims to protect hardware from damage caused by beams. In addition, a human protection system is required to secure the radiation safety of individuals involved in accelerator operations and experiments. These two safety systems have different purposes, and systems dedicated to their own purposes should be installed. However, both functions—machine protection and human protection—were implemented in one system, and the wiring and logic were very complicated.

### Beam Interlock System

In the RIBF accelerator facility other than RILAC, a beam interlock system (BIS) was introduced in 2006 as a machine protection system. The BIS is a system that stops the beam immediately by exciting a beam chopper that deflects a beam just downstream of the ion sources. The BIS

also inserts one of the Faraday cups that is pre-assigned according to the position of the trouble. The BIS uses the MELSEC-Q series as the PLCs [13]. The RIBF BIS comprises five stations. Each station has a CPU module (or modules) and is connected to each other by a MELSECNET/H loop configuration for inter-CPU communication.

### System Requirements

In developing a machine protection system for the SRILAC project, the following requirements should be fulfilled [14]:

- Avoid as much complexity as possible in both the hardware and software. Human protection and machine protection should be clearly separated.
- The main part of the system logic should follow the RIBF BIS.
- Select hardware that can be maintained for a long time.
- The entire system development and operation process should be completed within our group to enable system modifications and quick troubleshooting.
- A higher-level system will be developed based on EPICS Channel Access (CA), which is the standard control protocol in RIBF.
- A much faster response is required to protect superconducting cavities than the usual response performance achieved by general PLCs.
- The system is scalable, enabling us to accommodate a sudden increase in interlock signals that are urgently required.

### Specification

We decided to use FA-M3 PLCs for the BIS of the upgraded RILAC (hereafter, SRILAC BIS). FA-M3 PLCs have been utilized in many RIBF projects [15] and are widely used in safety systems. Because the number of program steps was observed to be large in the prototype, the F3SP76-7S, the most powerful CPU module at the time of system construction, was adopted as the sequence CPU module. The main sequences of the SRILAC BIS were implemented on the F3SP76-7S, a Linux CPU, F3RP71-2L, was also installed as a means of realizing higher-level systems such as the user interface with EPICS, resulting in a multi-CPU configuration.

### Communication

The SRILAC BIS avoids the use of inter-CPU communication, and the main unit with the CPU module installed communicates with seven sub-units via an optical FA bus. In this system, the FA bus network is redundantly configured with an optical fiber loop. Based on the cable length and the number of input points, the I/O refresh time of the FA link was estimated to be approximately 110  $\mu$ s in this configuration.

### System Logic

As shown in Fig. 2, various accelerator components and monitors the input interlock signals to the SRILAC BIS

and the SRILAC BIS output signals activating the beam chopper switch. Accelerator operators can set the options of the BIS, such as enable/disable interlock, trigger level of analogue inputs, and holding/unholding alarm status for each input signal according to the operation mode. When an anomaly is detected, the chopper stops the beam and inserts the Faraday cup predetermined according to the position of the anomaly.

Table 1: Number of I/O Signal Points Used in the Main Unit and Seven Sub-units of SRILAC BIS. The numbers without parentheses shows the number of I/Os installed and those in parentheses are the number of I/Os actually used as of October 2021.

	Main	#1	#2	#3	#4	#5	#6	#7
DI	56 (36)	56 (41)	32 (29)	32 (32)	32 (28)	32 (17)	32 (10)	0
DO	56 (8)	56 (2)	32 (4)	32 (6)	32 (0)	32 (0)	32 (2)	0
AI	8 (1)	8 (1)	8 (8)	8 (0)	8 (0)	8 (0)	8 (0)	0

### I/Os

In general, PLCs can realize a system with a relatively slow response time of a few milliseconds by using standard input modules and transistor output modules (standard I/Os). On the contrary, to realize a system with a response time faster than 1 ms, a field-programmable gate array (FPGA) is selected [14]. In the case of the SRILAC operation, a fast response time is required to stop the beam when triggered by discharges occurring in superconducting cavities. We selected the FPGA-based high-speed IO module (F3DF01: FPIO module) [16] to implement the logic. It has 24 input points and 24 output points as high-speed I/Os with an embedded Xilinx Spartan®-6 LX FPGA. As the logic can be implemented without going through the sequence CPU module, it can be processed in parallel without being affected by the scan time of the program running on the sequence CPU module side. In this system, each input signal of the FPIO module is enabled/disabled via the internal registers of F3SP76-7S. Table 1 lists the number of inputs and outputs used in SRILAC operation.

### Performance

The response speed of standard I/O was measured. The conditions were as follows: an interlock signal was input to the F3XD32-3F of subunit #6 at a 100-Hz repetition rate, and the system response time between the input signal and the corresponding output signal to the chopper switch was measured. We confirmed that the system operated at an average of 6 ms. We also measured high-speed I/O. An interlock signal of 100 Hz was input to the FPIO module installed in the main unit, and the time until the output signal to the chopper switch was measured as approximately 78  $\mu$ s.

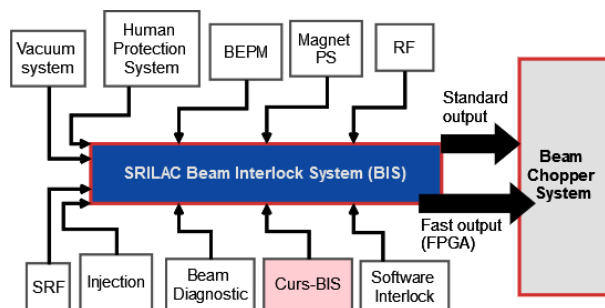

Figure 2: Flowchart of the entire system of machine protection for RILAC operation. The SRILAC BIS is shown as the central blue box. The beam is stopped by the beam chopper by inputting the interlock signals from other systems. There are two outputs—fast and standard.

### Curs-BIS

During the SRILAC beam commissioning, a software interlock based on CA was used to detect fluctuations in the excitation currents of the magnet power supplies. Although the software interlock is easy to implement, its reliability and response performance are not high. As the sub-system of RIBF BIS, a beam interlock system driven by a change in current (Curs-BIS) [17] has been developed and used to protect hardware from unintentional changes in the excitation currents of the magnet power supplies. The Curs-BIS has been verified to be effective based on the operation experience of the RIBF BIS up to October 2021, and it has also been introduced to the SRILAC BIS in that all electromagnet power supplies upstream the cryomodules of SRILAC are included. In the near future, Curs-BIS will be installed in all magnet power supplies, including other courses in RILAC.

## INTEGRATION WITH SCADA SYSTEM

The MELSEC iQ-R series PLCs are utilized as the controller for monitoring three SRILAC cryomodules, a differential-pumping system, and the readout and settings of the low-level radio frequency (LLRF) system. They work as supervisory control and data acquisition (SCADA) systems. To implement higher-level applications, they should also be integrated into the EPICS.

In the case of EPICS, NetDev as the device support software is adopted to interface the MELSEC iQ-R series with EPICS IOCs, because the MELSEC communication protocol (MC protocol) is a communication protocol with other systems, as in the conventional MELSEC Q series. The IOCs are called virtual-IOCs, which are constructed on a Linux environment with VMware vSphere Standard, and four PLCs for the LLRF system, cryomodules, and the differential-pumping system, are connected to five IOCs, with approximately 5,000 process variables (PVs) in operation.

## LABVIEW-BASED SYSTEM

In the control system of the SRILAC project, not only the EPICS IOC running on Linux but also the Windows-

based EPICS IOCs are in operation for the BEPM [5] and N<sub>2</sub> gas-jet curtain system [6], and control systems were developed based on LabVIEW. The advantage of the LabVIEW-based system is that the hardware interface is often already provided, and thus development costs can be reduced. On the contrary, LabVIEW-based systems are often operated as two-layer control systems that comprise a PC and devices. We introduced CALab [18] into these LabVIEW-based systems as a SoftIOC, which behaves as a Windows IOC. As a result, these LabVIEW-based systems have been successfully integrated into other EPICS-based systems.

## HIGHER-LEVEL APPLICATION

### Data Archive System

With the number of archived data points expected to increase dramatically owing to the operation of SRILAC, the Archiver Appliance was deployed to improve the data archiving performance [19]. Since 2009, RIBF has been using the RIBF control archive system (RIBFCAS) developed by RIKEN Nishina Center as a data archive system for the data generated by the EPICS IOCs [20]. In contrast, MyDAQ2, developed at SPring-8 as a data store, was also introduced mainly for non-EPICS-based systems [21]. In the RIBF control system, MyDAQ2 is utilized not only as a data store, but also as a method to read data from a non-EPICS-based system through an EPICS CA without EPICS device support software [22]. To realize a user-friendly system for data visualization, the data of RIBFCAS, MyDAQ2, and Archiver Appliance should be visualized on the same system. Therefore, we herein developed a system that implements a Web API to convert RIBFCAS and MyDAQ2 data into the JSON format, thereby making it possible to unify the data format with the Archiver Appliance and display the data with the same viewer software. The maximum data-acquisition cycle was improved to 10 Hz, compared to a cycle of 1 to 20 s in conventional systems.

### Operator Interface

To develop the operator interface (OPI) for SRILAC, we use Control System Studio (CSS) as well as MEDM/EDM, which we have been using for a long time. The developed RF control screen for the SRILAC is shown in Fig. 3. In the case of MEDM/EDM, the GUIs are developed on a server installing CentOS7.7, and the developed GUIs are displayed on the screen of each local machine by X11 forwarding. Therefore, the development and execution of the GUIs are performed on the same server. On the contrary, in the case of CSS, running multiple instances on a server is difficult; therefore, CSS is installed separately in each local environment. At this time, we introduced ownCloud [23] as a means of sharing the most recent OPI files with the executors. ownCloud is a system that allows us to introduce online storage such as Google Drive through an intranet and is effective in overcoming the complexity of file sharing using NFS, wherein detailed access control of OPI files to users is difficult.

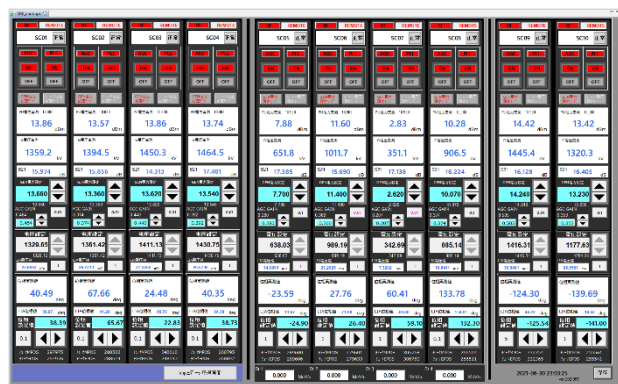

Figure 3: Screenshot of superconducting radio frequency cavities control panel developed by CSS.

## CONCLUSION

New control systems have been developed for components newly introduced in the SRILAC project. In addition, several improvements have been made to solve the limitations of controlling the existing components used in RILAC. The development and implementation of the SRILAC BIS were successfully completed. The anomaly signals from all magnet power supplies, RF systems, and vacuum gate valves are input to the SRILAC BIS, and the beam can be immediately stopped to protect the hardware by triggering the beam chopper. The integration of the LabVIEW-based system into EPICS, which had been a serious issue in the past RIBF control system, was also accomplished, and higher-level applications can now be developed in a unified manner using the CA protocol. As a result of these efforts, beam commissioning was successfully completed in 2020.

## ACKNOWLEDGEMENT

The authors would like to thank Dr. Rok Hrovatin in Cosylab for technical advice with development of the machine protection system.

## Abstract

As a large complex fusion research device for studying field reversed configuration (FRC) plasma, HUST FRC (HFRC) is composed of many subsystems. In order to coordinate all systems and ensure the correct, orderly and stable operation of the whole experimental device, it is very important to have a unified and powerful control system.

HFRC SCADA (Supervisory Control And Data Acquisition) system has selected the in-house developed CFET (Control system Framework for Experimental Devices Toolkit) as the control framework, with advantages of strong abstraction, simplified framework, transparent protocol and flexible extension due to Web technology.

## Introduction

Growing worldwide demand for energy, and problems of scarcity and environmental impact associated with conventional sources are the challenges facing humanity [1]. The energy industry is facing decades of transformation. On a longer scale, nuclear fusion will be part of a catalog of more sustainable energy sources [2].

Field-reversed Configuration (FRC) has the advantages of complete axis symmetry, relatively simple structure,  $\beta \sim 1$  and so on [3]. Therefore, it is of great significance for the research of new fusion configuration, and the future exploration of miniaturization and economization of the fusion reactors [4, 5]. HUST Field-Reversed Configuration (HFRC) is a pre-research platform for field-reversed configuration research device based on plasma's colliding and merging, which is under development.

HFRC is composed of many subsystems such as magnets, vacuum, power, and diagnostics. It's important to have a unified control system considering the diversity and complexity of the subsystems. This paper describes the design and implementation of control system specially designed for HFRC.

HFRC SCADA (Supervisory Control And Data Acquisition) system includes the global control system, which coordinate all subsystems, and control systems in various subsystems such as the pulse power supply control system. It also offers a customizable and pluggable web based HMI for better operation. Users can design the HMI by simply dragging and dropping widgets in the browser.

At present, HFRC SCADA has been initially deployed in daily experiments of HFRC, which will provide valuable

experiences for future control system design of large experimental device.

## Design of HFRC SCADA

**Micro Service** HFRC SCADA adopted the decentralized model on the whole, and it can mainly be divided into two parts: central control system and subsystems. The main function of central control system is to coordinate the run of whole experimental device, and all subsystems need access plant operate network and accept the monitoring and the dispatch from central control system. The main subsystems are charger control system, pulse power control system, central timing control system, distributed timing control system and data acquisition system. Each subsystem offers different service to others. Fig.1 shows the overall structure of the whole system.

Figure 1: Overall structure of the whole system.

HFRC SCADA builds the whole system as a suite of small services, each running in its own process and are independently deployable. Adopting micro services makes HFRC SCADA simpler to deploy and understand, and minimizing the risk of change.

**FSM (Finite State Machine) Pattern** The discharge process of HFRC can be seen as a sequential transitions of states. HFRC SCADA uses FSM mode to control the flow of discharging and handle exceptions.

FSM is reliable, easy to understand, predictable and safe. There is only one state active at any one time, which drastically reduces the chance of unforeseen errors or unexpected behavior in the system.

**Observer Pattern** In observer pattern, any other object can be registered on an observed object, which will function as an observer. The first object, also called the subject, informs registered observers each time it is modified [6].

As HFRC SCADA is a distributed event handling system, observer pattern works well in implementing coordination of subsystems. Each subsystem can act as both an observer and a subject.

<sup>†</sup> email address: wfy@hust.edu.cn

**CFET** HFRC SCADA selects the in-house developed CFET (Control system Framework for Experimental Devices Toolkit) as the control framework. CFET is a general software framework for fusion device integrated control system development based on Web technology, and can be used as supervisory control and data acquisition (SCADA) software.

Based on the technology of Web, CFET adopts HTTP protocol and RESTful design principle as the general communication protocol of the system. Under the CFET framework, the object realizing the same business function logic is called as a Thing. As is shown in Fig. 2, all resources in CFET system can be accessed by an URL through the internet. It is just the same as the URL we meet in the browser and someplace else. The head of the under UDA is the address of the CFET Host and in the end is the query string. One URL can locate an resource of a CFET Thing in a CFET Host of a CFET CODAC system [7].

Figure 2: CFET abstract model.

Under the CFET framework, each subsystem can access plant operate network and realize the function of coordination and monitoring.

### Hardware Module

The most commonly used field-reversed plasma formation method is based on the Field-Reversed Theta-Pinch (FRTTP) formation [8]. HFRC device is mainly divided into plasma formation area, collision fusion and compression area. The FRTTP is located in the formation area and is mainly used for the formation and injection of FRC plasma. The control system controls the discharge process mainly by orchestrating the power supply in the formation area.

In order to obtain the desired results, HFRC has strict requirements on the discharge timing. If the trigger timing deviates more than expected, the obtained current waveform will not match the expected one, and the result will be unsatisfactory. Considering the adaptability to the CFET framework and the problem of generating the trigger timing signal with high accuracy, the formation area power controller is developed independently.

As is shown in Fig. 3, formation area power controller hardware mainly includes MCU real-time slow control board, FPGA trigger board, AC-220V to DC-12V power supply, three-terminal interface and 1U Standard Chassis.

MCU real-time slow control board is responsible for the generation of slow control signals, such as heating signals, temperature signals. FPGA trigger board generates high-precision trigger signals.

Figure 3: The formation area power controller.

### Data Acquisition, Archive and Access

Data acquisition subsystem adopts CFET as framework. CFET's high robustness and low coupling performance allow the subsystem to be deployed in HFRC and other systems with data acquisition requirements.

Data acquisition subsystem is compatible with common formats of data storage and provides full support for files in formats such as HDF5. Both data file and MDSplus are supported to upload experimental data. The MongoDB database is used as the underlying software for the experimental file data access.

HFRC data acquisition subsystem offers different ways of accessing data with full functionality, simplicity and high performance.

### HMI

HFRC SCADA implements HMI based on Web technology. Users only need a browser to supervise control and acquire experimental data. HMI also supports UI customization, which means users are able to design their own interfaces. Figure 4 shows the current global control interface.

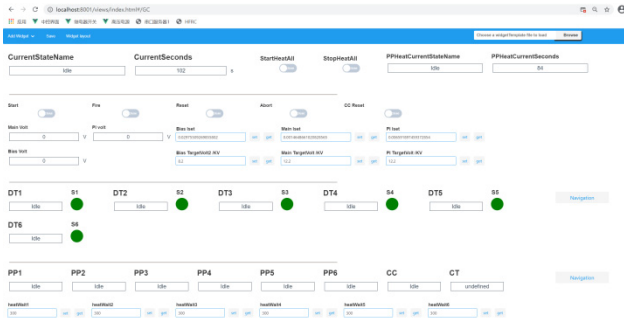

Figure 4: The global control interface.

### CONCLUSION

This paper introduces the design and implement of Web Based SCADA System for HFRC in terms of the overall design of the system, hardware module, data acquisition and HMI. HFRC SCADA is able to orchestrate all the instruments and devices to conduct a successful experiment, as well as collect and archive the scientific data generated during the experiments. It also offers a customizable and pluggable web based HMI for better operation.

# CERN SCADA SYSTEMS 2020 LARGE UPGRADE CAMPAIGN RETROSPECTIVE

Lukasz Goralczyk<sup>†</sup>, Alexandros Foivos Kostopoulos, Brad Schofield, Jean-Charles Tournier  
CERN, Geneva, Switzerland

## Abstract

In this paper we report the experience from a large-scale upgrade campaign of SCADA control systems performed during the second LHC Long Shutdown at CERN. Such periodical upgrades are dictated by the ever evolving SCADA WinCC OA system and the CERN frameworks evolution used in those control systems. These upgrades concern: accelerator control systems, e.g. quench protection system, powering interlocks, magnet alignment; control systems devoted to accelerator facilities such as cryogenics, vacuum, gas and other global technical infrastructure systems as well as the CERN electrical distribution system.

Since there are more than 200 SCADA projects covering the CERN accelerator complex and technical infrastructure, any disruption requires careful coordination, planning and execution with process owners. Having gained experience from previous campaigns and reaching a new level of automation we were able to make visible improvements by shortening the required time and reducing the personnel required. Activities, lessons learned and further improvements are presented as well as a comprehensive statistical insight of the whole campaign.

## INTRODUCTION

Software upgrades are an inherent process in modern computing which also applies for present-day SCADA (Supervisory Control And Data Acquisition) applications and the infrastructure in which they run. Upgrades are a necessity to keep systems secure, provide new features and avoid software obsolescence.

At CERN there are numerous industrial control systems in different domains such as machine protection, cryogenics, cooling and ventilation and the electrical distribution system. Together they account for a total of around 200 SCADA applications. These applications are often critical for the operation of CERN's accelerator complex and experiments. The large number and broad scope of these applications poses several challenges with respect to upgrades, a key challenge being the creation of an upgrade plan which does not interfere with the operation schedule.

At the end of 2018 CERN entered its second Long Shutdown (LS2) period that normally lasts around two years (in 2020 due to COVID-19 pandemic, it was extended). This was a perfect opportunity to perform a large-scale campaign to upgrade SCADA applications to the latest software packages, as well as to perform some

housekeeping activities (e.g. server maintenance). In most cases, operational constraints are not as strict as is normally the case outside of long shutdown periods.

In this paper we give an insight into the upgrade campaign that took place in 2020. We start by giving details about the motivation behind the upgrades, planning goals and the scope. Differences with the previous campaign, carried out in 2017, will be also discussed. Improvements implemented from that campaign, as well as new enhancements are a topic of another chapter. We follow by presenting details about our experiences – the good and the bad. We conclude with proposals for further improvements.

For details about the SCADA service at CERN as well as software and infrastructure details, the reader is referred to [1].

## MOTIVATION, SCOPE AND PLANNING

For the 2020 campaign the motivation was:

1. Siemens/ETM has decided to stop providing support for the version 3.15 of WinCC OA [2], the software used for most of the SCADA applications at CERN. It was, therefore, necessary to upgrade all the CERN WinCC OA-based SCADA systems to the latest version of WinCC OA.
2. New features that came with the updated JCOP [3] and UNICOS frameworks [4] depended on newer releases of WinCC OA.
3. Relaxed intervention restrictions given by the LS2 period.

Planning activities started several months before LS2 began. Similarly to the 2017 upgrade campaign all control domain representatives were interviewed to gain information about the planning restrictions, acceptable downtime and any additional requests. It was also an opportunity to present how the upgrades would be executed.

With this data gathered, an initial schedule was proposed and later agreed upon with the representatives. The upgrade calendar had to take into account some restrictions as: criticality, overlap with other upgrades, operation schedule and availability of experts.

Despite the long duration of LS2, the initial assumption was to finish all upgrades in less than 6 months, with the majority of applications upgraded in the first quarter of 2020. The COVID-19 pandemic forced us to put all pending upgrades on hold, abandon the initial schedule and, later, adjust it again conditioned by the COVID-19 protective measures (e.g. teleworking). This resulted in the upgrades being spread throughout the year.

<sup>†</sup> lukasz.goralczyk@cern.ch

The initial scope of the upgrade was around 250 applications, but with some major improvements and the consequent simplification in the number of applications in one of the largest control project at CERN, the Quench Protection System, the scope was reduced to around 200.

## COMPARISON WITH 2017 CAMPAIGN

There are several differences when compared with the previous SCADA applications upgrade campaign; these are summarized in Table 1.

Due to the relatively minor number of changes in the new WinCC OA version, the JCOP and UNICOS frameworks did not require as many adaptations as in the 2017 campaign. This allowed for a shorter testing period. One major change was the switch from the ISO8859-1 character encoding to UTF-8. Care had to be taken to ensure that the upgraded applications text was displayed correctly, as well as not to cause any internal problems.

Table 1: Upgrade Campaign Comparison

Campaign	2017	2020
WinCC OA	3.11 → 3.15 major change	3.15 → 3.16 minor change
Character encoding	ISO8859-1	UTF-8
Operating system	SLC6 <sup>1</sup> → CC7	CC7 minor version
Timing and planning	EYETS <sup>2</sup> strict	LS2 relaxed
Resources	7 persons	4 persons
Tooling	Graphical user interface (GUI)	Command line interface (CLI)

In the previous campaign, a major change in the operating system (OS) was a hurdle as it was a considerable change, significantly extending upgrade time, requiring extra staff and a notably larger validation period. The campaign in 2020 had only a minor OS version change and its validation with a newer WinCC OA software was shorter and smoother.

The LS2 period was longer than EYETS (End of the Year Extended Technical Stop) allowing for a more relaxed planning, although the initial assumption was to finish the upgrades in the first half of 2020, with the majority of them in the first quarter. It's worth noting that despite the fact that a number of industrial installations were not operational, many of their control systems were still in production and required utmost care in planning and execution.

It's important to mention that other aspects of the process have not changed; these include:

1. Upgrade schedule to strictly follow directives from control domain representatives.
2. Individual upgrades execution composed of many individual steps: around 70.

<sup>1</sup>Scientific Linux CERN

<sup>2</sup>Extended Year-End Technical Stop

3. Close cooperation with controls representatives to ensure proper operation after the upgrade.

## TOOLING IMPROVEMENTS

New tooling around the upgrade process was built on the previous collection of Python and bash scripts and libraries that interacted with WinCC OA.

Two new main tools were developed: *wccadm*, a Python 3 library to interact with WinCC OA and *wccauto*, a simple Python 3 framework to execute predefined steps. *wccadm* substituted a previous, similar, library which was based on unsupported Python 2. It aims to be a more reliable and complete interaction environment for WinCC OA. A major effort was made to make it easy to develop with as well as to have a richer logging support. Well formed and informational (debug) messages turned out to be crucial in the validation and, later, in the execution phase of the upgrade.

*wccauto* is an environment to develop specialised modules and execute them in a predefined order. Each module implements one particular function, which can be something as simple as displaying a message or, a more complex functionality like saving the SCADA application health status. *wccauto* is also an execution environment, where a predefined set of steps (modules), called plans, are run in an orderly manner (examples of steps could be 'display a message', 'copy a file', 'start the application'). It provides a command line interface and collects detailed logs from the upgrade. A typical production plan consisted of around 70 steps. Depending on the needs, a plan could be adjusted for non-standard applications.

The new tools exclusively use a command line interface (CLI); this differs from the previous approach which provided a graphical user interface (GUI). The switch simplified the execution as only a secure shell (ssh) connection was needed. It also allowed automatic offline tests performed on backups of production SCADA applications; a special non-interactive plan was used for that purpose.

Some of the upgrade steps that previously had to be executed manually were automated, leaving only a handful of operations requiring attention. The majority of the steps would execute automatically one-by-one. The tools would always provide feedback messages of what is being currently done. In case of a problem, a clear error message would be displayed with, if possible, a proposed solution. A number of pre-flight checks were done before the upgrade to detect problems early and save precious time later.

In addition to *wccadm* and *wccauto*, some supplementary programs were created including one to take and compare screenshots of synoptic views before and after the upgrade. This tool was used to detect differences in panel rendering between the old and the new version of WinCC OA, including problems related to the character encoding switch from ISO8859-1 to UTF-8. At least one bug in a panel widget, used by many applications was detected and fixed, as well as multiple

panels in the PSEN application, used to supervise CERN's electrical network.

Each upgrade would produce a detailed log that would be recorded in the ticketing system. It also provided a source for post-upgrade analysis of the process. Bottlenecks could be identified and further improvements could be proposed.

## CHALLENGES

Such a large scale upgrade, spanning across many control domains, poses several challenges, both at the preparation phase as well as during the execution period.

The creation of the schedule started by meeting with all control domain representatives. The purpose was to present early enough the upgrade, explain the impact on the supervision layer and the availability of the control system to the operation team and learn if there were any operational restrictions and when the upgrade should not be done.

After collecting this initial data a draft of the schedule was created. It grouped SCADA applications by their domains and planned them such that all of them would be done before mid of 2020. Any restrictions and particular wishes were taken into account. Special gaps were introduced to allow rest time for the team and as a safety net in case of unforeseen problems. Naturally the schedule would evolve with time as teams would make adjustments.

One serious, unforeseen external event that interfered with the schedule was the start of the COVID-19 pandemic. At the very beginning, as events quickly developed, we decided to put planned upgrades on hold (with some exceptions). Later we cancelled the current schedule and changed the modus operandi to a more ad-hoc planning. In the end a new schedule was created and agreed with representatives for the remaining SCADA applications. Due to lockdown and the resulting restrictions of on-site presence at CERN, it became clear that it would be necessary to perform upgrades remotely. Initially we approached this with great caution. With time we gained confidence and could resume the upgrades, doing them almost exclusively remotely. See Fig. 1.

Figure 1: Comparison of upgrade counts in time between initial and adjusted planning.

At any point in time the schedule had to take into account fewer staff availability compared to the previous campaign. It was desired that the load should not reach 100% in order to give time for other parallel activities like

support, operations or other developments. Thanks to the improved tooling and documentation the process was not as taxing as with the previous upgrade. For numerous applications the upgrade could run mostly in the background.

## WHAT WENT WELL

Despite changes in the schedule and fewer committed resources, we succeeded in upgrading all the SCADA applications.

Developed tools and procedures proved to work well and be very reliable. They provided an intuitive interface with clear instructions on what to do and displaying the currently executed operation. In case of problems, a clear and understandable message would be displayed. Complexity of the process was well hidden from the user. Even after a longer break there was no need for an earlier procedure review as following the tool simple instructions was enough. It is important to mention that the same procedure (a plan, which as mentioned before, is a series of simple steps to be executed) was applied to the majority of the upgrades, thus avoiding possible confusion from constant changes. Parallel upgrades were possible and performed whenever possible thus greatly reducing the impact on supervision unavailability.

The ability to easily change the upgrade plan allowed us to adopt the process to non-standard SCADA applications (see Fig. 2). Additionally any reports of possible improvements would be easily accommodated in the upgrade plan.

Figure 2: The number of projects using an upgrade plan (vertical axis) vs the time each plan was first used.

A key factor to the success of the campaign was the massive offline testing of the upgrade procedure done before the execution phase. It gave us the confidence especially needed for newly developed tools. A number of problems were detected thanks to detailed logs collected during the test run.

The announced total time needed for a single application upgrade was set to 4 hours initially, based on the experience of the 2017 campaign, but was then reduced to 2 hours, due to improvements made to the tooling. After the expected initial learning phase, the time was further reduced to 1 hour. See also Fig. 3.

Figure 3: How upgrade time changed throughout the whole campaign.

The LS2 period gave us the comfort of a more relaxed upgrade schedule. Despite ongoing interventions we could still find time to provide support and respond to other client requests.

Finally, the rich logs produced during the upgrades gave us an interesting insight on the whole process, such as where the bottlenecks were, and what the most common errors were in the process. The analysis will prove useful in indicating what to improve in the future.

## WHAT DID NOT GO WELL

Not everything went as planned and there were a couple of obstacles we needed to overcome. This section presents the lessons learned from events that didn't go well.

The execution planning was done using an Excel spreadsheet. This was initially a good choice because of its simplicity and ability to view it online using existing infrastructure. Data present in the spreadsheet was later used to create tickets in a tracking system (Atlassian Jira [5]), to enable traceability and integration with a shared calendar (Outlook). This combination was not well suited for constant, large changes. Applying changes to a selected set of tickets was time consuming. A solution to this problem would be to use a dedicated tool that would interact with the ticketing system and a shared calendar. It could also automatically create an initial schedule given some basic rules.

Despite the effort put into the automation of the process, manual steps still existed. List of top 4 slowest steps can be found in Table 2, majority of them is manual. Their automation was either not possible or too costly in terms of time. Automation not only saves time, but also prevents mistakes – we experienced that a couple of times. After the upgrades were completed some of those manual steps were automated. For changes in external systems we contacted other teams to help us with the automation.

In several instances, multiple applications were upgraded in parallel. This was due to various reasons, like a request from the control domain representative or the fact that applications hosted on the same server must be upgraded at the same time. In most cases, this parallelism saved time. It was, however, very onerous for the person performing the upgrade, and could negatively affect the

timing, even at the presence of any single problem. The lesson learned was to put a limit on the number of parallel upgrades handled per person; this could be an input for a future automatic scheduling tool.

Table 2: Top 4 Slowest Upgrade Steps (Median)

Upgrade Step	Manual	Time in Minutes
Update of application start-up scripts	Yes	6
Pre-upgrade scripts	Yes	3.5
Post-upgrade backup	Yes	3.5
JCOP and UNICOS components upgrade	No	2.5

We also encountered a problem with the SCADA software we use – WinCC OA. Despite extensive testing and validation, a few weeks after the first applications were upgraded, a memory leak caused a crash. The problem manifested itself under very specific conditions. Upgrades were temporarily put on hold and a fix was quickly provided and applied to the already upgraded applications. Intentional gaps in time, that were strategically inserted in the planning from the beginning, helped mitigate the impact of various unexpected delays on the overall schedule.

## FUTURE IMPROVEMENTS

After the last application was upgraded we already had a good idea about future improvements.

The key to further reduction in the upgrade time is the automation of the remaining manual steps. This will also open the door to an interaction-less upgrade. The revert (start from scratch) operation should also be automated – in specific cases, when an upgrade needed to be repeated, this was done manually.

The most natural evolution of our tools would be to incorporate Ansible [6], an IT automation solution, which perfectly fits our needs. It provides, out of the box, the functionality of *wccauto* and much more. Rich features and plugins can make the process even more resilient to problems and scale better.

These advancements in the tooling should allow us to do offline upgrades, a method in which the process is performed outside of the production system. This method was previously proposed in [1]. The planned use of SCADA applications inside containers could give us similar opportunities.

We should also consider using a dedicated scheduling software, that, based on resource constraints, will automatically create/adjust the planning of the upgrades. This could be either an in-house developed or an existing commercial or open-source software, and it would be a great aid during the initial phase as well as later in the campaign, when changes are unavoidable.

## CONCLUSION

The CERN SCADA systems upgrade in 2020 followed a steady incremental progress. Flexibility and adaptability in the planning were needed in order to accommodate the operational restrictions posed by the different domains.

The effort placed on automation paid off, by enabling more efficient, agile and error-free upgrades.

The success of the campaign was visible on the overall decreasing intervention times per upgrade and, in particular, on the less human resources needed. The improvements introduced in the tooling were essential to reach this achievement.

The experience gained during the previous campaign in 2017 constituted the base of this accomplishment.

# LINAC-200 GUN CONTROL SYSTEM: STATUS AND PLANS

M. Nozdrin\*, V. Kobets, V. Minashkin, A. Trifonov  
Joint Institute for Nuclear Research, Dubna, Russia

## Abstract

Due to the development of the global Tango-based control system for Linac-200 accelerator, the new electron gun control system software was developed. Major gun electronics modification is foreseen. Current gun control system status and modification plans are reported.

## INTRODUCTION

Linac-200 accelerator [1] is the core of the new electron test beam facility in JINR. It's quite hard to obtain necessary beam quality with standalone control subsystems, so the new global control system based on Tango is being developed [2]. In the frame of this work the existing gun control system part based on a standalone PC should be exchanged to a new one (Tango device & corresponding client).

## HARDWARE

### Electron Gun

Triode MIT-designed DC gun is used [3, 4]. Gun is placed in the SF<sub>6</sub> filled tank (pressure 6 atm) for better electric durability. Gun and cathode parameters are given in Tables 1 and 2 correspondingly.

Table 1: Parameters of the Linac-200 Gun

Type	Thermionic
Max. energy	400 keV
Beam intensity (peak)	200 mA
Normalized emittance	8 $\pi$ mm mrad
Pulse duration	200 mA

Table 2: Parameters of the Linac-200 Gun Cathode

Type	Dispenser
Max. energy	W + 20% Ba, Ca & Al oxides
Diameter	8 mm (S = 50 mm <sup>2</sup> )
Working I & U range	6.5 V / 4 A to 8.8 V / 5 A
Lifetime	15000–20000 hours

Cathode is mounted at the end of the HV column — multisectional vacuum insulator separating the vacuumed beam chamber and the gas-filled gun tank. Gun electro-optical system consists of the extractor electrode and 15 anodes with forced resistive ( $R = 200$  M) potential distribution (about 30 kV per gap).

First focusing anode voltage can vary in the range from 8 to 20 kV. Extractor electrode pulse is generated by Marx

generator. Possible voltage is from  $-400$  V (turnoff voltage) to 5 kV, pulse length—from 100 ns to 50  $\mu$ s.

Schematic view of the Linac-200 electron gun control system structure is presented at Fig. 1. Controller board architecture is shown at Fig. 2. Gun optics and electronics scheme is shown at Fig. 3.

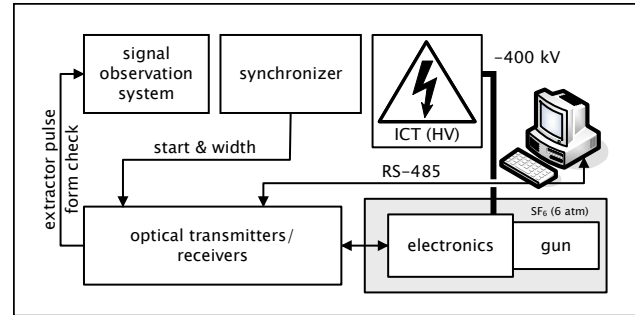

Figure 1: Linac-200 gun control system structure.

### Gun Electronics

Cathode electronics is housed on the hot deck inside the tank. All cathode electronics assembly is "suspended" at a potential of  $-400$  kV while the accelerator beamline is grounded.

Electronics consists of the following boards:

- Controller board acts as interface between the cathode electronics and the control computer.
- 50 kHz board supply transforms input voltage of 187 V / 50 Hz to  $2 \times 65$  V / 50 kHz.
- Filament supply board sets the cathode filament current.
- Extractor pulser ensures the gun extraction pulse with necessary parameters.
- 1st focusing electrode voltage board is self-explanatory.

### Controller Board

Board includes ATmega32 microcontroller, 4 DAC and 16 ADC channels, input register with 8 inputs, and output register with 8 outputs (TTL).

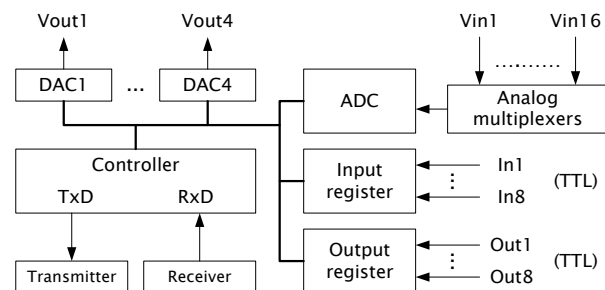

Figure 2: Controller board architecture.

\* nozdrin@jinr.ru

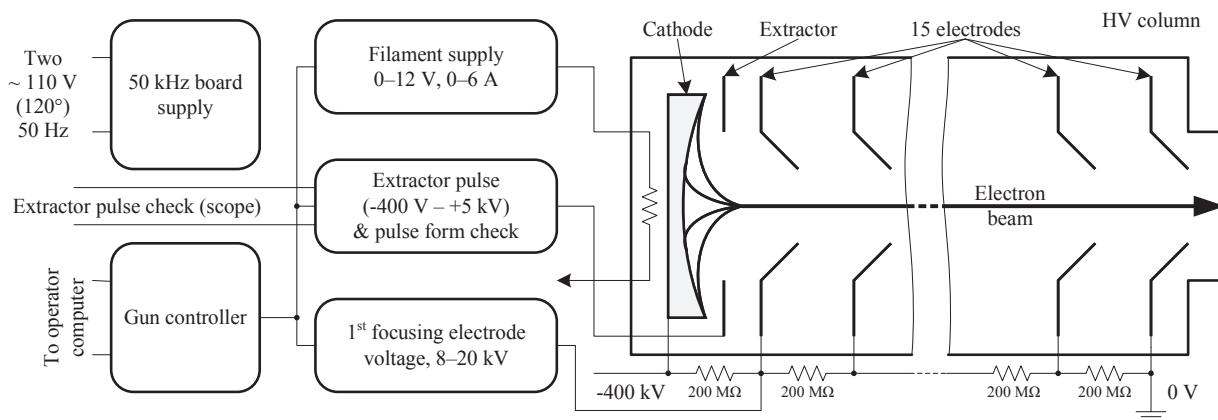

Figure 3: Gun optics and electronics.

Current implementation uses the following channels:

- 3 DAC are responsible for reference voltages setting (to control filament supply, 1st focusing electrode and extractor voltages).
- 6 ADCs are used for measurement of the gun analog parameters (filament voltage and current, cathode electronics board voltage, pressure and temperature of the SF<sub>6</sub> gas, and 1st focusing electrode voltage).
- 2 input register stand for discrete parameters—status of two cathode electronics coolers in the tank (ON/OFF).

The rest channels are for future use / as spare ones.

## Communication Line

To exchange information between the cathode electronics and outside equipment (−400 kV potential difference), optical fibers are used. Outside the gun RS-232 is used, than it converts to RS-485 to transmit information to control room (and receive it from it), and again to RS-232 to connect to the control PC.

## New Setup

The only device changed in the frame of the integration of the gun control system to the global Tango-based system, is the control PC. It is changed to the same form-factor 4U industrial PC, which now runs under Debian 9. Tango server runs on this PC, client—at operator PC (as all the clients do). All the rest equipment, including the communication line, remains in service so far.

## SOFTWARE

### Communication Protocol

Information exchange between the gun controller and control computer is performed via the following protocol. PC (master) sends four bytes (device address, controller function to perform, and two data bytes) and waits an answer from the controller. Delay between bytes is about 50 μs. Gun controller (slave) receives these four bytes, and sends an answer:

- Three bytes in the case of normal operation. First byte is the same as in control message, the other two contain data.
- Two bytes in the case of error. First byte again repeats the control message one, second byte contains an error code.

Timing diagram of one data exchange cycle is presented at Fig. 4. Full duration of one cycle is about 1 ms.

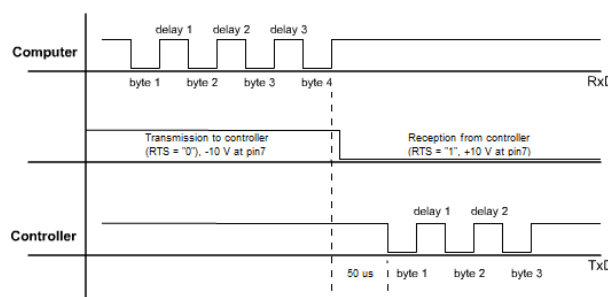

Figure 4: Timing diagram of one data exchange cycle between gun controller and control PC.

## Standalone

The control software version developed for initial Linac-200 startup [5] was written in the Borland Pascal 7.0 under DOS and was interacting with the serial port using the Port predefined array. Next version was developed in Borland Delphi (Object Pascal) and was running under Windows XP [6].

### Tango Device Class (Server)

Tango class Gun is written in C++ and runs under Debian 9. Due to communication protocol nonstandartness the UART driver was also included (instead of using corresponding communication device classes from Tango catalogue. Class structure in Pogo class generator is shown at Fig. 5.

### Tango Device Client

The client application (Fig. 6) provides a graphical interface for controlling the electron gun. It is implemented in

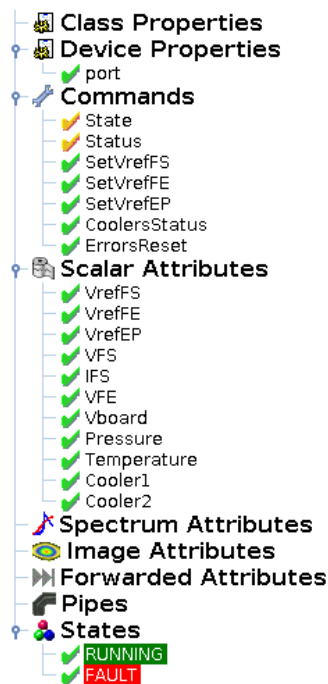

Figure 5: Gun class structure in Pogo.

C++ using the Qt5 framework and QTango library, and has the following functionality:

- control of the filament supply reference voltage;
- control of the 1st focusing electrode reference voltage;
- control of the extractor reference voltage;
- monitoring of the filament supply real voltage and current;
- monitoring of the 1st focusing electrode real voltage;
- provides information about the electron gun device server status.

Figure 6: Gun client application.

Some gun parameters ( $\text{SF}_6$  pressure and temperature, cathode electronics board voltage) are not presented, because corresponding sensors are not installed yet.

### Emulator Tests

For preliminary testing the gun emulator was developed. The initial idea was to develop it also as Tango device by making use of an event mechanism. But it turned out that minimal polling interval is 5 ms (which is not sufficient). So the emulator was written as a common Linux C++ console application.

The emulator is a "semihardware" one, it takes one COM-port and acts like it is a gun controller I/O. So it's possible to work both with two PCs (one represents "gun", another—control computer), or with one PC representing both "gun" and control computer at different COM-ports.

The first configuration (two PCs) was used during emulator development and debugging. New PC with emulator was connected by RS-232 to the old gun operator PC. The emulator was considered as fully ready only when it could be fully recognized by the old (standalone) GunCtrl software as the real gun (no any errors, correct data exchange etc.)

After that, debugging of the Tango device class has been performed (now using one PC configuration with two ports connected by RS-232).

## CONCLUSION & OUTLOOK

- C++ Tango device class and QTango client for Linac-200 electron gun were developed.
- C++ gun emulator was developed for testing.
- All software was successfully tested with emulator, tests with equipment will start after the end of the accelerator shutdown.
- The following hardware R&D is planned:
  - Bench for cathode electronics tests and repair works.
  - Full redesign of the cathode electronics using modern components.

# PVEcho: DESIGN OF A Vista/EPICS BRIDGE FOR THE ISIS CONTROL SYSTEM TRANSITION

K.R.L. Baker\*, I.D. Finch, G.D. Howells, A. Saoulis,  
ISIS Neutron and Muon Source, Didcot, United Kingdom  
M. Romanovschi, University of Manchester, United Kingdom

## Abstract

The migration of the ISIS Accelerator Controls System from Vsystem to EPICS presents a significant challenge and risk to the day-to-day operations of the accelerator. An evaluation of potential options has indicated that the most effective migration method to mitigate against this risk is to make use of a ‘hybrid’ system running Vsystem and EPICS simultaneously. This allows for a phased porting of controls hardware from the existing software to EPICS. This work will outline the prototype Vsystem/EPICS bridge that will facilitate this hybrid operation, referred to as PVEcho. The bridge has been developed in Python, utilising existing communication from Vsystem to an MQTT broker developed as part of a previous project. Docker containers have been used for its development to create a test environment that allows the software to communicate with other active services currently used at ISIS.

## INTRODUCTION

The ISIS Neutron and Muon Source [1] has been operated using Vista Control Systems’ commercial product Vsystem [2], colloquially referred to as Vista, since 1998. Recently, a study was undertaken to evaluate its use against that of the Experimental Physics and Industrial Control System [3] (EPICS) at ISIS. The study determined that the control system should be migrated to EPICS [4]. One of the key benefits of the migration will be to promote collaboration with other facilities at Rutherford Appleton Laboratory, such as ISIS Instrumentation [5], Central Laser Facility [6] and Diamond Light Source [7], also using EPICS.

In order to minimise the impact on business-as-usual at the facility, a phased porting of control of hardware is the desired option for the transition. This requires the development of bridging software that will map approximately 33,000 channels that exist in Vsystem to an equivalent EPICS Process Variable (PV). This will allow a progressive migration of the operator control screens in the main control room (MCR) alongside a gradual transition of hardware without interrupting operator control. The current control screens are produced using Vsystem’s Vdraw [8] tool but will be migrated to screens created using CS-Studio Phoebus [9] as part of the transition. Phoebus is the suite of applications that can be used to display screens as well as probe EPICS PVs.

The use of a bridge also elegantly permits some legacy hardware that cannot be converted to EPICS to still be run

using Vsystem but using Phoebus control screens. PVEcho will serve as this bridge, responsible for replicating the behaviour of the current control system in EPICS.

## PVEcho

Each component of hardware that comprises the accelerator controls system is associated with a group of unique channels through which value changes in the hardware can be communicated. During the migration, we will need to exactly replicate each of these channels that currently operate through Vsystem as an equivalent EPICS PV, including their value, alarm and display configuration. Each Vsystem channel and corresponding mirrored EPICS PV needs to be kept synchronised. This in turn will allow the control system to operate with either the Vsystem channel or the EPICS PV acting as the source of truth.

In the early stages of the transition, the majority of channels will still be operated through Vsystem while long-term EPICS equivalents are being developed. In this case, the source of truth will be the Vista channels and changes in their values and alarm limits will be broadcast from Vista to EPICS, handled by the vistatoepics (v2e) program. Once the control of hardware of specific channels has been ported to EPICS, the source of truth will transfer. Now, changes to the PV will be monitored and transferred from EPICS to Vista via MQTT [10] messages. This is handled by the epicstovista (e2v) program. The vistatoepics and epicstovista applications work in tandem to make up the PVEcho bridge, a visual representation of which can be seen in Fig. 1. The long-form names are used for descriptions of the applications, while the shorthand versions (v2e and e2v) are used for simplicity in the codebase and in diagrams. More details about the individual programs will be given in subsequent sections of this paper.

To track which channels have Vista or EPICS representing their true value, we have created a PVMonitor utility class to use in both programs. A list of channels to monitor are defined in a file which the PVMonitor regularly checks for changes (in our case once per second). When a change is noted, the monitor determines which channels have been added or removed relative to the file’s previous state, and starts or stops tracking those channels accordingly. This method allows a lot of control and flexibility over the channels to be replicated in EPICS, allowing the transition of individual channels at a time. As the same class is used in both applications, “channel” may be substituted for PVs when referring to epicstovista, where the same approach is used.

\* k.baker@stfc.ac.uk

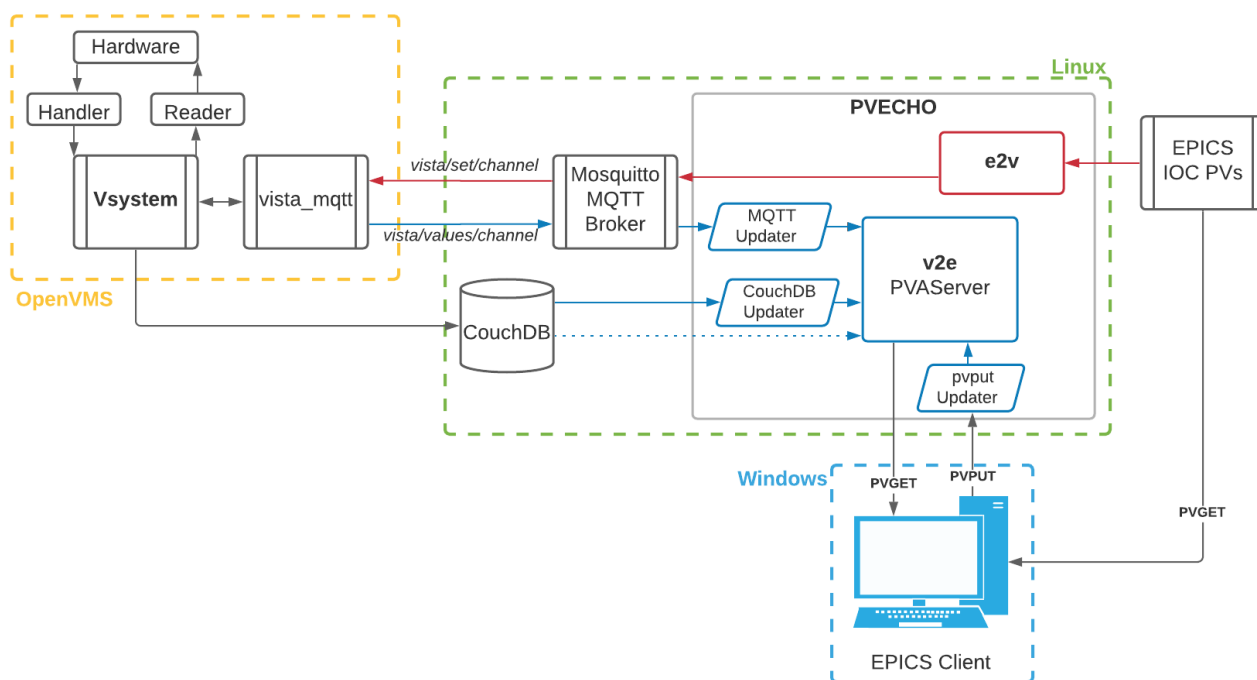

Figure 1: An overview of how PVEcho will integrate into the ISIS Accelerator Control System. VSystem will remain operating on OpenVMS, while newer systems and EPICS will operate on Linux, with the MCR running Phoebus [9] screens through Windows. Arrows in dark blue represent the flow of data from a Vsystem channel through to EPICS (v2e). They also indicate the Updater classes that parse incoming data. Dotted lines indicate an initialization step in the creation of PVs. Arrows in red follow the flow of information from EPICS to Vsystem (e2v). PVEcho interfaces to Vsystem through a Mosquitto MQTT broker [10] and the vista\_mqtt service [11].

Both vistatoepics and epicstovista components of PVEcho will leverage the MQTT messaging service linked to Vista, named vista\_mqtt, set up as part of a previous project within the ISIS controls group [11]. The vista\_mqtt service interfaces to Vsystem through topics associated with each Vsystem channel. When a value in Vista changes, the application (originally developed in Python but being migrated to C++) generates an MQTT message with the updated value and sends it to a read-only “values” topic associated with the channel. If a message is published to the channel’s “set” topic, the application triggers a Vsystem set command to change the value of the channel within the control system. Vistatoepics will make use of the former, read-only case, while epicstovista will utilise the writable topics.

By subscribing to the MQTT value topic associated with a Vsystem channel we can monitor changes to its value through the clients and callbacks available in MQTT’s python library [12]. The changes are then echoed to EPICS through vistatoepics. Similarly, we track changes to the EPICS PVs through pvapy’s [13] Channel client and we set the value of its corresponding channel in epicstovista by publishing a message to the channel’s set topic in MQTT.

The programs will also exploit the CouchDB [14] database set up by the group to store metadata associated with each Vsystem channel. The database stores information such as the channel type (e.g. integer, float, boolean, string) and display formatting, as well as alarm type and limits if applicable.

In the case of vistatoepics, this information is used to define the structure of the PV to be created. In both programs it is also used to define how to parse incoming values to a format appropriate for the system where it will be echoed, based on the channel’s type.

## VISTA TO EPICS (V2E)

The PVEcho bridge is designed to replicate the entire Vista control system, rather than individual devices that usually constitute a distributed control system. This places a focus on the ability to dynamically add, remove or edit PVs on the server created to host the replica PVs without having to restart the program, which would interrupt operation of the accelerator. Therefore, a PVAServer from the pvapy library was favoured over the traditional IOC for the vistatoepics component of PVEcho. On running the vistatoepics program, the configuration that dictates the services to connect to and the necessary files to be read into memory is loaded and parsed. In this case, files include a record of the CouchDB entries containing the metadata for the Vsystem channels, the mappings of reference channels to their setter channels and the list of PVs to monitor. The benefit of using this approach is that we can tailor our configuration file for production or development and testing purposes.

Once all of the relevant classes have been instantiated, we enter the main loop of the program. It continuously checks

the monitor file for changes, acts accordingly for the PVs that have been added or removed from the list and then goes on to check for any changes to CouchDB. This continuously runs until the program is interrupted, as illustrated by Fig. 2.

### Initialisation

On start-up and initialization of the vistatoepics component of PVEcho, a snapshot of the existing configuration for each of the channels on Vsystem is captured using the ISIS CouchDB database. The channel metadata (such as the display and alarm configuration) associated with each channel in the monitor list is then translated into a format appropriate for EPICS.

### Monitoring

Once the PVs have been created on the server, changes to their value and metadata are tracked through three different avenues: MQTT topic messages from Vista, CouchDB updates and EPICS pvput commands. Each source produces updates in a different json format so a fleet of customised 'Updater' classes are used to manipulate the data from the raw input into a structure appropriate for use with the pvapy PvObject.set() method which is used to apply the changes to the PV. The PV is then updated on the server so that changes are visible to EPICS clients such as Phoebus [9] control screens.

#### 1. MQTT

As described previously, once a PV has been created, we subscribe to the original channel's corresponding MQTT topic, published from Vsystem, which tracks changes to the PV's value.

#### 2. CouchDB

CouchDB shadows the Vsystem databases for each channel so it acts as a source of truth for the channel metadata that is not accessible through MQTT. To keep PVs consistent with their channel, we track changes to Vsystem database files through alterations to CouchDB using the CouchDB Python client [15] and modify the PV's metadata to match the updated values from Vista.

#### 3. pvput

PV values and metadata may also be changed by the operators through pvput commands using Phoebus control screens. As we are using custom classes that inherit from the original pvapy PvObject class for different channel types, when an update comes through we need to ensure that our object is updated correctly on the server.

### Alarm Management

The vistatoepics component of PVEcho is also responsible for mirroring the current alarm management in Vsystem. Implementing the alarms from the outset will allow us to start using EPICS alarm handling and monitoring software throughout the transition, as well as minimise operational changes for the crew. The mapping of range and binary

match alarms is relatively straightforward as EPICS defines these alarm types natively. Vsystem also offers the option of integer match and reference alarms [16], which do not have a corresponding native type in EPICS.

An example of where an integer match alarm might exist is a pump that operates in multiple modes. These could include pump operating states such as 0=off, 1=on, 2=fault, 3=standby, 4=turbo, where only state 2 should trigger an alarm.

A reference alarm is a channel where the alarm limits are determined by the value of a different Vsystem channel according to some calculation. The channel that dictates the reference channel's alarm limits is referred to as its "setter" channel. The alarm limits are recalculated for the reference channel whenever the value of the setter channel changes.

In order to replicate Vsystem as closely as possible within EPICS, the logic behind the Vista alarms has been implemented manually within the Updater classes. This was primarily possible because of the freedom of control over alarms that the pvapy library allows as well as the availability of the alarm definitions (for example type, limits, setter channel) for each channel in CouchDB.

- **Range** With each new update to the value or the metadata, the current value is compared to the most recent alarm limits to determine its alarm state, either MAJOR, MINOR or NO ALARM.
- **Binary Match** The alarm state is set to raise a major alarm if the current value matches that of the defined alarm match value.
- **Integer Match** The alarm state for integer match alarms is determined by comparing the value of the PV with its highAlarmLimit. On initialisation, this and all the other limits are set to be equal to the alarm match value from Vsystem. To circumvent the issue where a user could change the value of the match alarm through one of the other limits (e.g. lowAlarmLimit), a custom function has been devised and implemented in the PvPutUpdater (seen in Fig. 1), whereby if the value of any of the alarm limits is changed on a match alarm PV, all of the alarm limits are modified to equal the updated value. We use the same approach to update the severity of the match alarm.
- **Reference** A mapping of reference alarm PVs and their setter channels are stored in memory. Whenever a PV updates, a check is performed to see whether the channel is a setter. If so, all of its reference channels are also updated to reflect the new limits and their alarm state is recalculated with the new limits.

### EPICS TO VISTA (E2V)

As previously mentioned, currently the ISIS control screens are created and run using Vista's VDraw tool [8]. The intention during the transition is to operate a hybrid User Interface (UI), transferring some screens to Phoebus/EPICS while others remain in VDraw/VSystem as control of hardware is ported. If a user changes the value of the PV in

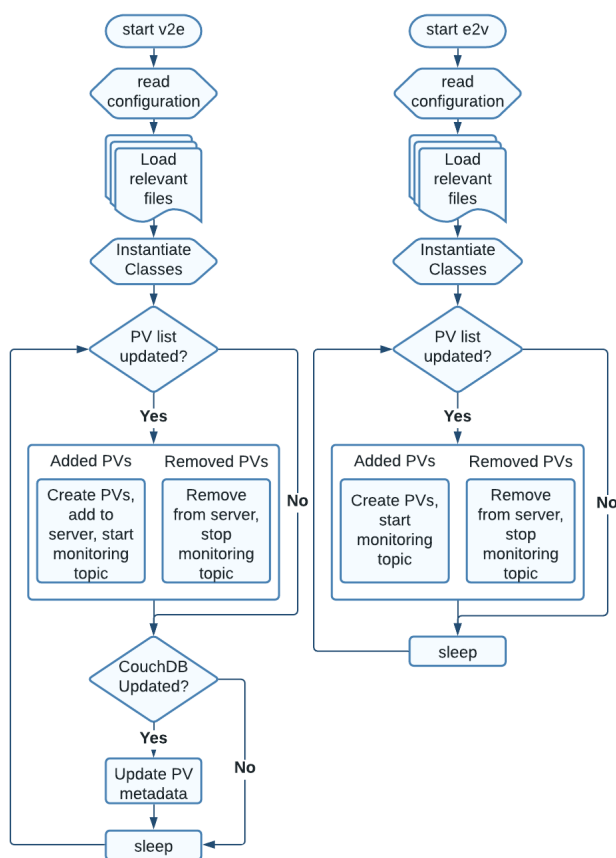

Figure 2: Flowcharts demonstrating the logic behind vistatopeics and epicstovista.

the ISIS MCR through a Phoebus screen where the hardware is still controlled by Vsystem, the change needs to be propagated from the EPICS Client to Vsystem to update the hardware. The same is true in reverse; if hardware is read via an EPICS IOC but the control screen is still operated by a VDraw screen, the PV values will need to be propagated to Vsystem. A pvapy Channel connection and callback is used to do this. As the update comes through via the EPICS callback, the values are converted to a JSON format that the Vsystem code on OpenVMS is expecting. The message is then published to the correct setter topic on the MQTT broker, which activates a set command in Vsystem [11]. The main loop of the program follows a similar structure to vistatopeics and can be seen in Fig. 2.

Alarmed channels are monitored in a similar way, but changes to the channel metadata are also tracked to provide updates if the alarm limits are changed through EPICS.

## DEVELOPMENT ENVIRONMENT

### Environment

The ISIS accelerator control system is also transitioning from OpenVMS to Linux as a base operating system. Therefore, in order to future-proof the design of the bridging software, PVEcho has been developed using Docker [17]

environments with a Linux operating system as the base of the containers, to isolate and replicate PVEcho's operating environment. Two separate containers will be used to run vistatopeics and epicstovista simultaneously, while isolating the processes to give greater control over their execution.

### Services

Alongside Linux and EPICS, PVEcho requires a connection to a number of other active services that ISIS utilises to monitor and maintain its control system. These include the ISIS MQTT broker [11] and the instance of CouchDB where channel metadata is stored. The use of Docker while developing PVEcho allowed connection to personally managed containers to prevent premature interaction with the live control system, minimising the risk of unintentional changes to existing channels.

### Testing

Throughout the development of the software, we have tried to implement software good practice wherever possible. This includes the application of unit and integration testing utilising GitLab's CI/CD facility and the unittest [18] framework in Python. Performance has also been monitored using an in-house virtual logging system [19] to track the CPU and memory use of each container while the software is running.

## FUTURE WORK

While functional, work on the current implementation of PVEcho is still ongoing. The accelerators at ISIS will primarily use the newer pvaccess protocol rather than channel access [11]. The current version of PVEcho only implements PVs using the pvaccess protocol, as highlighted by the use of a PVAServer to host the PVs. Future work on the software will incorporate channel access, ensuring that any changes to Vsystem channel values are broadcast to channel access PVs as well as their pvaccess equivalents.

Future developments will also include the addition of delayed alarms that are currently in use with VSystem. Additionally, the PVMonitor class should be modified to allow the bulk addition and removal of PVs from the monitor list as devices containing groups of PVs are migrated, to reduce the risk of user error in the transfer of channel names. Stress testing of the live system should also be completed to ensure that the software can cope with the day-to-day frequency of messages and surges in demand.

## CONCLUSION

A prototype of the bridge connecting Vsystem to EPICS has been created to mimic more than 33,000 channels live on the ISIS accelerator control system. PVEcho will allow a hybrid system running both Vsystem and EPICS to be utilised as control of hardware is progressively migrated to EPICS, without incurring the risk of interrupting accelerator operations. The prototype is due to be tested in deployment before the end of the 2021 ISIS long shutdown [20].

# DIGITISATION OF THE ANALOGUE WAVEFORM SYSTEM AT ISIS

W. A. Frank\*, B. R. Aljamal†, R. Washington

STFC Rutherford Appleton Laboratory, Didcot, Oxfordshire, UK

## Abstract

The Analogue Waveform System (AWS) at the ISIS Neutron and Muon Source is a distributed system that allows operators to select and monitor analogue waveforms from equipment throughout the facility on oscilloscopes in the Main Control Room (MCR). These signals originate from key accelerator systems in the linear accelerator and synchrotron such as the ion source, magnets, beam diagnostics, and radio frequency (RF) systems. Historical data for ISIS is available on the control system for many relevant channels. However, at present, to avoid disrupting the oscilloscope displays in the MCR, only an hourly image capture of the AWS waveforms is stored. This is largely inadequate for potential data-intensive applications such as anomaly detection, predictive maintenance, post-mortem analysis, or (semi-)automated machine setup, optimization, and control. To address this, a new digital data acquisition (DAQ) system is under development based on the principle of large channel count, simultaneous DAQ. This paper details the proposed architecture of the system and the results of initial prototyping, testing, and commissioning.

## INTRODUCTION

The Analogue Waveform System has been a key part of accelerator operations since the inception of the ISIS Neutron and Muon Source in 1984 [1]. At present, it is a distributed analogue waveform switching system that allows operators to select and monitor signals from equipment throughout the facility from the Main Control Room (MCR).

Recently the particle accelerator community has been turning to the increasingly mature fields of machine learning and data science to help manage the inherent complexity of these facilities [2]. Therefore, to modernise the current system in order to meet the data needs of these techniques, a new digital data acquisition system (DAQ), called the Digitised Waveform System (DWS), is under development. The new system aims to increase the signal capacity, improve flexibility, as well as signal integrity of the system. Further benefits are expected from the ability to store and archive descriptive statistics of the waveforms and raw waveforms for specific applications.

## EXISTING AWS SYSTEM

The AWS consists of three main cable trunks. Each trunk can, in principle, connect any number of ISIS Controls CPCI System (CPS) crates [3] using a daisy chain topology. Each CPS crate provides 32 analogue inputs to the system. However, at most six signals from all the CPS crates connected

on a single trunk can be multiplexed to a bank of Tektronix TDS3014B oscilloscopes in the MCR.

The CPS crates contain a Kontron CP3004-SA CPU board, Pickering PXI switching matrix modules (40-531-022/40-531-023), a custom six channel fully differential amplifier board, and a seven segment I/O display board. Inter-crate communication is over the CompactPCI [4] backplane. The direct analogue trunks provide negligible signal transmission latency but limit the flexibility of the system and make expanding the signal capacity difficult. The fast update rate of the oscilloscopes ensure real-time capture of each 50 Hz acceleration cycle.

There are currently 13 AWS CPS crates installed across the facility, providing 416 inputs to the system. Control and status monitoring of the AWS as well as triggering from the ISIS Timing System is provided by the ISIS Control System [5], based on the VSystem SCADA/HMI toolbox from Vista Control Systems [6].

## DWS SYSTEM OVERVIEW

### Hardware

Recent technological developments have brought down the cost of high-performance and high channel count digitisers. This has made possible the option to replace the multiplexed analogue approach with a largely digital paradigm consisting of network connected digitisers. A similar one-digitiser-per-device approach with the DAQ placed as close to the accelerator device as possible has recently been proposed and implemented at the Facility for Antiproton and Ion Research (FAIR) [7].

For the DWS, the selected DAQ hardware is the ACQ2106 carrier units from D-TACQ Solutions fitted with two or three ACQ482 ELF modules [8]. These digitisers provide excellent analogue and digital performance at a competitive cost per channel. In addition, it has built-in EPICS support, providing extensive monitoring, supervisory and control features that reduces integration efforts for the new EPICS based control system at ISIS [9]. Each ACQ482 has 16 differential inputs with an analogue bandwidth of 10 MHz and ADC clock speeds up to 80 MSPS. The bandwidth is sufficient to digitise the  $\leq 1$  MHz analogue bandwidth of the existing AWS. The signals from the AWS are connected to the VHDCI input connectors of the ACQ482 with 32 channel dual pin LEMO 1U, 19" panels. A total of nine ACQ2106 units will cover the existing system capacity of 416 channels, with the option to install additional units to cover any future capacity requirements.

The Rear Transition Module (RTM-T) in the ACQ2106 units connects to the DAQ server fitted with AFHBA404 PCI Express Host Bus Adapters via LC terminated OM3

\* william.frank@stfc.ac.uk

† basil.aljamal@stfc.ac.uk

50/125 $\mu$ m optical fiber. Avago AFBR-709SMZ SFP+ transceiver modules are used for the ACQ2106 and AFHBA404 connections. The AFHBA404 is a standard PCIe x4 Gen 2.0 card which provides four SFP+ transceiver ports at up to 6 Gbps [10]. The DAQ server is a Dell PowerEdge T440 Tower Server configured to be rackmountable fitted with an Intel Xeon Gold 5120 CPU at 2.20 GHz. The server has 256 GB of RAM installed and is fitted with a 3.5 TB SSD. A demonstration system, shown in Fig. 1, has been setup and tested for use with signals from various diagnostics systems at ISIS.

Figure 1: The demonstration system for the DWS connected to signals from various diagnostics systems at ISIS.

The DAQ is triggered and synchronised with the ISIS Timing System (200 kHz timing signals over twisted pair (RS-485)) via in-house CPS Type-T timing cards. An in-house 1U, 19" Timing Trigger Mixer unit is used to convert the differential RS-485 signals on the CPS Type-T BNO connectors to TTL compatible single-ended pulses for use with the external single-pole LEMO trigger input on the ACQ2106s. An overview of the DWS is shown in Fig. 2 and a summary of the specifications for hardware components of the DWS system is shown in Table 1.

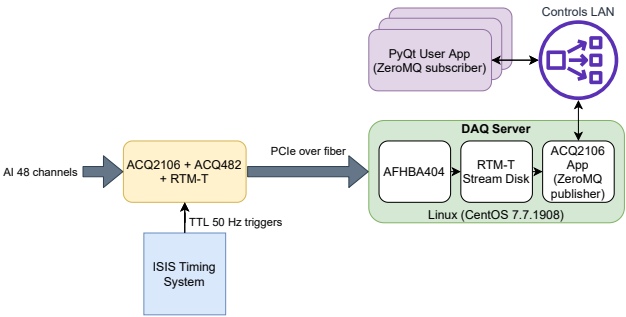

Figure 2: Overview of the DWS.

### Software

The DAQ server is set up with CentOS Linux release 7.7.1908 (Core) patched with the real-time Linux kernel.

Table 1: DWS Hardware Specifications

Item	Specification
Dell PowerEdge T440 Tower Server	Intel Xeon Gold 5120 CPU at 2.20 GHz, 14 cores, RAM 256 GB, SSD 3.5 TB.
D-TACQ Solutions ACQ2106, x3 ACQ482, MGT482	48 simultaneously sampled differential analogue inputs, 14-bit, 1 MS/s, $\pm 10$ V. PCI-Express over fiber, streaming data over 400 MB/s.
D-TACQ Solutions LEMO Panel	1U 19" rack-mount panel. 32 dual pin LEMO connectors. Differential connection. 100 V Zener diode transient protection.
D-TACQ Solutions AFHBA404	PCIe x4 Gen 2.0 card which provides four SFP+ transceiver ports at up to 6 Gbps.
CPS Type-T, Timing Trigger Mixer	2.5 $\mu$ s TTL compatible timing trigger pulses at 50 Hz on single-pole LEMO. Remotely configurable delay time with a resolution of 5 $\mu$ s.

The AFHBA404 Linux device driver is used along side the RTM-T-stream-disk application software [11], both released by D-TACQ Solutions under GNU General Public License v2.0 [12]. The AFHBA404 writes 2 MB buffers directly to memory using DMA operations. Each 2 MB buffer contains 16384 samples, on 48 channels, 16-bit data which corresponds to 16 ms of data on each channel at 1 MS/s. The driver provides the address for the DMA engine to do this. RTM-T-stream-disk creates a series of fixed size binary files in RAM which are overwritten cyclically. The binary data files are consumed by a custom, in-house developed, application that employs the Linux inotify API [13] to monitor the data files and return events when the data files have been written and closed. The data files are then read out in real-time, before they are overwritten by the driver. The ZeroMQ protocol is used for data exchange between the DAQ server and other client applications over controls network using the publish/subscribe messaging pattern to achieve minimum latency. Latency measurements have been performed on the ISIS machine controls network which showed that latency is linearly related to message size. An average latency of 2–6 ms was found for expected message sizes of 30–60 kB. Throughput measurements were also performed over varying message sizes which showed negligible impact on throughput with an approximate throughput of 94 Mbit/s. ZeroMQ was selected as it allowed greater flexibility in terms of client host operating system and programming language, as well as high scalability across multiple machines. Every channel of

data uses a separate TCP port and is identified with a unique ZeroMQ topic [14]. The data stream is currently started and stopped remotely using the acq400 Host API Python module provided by D-TACQ. The plan is for this to be migrated into the user application in future.

For data visualisation, use of EPICS based Phoebe user displays was investigated. However, it was found that the update rate of approximately 3 Hz was not sufficient for the real-time waveform requirements of the system (4 channels, 16-bit data, 16384 points per waveform at 50 Hz). As a result, a PyQt based application has been developed for real-time user application data visualisation called "DWS Live Viewer" (Fig. 3). The application is a ZeroMQ client that subscribes to selected channels streams and plots them in real-time.

Figure 3: DWS live viewer.

## Data Storage Strategy

One of the most important features in the new DWS system is that signals are available in a digital form so digitized waveform storage becomes possible.

An approximate calculation was done to estimate the required storage capacity for 416 signals sampled at 1 MS/s for 16 ms interval synchronised with the machine repetition clock (50 Hz) for 10 weeks run cycle which is around 3.8 petabytes. This volume of data is beyond our capacity to maintain, and therefore the following short-term data storage strategy will be used:

A one minute long ring buffer of raw data for each signal used for diagnostics purposes especially during machine startup and beam commissioning. Another use case is post-mortem data logging. In this case, when an interlock occurs pre-interlock data writing stops and post-interlock data writing starts for a specified amount of time.

For long-term data storage, the proposed solution is to store statistical properties (mean, median, standard deviation, minimum, and maximum) of the raw data rather than storing the waveform data itself.

Raw data from each channel will be received by subscribing to the ZeroMQ stream with the corresponding topic for the channel of interest. Statistical properties will then

be calculated and pushed into Telegraf which will aggregate data points into big chunks for efficient data writing into InfluxDB [15]. InfluxDB is a high-performance time-series database optimised for query and visualization of timestamped data. With this solution, a significant reduction in storage capacity and pre-processing overhead can be achieved.

Some applications may require raw waveform data because statistical properties alone aren't sufficient. For cases like this, a ZeroMQ based stream processing pipeline will be implemented to do online data processing rather than batch processing on big data sets of stored raw data.

A summary of the software components of the DWS system is shown in Table 2.

## SUMMARY AND FUTURE WORK

The proposed architecture for a new digital DAQ system for the digitisation, visualisation and storage of waveform

signals from the AWS at ISIS has been presented and described. A demonstration system has been setup and tested for use with signals from various diagnostics systems at ISIS. This demonstration system has been newly setup during a long shutdown in ISIS operation. As such, an Agilent 33220A function generator connected to the controls network is currently being used to provide representative waveforms for initial testing and commissioning. Remote control and configuration of the function generator is provided by the PyVISA Python package along with the Keysight IO Library Suite. Waveforms from the existing diagnostics systems will be targeted during the initial beam commissioning prior to the user cycle in January 2022.

Investigations are also underway for two additional tiers of hardware for both low bandwidth signals ( $< 100$  Hz) and those above the bandwidth of the existing AWS (1–500 MHz) that currently sit outside the system. For slow signals a bespoke solution is under development. For the high speed signals, for example from the synchrotron extraction kicker, dedicated digitisers ( $< 10$  channels total) based on MicroTCA [16] will be investigated.

Currently time-stamping of each cycle of data (at 20 ms intervals) is provided on the DAQ server which is synchronised with a NTP server. It is noted that the D-TACQ ACQ2106 digitiser units are White Rabbit (IEEE 1588-2019) [17] compatible and accurate sub-nanosecond time-stamping of the data could be investigated in conjunction with any future development of the ISIS timing system.

The ACQ2106 units are also supplied with calibration data. The calibration data allows client applications to convert raw binary data from the ADC to calibrated voltage readings. So far this has not been implemented but in future the data will be calibrated prior to visualisation.

## ACKNOWLEDGEMENTS

The authors express their sincere thanks to Peter Milne at D-TACQ Solutions for his help and support with the initial prototyping, setup and testing of the D-TACQ Solutions equipment.

# UPGRADING THE NATIONAL IGNITION FACILITY'S (NIF) INTEGRATED COMPUTER CONTROL SYSTEM TO SUPPORT OPTICAL THOMPSON SCATTERING (OTS) DIAGNOSTIC

Lawrence Livermore National Laboratory, Livermore, USA

## Abstract

With the ability to deliver 2.1 MJ of 500 TW ultraviolet laser light to a target, the National Ignition Facility (NIF) is the world's most energetic laser. This combination of energy and power allows the study of materials under conditions similar to the center of the sun. On fusion ignition experiments, plasma generated in the interior of the target shell can detrimentally impact the implosion symmetry and the resulting energy output. We are in the final stages of commissioning a significant new diagnostic system that will allow us to better understand the plasma conditions and improve our symmetry control techniques. This Optical Thompson Scattering (OTS) system consists of two major components: a probe laser beamline capable of delivering a world first 1 J of energy at 211 nm, and a diagnostic that both reflects the probe laser into the target and collects the scattered photons. Between these two components, the control system enhancements required integration of over 450 components into the existing automation suite. This talk will provide an overview of the system upgrade approach and the tools used to efficiently manage and test changes to both our data and software.

## BACKGROUND INFORMATION

The purpose of the NIF is to continue research into nuclear fusion, specifically laser driven inertial confinement fusion (ICF). To accomplish this, NIF uses 192 lasers. When combined, the lasers can deliver up to 2.1 MJ of energy at 351 nm. For a sense of scale, the NIF building containing the lasers stands four stories tall and can fit three American football fields on the roof.

Responsibility for driving the NIF through its experiments lies with the Integrated Computer Control System (ICCS). At the lowest level, ICCS provides direct control of devices for manual operations during maintenance and troubleshooting tasks. On top of that, it provides multiple layers of automation which allow less than a dozen operators to configure and control more than 66,000 control points on over 2,300 processors and embedded controllers through the course of a shot cycle.

Behind the scenes ICCS has chosen a data driven architecture to keep things manageable. A predominantly Java code base of over 3 million lines of code provides the basic implementation of each control type, the hooks to communicate via Common Object Request Broker

Architecture (CORBA) protocols, and the automation frameworks. Going along with this, an Oracle database stores all information needed to instantiate the control points, automation scripts, and the experiment configurations.

## OTS LASER SYSTEM UPGRADE

As part of the NIF team's continued effort to improve our understanding of the plasma conditions, we recently deployed a diagnostic capable of measuring OTS from the imploding target. This method significantly improves the precision at which we can measure the plasma's temperature, density, and flow velocity. From this we'll gain a better understanding of how the laser interacts with the plasma, and how we can further reduce unwanted interactions. This in turn will lead to even better symmetry during the implosions and higher fusion yields. [1]

This upgrade consists of two large scale pieces: the OTS Laser (OTSL) and the OTS Diagnostic (OTSL-D). Unlike previous upgrades such as the Advanced Radiographic Capability (ARC), OTSL did not reuse any of the existing NIF beam path. Instead, we built a new room in NIF's switchyard 1 to house the front end and amplification components. The laser light follows a new beam path into the target area. Just outside the target chamber wall, we convert the laser light from the front end's 1053 nm to 211nm.

OTSL-D consists of two primary components. First you have the diagnostic package consisting of a spectrometer and alignment cameras. This package was specifically designed to work with either OTSL at 211 nm or a standard NIF 351 nm beamline as the probe laser. This allows us to install the diagnostic in multiple locations and inspect the target from multiple angles. In addition to the diagnostics, OTSL-D contains a separate set of alignment mirrors and cameras in a laser launch package. Due to the location where OTSL enters the target chamber, it cannot fire directly into the hohlraum's laser entrance holes. To get around this, we reflect OTSL off the laser launch mirrors and into the target.

## OTS Software Upgrade Scope

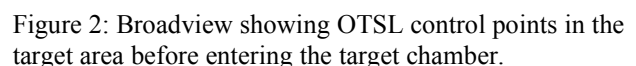

To support the OTSL system, we needed to modify every layer of the ICCS system. Down at the Front-End Processor (FEP) layer, we made code changes to support multiple new device types, such as energy diagnostics,

In the next layer above, our automatic alignment team implemented a large number of new alignment loops. [2] While some of these loops were similar to existing NIF alignment loops, some operations (such as the tuning the 5 $\omega$  converter crystals) required brand new approaches and image processing. Also in this layer, we needed to expand our pulse shaping system to support the new OTSL front end. Rounding this layer off, we needed to expand our status and propagation processes to handle all of the new control points.

Last but definitely not least, multiple GUI changes were needed as part of this effort. Each of the new device types required a brand-new maintenance panel. In addition, we added new broadviews aligning with the OTSL control points diagram (Fig. 2). Several of our maintenance and commissioning tools were expanded to work with the new OTSL devices. Finally, we added tools to existing maintenance panels to assist with commissioning the system, such as real time image processing to our video displays.

Given the amount of data we deal with, the ICCS team has developed a number of tools to simplify manipulation of our databases. These tools range from very generic to

QuickMod

Originally introduced as a way for non-software developers to safely and efficiently make database changes, QuickMod rapidly became our standard method of making database changes. At the highest level, QuickMod translates Excel files into a SQL statements. Every sheet in the file can perform one of four basic operations (INSERT, UPDATE, DELETE, or CLONE)

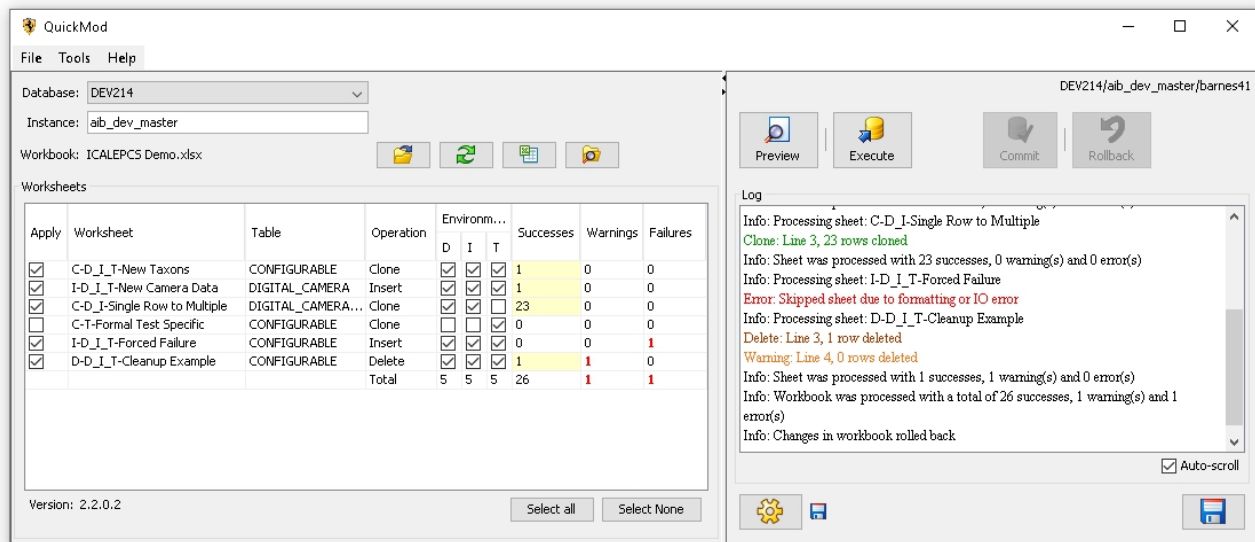

Figure 3. QuickMod GUI Interface.

on a single table. The first three operations align with the standard SQL definitions. Our clone operation combines multiple SQL statements to atomically query a table, modify the results, and insert the new rows back into the same table. QuickMod also evaluates Excel functions before applying each sheet. This allows for concise workbooks that can tailor themselves to each environment. For example, we commonly create workbooks that derive machine hostnames based upon the environment the data is being applied to (development, integration, formal test, or production). To round all this out, QuickMod provides a simple GUI interface (Fig. 3) for application of single files and a command line interface for release automation. The GUI interface provides users quick feedback on the success/failure of each operation and the ability to roll back changes before committing them to the database.

QuickMod has demonstrated several advantages. First, it provides an easy method for non-software developers to make database changes. We frequently have a software developer build an example Excel file for a subject matter expert (SME). The SME can then adjust values in the Excel file and have operations modify the database without further involvement of the software team. Second, the input files can easily be reviewed both before and after application to the database. Third, QuickMod provides a convenient place to implement validations and restrictions not easily performed by the database. For example, the ICCS architecture allows for multiple developers to work in their own personal instances while sharing the same database schema. This was done by adding an INSTANCE column to almost all database tables. Since developers rarely need to modify multiple instances at once, QuickMod restricts application of changes to a single instance at a time. Developers still have the option of falling back to SQL if they truly need to modify multiple instances simultaneously. Fourth, the granular feedback provided by the QuickMod GUI has reduced the time needed for developers to track down errors in their data changes. After executing, QuickMod

provides the number of successful changes, warnings (e.g. an update that modified no rows), and errors on both a per sheet and per row basis. It also provides a log window with full details including the exact row/sheet that caused the error. Finally, by controlling the files in our configuration management system and deploying via command line automation, we ensure we deliver the entire set of intended changes to each environment.

While QuickMod is exceptionally useful tool, there are a few challenges that made it insufficient for a project the size of OTSL. The largest challenge comes from the domain knowledge needed to initially construct an input file. The ICCS configuration database contains over 1400 tables. Within each of those tables, we have a mix of columns that need to change with every entry and those that rarely change. Thus, developers frequently find themselves needing to consult domain experts both to simply identify the needed tables, as well as to identify what questions they need to ask of external teams. The next challenge comes from the quantity in data. This shows up in individual typos, copy and paste errors, as well as simply identifying when rows or sheets are missing.

### Batch Cloning

To help deal with the challenges of using QuickMod alone, we created a batch cloning tool. For input, the tool takes in a list of existing control points, their new names, and new processor information. The tool first reads in all data related to the existing control points. It then adjusts the data based upon the new names and processors. Next, it removes any duplicate data. For example, when multiple digital input/outputs are defined on the same card/processor combination, it consolidates the data to a single definition of that card. As output, the tool generates an Excel file already formatted for use in QuickMod. In doing so, it highlights columns that developer likely needs to update after consulting external teams. Finally, the tool ensures that the output files will

create emulated devices in offline environments and real devices in production.

We ended up using the batch cloning tool for around  $\frac{3}{4}$  of the OTSL data, and it quickly showed its benefits. With the first batch of OTSL control points, it cut the effort needed in half. And that time includes the effort to develop the tool. While it didn't completely eliminate the need to reach out to the domain expert for each device, it drastically reduced the amount of information needed. It also removed the possibility of missing data.

After using the tool, we also found that it introduced some new challenges of its own. Specifically, the tool did not make it easy to respond to requirements changes after the developer had started their work. The batch cloning tool excelled at getting the first 80% of the work done. After that, a developer needed to manually update the generated QuickMod file to include information gathered from other teams. Since all changes were consolidated into a single file, developers frequently would choose to manually respond to requirements changes instead of rerunning the tool and having to restart their work. The second challenge showed up when we started commissioning. Since the tool copied all data related to the source control points, it frequently copied too much data. Many of our control points have named configurations that we call setpoints. We found a number of instances where we deployed setpoints that either didn't make sense with the newly deployed control point or caused confusion since they were supposed to be created during commissioning.

### Templates

Learning from our experiences with the batch cloning tool, as well as other data heavy project, the ICCS team choose to upgrade QuickMod to support templates. The templates are initially designed by a domain expert. They start with a definition sheet that contains both documentation on how to use the template and a section where each row equates to one new control point being generated when applied. After that, the Excel file contains all of the data necessary to make a single instance of a control point. Unlike a standard QuickMod input file, fields that we expect to change are replaced with template variables (such as <<name>>). When QuickMod applies the file, it will run all sheets after the definition sheet once for every new control point being added. And before each run, the template variables are replaced with the values defined in the definition sheet.

While this new system initially requires more time from a domain expert, it has shown several advantages. First, non-experts can use the templates with little to no input from the domain expert. Frequently the documentation provides enough guidance on what questions to ask other teams, and which columns the developers need to worry about changing. Second, a developer can easily respond to a change in requirements. For example, changing a control point's type frequently boils down to removing a row from one definition sheet and adding a new row in different template. Third, since the templates are

essentially the data for a single instance, they become easy to generate and review. In ICCS, most of our control types have data in less than ten tables, and frequently only have one to four rows per table.

## TESTING THE CHANGES

For testing changes of this magnitude, ICCS both reused existing testing frameworks (both automated and manual) and adapted some of our ancillary tools to assist in testing. This allowed us to deploy the software with high confidence that minimal adjustments would be needed in production. It also allowed us to rapidly make significant code changes when the new energy diagnostics were significantly upgraded after our initial software deployment.

### Testing Device Control Changes

Our front-end processor (FEP) layer is responsible for making any piece of hardware available via a CORBA interface. We have two automated test frameworks responsible for unit and integration testing this layer. Both frameworks are built on top of JUnit and tied into our nightly build system. We designed the unit test framework to minimize the effort needed add new tests. Developers simply need to add a single line annotation to either the class or to individual test functions in order to designate a test suite. When the test framework runs, it scans the compiled code base for these annotations and dynamically builds up the test suites to run. We currently have two test suites fast and slow which respectively take approximately 2 minutes and 10 minutes to run. These tests predominantly focus on validating individual Java class.

The second framework performs black box testing via the CORBA communications layer. We introduced this framework when we ported the FEP layer to Java [3] and continue to expand it with every new control type. Given that a single CORBA interface frequently supports multiple different models of hardware (e.g. different cameras), we needed the ability to rerun the same test classes on different control points in our system. To support this, we choose to define the test suites in our configuration database. We then created a custom JUnit test runner that ties into a running instance of our system and queries the database to determine the tests that need to run. The runner also gives us the capability to run multiple test suites in parallel under different Java virtual machines. In addition to the test runner, we created a few JUnit rules to assist with common low-level operations (such as locking out control points). The framework also provides utility/base classes for testing areas where the functionality is relatively similar across control types (e.g. our interfaces for setpoints/named configurations). For a sense of scale, the test suites in this framework take between 5 minutes and 6 hours to run.

### Testing Shot Automation Changes

In our offline integration environment, we predominantly rely on nightly runs of our automated shot

tester (AST) [3]. We currently have AST run five shots in each of our three releases under active development. To maximize our testing coverage, the experiments are specifically designed to have a mix of capabilities (such as OTSL). With each of these shots, AST will do its best to drive each shot to completion and provide a report on any failures 15 minutes before by our morning meeting. AST also provides us the capability to run shots on demand throughout the day.

In addition to AST testing, we perform a large variety of manual tests on shot changes. During integration testing of new functionality, developers will manually check all shot operations (e.g. positioning control points or verifying positions). In formal test, our QA will run multiple manual shots to confirm expected operations. They will explicitly test any verifications responsible for machine safety on a new or modified component (a different system is responsible for personnel safety checks). After deployment to production, we perform a final round of testing during the initial commissioning test shots. This testing includes manual verification that the automation layer correctly positioned all new control points, and a final verification of all machine safety checks.

## COMMISSIONING THE SYSTEM

Due to the amount of new hardware with OTSL, we needed to come with a way up with a commission and tune the system without interfering with NIF's ability to continue experiments. We initially started by providing the OTSL team with an interface into the control system that could only access the OTSL control points. The team was then required to manually setup and fire OTSL. After attempting a few shots in this manner, we quickly realized the need to partially automate the process. To do this, we made use of our Target Alignment Assistant Tool (TAAT) [4]. TAAT was originally designed to allow rapid automation of alignment procedures for unique targets. As such, it reads in specially designed Excel files that define the scripted actions to take, where to ask the user for input, and where to branch if necessary. It then provides a basic user interface while it sends the corresponding CORBA commands into the system. With this, we were able to reduce the time to manually arm and archive OTSL devices during each iteration of a tuning shot from 1 hour to 5 minutes.

## COMMISSIONING THROUGH COVID

With the ICCS team working almost exclusively from home, the pandemic pushed us to rethink and develop new strategies for supporting remote troubleshooting and commissioning operations. One of the strategies has worked out so well that we plan to continue using it even after the team returns on site. When a team working on NIF needs assistance, they initially setup a video teleconference and reach out to the domain experts needed. As part of the teleconference, the operations

team will share the desktop of the console where assistance is needed. This allows the experts to simultaneously see what's going on in the control room, have a meeting with everyone involved, and still access tools that they have on their development machines. Building on top of this, the ICCS team maintains a Microsoft Teams channel providing summaries and status updates for any unplanned assistance requests.

The remote desktop capabilities have proven exceptionally useful in many ways. The most significant improvement is that we can have experts see the operators' screens and no longer need to rely on their descriptions of what they're seeing. This both reduces confusion and allows experts to notice small items that the operators may have overlooked or assumed were normal. This has also proven extremely useful for the alignment team, as they can now watch the alignment cameras in real time. Additionally, this functionality allows developers to remotely troubleshoot problems in labs that previously would have required them to don protective equipment and operate under escort due to safety hazards.

The strategy has also made the team more effective both when commissioning and troubleshooting operations outside of normal hours. The easy availability of teleconferencing has significantly reduced instances of multiple groups working on the same problem in parallel in their own communications silos. The Teams channel has provided management an easy way to stay apprised of problems in production. It has also improved the details available for deep dive troubleshooting the next day. Finally, the ability to work effectively from home has been a boon for SMEs that need to support shot operations well outside of their normal hours, or for extended duration shots.

## CONCLUSION

The ICCS team successfully leveraged custom data manipulation tools, automated testing, and a remote work strategy to efficiently deliver controls for the OTSL system. For other teams considering similar tools and strategies, we have a few recommendations. First, focus on keeping each iteration of a tool/process change small and focused. This will lead to tools being completed faster and easier. It also keeps you from sinking significant effort on a tool that might not fully meet your needs. Second, always consider making tools more generic to allow for reuse in unforeseen circumstances. For example, when we initially wrote TAAT, we had no inkling that we would use it to automate non-alignment activities. Third, always keep an eye out for automation opportunities, especially testing.

## ACKNOWLEDGEMENT

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

# VSCODE-EPICS, A VSCODE EXTENSION TO ENLIGHTEN YOUR EPICS CODE

Victor Nadot†, Alexis Gaget, Francis Gohier, Françoise Gougnaud, Paul Lotrus, Stéphane Tzvetkov, \*IRFU, CEA, Université Paris-Saclay, F-91191 Gif-sur-Yvette, France

## Abstract

vscode-epics is a Visual Studio Code extension developed by CEA Irfu that aims to enlighten your EPICS code. The development was originally initiated by one of our students in 2017.

This module makes developer life easier, improves code quality and helps to standardize EPICS code.

It provides syntax highlighting, snippets and header template for EPICS files and snippets for WeTest[1].

vscode-epics module is based on Visual Studio Code language Extension and it uses basic JSON files that make feature addition easy.

The number of downloads increases, version after version, and the various feedbacks we receive motivate us to strongly maintain it for the EPICS community. Since 2019, several other laboratories of the EPICS community have participated in the improvement of the module and it seems to have a nice future (linter, snippet improvements, specific language support, ...).

The module is available for free on Visual Studio Code marketplace[2] and on EPICS extension GitHub[3]. CEA Irfu is open to bug notifications, enhancement suggestions and merge requests, in order to continuously improve vscode-epics.

## FEATURES

The syntax highlighting (Figure 1) provides the functionality to detect the EPICS keywords for a large scope of EPICS files (".db", ".template", ".substitutions", ".cmd", ".st", ".proto", ".c"). As a concrete example, record types, record fields, macros and comments are supported for ".db" files.

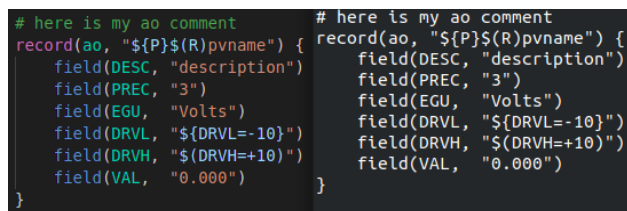

Figure 1: With and without syntax highlighting.

Snippets are yet an even more powerful feature of the extension (see Figure 2). It makes it possible to generate any records with the basic EPICS fields. They are very valuable for new EPICS developers.

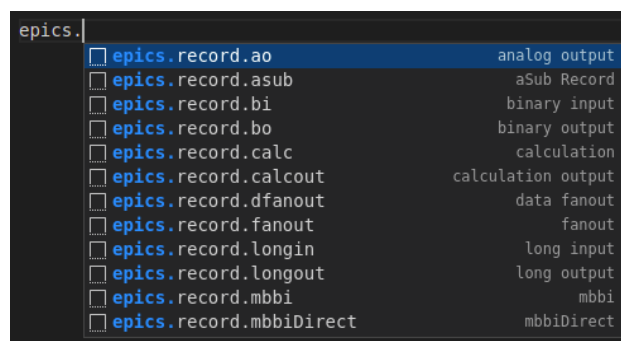

Figure 2: Scrollable list of available snippets.

Another interesting feature is the header template generation (see Figure 3). Largely inspired from our collaboration with ESS, the headers are composed of the following fields:

1. "file": the file name is automatically written at the top of the header. This is useful when you use substitution files that generate a large ".db" file with all your templates inside. Thus, you can easily see the different template demarcations in the generated ".db" file.
2. "author": the author and company references.
3. "description": a short presentation describing the file scope.
4. "macros": in order to improve code readability, it is strongly advised to add the list of the macros used in the file with a short description. They are split in two types. Mandatory: they are required to be defined at higher level to use the template. Optional: they have default values so they are not required to be defined at higher level to use the template;

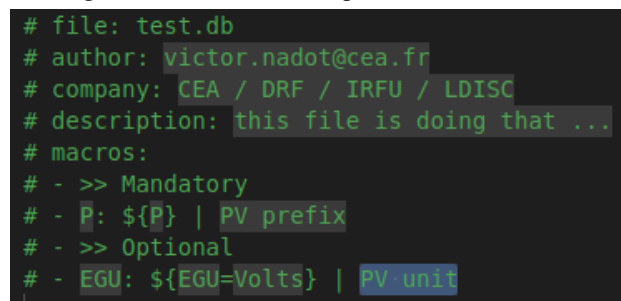

Figure 3: File header provided by vscode-epics extension.

More snippet can be added as long as the language you are using is part of the EPICS extensions[4]. For instance WeTest, a software developed by CEA/Irfu to automate acceptance tests and shared with EPICS extension, has snippets integrated to epics-vscode module.

Besides making developer life easier, vscode-epics extension improves your code quality and code homogeneity

\* † victor.nadot@cea.fr

across your developments. Indeed, the snippets feature will suggest the most used EPICS fields by record (they are not absolutely required but they help to improve the overall quality of your EPICS database). Here is a concrete example: an “ao” snippet would suggest to fill limits (DRVL/DRVH), unit (EGU), and precision (PREC). Note that for all snippets, the description (DESC) field is also suggested. All of these fields are not mandatory to make your EPICS database work, but it really improves it, especially from the client side: units can be displayed on GUI, GUI widgets can use PV limits, etc.

vscode-epics extension is based on JSON files in order to describe its different features. It makes it easy to read, to understand the implemented features and to add new ones.

## EXTENSIONLIFE

The number of downloads increases quite linearly (see Figure 4), version after version, and the various feedbacks we receive motivate us to strongly maintain it for the EPICS community.

Figure 4: Vscode-epics extension downloads over the years.

Since 2019, some laboratories of the EPICS community have participated in the improvement of the module with significant contributions made by (see Figure 5):

- Institute of Plasma Physics (IPP CAS)
- European Spallation Source ERIC (ESS)
- Stanford Linear Accelerator Center (SLAC)
- Diamond Light Source (DLS)

It really is encouraging to receive some contributions from the EPICS community.

Figure 5: Contributions over the years.

The module is available on Visual Studio Code marketplace and on EPICS extension GitHub. CEA Irfu is open to bug notifications, enhancement suggestions and merge requests to continuously improve vscode-epics.

The current release is 1.1.0. The changelog (and the git history) is tracing the whole code history. In order to manage issues, I use the GitHub “Projects”. Its kanban provides a good view of the tickets (see Figure 6).

Figure 6: Vscode-epics kanban on Github.

## FUTURE DEVELOPMENTS

There are few features in the pipelines, prioritized in two categories: confirmed and enhancements. There is also a “help wanted” column that contains the linter enhancement. The vscode-epics linter requires a bigger development so any help from the EPICS community, especially from someone with a linter development experience, would be appreciated. In addition, some automatic tests will be needed to avoid regressions.

Recently a colleague from Irfu CEA started a similar project for Vim (and NeoVim): epics-syntax.vim[5]. vscode-epics extension JSON files were a useful starting base. However, for now, only syntax highlighting is supported. In the longterm the same features as vscode-epics should be supported.

## CONCLUSION

vscode-epics extension improves the EPICS code homogeneity and makes EPICS developers’ life easier thanks to its syntax highlighting, snippets and other features.

The extension has reached a stable state for several months now. The code is available on EPICS extension GitHub repository, it is open to merge requests and issue opening. GitHub kanban makes it easy to manage, and it provides the EPICS community with a good overview of the current project status.

# TangoGraphQL: A GraphQL BINDING FOR TANGO CONTROL SYSTEM WEB-BASED APPLICATIONS

J.L. Pons, European Synchrotron (E.S.R.F), Grenoble, France

## Abstract

Web-based applications have seen a huge increase in popularity in recent years, replacing standalone applications. GraphQL provides a complete and understandable description of the data exchange between client browsers and back-end servers. GraphQL is a powerful query language allowing API to evolve easily and to query only what is needed. GraphQL also offers a WebSocket based protocol which perfectly fits to the Tango event system. Lots of popular tools around GraphQL offer very convenient way to browse and query data. TangoGraphQL is a pure C++ http(s) server which exports a GraphQL binding for the Tango C++ API. TangoGraphQL also exports a GraphiQL web application which allows to have a nice interactive description of the API and to test queries. TangoGraphQL has been designed with the aim to maximize performances of JSON data serialization, a binary transfer mode is also foreseen.

## INTRODUCTION

Today, at the ESRF [1], we use mainly Java standalone applications for the accelerator control system. These applications are built on top of the Java Swing ATK framework [2] and Tango java APIs. Today, regarding GUI technologies, we see almost only development around web technologies such as React, Angular, Vue.js, Bootstrap, Material UI, etc... It is natural that we migrate our GUIs to web based applications. Java ATK is based on the Model View Controller model. React (Facebook) offers a very convenient way to implement this model using hooks. GraphQL [3], initially developed by Facebook in 2012, was moved as open source to the GraphQL foundation. A JavaScript Tango Web ATK built on top of React and GraphQL is currently under development at the ESRF. This framework is designed in order to ease as much as possible the migration of our Java applications.

## ARCHITECTURE

### MVC Model using React

React function components offer hooks that can be used to implement the MVC model. The key idea is to use the state hook and to pass the setState function handle as a dispatcher to the model. A useEffect hook handles the subscription in the listener list of the model as shown in Fig. 1.

The model (the GraphQL client) makes access to Tango devices using the TangoGraphQL server either through basic HTTP requests or through WebSocket as shown in Fig. 2.

Figure 1: MVC using React.

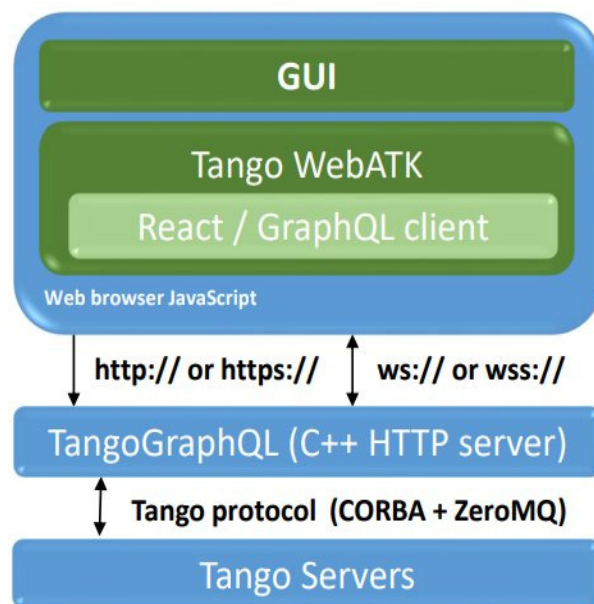

Figure 2: Architecture.

## GRAPHQL

### GraphQL vs REST

Compared to a REST API, GraphQL is a true query language allowing clients to query only what is needed in a single HTTP request. GraphQL also provides an introspection system giving information about the supported schema. GraphQL uses GraphQL query to perform introspection. The GraphQL foundation provides a web application called GraphiQL, based on this introspection system, enabling users to write query using modern tools such as completion, syntax checking and documentation browsing. It uses the Tango GraphQL schema definition [4] to provide all these features to the Tango GraphQL API. TangoGraphQL C++ server also exports a GraphiQL interface.

Figure 3: WebATK Panel.

### GraphQL Tango API

The GraphQL Tango API must provide all calls needed to build any applications including generic applications such as ATKPanel. WEBATkPanel shown in Fig. 3 makes an introspection of the Tango device to display all its attributes and commands.

GraphQL defines 3 types of request: query, mutation and subscription. Queries are read only requests (basically a Tango read\_attributes call), mutations are write requests (write\_attributes or command\_inout) and subscriptions are used to register to Tango events. The requests are sent to the server via a HTTP POST request.

When registering to an event, the TangoGraphQL server will push JSON frames when a Tango event is sent by the Tango server. When using the GraphQL over WebSocket protocol [5], the client (and the server) use the socket in a bidirectional mode (full duplex), which means that the client (or the web server) can send or receive requests at any time.

## PERFORMANCE

### Error Management

The GraphQL error management standard is not very convenient. When a node cannot be returned, the GraphQL standard impose that the node must be null and an additional errors JSON block has to be filled with errors. With large queries which may contain lots of errors, the browsing of this additional error tree is a bit heavy. TangoGraphQL server handles Tango errors as queries for best performance and keep GraphQL standard for parsing errors.

### Binary Transfer

A GraphQL internal parser has been written from scratch and designed to support a true binary JSON transfer currently under development. Binary transfer is not a part of the GraphQL and JSON standard but it can be added without breaking the GraphQL compatibility by using HTTP header. Despite the fact that TangoGraphQL uses fast floating point serialization algorithm Grisu2 [6] from Florian Loitsch, image and spectrum need to be transferred in binary format in order to reach good performance at both server and client side. On the client side, binary transfer can be easily achieved using native JavaScript DataViews and ArrayBuffer. Table 1 shows timing measurement of the TangoGraphQL C++ server for a spectrum of 16383 random double values, the JSON encoding in text format is done using Grisu2.

Table 1: TangoGraphQL Server Performance

	TEXT, 16digits	BIN, 64bits
Get HTTP request	1ms	0.9ms
Tango reading	0.9ms	0.9ms
JSON encoding	6ms (Grisu2)	0.3ms
Send HTTP response	0.4ms	0.3ms

### Asynchronous Group Calls

When the client needs to retrieve data from several devices (typically the state of n devices), the client can construct a GraphQL request using labeling. The server can detect labeled read\_attributes calls and launches parallel asynchronous calls using Tango Group calls.

### Load Balancing

TangoGraphQL is also a Tango server and can be configured, monitored or instantiated using standard Tango tools. It also has attributes that indicates number of connected clients, number and type of connections, network transfer, etc... The client can use this information to select the less loaded instance among a set of running TangoGraphQL servers as shown in Fig. 4.

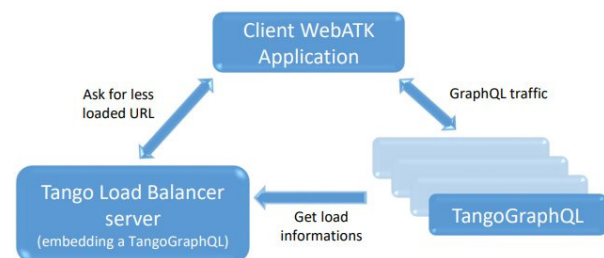

Figure 4: Load balancing model.

## TCP Connection

TangoGraphQL server uses multi-threaded connection handling and is HTTP 1.1 compliant. It uses the fact that in HTTP 1.1 the TCP connection can be persistent (keep-alive). The server keeps a “device factory” during all the TCP connection life cycle. This prevents from re-importing and re-introspecting each time Tango devices and avoids unwanted overhead with the Tango database and devices. When the connection is closed, TangoGraphQL releases all allocated resource associated to the connection.

## CONFIGURATION

TangoGraphQL server can be configured using Tango properties:

- *Port*: HTTP server port (default is 8000)
- *IdleTimeout*: Timeout before closing a HTTP connection (default is 60s)
- *Authentication*: None or Basic
- *Users*: List of allowed users, (List of userName: sha1Password)
- *AllowMutation*: Allow mutation mode (ALWAYS, AUTHENTICATED, NEVER).
- *exportGraphiQL*: True to enable GraphiQL (available via [http\(s\)://host:port/graphiql/](http(s)://host:port/graphiql/))
- *httpsEnable*: Enable HTTPS server (need certificate)
- *httpsCertificate*: Link to the certificate file cert and its privKey file. (The server needs read access to this 2 files)
- *ResolveClientIP*: Resolve names in (connected) clients attribute

## AUTHENTICATION AND ACCESS CONTROL

TangoGraphQL uses Open SSL for https with basic HTTP authentication scheme. Single SignOn authentication scheme is currently under development. Tango Access Control cannot be implemented using Tango 9 as it is not possible to set a username for a Tango client thread. This will require new feature of Tango 10.

## CONCLUSION AND DISCUSSIONS

After an investigation done at the ESRF of the 4 present solutions (including the one presented in this paper) for a Tango backend, GraphQL appears to be the best alternative.

- Tango Rest API (java REST API on top of Apache) [7]
- RestDS (& RestDS2) (C++ REST API on top of boost HTTP server) [8]
- MaxIV TangoQL (Python GraphQL on top of AIOHTTP & Graphene) [9]

In this paper, a C++ implementation of a Tango GraphQL schema is presented and express the minimum requirements we have at the ESRF in order to make the transition from our Java applications to Web applications possible. The GraphQL schema is not fixed; it may evolve over time, using deprecations, for example. The schema proposed here is still open to discussion. The goal is for the

community to converge on a common GraphQL specification which can be supported by multiple implementations.

# INTEGRATING OPC UA DEVICES IN EPICS

R. Lange<sup>†</sup>, ITER Organization, 13067 St. Paul lez Durance, France  
R. A. Elliot, K. Vestin, European Spallation Source, 221 00 Lund, Sweden  
B. Kuner, C. Winkler, Helmholtz-Zentrum Berlin, 14109 Berlin, Germany  
D. Zimoch, Paul-Scherrer-Institut, 5232 Villigen PSI, Switzerland

## Abstract

OPC Unified Architecture (OPC UA) is an open platform independent communication architecture for industrial automation developed by the OPC Foundation. Its key characteristics include a rich service-oriented architecture, enhanced security functionality and an integral information model, allowing to map complex data into an OPC UA namespace.

With its increasing popularity in the industrial world, OPC UA is an excellent strategic choice for integrating a wealth of different COTS devices and controllers into an existing control system infrastructure. The security functions extend its application to larger networks and across firewalls, while the support of user-defined data structures and fully symbolic addressing ensure flexibility, separation of concerns and robustness in the user interfaces.

In an international collaboration, a generic OPC UA support for the EPICS control system toolkit has been developed. It is used in operation at several facilities, integrating a variety of commercial controllers and systems. We describe design and implementation approach, discuss use cases and software quality aspects, report performance and present a roadmap of the next development steps.

## INTRODUCTION

Open Platform Communications Unified Architecture (OPC UA) is an open standard architecture intended to improve and expand interoperability in the Industrial Automation industry. It is a machine-to-machine communication protocol for industrial automation developed by the OPC Foundation [1] and released in 2008.

While its predecessor, OLE for Process Control (OPC; re-branded as OPC Classic) was developed by Microsoft and used a transport layer based on proprietary Microsoft software (e.g., OLE, DCOM), OPC UA focuses on platform independence and uses well-known open standards like TCP and TLS.

Over the last years, OPC UA has become increasingly popular in the world of Industrial Automation. Across all vendors, framework and device types, it is a key word for interoperability and integration, boosted by the OPC Foundation's certification program that ensures high levels of compliance.

## OPC UA ARCHITECTURE

### Features

OPC UA integrates all functionality of the OPC Classic specifications into a single extensible framework, providing (see [1]):

- Functional equivalence: all OPC Classic specifications are mapped to Unified Architecture.
- Platform independence: hardware and operating system portability covers everything from embedded systems to cloud-based infrastructure.
- Security: encryption, signing, authentication and auditing allow messages to be transmitted securely with verifiable integrity.
- Extensibility: new features can be added without affecting existing applications.
- Information modelling: a framework helps defining complex information.

### Core Concepts

The client-server communication model of OPC UA is layered: on top of a *transport*, which can be secured, the client opens a *session* to a server. Within that session, every piece of information is an *item* that can be written or read. Items are uniquely identified by a *nodeID*, consisting of a *namespace* number and an *identifier*, which can be numerical or a name string. To overcome the disadvantage of having to look up nodes by their name with every access, the client can *register* nodes with the server, to allow optimizing their name resolution.

Each item has a typed value, which can be of a basic data type, an array thereof, a union, or a structure consisting of multiple named elements, which are themselves of basic type, arrays, unions or structures.

Opening *subscriptions* in the session allows monitoring items for changes in their values. The subscription has a configurable *publishing period*, but any monitored item in the subscription can use a different *sampling period* for updating the value from the underlying device. For values that are sampled faster than their subscription is published, data loss can be avoided by defining a server-side queue.

OPC UA *methods* are basically remote procedure calls. They allow the client to send parameters (which can be of structured data types) and can return results to the client. All handshake and synchronization is part of the protocol specification and done within the client and server libraries.

<sup>†</sup> ralph.lange@iter.org

## INTEGRATION OF CONTROLLERS

In the existing approaches to integrate industrial controllers in control systems, a number of issues can be identified that can benefit from the application of OPC UA.

### *Industry Standard*

Integration of industrial controllers in control systems is a field of mostly proprietary protocols, which are usually vendor and sometimes device series specific. Setting up the communication with a new controller from a different vendor means switching to (or developing) a new driver, dealing with the issues and subtleties of a new protocol, gathering knowledge with a very narrow scope. For facilities with a long life time and in-kind contributions, the accumulation of driver software eventually induces a heavy maintenance burden.

Using an industry standard greatly reduces the amount of software related to the integration. Knowledge of the protocol is wide spread. Independent certification lowers the risk of particular devices behaving unexpectedly.

### *Symbolic Addressing*

In some of the controller communication protocols, low level addressing is done through byte offsets in data blocks inside the controller, e.g. for the Siemens S7 communication [2, 3] and the TCP data block send/receive [4]. Such offset addressing is brittle and susceptible to misalignments between the client and the controller. Several configuration approaches include the generation of both the data blocks on the controller and the configuration of the client as well as strict version tagging and checking to reduce the risk of mismatch [5, 6].

Symbolic addressing makes the client configuration much more obvious and handles modification of the controller software in a robust fashion. Controller and client development workflows can be cleanly separated and have a clear interface.

### *Structured Data*

Modern industrial controller programming uses object-like blocks that are repeated when systems are scaled up. Such programming techniques inherently produce hierarchical data structures on the controller. Mapping these objects into a flat structure for the controller communication (e.g., for the send/receive driver [4]) needs additional programming on the controller that adds complexity, needs development resources and uses run time resources on the controller.

Using OPC UA, the controller structures are directly mapped into the OPC UA namespace. No additional programming is needed on the controller. The client configuration directly uses the server-side hierarchy.

### *Remote Procedure Calls*

Existing communication protocols are usually data-centric – they cover reading and writing data from/to the controller memory. Many control systems integrations have a concept of commands, which needs to be implemented on

top of the data-centric interface. Such implementations require additional effort and programming on both the client and the controller for the synchronization (handshake).

Industrial controllers map the OPC UA *methods* feature (see below) to the execution of a function block, including the transmission of parameters and return values. This allows for a very simple yet rich and powerful implementation of commands.

### *Security*

Specific applications, e.g. in the context of medical accelerators and for communications with safety and interlock systems, require or benefit from using the security features of OPC UA.

Secure OPC UA communication also allows running connections over insecure or open networks, e.g. wireless or remote connections.

### *Embedded OPC UA Servers*

Some popular standard PLCs, like the Siemens S7 1200 and 1500 series, can run OPC UA servers embedded inside the controller. This allows for a slim and simple integration architecture, avoiding additional layers of hard- and software between controller and integration.

## EPICS DEVICE SUPPORT

From the beginning of the project, the goal was to provide a solution completely based on free and open software.

However, based on an evaluation of existing OPC UA clients, the C++ Based OPC UA Client SDK by Unified Automation [7] was selected as the first client library to be supported. Other candidates were disregarded because of incomplete implementation of the OPC UA specification, low robustness in failure scenarios or poor consistency of their API with EPICS concepts.

Consequently, the OPC UA Device Support module is also written in C++, using an architecture that supports adding other low level client libraries. A second implementation is currently being added to the project, based on the client library of the open62541 [8] project.

### *Layered Structure*

The interface to the EPICS Database supports all applicable record and data types from EPICS Base. In addition to the configuration of sessions and subscriptions, a set of tracing and debugging functions is available to be used from the EPICS iocShell.

Below that, a generic layer of interfaces (C++ virtual base classes) follows the core definitions of OPC UA: session, subscription, item and data element (implementing one value inside a structure) are interfaces to their respective implementations by the client library. A set of helper classes (implemented as templates) covers functionalities that all client libraries need to provide.

The lower layer provides implementation and adaptation of the generic APIs to the specifically used client library. In the case of the Unified Automation client, this part con-

tains a pretty straightforward mapping to the SDK's interfaces. The open62541 based implementation adds a fair amount of complexity in this layer, wrapping around the simpler C APIs of the open62541 client.

Recently, a second implementation of an EPICS Device Support for the open62541 client has been announced [9], suggesting that this client in its current state is a viable alternative.

### Robust Support for Structured Data

Structured data needs to be well supported, as the Siemens S7 embedded OPC UA server (one of the main use cases) performs much better when using structured data compared to addressing every element as a separate OPC UA item.

Interfacing structured data to the EPICS Database pushes for a separation between the item with its configuration parameters and the elements (values) of the structure that are each connected to a different EPICS record. This is reflected in the implementation: A single item record (an additional EPICS record type) carrying the item related configuration connects to the item object below. Many regular EPICS records carrying the single value related information and their address relative to the structure root connect each to one data element object below. The addressing information from the data element records is used to create a tree of data element objects that represents the expected structure. As the OPC UA server may change its internal structure between sessions, this IOC side tree must be mapped against the structure that is actually found on the server every time a session is established or re-established.

Writable data structures can be handled in two modes: When many elements of a structure are changed in one moment (e.g., when loading back snapshot data), OPC UA sending can be triggered explicitly by writing to a field of the item record. When only single elements of a structure are written at a time (e.g., while operating), OPC UA sending can be triggered automatically whenever a data element is written to.

## SOFTWARE QA

### Static Code Analysis

Static code analysis is being performed on the module as part of the Continuous Integration setups, making sure that the code is consistently showing high quality ratings. The public service Codacy is used for static analysis of the code in the public upstream repository [10] in addition to ITER's local installation of SonarQube [11].

### Unit Testing

Unit tests have been introduced for the helper classes in the generic layer. Coverage, however, is still very limited. Unit tests for the lower level code would be highly desirable, but will need a noticeable investment. A possible approach would be using a mock of the client library APIs with GoogleTest [12] to allow separate testing of the integration layer.

### End-to-End Testing

An end-to-end test suite was developed to provide confidence that the device support module functions as expected, in terms of correctness and performance. It also serves to test for any regression that may be introduced, as the tests can be triggered to automatically run for all new commits to the source repository.

The test setup comprises of a software OPC UA server, implemented using open62541 [8], two IOCs, and a Python-based test suite using pytest [13]. In order to communicate with both an EPICS IOC and the OPC UA software server directly, both the PyEpics [14] and opcua [15] Python modules are used. Running of the software server and IOC is handled during test execution by way of test setup and teardown methods.

The OPC UA test server hosts a set of items, covering all supported OPC UA data types. *Connection tests* validate the ability of the EPICS module to connect, reconnect and disconnect from the OPC UA server under a variety of conditions. *Variable tests* verify that that EPICS module correctly translates variable values to/from the types used on the OPC UA server. *Performance tests* are used to characterize the performance of the EPICS module in terms of execution time and memory consumption. *Negative tests* ensure that the EPICS module is able to handle error cases and incorrect inputs gracefully.

The test suite is currently in active use at the ESS facility to provide regression testing under the localized EPICS build system, ensuring that any changes to EPICS environment or OPC UA module have no detrimental impact on the relevant devices in the control system.

A second set of automated tests based on the same framework has been defined for the ABB Power SCADA integration at the ESS to allow efficient regression testing on the final application level as well as on the device support level.

Both test suites are configured to be executed as part of the ESS build pipeline for any new merges against the device support or application modules.

## A COLLABORATIVE EFFORT

In 2016, B. Kuner at the Helmholtz-Zentrum Berlin evaluated available public and commercial OPC UA client libraries and settled on the C++ Based OPC UA Client SDK by Unified Automation [7]. He created a prototype of the EPICS Device Support [16], robust enough to be used in production at BESSY II and ITER for several years.

After performance measurements using the prototype at ITER were showing solid results, R. Lange started the full implementation [17] in 2018, based on the design outlined above. Other institutes were doing evaluations of the module while it was being developed.

In 2020, R. A. Elliot and K. Vestin began working on the end-to-end test suite described above, which will be merged to become part of the main project in the next version.

In 2021, C. Winkler was helping to finalize and test the Windows build of the Device Support. D. Zimoch and

C. Winkler started the integration of the open62541 client library, which is still ongoing and is likely to be added to the main project soon.

## CURRENT STATUS AND ROADMAP

The EPICS OPC UA Device Support module is stable, mature and robust. It is used by several institutes against different OPC UA servers in productional setups. Table 1 shows a list of currently known applications of the module and their status.

Table 1: Existing Users and Applications (incomplete)

Facility	OPC UA Server	Status
ASIPP	LabVIEW	production
	PLC Siemens S7-1500	production
Australian Synchrotron	PLC Siemens S7-1500F	near production
BESSY II @HZB	PLC Siemens S7-1500	production
	Phoenix Contact Softing uaGate	production
CHIMERA @CCFE	PLC Siemens S7-1500	development
	LabVIEW	development
ESS	PLC Siemens S7-1500F	production
	ABB Power SCADA	near production
	Siemens DESIGO	development
Fermilab	Kepware KEPServerEX	testing
	PLC Siemens S7-400	development
IPR	PLC Siemens S7-1500	testing
ITER	PLC Siemens S7-1500	production
	Siemens WinCC OA	production
KATRIN @KIT [18]	PCVue	production
	LabVIEW	prototyping
PSI	PLC Siemens S7-1500	development
Varian ProBeam <sup>1</sup>	PLC Siemens S7	production
	PLC Beckhoff	production

A requirement specification exists and is kept up-to-date [19]. The remaining feature from this document that needs to be implemented is the support for OPC UA methods – this effort has been started.

Comprehensive user level documentation still needs to be added. The existing “cheat sheet” documentation is sparse.

The unit tests and the end-to-end test suite need to be extended and completed to achieve a better level of test coverage.

<sup>1</sup> On Windows and VxWorks platforms.

# THE EVOLUTION OF THE DOOCS C++ CODE BASE

L. Fröhlich\*, A. Aghababayan, S. Grunewald, O. Hensler, U. F. Jastrow, R. Kammering, H. Keller†, V. Kocharyan, M. Mommertz, F. Peters, A. Petrosyan, G. Petrosyan, L. Petrosyan, V. Petrosyan, K. Rehlich, V. Rybnikov, G. Schlesselmann, J. Wilgen, T. Wilksen,  
Deutsches Elektronen-Synchrotron DESY, Germany

## Abstract

This contribution traces the development of DESY's control system DOOCS from its origins in 1992 to its current state as the backbone of the European XFEL and FLASH accelerators and of the future Petra IV light source. Some details of the continual modernization and refactoring efforts on the 1.5 million line C++ code base are highlighted.

## INTRODUCTION

DOOCS [1, 2] started out at DESY in 1992 as a control solution for vacuum devices – ion getter pumps and similar equipment – for superconducting cavity test stands. Later it was ported to the HERA [3] proton storage ring to replace an older predecessor. It was built around Sun Microsystem's remote procedure call protocol (*SunRPC*) that continues to be used today in many well-known services such as the Network File System (NFS) under the newer name Open Network Computing RPC (*ONC RPC* [4]).

At the time, object-oriented programming was quickly establishing itself as the dominant programming paradigm, which lead to the new system being called the "distributed object-oriented control system", DOOCS. It was implemented in C++, the natural choice for developing reliable software that could use high-level abstractions, work with limited resources, and access hardware efficiently. Java, the next "big" language to champion object-orientation, would not be released to the public until 1994/1995 [5].

The C++ of the year 1992 was quite different from modern versions of the language. It was six years before the first ISO standardization of the language [6], and many features taken for granted today were still in their infancy: Templates, namespaces, and exception handling had just been specified [7] but were not or only partially available on the compilers of the time. The standard template library (STL) and even the `bool` type would not be standardized until 1998. It is therefore only natural that early DOOCS sources, although heavily using classes and inheritance, look more like low-level C than modern C++ from today's perspective.

These first years established the backbone of DOOCS and formed many of the conventions that shaped the development of the code over the following two decades. Although the code was continually extended and maintained, its basic style changed relatively little until some years after the introduction of C++11 [8]. Although the new standard could not be adopted for the core libraries until 2018 due to lack of compiler support on the Solaris platform, it lead to re-

newed interest in C++ and modern programming styles and attracted new developers. Gradually, more and more effort was put into the modernization of the code base. We are going to highlight a few of the changes made during this ongoing modernization effort below. For orientation, we first give a brief overview of the DOOCS code base.

## CODE ORGANIZATION

DOOCS consists of multiple libraries, tools, and servers, the biggest part of which is written in C++<sup>1</sup>. Two libraries form the core of almost every DOOCS application:

- The DOOCS client library (*clientlib*) provides the basic functionality to list names() from the DOOCS namespace and to send get() and set() requests over the network. It also offers interoperability with other control systems such as EPICS [10] and TINE [11, 12] by exposing some of their native functionality via the DOOCS API.
- The DOOCS server library (*serverlib*) provides the building blocks for a DOOCS server which accepts requests from the network. It contains classes for *properties* of various data types and allows instantiating these properties as members of *locations* with user-defined functionality. It also handles archiving, configuration management and related tasks.

These two libraries are complemented by approximately one hundred other DOOCS-related libraries of various purposes, ranging from support for specific hardware like cameras over interfaces to data acquisition (DAQ) systems to high-level algorithms for particle tracking.

Most of the DOOCS applications are servers. They connect hardware devices such as beam position monitors or vacuum pumps to the network, process and archive data, run feedback loops, and execute complex algorithms for advanced data evaluation. Currently, our repositories contain source code for more than 500 different server types. For most of these, multiple instances are running at one or more of DESY's accelerator facilities. Between libraries and servers, the C++ code base consists of ~8000 source files with a total of ~1.5 million lines of code<sup>2</sup>.

Figures 1 and 2 show the development of the number of lines of code in the client- and serverlib over time. It is worth noting that the clientlib was dominated by C code between

\* lars.froehlich@desy.de

† retired

<sup>1</sup> Notable exceptions are the JDOOCS client library for Java and tools based on it such as the graphical user interface builder *jddd* [9]. Client libraries for Python, Matlab, and LabView also exist and have spawned a multitude of tools in these languages.

<sup>2</sup> We count lines of code excluding comments and blank lines using the `cloc` [13] utility.

Figure 1: Lines of code excluding comments and blank lines in the DOOCS clientlib. The plot differentiates between C implementation files, C++ implementation files, header files, and C++ unit tests. From 2003 to 2020, the library was dominated by C code from the included TINE client library.

Figure 2: Lines of code excluding comments and blank lines in the DOOCS serverlib. The plot differentiates between C++ implementation files, header files, and C++ unit tests. Development started in 1992, but the history preceding the year 2010 has been lost.

2003 and 2020 because of the inclusion of the full client and server sources for the TINE control system. Since last year, TINE is linked as an external shared library. This has allowed us to preserve the full set of interoperability features without having to deal with compiler warnings from its legacy code base. A small amount of C code still remains for the interface with the RPC library.

## MODERNIZATION OF CODE AND DEVELOPMENT TECHNIQUES

Modernizing a code base whose oldest parts date back to 1992 has its risks. For the most part, bugs in the existing code have been ironed out many years ago, and refactoring tends to introduce new ones. The almost complete absence of unit tests until 2018 means that inadvertent behavior changes introduced through modifications are very hard to detect. Many desirable changes in libraries are also impossible without sacrificing the stability of the application programming interface (API), causing the need to adapt huge numbers of dependent projects.

While all of these can be good reasons to leave existing code untouched, we also observed several tendencies that slowly became a cause for concern:

- Certain parts of the code had become so complex that they could only be understood by single developers.
- Introducing new features was becoming harder and more error-prone.
- Attracting new programmers to actively participate in the development was becoming harder.

All of this lead us to the conclusion that a careful modernization not only of the code base, but also of our development techniques would be necessary to prepare DOOCS for future projects. We set ourselves the following goals:

- Improve the *readability* of the code to make it easier for all developers to understand how it works.
- Improve overall *maintainability* by better code organization and reduced complexity.
- Improve *stability* by eliminating sources of bugs, memory leaks, and undefined behavior.
- Improve *teamwork* by collaborative development techniques and code reviews.

We discuss some of the measures taken in this spirit below, but the list is necessarily incomplete. In fact, outside of the core libraries individual developers have wide freedoms to adopt them only partially or to go far beyond them.

### More Modern C++ Constructs

A huge part of the changes that started in the middle of the 2010s regards the use of the C++ language and its standard library itself:

*Language standard:* Solaris was dropped as a development platform for DOOCS in 2018. This has allowed us to use the C++14 [14] standard with the compilers for all remaining supported platforms since then. We expect to upgrade to C++17 [15] and possibly later standards in the coming years when support for a few old Linux distributions is dropped.

*Templates* had practically been banned from the core libraries after bad experiences with compilers in the 1990s. Through their (re-)introduction, the amount of duplicated code could be reduced dramatically while improving the uniformity of interfaces and their type safety at the same time. One of the visible effects for DOOCS users is the availability of a full set of signed and unsigned integer types in various bit widths.

*Const-correctness* was largely ignored in the original APIs. Retrofitting *const* modifiers across API and inheritance boundaries can be a delicate task as it often involves changes

to multiple projects at the same time. Although a lot of work remains to be done, the public APIs have already improved a lot and make it much easier to write const-correct code.

*String handling* in the original core libraries almost exclusively meant dealing with C strings or raw memory. Some of that code was rewritten to use the standard `string` or `string_view` classes, dramatically reducing complexity, line count, and room for errors. Virtually all of the user-facing API now uses these classes in function signatures instead of `const char*` or even `char*`.

*Memory handling* was mostly based on raw pointers and explicit use of `new` and `delete`, making new code prone to memory leaks. This type of code is gradually being replaced by STL containers, RAII (resource acquisition is initialization) types, and smart pointers.

*Algorithms* from the STL were not widely used in the original code base. Their increased application helps make many code passages much more succinct and readable.

*Standard types* have replaced entire platform-specific libraries. For instance, the standard `thread` is now used instead of its counterpart from the POSIX threads library.

*Strong types* are gradually being introduced to replace fundamental types like `int` for specific applications (e.g. `Timestamp`, `EventId`). This makes it harder to confuse function parameters and allows enriching the type with functionality and invariants.

## Unit Tests

Apart from a few very limited integration tests, none of the core libraries had a real test suite until 2018. At this point, we started writing unit tests using the Catch2 [16] framework. Most tests are written to assert the current behavior of the code before modifying or refactoring it. Unfortunately, parts of the code have complex dependencies that make testing hard. This situation can only be improved through partial rewrites in the long run. Both the client- and the serverlib remain severely undertested with 1 line of tests for 16 lines of code for the former and 1:8 for the latter, but the test suites are growing continuously.

## Build System

We are in the process of changing our build system from `make` to `Meson` [17]. Overall, this makes our build setup much simpler and less platform dependent. `Meson` was chosen over similar alternatives because of its comparatively simple syntax and because of in-house expertise.

## General Utility Library GUL14

Even in comparatively small C++ code bases, some basic functionality gets implemented again and again because it is not available through the standard library – for instance, a function to determine if a string contains another string<sup>3</sup>. This has led to the development of several *base libraries* [18–20] in the industry attempting to fill this gap.

<sup>3</sup> A `contains()` member function for the standard `string` class is only expected for the 2023 language standard.

Figure 3: Lines of code excluding comments and blank lines in GUL14. The plot differentiates between header files, C++ implementation files, and unit tests. We do not count the header of the Catch2 unit testing framework which is included in the library.

We evaluated several of them and, amid concerns about their impact on our build process, found all of them lacking some specific functionality that we needed.

In August 2018, we therefore started the development of our own *General Utility Library for C++14* (GUL14). The library gathers code of wide applicability that has no external dependencies except for the C++ and C standard libraries. Specifically, it is free from control system specific code. Among other fields, it covers string operations, concurrency, time, statistics, numeric utilities, containers, and backports of features from post-C++14 standard libraries (e.g. `string_view` and `span`).

As it forms the basis for all other DOOCS libraries and applications, we strive for a very high quality level for GUL14:

- *Style*: Code must adhere to our C++ style guide and it should follow the C++ Core Guidelines.
- *Documentation*: Every function, type, or other entity in the API must be fully documented. This includes a clear description of purpose and functionality. For functions, all parameters, return values, thrown exceptions, and pre-/postconditions are described. For classes, all class invariants are clearly stated.
- *Unit tests*: Every entity in the library must have a set of associated unit tests.
- *Code review*: Every commit to the library must be reviewed by at least one developer. Every developer must ensure that all of the other quality criteria are fulfilled.

As shown in Fig. 3, the library is dominated by template code residing in header files. The unit test suite has more lines of code than the library itself.

GUL14 is open source and published under the GNU Lesser General Public License v2.1 [21]. Unfortunately we currently cannot publish the code on a third-party platform

like Github, but the source code and documentation are publicly available [22] and external contributions are welcome.

### Code Review

Code reviews are an excellent method to screen code changes for defects. Maybe more importantly, they foster mutual learning between developers and thereby help spread expert knowledge. Unfortunately, they also take a substantial amount of time. Owing to the already high workload on our development team, we have adopted a multi-layered guideline:

1. For GUL14, every commit must be reviewed and accepted by at least one other developer.
2. For the client- and serverlib, all but trivial commits must pass review.
3. For other libraries, code review is strongly encouraged.
4. For servers and tools, code review is optional.

Code reviews typically take place via merge requests on an on-site Gitlab web server.

### Continuous Integration

The code for the core libraries is automatically compiled and tested on multiple platforms by the Gitlab system after each commit. In part, this includes address sanitizer and undefined behavior sanitizer builds, which generally provides excellent early warnings against faulty code. We are also looking into continuous delivery (CD) workflows for the future.

### Cross-Project Refactoring

Some refactorings, especially API changes in libraries, require invasive modifications in user code. Although we generally try to avoid such changes, a few of them are deemed essential to fix architectural problems. Since DOOCS is used almost exclusively at DESY with only few external users, we are in the lucky situation that we have control over almost all user code in our version control repositories. Refactorings of low complexity (such as renaming a class member or a header file) can therefore be automatically applied via text substitution scripts. Where possible, the old API is marked as deprecated and remains available for 1–2 years until it is finally removed.

### Training

Educating new programmers is essential to maintain a capable control system software team. To this end, we are providing a regular series of remote lectures on DOOCS related topics. A C++ style guide provides orientation on common coding conventions.

## CONCLUSION

Next year, DOOCS will turn 30. As in any code base of this age, some problems have accumulated over time and tend to hinder further development. Since the mid-2010s, however, we have invested more and more effort into the continuous refactoring of the code and into a modernization

of our development process. We try to take advantage of established best practices, of recent improvements of the C++ language itself, and of modern tooling to improve the quality of the code and the cooperation between the developers. The feedback received from our users makes us hopeful that we are on the right path to prepare DOOCS for the future.

## ACKNOWLEDGEMENTS

We would like to thank J. Georg, M. Hierholzer, D. Kalantaryan, M. Killenberg, and T. Kozak for contributing patches and bug reports for the core DOOCS libraries. Innumerable colleagues from the M-, FS-, and FH- groups have helped shape the development of DOOCS over the years and deserve our gratitude. We also acknowledge the continuous support by the machine and research divisions at DESY, the Helmholtz Association of German Research Centers, and the European X-Ray Free-Electron Laser Facility GmbH.

# APPLICATION OF EPICS SOFTWARE IN LINEAR ACCELERATOR

Yuhui Guo<sup>†</sup>, Nian Xie, Rui Wang, Haitao Liu, Baojia Wang  
Institute of Modern Physics, Chinese Academy of Sciences, Lanzhou, China

## Abstract

The institute of modern physics (IMP) has two sets of linear accelerator facilities, they are CAFe (China ADS front-end demo linac) and LEAF (Low Energy Accelerator Facility). The Main equipment of LEAF facility consists of ion source, LEBT (Low Energy Beam Transport), RFQ (Radio Frequency Quadrupole) and some experiment terminals. Compare with LEAF, CAFe equipment has more and adds MEBT (Medium Energy Beam Transport) and four sets of superconducting cavity strings at the back end of RFQ. In the process of commissioning and running linac equipment, The EPICS Archiver application and Alarm system are used. According to the refined control requirements of the facility sites, we have completed the software upgrade and deployment of the archiver and alarm systems. The upgraded software system have made the operation of linac machines more effective in term of monitoring, fault-diagnostic and system recovery, and becomes more user-friendly as well.

## INTRODUCTION

The CAFe is a prototype of ADS proton superconducting linear accelerator. It mainly includes a compact ECR (Electron Cyclotron Resonance) ion source, a low energy beam transport LEBT section, a radio frequency quadrupole acceleration system RFQ, a MEBT, 4 sets of CM superconducting cavity strings, a HEBT (High Energy Beam Transport) and a beam dump with the function of measuring current intensity and absorbing the energy from ion beam [1,2]. The layout of CAFe facility is shown in Fig. 1.

Figure 1: The layout of the CAFe facility.

The CAFe facility can provide a high power beam with the beam intensity of several mA. At the same time, CAFe, as a new research device, needs to do some research on the operation mode of the machine.

The LEAF contains a 45 GHz fourth-generation superconducting high-charge state ECR ion source, a 300 kV high-voltage platform, an advanced RFQ heavy ion accelerator capable of accelerating a variety of ions, and a DTL

energy regulator. LEAF is a research facility of the low-energy, high-current and high-charged heavy ion [3]. The layout of the LEAF is shown in Fig. 2.

Figure 2: The layout of the LEAF facility.

LEAF can provide pulse (beam energy range of 0.1-20 MeV) and continuous beam with high beam intensity, high charge state and many kinds of ions. The core parts of the LEAF are superconducting high charge ECR ion source and RFQ accelerator. They are the most key equipment of the front-end injector for the next generation large heavy ion accelerator. Therefore, the development of the LEAF will build a good foundation for the development of the next generation high-power high current heavy ion accelerator.

During the commissioning and operation of the LEAF and CAFe accelerator systems, the upper-level applications have a similar requirement for both systems. For example, the alarm system needs to monitor whether values of the defined PV variables exceed their safety threshold ranges, and the data archiving system needs to store the historical relevant PV data from the systems for fault location diagnosis and error analysis.

For the alarm system, the BEAST software package is used for the LEAF, which is mainly composed of Alarm-ConfigTool, Alarm Server, JMS (Java Message Server) and Alarm Client GUI. In the control system of the CAFe facility, we use the alarm module from the EPICS Phoenix software to upgrade the BEAST-based alarm system. Compared with ActiveMQ message publishing technology, Kafka with its own alarm message publishing technology has much higher data throughput and is more suitable for processing large-scale real-time data streams.

For the data archiving system, we used the Channel Archiver and Archiver Appliance software packages in the EPICS software tool to build two data archiving systems with redundant functions. The Channel Archiver software package was released earlier, and its client software is relatively rich. The Archiver Appliance is a new data archiving system and adopts a multi-level storage method. It also provides a Web front-end management interface, allowing

<sup>†</sup>Email address: guoyuhui@impcas.ac.cn

users to directly archive, query and manage PV variables through web pages.

## OVERALL STRUCTURE OF THE SOFTWARE SYSTEM

As the types of field equipment of linear accelerator are varied and the installation positions are relatively scattered, we use a network-based distributed software structure to construct the upper-level application software system. The software structure is shown in Fig. 3.

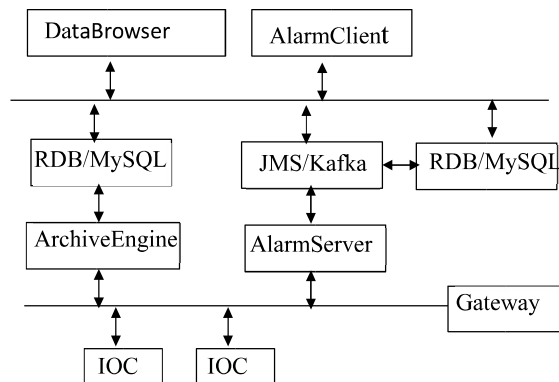

Figure 3: Software structure of data archiving and alarm system.

The CSS-based DataBrowser and AlarmClient tools are used for our operation interface which provides the functionalities of querying the operating status of the equipment and displaying the alarm information. For the alarm system and archiver system, they have been very well integrated in CSS. By relatively simple parameter configurations, Users can easily query and display required operation data.

ArchiverEngine is mainly responsible for reading the real-time data from listed PVs from all IOCs, and then saving it to the historical database; AlarmServer is the core of the alarm system and communicates with the IOC through the CA (Channel Access) protocol to monitor the alarm status of PV values and publish the alarm messages.

In order to improve the reliability of the data link connection when reading a large number of PV variables, and at the same time to classify and manage these data, the EP-CIS gateway tool is used between IOCs and the upper data processing engine to achieve the security control of data access and data classification.

## ALARM SYSTEM

When the operating status of the field equipment changes, especially when a fault occurs, the alarm system will issue alarm information to the accelerator commissioning, operation and maintenance personnel or equipment maintenance personnel through software user interface, voice, SMS(text messages) or other methods. The alarm system should not be used to replace the equipment protection functions of the Interlock system. It provides data for equipment operators to analyze the causes of equipment failures, but sometimes it also increases the

burden of data analysis for operation and maintenance personnel. During accelerator beam commissioning, the physical personnel can use the electronic log software to realize the recording function of the alarmed equipment and the processing methods of the operation and maintenance personnel. Clog electronic log is used in CAFE facility, which is provided by CSNS.

The alarm system based on the BEAST software package can import the database configuration file into the relational database through the AlarmConfigTool tool. The Alarm Server is used to read the configuration information from the relational database, monitor the alarm information of the PV channels in the IOCs, and pass the alarm information to the client through the JMS; JMS acts as a communication channel between alarm client and server to transmit alarm messages, receive log information of other applications etc. The Alarm Client GUI is used to display alarm information in real time. The demand statistics of some alarm equipment of LEAF system is shown in Table 1.

Table 1: Main Alarm Device Information Statistics of LEAF Facility

Device name or system	Threshold Value	Alarm message is displayed
RFQ cooling water system	Water temperature 36°	RFQ water temperature alarm
	Water flow 20L/min	RFQ water flow alarm
	Water pressure 0.3Pa	RFQ water pressure alarm
Vacuum system	LEBT 10-5mbar	LEBT vacuum alarm
	RFQ 1.1x10-5mbar	RFQ vacuum alarm
Water quality monitoring	Water resistance 9 MΩ	Water resistance alarm
	Level of water tank 1.5m	Water level alarm of tank
	Supply-water pressure 4 bar	Water pressure alarm of water

The data source monitored by the Alarm system can come from the device IOC or the PV variables published by the soft IOC. For example, the Alarm system of CAFE can monitor the change of the PV values published by using the pccapy software package to realize the alarm of the soft protection logic value in the MPS system. The operation interface of the alarm system is shown in Fig. 4.

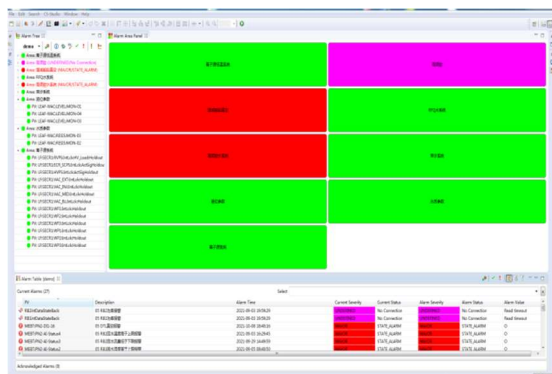

Figure 4: Operation interface of the Alarm system.

As shown in Fig. 4, the alarm system of LEAF includes 9 alarm modules, which are ion source cryogenic system, vacuum system of energy increasing and decreasing section, radio -frequency cavity water temperature system, liquid level parameters, ion source system, radio-frequency cavity, RFQ Water system, beam diagnosis system and water quality system.

In the construction of the alarm system of the CAFE facility, we adopt the Phoebus-based CSS software system for interface development and deployment. Phoebus is the current variant of Control System Studio [4]. Compared to the environment of the early CSS software, it no longer depends on EclipseRCP. Instead, it offers software tools such as Display Builder, Data Browser, Probe, PV Tree, Alarm, Scan and so on. The Phoebus software architecture is simpler, and the development environment is easy to set up, all of which help greatly improve the user experience. It is a very suitable for the development of control system operation interface.

Alarms in Phoebus are composed of server and client modules [5]. The server sends alarm messages to the Kafka middle message plug-in by monitoring the changes in the alarm status of the PV variables issued by each IOC. The alarm interfaces that can be displayed on the Phoebus software are Alarm Tree, Alarm Table and Alarm Area Panel.

The alarm module in Phoebus software is used to deploy the alarm system, which can provide users with a concise, manageable and operable alarm interface, realize the visualization of alarm data and improve the real-time performance of fault handling.

## DATA ARCHIVER SYSTEM

In the process of accelerator commissioning and operation, the equipment fault location and fault analysis based on the data archiving system is very important. When equipment failures or beam current accidents occur, accelerator physics personnel need the data archiving system to provide historical data of related equipment to facilitate post-accident handling and cause analysis.

Previous archive systems were built based on the EPICS Channel Archiver tool, using MySQL for data storage and running a database server on Linux, and mounting the IBM DS3512 disk array for data storage as well. KeepAlived is used to achieve high availability of the database server [6]. The archive system communicates with the front-end IOC

using the ArchiveEngine tool, and the browsing and query of archived data is realized by the DataBrowser tool in the CS-Studio software.

As the scale of data in the archive database becomes larger and larger, the speed of reading and retrieving the data stored in the MySQL database becomes slower and slower. At the same time, the BEAUTY-based archive system does not provide friendly interfaces of information query and management. Therefore, we upgraded the archive system of these two facilities (LEAF and CAFE) with Archiver Appliance.

The new archiving system includes IOC data collection, data archiving engine (Archiver Appliance) and data query and information management tools. Its software system structure is shown as in Fig. 5.

Figure 5: The structure diagram of Archiver Appliance.

The Archiver Appliance reads PV data according to the PV variable name, data sampling mode and frequency in the configuration file, and stores the collected data in a structured file in PB format. The DataBrowser supports Archiver Appliance's PB/HTTP protocol and accesses it through the pbrow interface. Users can directly access and query the Archiver Appliance data system through a browser and receive Web response of user filing to their query requests. The web operation interface of the Archiver Appliance system is shown in Fig. 6.

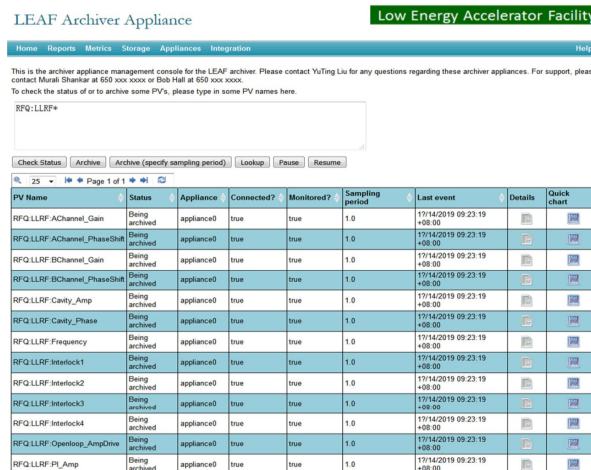

Figure 6: The Web operation interface of Archiver Appliance.

The data archiving system based on the Archiver Appliance solves the problems of low data index efficiency and inconvenient background management in the past. At the same time, the upper human-computer interaction interface is designed by using CSS software system based on Phoebus, which provides convenience for physical personnel to access experimental data and fault diagnosis and analysis.

## CONCLUSION

Compared with the alarm system of ActiveMQ message mechanism, the accelerator alarm system based on Kafka streaming data platform can effectively improve the data throughput of the system and the real-time performance of alarm information release.

The archive system software of Channel Archiver was released earlier, and its client software is relatively rich. The new Archiver Appliance software uses a multi-level storage method, which can retrieve 1 Hz double-precision data for one day within 0.5 seconds. It also provides a Web front-end management interface, which has more advantages in system information management and fast data retrieval.

After the upgrade and redeployment of the above application software, the usability of the data service in the control systems of the two facilities is improved, and better user-friendly interfaces are provided for data query and operations. The upgraded software systems run more stable, and the user interfaces are more friendly, which improves the maintainability of the accelerator device for long-term operation.

# THE DEPLOYMENT TECHNOLOGY OF EPICS APPLICATION SOFTWARE BASED ON DOCKER

R. Wang<sup>†</sup>, Y. H. Guo, B. J. Wang, N. Xie, IMP, Lanzhou 730000, P. R. China

## Abstract

StreamDevice, as a general-purpose string interface device's Epics driver, has been widely used in the control of devices with network and serial ports in CAFe equipment. For example, the remote control of magnet power supply, vacuum gauges and various vacuum valves or pumps, as well as the information reading and control of Gauss meter equipment used in magnetic field measurement. In the process of on-site software development, we found that various errors are caused during the deployment of StreamDevice about the dependence on software environment and library functions, which because of different operating system environments and EPICS tool software versions. This makes StreamDevice deployment very time-consuming and labor-intensive. To ensure that StreamDevice works in a unified environment and can be deployed and migrated efficiently, the Docker container technology is used to encapsulate its software and its application environment. Images will be uploaded to an Aliyun private library to facilitate software developers to download and use. At the same time, some technical implementations, to ensure the safety of containers and host, for communication security between containers and system resource management should be taken on our host. In the future, the large-scale efficient and stable deployment of StreamDevice software can be realized by pulling images on the server installed with Docker, avoiding a lot of repetitive work and greatly saving the time of control technicians.

## INTRODUCTION

CAFe equipment, the CiADS superconducting linear accelerator prototype, was built in 2018 to validate the superconducting linear accelerator for CiADS with 10 mA continuous beam current. The equipment consists of the ion source, low-energy transmission section, RFQ, medium-energy transmission section, superconducting linear accelerator, high-energy transmission section, and beam terminal collector. The equipment layout is shown in Fig. 1. The overall parameters of the equipment include the beam intensity of 10mA, the beam energy of 25-40MeV, the RF frequency of 162.5MHz, as well as the temperature of 4.5k [1-3].

Figure 1: Layout of CAFe superconducting proton linear accelerator.

At present, EPICS is mostly used in the CAFe equipment control software of the Institute of Modern Physics, Chinese Academy of Sciences. The experimental physics and industrial control software adopt the standard distributed control system model and run stably. The device driver is developed with unified system architecture. It has gradually replaced LabVIEW as the mainstream software architecture and development tool for the accelerator control system in China and abroad. StreamDevice module is needed to realize serial communication equipment and drive control, which has the interface of the asynchronous drive module (ASYN) and can provide equipment support for EPICS [4].

With the upgrading of CAFe equipment, the servers have also been updated. In practice, it is found that there are often encountered unknown errors in the installation of EPICS on each new server. A lot of manpower and time will be paid to find the cause of the problems and solve methods. But the solutions do not possess universality. In order to improve the deployment efficiency and reduce the difficulty of application migration, Docker [5] is used to encapsulate EPICS + StreamDevice to assure the unification of the operating environment on different machines. At the same time, a series of security problems existing in the current container should be optimized and improved.

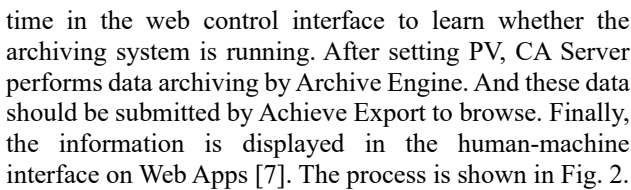

## FUNCTIONALITY AND REQUIREMENTS

An asynchronous drive module (ASYN) interface was integrated with StreamDevice, which supports serial ports (RS485, RS232), IEEE-488 (GPIB or HP-IB), and Ethernet interfaces. It can realize the communication between serial ports and Gaussian power supply. The communication rules are specified by writing protocol files, and PV information is defined by DB files [6]. The result of the EPICS reads and sets the equipment information was achieved. Because the StreamDevice, a model of EPICS, was used to develop of I/O IOC for power and Gauss meter.

StreamDevice can analyze web pages by regular expressions, as well as read this important information in real

<sup>†</sup> wangrui@impcas.ac.cn

Figure 2: StreamDevice is used to monitor the running status of your app and parse web pages.

EPICS has been widely used in the field of CAFE equipment control. The application based on EPICS has good portability, scalability, reusability, and maintainability. EPICS can be divided into three parts from top to bottom: the upper layer is the operator interface OPI, which can complete the human-machine interaction (HMI) process. The middle layer is the input and output controller, referred to as the IOC. The lower layer is channel protocol CA, CA protocol is divided into two parts: CA client and CA server [8]. The servers running IOC can be accessed via TCP/IP by the client. ASYN provides driver support for communication with hardware devices. StreamDevice, a generic EPICS device, can control devices by sending and receiving strings [9].

which installs EPICS + StreamDevice in the container. After all, the container will be committed as a new image.

### Images Security Restrictions

The official image registry allows all Docker hub users to visit. All the application projects on it are open source, which allows all users to pull and change. This openness breaks the technical barrier and facilitates project delivery. At the same time, there are some immeasurable security risks of data breaches and image misappropriating [12]. The private image stowage was built through Aliyun to increase the authentication mechanism when attempting to pull the image. This method can limit the pull permissions, as well as ensure the security of the image.

## Container Resource Security Mechanism

The container is different from the virtual machine. There is no independent resource allocation to make it impossible to isolate resources at the system kernel level. Since the Docker container shares the operating system kernel with the host, there is a risk that the container is controlled by the attacker to obtain the access rights of the host file. Or the attacker obtains the root permission by illegal means to control the host and other containers on the host. It will result in the escape of the container, or even that the Docker container exhausts the host to make the host or other containers pause or die [13]. In summary, it is necessary to limit the resources of container access to host through Cgroup and SELinux, and the details will be described in the test section.

## Container Network Security Mechanism

Docker's default network communication mode is bridge mode, which will virtualize a docker0 bridge on the host computer, and connect all the containers used in this mode on the host computer to the bridge. At this time, all Docker containers can reach each other, which makes attackers may threaten the safety of the host computer and the container through broadcast storms, sniffing, ARP fraud,

and other attacks [14]. When Docker containers provide services alone (such as EPICS + StreamDevice in this paper) without requiring multiple Docker containers to form micro-services, it is necessary to prohibit communication between containers, which can be achieved by setting the parameter dockerd-icc.

## PERFORMANCE

### Image Testing

The basic image used in this paper is the official image of Ubuntu 18.04. Based on this image, the dockerfile [15] file is written. The basic image, the author's signature, the working path, and the container number are specified. The host directory file is mounted and the environmental path is edited. Each step can be seen as an additional layer in the original image.

After entering the container, EPICS is installed and then Asyn and StreamDevice are deployed. The deployment results and PV display results are tested. EPICS + StreamDevice in Fig.4 has been successfully deployed in the container. Committed the successfully tested container as a new image and pull the packaged image on the required server.

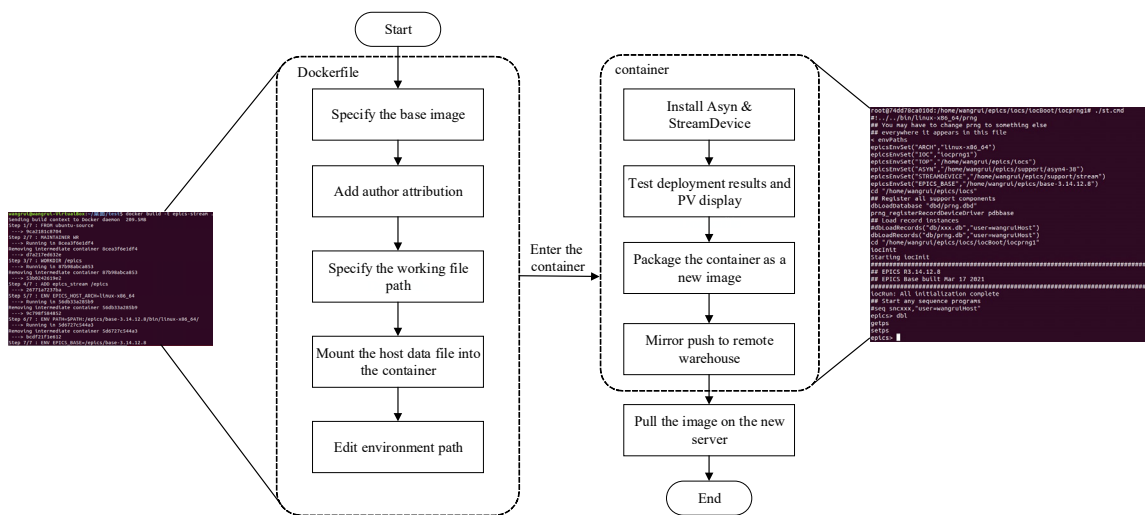

Figure 4: Containers are built by dockerfile and EPICS was deployed successfully with the PV is displayed.

### Mirror Access Authentication Test

By establishing a private image storage under the Aliyun platform, the problem of image pulling authentication can be solved. First Aliyun account should be logged in to establish an image storage and create a namespace. Then the image Tag that needs to be uploaded should be changed on the host running docker. The image is uploaded through the push command. When the image needs to be pulled, the remote Aliyun image storage needs to be logged in through docker, as well as the pull command can be used only after the authentication is completed, which limits the pull of private image by users who cannot complete the login authentication to a certain extent. The process is shown in Fig. 5.

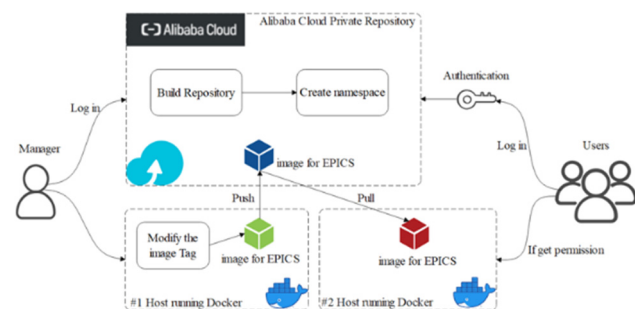

Figure 5: Aliyun private repository image access authentication.

## Resource Limit Testing

Cgroups can limit resource items such as CPU, memory, and disk I/O speed of the Docker container to avoid a single container running out of hardware resources on the host. Table 1 takes memory as an example to show the difference of system resources occupied by containers under the condition of whether to open Cgroups constraints. After the Cgroups memory limit was opened, the process is killed if

the container actually uses more memory than the limit. If Cgroups was not used to limit memory, the container will occupy too much memory of the host, which may lead to the death of other containers. Experiments show that the container takes up five times more memory than using Cgroups. Finally, Docker's mandatory access control of host resources is implemented by starting the SELinux mechanism.

Table 1: Cgroups Memory Limit Comparison

Status	System total memory(MB)	Set limited memory(MB)	Memory usage(MB)	Percentage of total memory
Use Cgroups	2048	200	1.08	0.05%
Do not use Cgroups		—	5.14	0.25%

## Network Communication Testing

The EPICS + StreamDevice container used in this paper provides services separately, so it should be forbidden to communicate with other containers running on the host computer. In the test environment, the IP of the EPICS + StreamDevice container is 172.17.0.2, and that of the Ubuntu container is 172.17.0.3. It is necessary to set `dockerd-icc = false` to prohibit communication between them, as shown in Fig. 6.

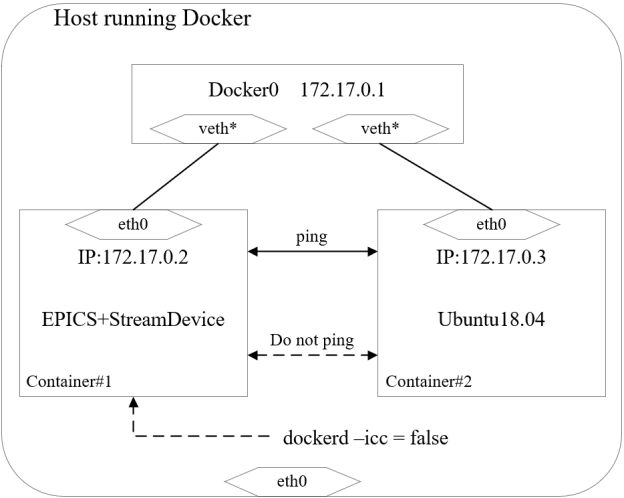

Figure 6: All containers running on the same host are in the same network segment, and if they are not restricted they can ping through each other, restarting the Docker service by limiting the icc parameter can achieve the purpose of prohibiting communication between two unrelated containers.

## SUMMARY

The packaging of EPICS application by Docker can effectively reduce the deployment difficulty of EPICS. It also reduces the cost of application migration and solves a series of problems caused by the difference between the test environment and the production environment. At the same time, a series of improvements are made on the level

of container for data information security problems in a production environment. The problem of container escape and container exhaustion of host resources is effectively prevented by container resource constraints of Cgroups and mandatory access control of SELinux. The container network security issues should be replied by prohibiting communication between containers that do not form a microservice, which can effectively reduce the risk that attackers misappropriate the information security of other containers or even host computers by holding a container. Finally, by uploading the fabricated image to the private cloud platform, the authentication mechanism is added to ensure the application of the image and its internal storage, as well as the safety of the data. The application of the accelerator control system can be deployed efficiently by the combination of Docker and EPICS technology, which can also save manpower and time. In this way, this technology has broad application prospects in the field of accelerator control.

# DESIGN OF A COMPONENT-ORIENTED DISTRIBUTED DATA INTEGRATION MODEL

Z. G. Ni†, L. Li, J. Luo, J. Liu, X. W. Zhou, Institute of Computer Application, China Academy of Engineering Physics, Mianyang City, China

## Abstract

The control system of large scientific facilities is composed of several heterogeneous control systems. As time goes by, the facilities need to be continuously upgraded and the control system also needs to be upgraded. This is a challenge for the integration of complex and large-scale heterogeneous systems. This article describes the design of a data integration model based on component technology, software middleware (The Apache Thrift\*) and real-time database. The realization of this model shields the relevant details of the software middleware, encapsulates the remote data acquisition as a local function operation, realizes the combination of data and complex calculations through scripts, and can be assembled into new components.

## INTRODUCTION

Large scientific experimental devices generally consist of dozens of heterogeneous systems, each of which is also an independent control system. The control system architecture of a typical large scientific facilities is a two-tier architecture consisting of a monitoring layer of the network structure and a control layer of the fieldbus structure. The monitoring layer is deployed on the virtual server and the console computer to provide centralized operations for control, status, and data storage. The control layer is deployed on the virtual server or embedded controller to provide real-time collection and control of the device.

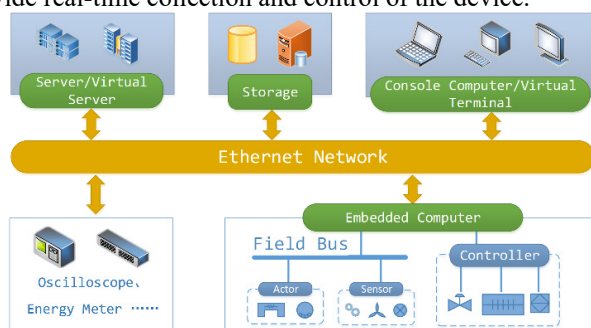

Figure 1: The control system architecture of the typical large scientific facilities [1].

As provided in Fig. 1, the monitoring layer is a software system based on Ethernet structure. It consists of a network switching system, a server system, and a console computer. It provides system services and human-machine interfaces for the facility control system, including control, monitoring, and data management.

At present, the integrated control system mainly used by large-scale laboratories and scientific research institutions around the world is EPICS or TANGO. In the automation

industry, excellent instrument manufacturers will not only provide corresponding secondary development libraries, but also corresponding EPICS interfaces or TANGO Devices.

EPICS[2] is a set of software tools and applications which provide a software infrastructure for use in building distributed control systems to operate devices such as Particle Accelerators, Large Experiments and major Telescopes. Such distributed control systems typically comprise tens or even hundreds of computers, networked together to allow communication between them and to provide control and feedback of the various parts of the device from a central control room, or even remotely over the internet.

Tango[3] is an Open Source solution for SCADA and DCS. Open Source means you get all the source code under an Open Source free licence (LGPL and GPL). Supervisory Control and Data Acquisition (SCADA) systems are typically industrial type systems using standard hardware. Distributed Control Systems (DCS) are more flexible control systems used in more complex environments. Sardana is a good example of a Tango based Beamline SCADA.

Of course, many earlier control system software was built using CORBA software middleware, or implemented using the TCP custom protocol.

## QUESTION

A few years later, the scientific experimental device will inevitably bring about the continuous upgrading of the system. How to adapt the control system and software to this change is a great challenge. The control system software constructed first needs to have a certain degree of scalability. Secondly, as technology evolves, the control system software needs to have a certain degree of compatibility; the early and current systems need to communicate and communicate, how to realize the communication between the early and current systems is a technical problem, which is a problem that this article needs to solve.

Another feature of the scientific experimental device is that the operator's demand is unstable. Users will constantly adjust their requirements based on their experience. We have to modify the code, compile, and test run, and the debugging time for software developers is very short, so the skills of software technicians are very high. If you can adapt to changes in requirements with zero programming, this is a great thing.

Therefore, we propose a component-oriented distributed data integration model, which is used to construct an implementation method of data acquisition and control from the device to the user interface.

In the following chapters, we first introduce the technologies that may be involved.

† email address: drops.ni@caep.cn.

## RELATED TECHNOLOGY

### *RPC and EDA: Thrift or Tango*

Remote Procedure Call (RPC) is an interprocess communication technique. It is used for client-server applications. RPC mechanisms are used when a computer program causes a procedure or subroutine to execute in a different address space, which is coded as a normal procedure call without the programmer specifically coding the details for the remote interaction. This procedure call also manages low-level transport protocol, such as User Datagram Protocol, Transmission Control Protocol/Internet Protocol etc. It is used for carrying the message data between programs. The Full form of RPC is Remote Procedure Call.[4]

Event-driven architecture is a design model that connects distributed software systems and allows for efficient communication. EDA makes it possible to exchange information in real time or near real time. It is common in designing apps that rely on microservices. The concept of event-driven architecture is mainly realized through the publish/subscribe communication model. Publish/subscribe is a flexible messaging pattern that allows disparate system components to interact with one another asynchronously. The key point here is that pub/sub enables computers to communicate and react to data updates as they occur. This is in contrast to the traditional request/response messaging pattern where data is updated at intervals, as a response to a user-initiated request. There are always two participants — a client and a server. The client makes a call over the HTTP protocol and waits for a server to respond with the requested content.

Thrift[5] is a lightweight, language-independent software stack with an associated code generation mechanism for RPC. Thrift provides clean abstractions for data transport, data serialization, and application level processing. Thrift was originally developed by Facebook and now it is open sourced as an Apache project. Apache Thrift is a set of code-generation tools that allows developers to build RPC clients and servers by just defining the data types and service interfaces in a simple definition file. Given this file as an input, code is generated to build RPC clients and servers that communicate seamlessly across programming languages, as provided in Fig. 2.

Figure 2: The software architecture of Thrift

Tango Controls is a free open source device-oriented controls toolkit for controlling any kind of hardware or

software and building SCADA (supervisory control and data acquisition) systems. Tango Controls is operating system independent and supports C++, Java and Python for all the components. Tango Controls is a hardware independent toolkit. That means you can use your driver to connect hardware with Tango Controls, as provided in Fig. 3.

Figure 3: Tango Controls can be used as a distributed system

### *Script Engine: Elk[6]*

Elk is a tiny embeddable JavaScript engine that implements a small but usable subset of ES6. It is designed for microcontroller development. Instead of writing firmware code in C/C++, Elk allows to develop in JavaScript. Another use case is providing customers with a secure, protected scripting environment for product customisation.

### *Realtime Database: LevelDB[7]*

LevelDB is a fast key-value storage library written at Google that provides an ordered mapping from string keys to string values. LevelDB has three basic operations: Get, Put, and Delete. Get retrieves a value given a key, Put writes a value into a key, creating the key if it doesn't exist, and Delete deletes the key and its value. There are open (takes a filename argument) and close functions for creating/loading and unloading a database, and functions that return iterators over all the keys and values. The keys and values can be any byte array and not just strings. This is useful if you have data that you want to store that you don't want to encode into a string. LevelDB supports atomic operations. You can run many operations at once in a single uninterruptible call.

## COMPONENT-ORIENTED DISTRIBUTED DATA INTEGRATION MODEL

### *Component of Integrated Control And Data Acquisition*

As provided in Fig. 4, CICADA is the Component of Integrated Control And Data Acquisition. CICADA implements a common component for data acquisition and integrated control. Data is stored in a real-time database, control logic is stored in JavaScript scripts, and the script engine is used to update data and dispatch commands regularly. It can exist as a distributed service in the local area network and be called by other component instances; it can also be used as a service access module of the client software to access other component instances; it can also be used as a server and implemented as an IO device control server; Replacing different RPC modules can be used as a bridge between different middleware software.

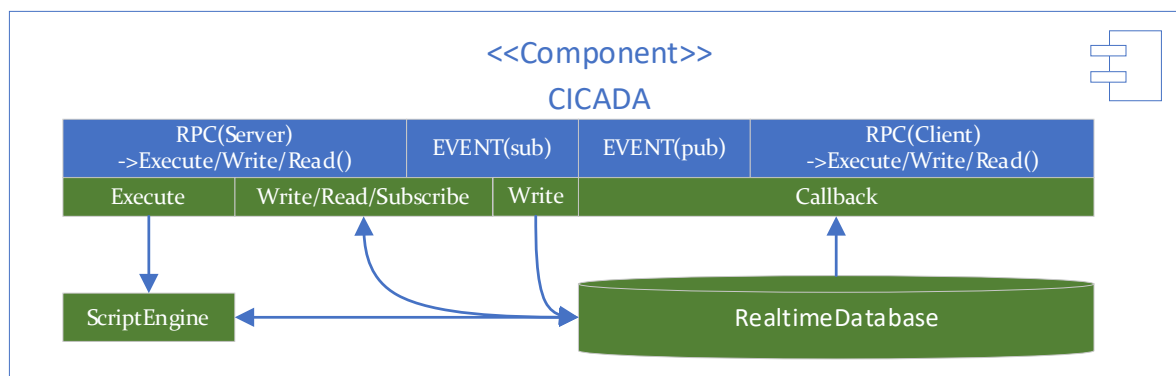

Figure 4: The composition structure of Component of Integrated Control And Data Acquisition.

The Data Centre (Realtime Database) is the data sharing centre of the components, which is responsible for storing and interacting data. The data tag can be configured with multiple attributes, what kind of behaviour is triggered after the data is executed or updated, whether the data is readable and writable, and so on.

The script engine is responsible for interpreting the executor to execute the script, interacting with the Data Centre, and realizing the logical operation of the data.

The local function set is responsible for basic functions such as executing scripts, reading and writing data, subscribing to data, and publishing data.

The RPC/EVENT module is responsible for information exchange between components, including RPC and event-driven methods, which can be used according to the application scenario, or both. The RPC/EVENT module is compatible with TANGO and Thrift software middleware, and supports expansion to CORBA or other software middleware products.

### The Entity of CICADA

CICADA has three forms of existence, one is to be integrated by the client software in the form of a dynamic library, as the data acquisition and integrated control module of the client software; the other is to exist as a system service and be dispatched by the client software as a device service, and at the same time As an example of the client software scheduling other components; one way is to exist as a device service, which can be accessed by system services or client software, and part of the RPC module is replaced by the hardware driver SDK.

When it exists as a service, we design a container for CICADA. It contains an administrative module that is responsible for management functions such as creating, restarting and deleting components, similar to the DServer module in Tango software middleware.

As shown in the Fig. 5, we usually divide the control software into three layers [8]: integrated control layer, system service layer and equipment service layer. In these three-layer control software, we can all use CICADA to realize the interconnection and intercommunication part of the software at their respective levels, which greatly simplifies the many-to-many access control function between nodes without worrying about the implementation details.

Figure 5: Use CICADA in the three-tier control software architecture.

### Connection between CICADA Entities

CICADA entities exchange information and control scheduling through software middleware, as provided in Fig. 6. Components run in their own containers, which can be servers or clients. As an independent microservice or client, the CICADA entity acts as a node in a distributed network. The corresponding connection relationship is established according to the business scenario. They are loosely coupled, and the update influence domain of the component is limited, which can be guaranteed The control system software of the entire facility can evolve forward relatively stably and smoothly.

Figure 6: Exchange information and control scheduling between CICADA Entities.

### Connection between early and current control systems

For example, the new system is implemented using TANGO software middleware, while the early system is implemented using Thrift software middleware. How to realize the information exchange between the early software system and the new system is a problem.

Figure 7: Use CICADA as a bridge between early and current control systems.

Now we use CICADA as a bridge between the two systems, basically zero programming can realize the information exchange function between the two software systems, as provided in Fig. 7.

## CONCLUSION

Through the design and realization of CICADA components, we achieved two goals: the interconnection between the early software system and the current software system, and zero programming to adapt to the rapid changes in software requirements. Of course, we implemented this component to adapt to a workaround under specific needs. Whether it is effective for a long time still needs time to test, and this component is not considered in terms of QoS, so it needs to be strengthened in the follow-up work. Hope to communicate with colleagues, we will make CICADA components better and more practical.

# WEB CLIENT FOR PANIC ALARMS MANAGEMENT SYSTEM

M.Nabywaniec\*, M.Gandor, P.Goryl, Ł.Żytniak S2Innovation, Cracow, Poland

## Abstract

Alarms are one of the most important aspects of control systems. Each control system can face unexpected issues, which demand fast and precise resolution. As the control system starts to grow, it requires the involvement of more engineers to access the alarm's list and focus on the most important ones. Our objective was to allow users to access the alarms fast, remotely and without special software. According to current trends in the IT community, creating a web application turned out to be a perfect solution. Our application is the extension and web equivalent to the current Panic GUI application. It was developed to be integrated with EPICS and TANGO control systems. It allows constant remote access using just a web browser which is currently present on every machine including mobile phones and tablets. In that paper the status of application will be presented as well as key features.

## ALARM SYSTEM IN TANGO CONTROL SYSTEM

TANGO Control System is object-oriented control system based on CORBA. It is widely used in order to create Supervisory Control and Data Acquisition system architecture. One of the most important advantages is that it is available under Open Software free license. TANGO is widely used in scientific facilities e.g. Max IV (Lund, Sweden), ALBA (Barcelona, Spain) or SOLARIS (Cracow, Poland) as well as in industry [1]. In institutes like synchrotrons the scientists and engineers are dealing with thousands of signals per second coming from different types of devices. It is clear that there is a need to monitor non-typical situations. Here comes the idea of alarm. It is asynchronous notification that some event happened, or a given state was reached. In scientific facilities using TANGO Controls the idea of creating a set of tools to manage alarms led to the creation of an alarm system. One of the most popular systems are PANIC and Tango Alarm System.

## PANIC

PANIC (Package for Alarms and Notification of Incidences from Controls) was developed in ALBA Synchrotron. It is a set of tools including API, Tango device and user interface for evaluation of a set of conditions and user notification. [2]

## PyAlarm

One of key elements of PANIC toolkit is PyAlarm device server [3]. According to documentation, it connects to the list of alarms provided and verifies their values. Each alarm is independent in terms of formula, but all alarms within

the same PyAlarm device will share a common evaluation environment. PyAlarm device allows also to configure mail or SMS notification as well as logging. That features are needed to ensure convenient alarm management for user.

## Panic GUI

Panic GUI is a desktop application implemented using Taurus library. It allows checking existing alarms and manipulate them.

Figure 1: Alarm dashboard in PANIC GUI

Moreover, PANIC allows user to modify alarm formula, acknowledge or disable alarm.

Figure 2: Alarm modification in PANIC GUI

## IC@MS

Although PANIC GUI is a useful application, it has some drawbacks. First, it is desktop application what means it requires installation, and it can be only run on a desktop Nowadays, there is a trend to move desktop applications to web. which can easily be open on wider range of different devices including mobile phones, tablets and desktop

\* mateusz.nabywaniec@s2innovation.com

Moreover, user experience is limited by Taurus library used to create interface. When creating web application, there are multiple modern frameworks which make websites look modern and easy on the eye. That are main reasons why we decided to create our web application. Our application is called IC@MS - Integrated Cloud Ready Alarm Management System. It provides the same functionalities as Panic GUI but also extends it with some new functionalities like adding devices supporting different protocols. What is important, IC@MS can be integrated not only with TANGO but also with alternative control system - EPICS [4].

## KEY FEATURES

In that section we want to describe most important parts of IC@MS and explain, why they make our application so useful.

### Cloud Ready

Our application is cloud ready. It means that it can be simply deployed to the cloud like Azure. It speeds up product deployment process. The application is easily accessible and is ready for future development for next versions.

### Signing Up

For IC@MS security is important. Only registered users can log in and see the dashborad. Moreover, we have introduced roles to manage access to different parts of our application. Thanks to that, in production mode, people with different access levels and permissions will see only parts related to their job.

### Alarm Dashboard

As well as in PANIC GUI, the most important part of application is alarm dashboard which allows seeing active and not active. When the alarm is triggered, its colour is changed what depends on severity. The most important and recent alarms are shown first. There are buttons to perform operations like acknowledging alarms, reset or disable.

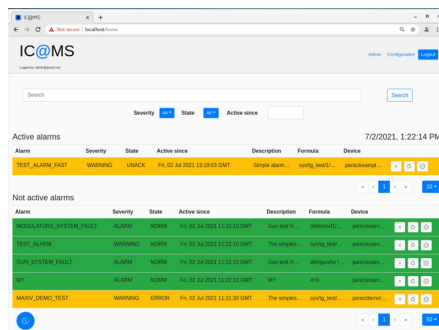

Figure 3: Alarm dashboard in IC@MS

User can easily create new alarms as well as modify existing ones using the form in the configuration page. User can include provide mail and phone number to get notifications about alarm. Moreover, IC@MS allows out of the box integration with any TANGO based device server.

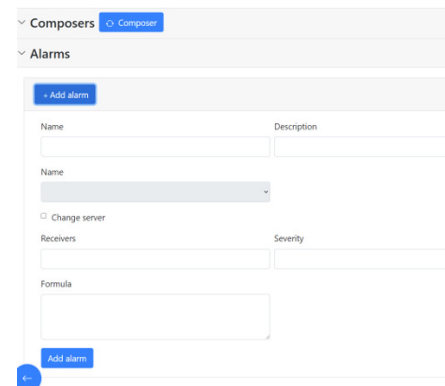

Figure 4: Creating alarm in IC@MS

### Data Sources and Composers

One of IC@MS's features - the configuration page, allows to create data sources and composers devices. Data sources are TANGO devices which provide data acquired from HTTP, MQTT or Modbus protocol. For example, it can be integrated with thermometer which uses MQTT protocol, MQTT data source is created and broker IP, port, topic provided. Composer is a device which propagates signal from many low-level devices (like data sources), and can be used to define alarm formulas.

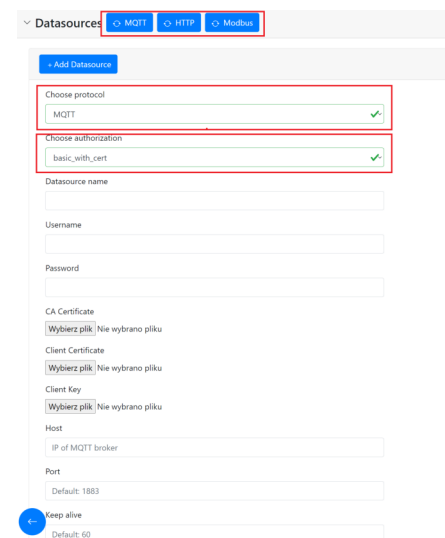

Figure 5: Creating MQTT data source in IC@MS

ALARM HISTORY

The next feature is alarm history page, which allows user to check history of alarms including dates, state and values of formula connected to that given alarm. Moreover, user can sort entries by date or severity.

DateTime	Event	Formula
Sat, 04 Sep 2021 05:52:54 GMT	TangoTest alarm	(! op(tg_testUmovable_alarm=0) AND op(tg_testUfong_alarm=30))

Date	Comment	Value
Sat, 04 Sep 2021 05:52:12 GMT	ACKNOWLEDGED- RESET	-124.11239534964608
Sat, 04 Sep 2021 05:47:55 GMT		-120.1840269686896
Fri, 03 Sep 2021 19:57:30 GMT		-242.05311044332897

Figure 6: Alarm history in IC@MS

CONCLUSION AND FUTURE WORK

That paper shows key features of web application based on PANIC GUI and how it can be used in order to fulfil

requirements of modern alarm systems. According to trend to use web applications, we see a great development potential for that project. Our plans include e.g. fixing navigation issues and extending phonebook.

## Abstract

At the turn of 2020/2021, the Tango community faced the challenge of a massive migration of all Tango software repositories from GitHub to GitLab. The motivation has been a change in the pricing model of the Travis CI provider and the shutdown of the JFrog Bintray service used for artifact hosting. GitLab has been chosen as a FOSS-friendly platform for storing both the code and build artifacts and for providing CI/CD services. The migration process faced several challenges, both technical, like redesign and rewrite of CI pipelines, and non-technical, like coordination of actions impacting multiple interdependent repositories. This paper explains the strategies adopted for migration, the outcomes, and the impact on the Tango Controls collaboration.

## INTRODUCTION

Tango Controls [1] is a free and open-source software ecosystem for building distributed SCADA systems. Nowadays Tango Controls consists not only of the middleware libraries providing the core functionality but also of many supporting applications, GUI toolkits, and other utilities. Tango Controls is developed by numerous contributors and members of the Tango community.

Maintaining such a large and complex project requires best-in-class tools for planning, development, testing, packaging, and version control. From 2016 till 2021 Tango Controls was using GitHub [2] for source code management and various other services, including Travis CI for continuous integration and JFrog Bintray for publishing release artifacts. At the end of 2020, Travis CI announced the shutdown of `travis-ci.org` [3], while `travis-ci.com`, previously focused on commercial software, received a new pricing model [4]. Soon after that, JFrog announced the shutdown of Bintray service [5]. These events resulted in a mass migration of Tango Controls software repositories from GitHub, Travis CI, Bintray, and other previously used service providers. The following sections describe the migration strategy, the challenges faced during the process, the outcomes of the migration, and the impact on the whole Tango Controls collaboration.

## MOTIVATION AND STRATEGIC DECISIONS

When in 2015 the tango-controls project was planning its migration out of SourceForge [6], both GitHub.com and GitLab.com were considered as its destination. In favour of GitLab was its licensing policy (GitLab maintains an Open Source Community Edition while GitHub is proprietary software), but GitHub was chosen because, it was then reasoned, its larger popularity would increase the visibility of Tango and facilitate the integration of third party services such as Travis-CI. Over the years, however, GitLab increased its user base considerably—in particular within the Tango developers because of GitLab being installed on-premises in many Tango Collaboration facilities. GitLab also greatly improved its CI integration, making it much more attractive than Travis CI (e.g. for its native support of Docker containers). Meanwhile, in 2018 Microsoft acquired GitHub—an event that already prompted many projects to move from GitHub to GitLab—and launched its own CI service called “GitHub Actions” [7] which also overcame many limitations of Travis CI. The definitive trigger for considering the migration of the tango-controls organization came at the end of 2020 with the announcement that Travis CI would start charging for CI time also to FOSS projects [4], which directly affected the key repositories in tango-controls.

### *GitHub Actions or GitLab CI?*

At this point, two alternatives were considered: either move the CI of the Tango projects to GitHub Actions or move the whole project to GitLab (other possibilities such as using GitLab for the CI but keeping the project infrastructure in GitHub were also considered but quickly discarded as impractical).

Obviously, staying in GitHub and only adapting the CI would entail less effort and, from the technical point of view, the GitHub Actions service was considered to be on-par with GitLab CI in terms of integration and features. However, the proprietary nature of GitHub weighted against investing effort on further integrating with it because of concerns about potential vendor lock-in. In contrast, the fact that GitLab’s Community Edition is Open Source and that the Tango Collaboration members are already experienced in both using and maintaining their own GitLab instances, eased the concerns even about the eventuality that GitLab.com

could restrict its current allowance of free CI time and other support for FOSS project [8].

When evaluating the extra effort required for migrating to GitLab vs staying in GitHub, the project import feature provided by GitLab was found to do an excellent job in automatically transferring a whole GitHub project (including its code, issues, wikis, etc). Therefore, it was concluded that the main effort for the migration of a project lies in adapting its CI, which would had to be done also if moving to GitHub Actions, since continuing on Travis CI was not an option.

Regarding the disruption due to the change for the individual users, it was considered to be heavily mitigated by the fact that GitLab's UI is very similar to that of Github, that most of our users were already using GitLab instances on-premises and that GitLab.com allows to log-in using existing GitHub credentials.

Finally, it was also considered that by using the same platform for the collaboration as that used locally in the member facilities would be beneficial for reusing code, configurations and skills, and it would facilitate transferring projects to and from the local GitLab instances and sharing knowledge within the collaboration.

## MIGRATION PROCESS

The various projects hosted in the tango-controls GitHub organization involve different subsets of the Tango Community, with different release cycles and development constraints. For this reason each project was allowed to choose its own schedule for the actual migration, but a "migration team" was constituted to coordinate the migrations, support the project administrators and provide both a set of tools and a common procedure for migrating.

The generic procedure for migrating a given project was implemented as follows:

1. If the project uses Continuous integration, its Travis and/or GitHub Actions .yml files are translated to an equivalent gitlab-ci.yml file and the result is tested on a temporary GitLab fork of the repository.
2. A list of participants to the project is compiled by means of a custom-made python script [9] that uses the GitHub REST API to scrape the account names of those who contributed code or participated in the discussions associated to Pull Requests and Issues of this project.
3. A migration date is set by the project administrators and the migration team. Then the participants identified in the previous step are notified that, at least 24h before the migration date, they should ensure that their GitHub account can be associated to a GitLab account (in practice this requires either that they login once into GitLab using their GitHub credentials or that they ensure that their GitHub account is set with a public email address also used in their GitLab account).

4. On the decided date, the migration team performs the actual migration as follows:

- (a) A new empty branch called "*moved-to-gitlab*" is created in the GitHub repository and set as its default branch. A single README file is added to it with a link to the new location in GitLab. The project description is also changed to "Moved to gitlab".
- (b) The GitHub project is "archived" (i.e., set as read-only)
- (c) The GitHub project is imported as a subproject in the GitLab.com tango-controls namespace. This is done using a dedicated "*tango-controls-bot*" account and the standard import tool provided by GitLab, which imports the whole git repository, the issues, the pull requests (merge requests in GitLab), the milestones, the releases the wiki, etc.
- (d) The *moved-to-gitlab* branch is removed from the fresh new GitLab repository and the proper default branch (e.g., "*main*" or "*master*" or "*develop*") is set instead.
- (e) The Tango Community is notified about the project migration via an email and a comment in a dedicated issue.

5. After the migration, the project admins may need to check and adjust the settings of the migrated project in GitLab (e.g., the project members, protected branches, etc.) and also manually adapt the documentation by replacing references to GitHub.com by the equivalent ones in GitLab.com.

## C++ Core Library and Related Projects

The migration of the C++ core library repository [10] to GitLab presented multiple challenges due to many interactions with various external services. Travis CI [11] was used for builds on Linux platforms and regression testing, Appveyor [12] was used for builds on Microsoft Windows, Coveralls [13] provided code coverage reports, and Sonar Cloud [14] calculated code quality metrics. Additionally, the ABI compatibility check was implemented using GitHub Actions.

**Linux CI** The jobs on Travis CI were building and testing the Tango Controls C++ core library on multiple versions of the Debian operating system inside Docker containers. The use of containers was dictated by the limited choice of operating systems available in Travis CI [15]. The images of these containers were maintained by the Tango Controls C++ core library developers and included all the software required to build and test the library. Whilst GitLab Runner provides a Docker Executor and is already running all test jobs inside containers, it was decided to keep existing Debian-based containers and run them using

Docker-in-Docker [16]. The reuse of the containers allowed to reduce the effort required for the migration. The adoption of Docker-in-Docker increased the complexity of the job configuration but it could not be avoided as currently Docker is anyway required to run the C++ core library tests.

Limited hardware resources of GitLab Build Cloud runners imposed an additional challenge on the migration process. The runners offer just one CPU core [17], compared to two cores available in Travis CI virtual environment [18]. This limitation resulted in failures of some timing-dependent tests designed for multi-core systems. Such tests required case-by-case analysis and minor changes in the implementation.

**Windows CI** Windows-based jobs from Appveyor were not migrated to GitLab CI/CD. Instead, Appveyor has been configured as an external CI provider for GitLab. There are plans to migrate these jobs to GitLab's Windows Shared Runners, but more work is still needed to enable this migration [19].

**External Services** During migration, it was decided to stop using external services for code coverage reporting and code quality metrics. For both use cases, GitLab already provides built-in features that integrate better with the rest of the platform. Coveralls was replaced with a CI job that produces a code coverage report in a standard Cobertura XML format. This report is then processed by GitLab and used for test coverage visualization in GitLab's merge request UI [20]. Sonar Cloud was replaced with a CI job that runs clang-tidy [21] and produces a Code Quality report artifact [22]. This allows GitLab to show any code quality changes in the merge request UI.

**Related Projects** The C++ core library developers also maintain a set of device servers and utilities implemented in C++ like DataBase [23], Starter [24], TangoTest [25], TangoAccessControl [26], tango-idl [27], or tango\_admin [28]. These projects do not use continuous integration or any external services, thus their migration followed the standard process of setting up appropriate "moved to" branches and importing the projects in GitLab's web UI.

The Tango Source Distribution [29] is another project closely related to the C++ core library. It used a Travis CI job to build an install-able package with the C++ library, essential device servers, and a set of Java-based tools. For the purpose of the migration, a new CI job was created in GitLab. As Ant tool [30] was used to drive the packaging process, translating the job definition from Travis CI to GitLab CI/CD did not require many changes. Additionally, the resulting package is now stored as a job artifact.

### *Python Core Library*

The Python core library [31] was using Travis CI service for compilation and tests with multiple versions of Python, including 2.x and 3.x releases. All test jobs were utilizing

Conda environments [32] to pull the required dependencies and set up a matching version of Python. Since Conda is also available as a Docker image suitable for use in GitLab CI/CD the migration process was relatively straightforward and required only translating the CI pipeline configuration into a format accepted by GitLab. The project was not using any other external services, which simplified the migration. The packaging process was not impacted and the PyTango package is still published to PyPi [33].

### *Java Core Library and Related Projects*

Java core libraries, including JTango, use Apache Maven [34] as a software project management tool to test, build and validate the package. Maven is also used to produce binary artifacts like JAR files. Testing and building the software was automated using Travis CI service that validated all the changes to the source code which was stored in GitHub. The main challenge during migration to GitLab was the rewrite of the CI pipeline into the format expected by Gitlab CI/CD.

During the migration process, the JTango CI/CD pipeline was completely redesigned to optimize the execution time and to automatically deploy artifacts into a remote repository. Also, the obsolete and duplicated CI jobs were removed. With Travis CI, artifacts were deployed automatically to Bintray [35] and manually into Maven Central [36] repositories, as they are very popular in the Java/Maven community. Because of the Bintray shutdown [5], a new location was needed to store packages and artifacts. The free Sonatype Nexus OSS repository hosting [37] was selected for this purpose as it is a popular way to release libraries to Maven Central. As a result, both snapshot and release versions of the Tango Controls core Java libraries are now automatically deployed to OSS and synchronized with Maven Central.

### *Documentation*

Tango Controls documentation is written in the Sphinx-compliant [38] reStructuredText format [39]. The documentation is published on the ReadTheDocs.io service [40].

The sources were kept on GitHub along with other Tango Controls projects. The project used Travis CI to test the documentation build process and to assure its quality in terms of warning-free builds, among others.

Moving the sources to GitLab was straightforward with the use of prepared scripts. In addition to setting up GitLab CI/CD (providing gitlab-ci.yml configuration file), Sphinx configuration file (conf.py) has been updated. The ReadTheDocs.io project was also reconfigured to reflect the new repository location.

The new CI pipeline takes advantage of the features provided by GitLab CI. For each merge request the documentation, including proposed changes, is built and the resulting HTML files are stored as CI job artifacts [41]. This gives the reviewer ability to check the visual quality of

the merge request directly in GitLab without doing a local build of the documentation on the reviewer's machine.

### Other Projects

Other software projects related to the core have been already migrated to GitLab or are in the process of migration (Taurus [42], Sardana [43], fandango [44], panic [45], HDB++ [46]). A developer has been assigned to the migration task of each of these projects. Some of the already migrated projects (fandango, panic) are also in transition from Python 2 to Python 3. The work done on GitLab migration allowed to implement CI/CD on these projects, taking advantage of the Docker images and jobs already configured. Migration of HDB++ Archiving project and the development of Docker images for archiving CI are assigned and expected to be completed in the next year.

## IMPACT ON PACKAGING

### Debian

Using GitLab enables a direct reuse of the CI pipelines from the official Debian packaging infrastructure [47] which is also based on Gitlab-CI.

### RPM

The Tango RPMs used to be built internally by MAX IV. With the migration to GitLab, we took the opportunity to move the Tango SPEC file repository [48] to the tango-controls group on GitLab. RPMs are now built using Copr [49], a build system and infrastructure provided by Fedora. This could have been done on GitHub as well, but using a gitlab-ci pipeline to trigger and test the Copr build made the task easier, as MAX IV has a lot of experience with their internal GitLab server. RPMs are built using the Tango Source Distribution release [29]. This is a single url to change in the SPEC file when next release will be available.

### Conda

Conda [32] packages are built using an archive of the repository. The repository url is specified in the *source* field as well as in the *metadata* of the recipe. The impact of the migration to GitLab is thus minimal. Some packages, like tango-database, were created after the migration and already use GitLab as source. Some, like cpptango, were created before. They will be updated when a new version is released.

### Bintray

Java core libraries were using Bintray [35] to store binaries and other artifacts like POM files. Publishing to Bintray was the main way of distributing JTango to downstream projects. After Bintray shutdown [5] and repositories migration a GitLab package registry was created for the JTango project [50]. This registry allows for storing JAR files for each JTango release. Additionally, integration of GitLab CI/CD with Maven allowed to refactor the build process and to distribute the binaries directly to OSS Sonatype

Nexus [37] which is currently the official remote registry for distributing the JTango Java artifacts.

## CONCLUSION

The migration process presented maintainers and developers with many challenges. A common, well-defined strategy and a detailed migration plan allowed for carrying out all necessary activities on time and consistently across multiple projects. A dedicated migration team provided support for administrators of various repositories and coordinated all the efforts related to the migration. Move from Travis CI to GitLab CI/CD caused some technical difficulties but in the end, it allowed for better integration with the rest of the GitLab platform.

The migration of Tango Controls software repositories to GitLab is still a work in progress. At the time of writing 49 out of 67 repositories in the tango-controls organization were already migrated. Critical projects like core software libraries are on GitLab since early 2021 and all development including issue handling, code review and continuous integration is performed there. Remaining projects will be gradually migrated over time or left on GitHub if there is no clear benefit in moving them.

## ACKNOWLEDGEMENTS

The authors acknowledge the support of the Tango Controls Collaboration for funding a number of the developments described here as well as the Tango Controls Community for bug reports, fixes, suggestions for new features and contributions.

# DEVELOPMENT OF ALARM AND MONITORING SYSTEM USING SMARTPHONE

W.S Cho\*, Pohang Accelerator Laboratory, Pohang, Republic of Korea

## Abstract

In order to find out the problem of the device remotely, we aimed to develop a new alarm system. The main functions of the alarm system are real-time monitoring of EPICS PV data, data storage, and data storage when an alarm occurs. In addition, an alarm is transmitted in real time through an app on the smartphone to communicate the situation to machine engineers of PLS-II. This system uses InfluxDB to store data. In addition, a new program written in Java language was developed so that data acquisition, analysis, and beam dump conditions can be known. furthermore Vue.js is used to develop together with node.js and web-based android and iOS-based smart phone applications, and user interface is serviced. Eventually, using this system, we were able to check the cause analysis and data in real time when an alarm occurs. In this paper, we introduce the design of an alarm system and the transmission of alarms to an application.

## INTRODUCTION

The off-line method of the past alarm system sets threshold points for Low, High, and Interlock information, outputs a sound through the speaker when the range is out of range, and the operator immediately analyses the contents and solves the cause. This is a useful solution in field situations. However, engineers cannot see real-time data or alarm information generated by the device.

The new real-time online alarm method selects the EPICS PV [1] data requested by engineers or users in addition to the specified threshold and checks the data or receives an alarm with their smartphone. The new alarm system uses multiple user subscriptions based on EPICS PV. If the user wants to receive an alarm or there is data that he wants to monitor in real time, the PV is registered in the alarm system through the smartphone application. For example, the beam current data of the storage ring is unique. However, individual users may have different desired alarm setting conditions. That is, some users may want to be notified when the current is less than 100mA, and another user may want to receive an alarm when the current is less than 50mA. The alarm system is completely individualized for each user so that alarms are sent or stopped according to different conditions required for each as shown in Figure 1. And when an unexpected failure occurs, the PV connection of the EPICS IOC may be disconnected, so the EPICS PV connection information can also be included in the alarm. The smartphone application to receive the alarm can be used in both Android and iOS environments. We chose Web App because it is important to reduce development time and simplify maintenance. Among the many frameworks used in Web

App, Vue.js [2] is applied. HTML5 and Java script can be easily handled, templates are modular, and switching to mobile or desktop environments is simple. Data can be checked up to 5 hours ago from the present using a line chart. In addition, to check the data of EPICS PV, the data value displayed in the application is updated in real time once every 3 seconds using Web Socket.

Figure 1 : Alarm system operation overview.

## ALARM SYSTEM

Each embedded device provides the user with the necessary data. These data are integrated through the EPICS Gateway server. The alarm system connects to the gateway server through a network by a process called the integrated alarm system core and collects data at a rate of up to 10Hz according to the data cycle updated for each device.

The EPICS JCA library was used to collect PV connection status and data by connecting to the IOC through the network. Users who use the alarm system select a PV to receive real-time monitoring and alarm services through a smartphone application. And when parameters linked to PV are set and saved, data monitoring starts immediately in the core process. All data is stored in InfluxDB while monitoring data. And the data is processed by analysing the parameters set by each user, and if the alarm condition is met, an alarm is immediately prepared to be sent to the user. Alarm information is stored in an event queue running as an asynchronous thread inside the core process. When data exists in the event queue, it immediately analyses the event contents and stores the event log and data from the last hour or so in SQL and the file system. When all processing is completed, a PUSH notification service is sent to an Android or iOS smartphone through Google Firebase service. When the user receives the PUSH notification service, the notification of the installed application is generated, and when the user selects the corresponding event, analysis can be performed together with the past data.

### Integrated Alarm System Core

Integrated alarm system core is developed in Java language and executed as a process inside O/S. This process is composed of 5 functions, and the role is divided for each function as shown in Table 1.

\* wscho@postech.ac.kr

Table 1: Integrated Alarm System Core Function

Function	Description
PV Status	Check PV status
Data Watcher	Data update interval monitoring
Event Queue	Alarm event information storage
Firebase	Message push service
Web Socket	Real-time data update support

PV status provides the user with IOC PV communication connection status information and PV data. If the PV communication connection state is disconnected, the IOC or internal network situation is not good. In this case, a notification is first sent to the user so that user can immediately check the IOC status or network status.

PV data watcher measures the time of data acquired at regular intervals. This is necessary because IOC works fine, but I have had experience with data not being updated. IOC acquires data through serial or ethernet connection with the device and transmits the data to PV. The general IOC data update period can be set through the SCAN of the EPICS record field. However, if the data is not updated for the time interval set by the user separately from the EPICS field information, it can be inferred that there is a problem in the connection between the IOC and the device. It is not easy to detect this communication problem so far, but through the newly developed alarm system, if data is not updated for a set period of time, it is possible to quickly identify any problem in the connection.

The event queue stores the user ID, time, value, and PV name in the database when the alarm condition is satisfied based on the collected data as shown in Figure 2. And it can be seen that the reason for the need for a user ID is that alarm sending conditions may be different for each user based on the same data.

Figure 2: Event queue in alarm process.

Google Firebase [3] provides an integrated environment to send notifications including event contents to various client environments such as Android, iOS, and web browsers.

WebSocket is a technology for the purpose of communication between the user's web browser and the server. It is used in the alarm system of PLS-II and supports sending and receiving messages freely in both directions. Therefore, it supports the function to monitor the current PV data in real time to the user. When the user runs the smartphone application, the user can check the PV name registered in advance and the value updated in real time, so that the user can check the situation in real time.

The inside of the class of the core process consists of PV name, user information, value, time information, and various functions. When the user sets the PV to be monitored, the requested PV creates a new class inside the core process. If another user requests a previously used PV, user information is added from the existing class. When the class is created, PV connection is immediately proceeded, and the following pseudo code is executed according to the alarm range specified by the user.

Pseudo code 1: Alarm condition

```

Data stored in influxDB
if (data < low or data >= high) AND flag then
    if nowTime - lastTime > intervalTime then
        alarm push
    end if
end if

```

The pseudo code monitors the PV and when the value is updated, it is saved in influxDB. And according to the first conditional statement, if the range of values is within the range set by the user and it is true to receive an alarm, the next conditional statement is executed. After subtracting the last stored time from the current time, it is compared with the alarm update time set by the user to determine whether to send an alarm. This function uses a simple algorithm in order not to send a large amount of alarm to the user's application whenever the value satisfying the alarm condition changes. For example, the current time is 10 and the previously stored time is 5. And it is assumed that the user sets the interval time to 3. In this case, since the condition is true, an alarm is sent to the user. If the user's interval time setting value is 10, the range of the value satisfies the alarm condition, but it is not transmitted to the user.

### Back-end (Server side)

Back-end performs a web server function that responds by processing user requests based on Node.js framework. Web server functions are divided into two main categories.

The user's smartphone application request is processed using RESTful API that is processed in HTTP protocol environment and performs commands such as POST and GET. Node.js can develop programs by distinguishing POST and GET commands from the same route address. When a user requests data, the GET function is used.

The user register function creates a token used by Google Firebase in the smartphone application when a new user is created. The token value is needed to send a notification to the user in the alarm system core process. When the token is sent to the web server through a specified route, the server issues a unique user ID that is a combination of alphanumeric characters and sends it to the application. Based on the issued user ID, the web server processes the inquiry request and provides data to the user.

The alarm history function can be checked by inquiring the alarm information previously stored by the alarm system core process. Alarm information is information stored in the file system based on the user ID and unique time of the PV registered by the user up to 5 hours ago. When the user selects the time information, the stored data is immediately loaded by the web server and the data is transmitted to the user application. Past data shows the entire PV registered by the user. That is, it is assumed that all PVs registered by the user are related.

Create and delete PV monitor registers or deletes the PV to be monitored by the user. When user registers PV, alias, formula application, LOW, HIGH, alarm interval, Y-axis log scale, alarm reception, etc. can be set. And the user PV update function can modify the values set during registration.

User PV list receives the list of all PVs registered by the user. If you use this function, you can check the real-time data along with the PV name in conjunction with the WebSocket session.

It maintains security between the server and the application. When providing web services, external attacks occur, so security must be set. Two-way communication data must be encrypted by setting SSL (Secure Socket Layer) and WSS (WebSocket Secure) as security settings. And it protects from external threats by altering HTTP server information and showing other server information to the attacker.

### Front-end (Client side)

Vue.js is a front-end framework and supports SPA (Single Page Application), so it can play the role of a smartphone application. And since it is possible to access the DOM (Document Object Model) interface in an easy way, it is possible to selectively update only the parts that need to be changed in interaction with the user. In addition, since it uses a modular method, it can be easily applied to other templates if a specific page or function is developed.

As a security function of Vue.js, the history function displays an error screen when an arbitrary route is connected without going through a set route.

In the layout design of the smartphone application, as shown in Figure 3, three bottom buttons are applied: HOME, HISTORY, and SETTING.

HOME shows a list of all PVs registered by the user and values that change in real time. If user select a PV name or an alias, user can check the data up to 5 hours ago in a graph. Therefore, even if a specific alarm situation does not occur, users can easily check the real-time information they want anytime, anywhere.

HISTORY shows the past records of alarms that have occurred to the user by alarm occurrence time, value, and PV name. If the user selects this list, user can check the historical data stored before the alarm in a graph.

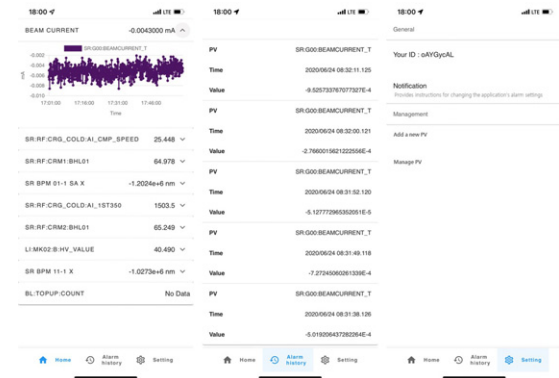

Figure 3: Smart phone application view (iOS).

SETTING can change the user's application usage settings. When an alarm occurs to the user, it is possible to turn on/off the function that the alarm information is exposed at the top of the smartphone screen through the notification function of the application. In addition, the function to add, edit, or delete PVs to be monitored can be performed.

## CONCLUSION

In this paper, we introduced a system that supports the real-time alarm function based on a smartphone application. It has become possible to support monitoring functions by individualizing the data of devices that users want and to respond quickly to failures. The read/write performance of InfluxDB time series data in the PLS-II alarm system shows satisfactory performance, but the clustering system is replaced and We plan to upgrade the performance of the data archiving system of PLS-II to collect more data through integration with the alarm system. Currently, the notification function is supported by using a simple algorithm that compares the specified threshold, but it aims to further improve the system through ML (Machine Learning) in the future. The main goal of ML is to predict and detect abnormal operation of the device in advance to strengthen the protection function. When the abnormality detection technology reaches the required level, it will be possible to develop a better system than now by interworking with the alarm system.

## ACKNOWLEDGEMENTS

I would like to thank the members of the PLS-II Accelerator divisions for their comments on the system and for testing the program.

# PORTING CONTROL SYSTEM SOFTWARE FROM PYTHON 2 TO 3 - CHALLENGES AND LESSONS

A. F. Joubert, M.T. Ockards, S. Wai, SARAO, Cape Town, South Africa

## Abstract

Obsolescence is one of the challenges facing all long-term projects. It not only affects hardware platforms, but also software. Python 2.x reached official End Of Life status on 1 January 2020. In this paper we review our efforts to port to the replacement, Python 3.x. While the two versions are very similar, there are important differences which can lead to incompatibility issues or undesirable changes in behaviour. We discuss our motivation and strategy for porting our code base of approximately 200k source lines of code over 20 Python packages. This includes aspects such as internal and external dependencies, legacy and proprietary software that cannot be easily ported, testing and verification, and why we selected a phased approach rather than “big bang”. We also report on the challenges and lessons learnt - notably why good test coverage is so important for software maintenance. Our application is the 64-antenna MeerKAT radio telescope in South Africa — a precursor to the Square Kilometre Array.

## INTRODUCTION

The MeerKAT radio telescope [1] is operational in the Karoo region of South Africa, with its 64 dish antennas. It is a precursor to the larger Square Kilometre Array project [2], and will be integrated into the mid-frequency array, SKA1 MID.

The focus of this work is to report back on our approach, and progress related to the effort of porting our codebase from Python 2 to Python 3 [3]. The telescope has many subsystems with their own teams and software codebases — here we look at the control and monitoring software system.

This paper is organised as follows. First, we briefly compare Python 2 and Python 3. We then discuss the motivation for change and strategies considered. The actual approach taken, and the results are then presented, before concluding.

## PYTHON 2 VS. 3

The main driver leading to the creation of Python 3 was to clean up problems with the language [4]. These changes were backwards incompatible by design. The most fundamental change is the representation of strings using Unicode by default, rather than 8-bit ASCII. This resulted in a clear split between binary data and text data.

There are a number of other changes [5], including: `print` became a function, module imports are now absolute, rearrangement/renaming of the standard libraries, more use of generators instead of concrete containers, division automatically promotes to floating point, classical classes are removed, and first-class support for asynchronous coroutines with `async` and `await`.

## MOTIVATION FOR CHANGE

Porting a codebase requires significant effort, and any changes introduces risks like bugs, downtime, and degraded performance. The benefits of porting need to outweigh these negative factors.

Positive factors:

- Python 2 is end-of-life since January 2020. This means no further changes or fixes to the interpreter will be provided.
- The ecosystem of Python packages are dropping Python 2 support. This also means no fixes, no security updates, an inability to benefit from future improvements in existing packages, and new packages. Another problem is that dependencies with unpinned requirements start to break, when a new version of a package adds Python 3-only features incorrectly.
- Linux distributions are no longer including packages for Python 2 [6]. While there are ways of installing Python 2 now, this is likely to get more and more difficult. A lack of Python 2 support on future Linux releases, means that we cannot upgrade our servers, and are “stuck” on old operating systems.
- In our opinion, software engineers tend to favour newer tools, and Python 2 is now considered “legacy”. There are new features in Python 3 that improve the development experience. Software engineers that enjoy the work they do are more motivated and committed to their projects.
- The remaining lifespan of MeerKAT, before it is consumed by SKA, is at least 5 years, so we need to be able to continue improving the software for at least that long.
- Revisiting the whole codebase while porting helps to increase the knowledge and understanding of the codebase, and can result in old bugs being discovered and fixed.

Negative factors:

- A huge amount of work is required, so other software features/improvements have to be delayed in order to allocate human resources to the porting project.
- Risk of introducing bugs which lead to incorrect operation, downtime or degraded performance.

Overall, we believed that the positive aspects make the exercise worth doing.

## STRATEGIES FOR PORTING

The Python porting book [7] outlines a few strategies for porting to Python 3.

Unfortunately, most of the projects in our codebase are libraries and therefore coupled during runtime (they must run

in the same Python environment with shared site-packages). This precludes us from any “big bang” approaches moving directly to python3, so our upgrade path will have to be staggered, by porting one package at a time.

The remaining approaches will be discussed below, ending with our selection.

### *Separate Branches for Python 2 and Python 3*

Maintaining two different branches and distributing two separate versions of the code. This is where the most effort and complexity involved. This would entail patches (pull requests) to the python2 codebase and a simultaneous patch/PR to the python3 with equivalent changes. In addition, the python2 codebase also has to be ported to python3 initially.

This is the most complex and expensive option.

### *Single Source (Python2), Two Distributions (Python2 and Python3)*

Keep the source in python2 and use python-modernize [8] to automatically convert the source to python3 compatible distribution packages. The python-modernize package wraps a tool called 2to3 [9]. There will be some upfront effort required to write “fixers” for code that cannot be automatically converted and some scripts to ensure conversion happens for every new change. Eventually, the handwritten codebase will have to be replaced by the generated python3 code.

**Where’s the complexity?** Verifying correctness of automated conversion and writing fixers or manually editing generated python3 code for edge cases. Some learning curve around 2to3 and distutils.

**What’s the benefit?** Since this is an additive change, the current way of developing can remain the same on python2. This allows the team to ease into python3.

**Risks** The python3 code remains a second class citizen and becomes maintained/de-prioritised. Code that is never run eventually becomes dead code.

### *Single Source, Single Distribution (Python2 and Python3 Wrapper)*

Using a wrapper layer and maintaining a codebase that is compatible in both python2 and python3. This entails leveraging linting and type-checking tools to ensure new changes are compatible with both and sometimes writing code that delegates to a wrapper/compatibility layer such as six [10]. We’d still want to use python-modernize or python-future [11] to do the initial conversion of the code to a compatible state.

**Where’s the complexity?** The compatibility layer might create a “type explosion” - e.g., python-future includes additional string and byte types. The toolchain would

have to be very strict and robust to detect and prevent any incompatible changes (linting, type-checking by pylint, mypy, pytype, etc.). The initial conversion *might* be trickier and more complex than simply writing python3 code.

**What’s the benefit?** A single codebase, albeit written in a strict style with a intersection set of python2 and python3 features.

**Risks** Some additional complexity in write-time and potentially ugly wrappers. A possibility that the Python 2-compatible code lives on forever.

### *Single Source (Python3), Two Distributions (Python2)*

Maintain the source in Python3 and convert to be Python2 compatible via automation. There will be upfront effort to convert the projects to strictly Python3 but (it also means a clean break into python3 when the time comes).

**Where’s the complexity?** We’d have to convert (and verify) an entire project upfront to python3. 3to2 conversion fixers would have to be written and maintained, however it’s most likely easier to introduce python2 compatibility to python3 code than vice-versa and conversion is throw-away effort.

**What’s the benefit?** Once a package is upgraded to python3, we can simply turn off the build to python2 when the time comes. It’s also most likely easier to introduce python2 compatibility to python3 code than vice-versa.

**Risks** Upfront effort to convert some packages might be huge.

### *Strategy Selection*

The two-branch strategy was considered too time consuming to pursue - all patches (pull requests) would have to be duplicated for each branch. That left 3 strategies, with the big difference between being whether or not to autogenerate production code. We decided against autogeneration, as this would result in two codebases (original, and autogenerated) that need to be verified by humans. Our code coverage from unit tests was not considered sufficient as the sole method of verification for the autogenerated code.

Thus the porting strategy selected was *Single source, single distribution (python2 and python3 wrapper)*. For the wrapper library, we chose python-future instead of six. They are quite similar, so there was not a strong deciding factor here.

## **APPROACH**

The details of the approach followed are described in this section. We look at the package dependencies, the size of the codebase (lines), and finally discuss the workflow adopted.

## Dependencies

There are several Python tools that can be used to determine a dependency graph for packages, including: `pydeps` [12], `snakefood` [13], and `pipdeptree` [14]

`pipdeptree` was chosen because it leverages `pip` [15] to determine dependencies on a package level, rather than file level (unlike `snakefood` which operates on file level). It also supports a `-reverse` flag (unlike `pydeps`) which shows which downstream packages require a given dependency, i.e. why that particular package is installed. This means we can limit our analysis to our own codebase's packages.

The goal was to rank packages based on their place in the tree. Packages that are dependencies for many others downstream are more risky whereas packages that are leaf nodes are less risky. However, our porting needs to start at the root of the dependencies (i.e., most used package). If we try to port a package with a dependency that only supports `python2`, we will not be able to test that package under `python3`, so we will have no confidence in the port.

Leaf nodes are typically where our application scripts are found. They make use of various libraries higher in the dependency tree to build the required functionality. Only when a leaf node has been ported can we start running some of the applications that make up our distributed control system under `Python 3`.

Unfortunately, the default `pipdeptree` output is in the form of text. There is a flag to output `graphviz` [16] `.dot` files but it does not support the `-only` flag to filter out packages we are interested in.

Some modifications are required to `pipdeptree` to make it work for our purposes. So `pipdeptree` was patched [17] accordingly. The resultant dependency graph is shown in Fig. 1. Our approach was to work from top to bottom, to ensure that we have `python3`-compatible versions of all dependencies.

## Lines of Code

As part of estimating the complexity of the work, we analysed code metrics, including the number of lines of code. This was done using a `Radon` [18]. The metric of interest was the number of source line of code (SLOC).

The total for all packages was 214 k SLOC, with the smallest package around 0.15 k SLOC, and the largest around 41 k SLOC. The average size was 9.7 k.

We intended to use these numbers to help with estimating the time to port each package. However, we found such a high variance (400%) in the time to port the first few packages that we thought it not useful. However, as we show in the results section, the metric can be of merit.

## Stdlib and Third-Party Dependencies

Besides the dependencies within our own codebase, we also need to determine whether our packages have stdlib or external/third-party dependencies that would prevent us from upgrading.

We leveraged the `caniusepython3` [19] tool to check.

To do so, we needed `requirements.txt` files for each project. This was done by installing each project in its own respective `virtualenv` then running `'pip freeze'`. These `requirements.txt` files were then passed to `caniusepython3`.

This helped us discover a number of third-party packages that we would need to find replacements for.

## Workflow

**Starting point** Initially, we ported the simplest package, with the least dependencies. This allowed for some learning, which we could apply to subsequent packages.

**Procedure** We created a wiki page with details of the procedure to follow. This was improved over time, and is summarised below. An important detail is that a pull request must be created and merged to the main branch after each step. This helps to ease the burden on the reviewers — smaller changesets are easier to review, and result in better quality reviews.

1. Evaluate the repository. This provides context for the developer — they may have minimal experience with the repository.
2. Clean up. Delete unused code and scripts to simplify the porting effort.
3. Update Continuous Integration (CI) to run `python3` tests (allow failure).
4. Futurize module (maintain `python2` support):
  - (a) Futurize stage 1 (modernize `python2` code only, no compatibility with `python3`)
  - (b) Auto code format (using `black` [20]). Since we are touching the whole codebase, now is a good time to make these kind of large scale changes (code was not previously auto-formatted).
  - (c) Futurize stage 2. This uses the `python-future` wrapper to provide `python3` support. We decided to avoid `unicode_literals` due to the drawbacks [21], and the `future.newstr`, as it leads to type confusion — lines like this were removed: `from builtins import str`.
5. Futurize module (add `python3` support). Get tests passing under `python3`. This includes updating dependencies, dealing with strings, and other `python2`-`python3` differences. This is also the time to update the `classifiers` and `python_requires` in the `setup.py` file.
6. Update CI to fail if `python3` tests fail, and to publish the `python3` package.
7. Verify that downstream packages still pass their `python2` unit tests. This ensures no regressions in the `python2` version of the ported code.

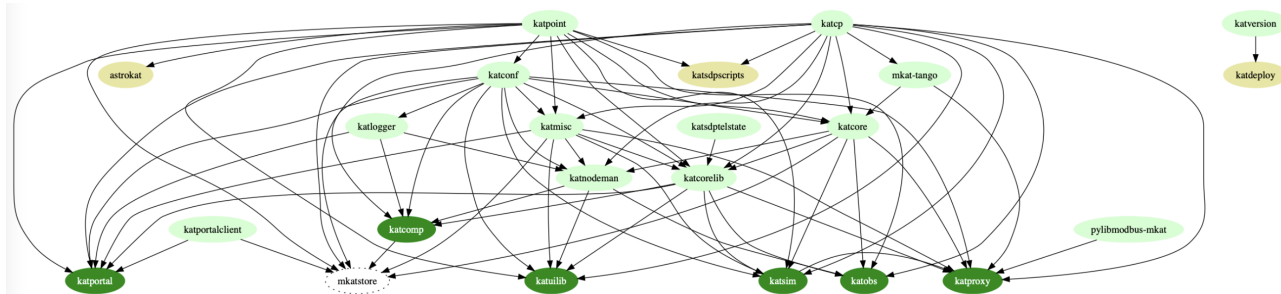

Figure 1: Python package dependency graph. Light and dark green packages are used at run-time, with dark green indicating the leaf nodes. Yellow packages are not used at run-time. White dotted packages are deprecated, and can be ignored.

8. Verify that the full integration tests for the whole codebase are still passing. Again, this is largely running under `python2`, until we get to the leaf nodes, but increases our confidence in the port.

Finally, once all the packages support python3, we would start dropping python2 support completely. This would enable python3 features like `async` and `await` to be used. It would also be possible to drop the `python-future` compatibility layer.

**Human resources** We follow an Scrum approach, with work divided into sprints. Initially, we added stories for porting packages into each sprint. This was a failure for a few reasons:

- It proved impossible to estimate the time to migrate a package. Stories we expected to fit in a sprint, would run to multiple sprints. Even as we re-estimated them each sprint.
- The assumption of “all developers are equally skilled” made by Scrum, meant that different people would work on porting in subsequent sprints. This meant a lot of the knowledge gained in previous sprints had to be learned afresh, by the new developers that had not done this kind of work before. It was very inefficient.

Due to these failures, we decided on an alternative approach: dedicate a single experienced software engineer to the task, with reviews from the technical lead. This work was handled outside of the Scrum process, negating the need for the problematic estimation. A downside was that we were not even able to speculate a completion date. The benefit being that one person would become an expert at the porting techniques and typical problems, allowing for a quicker completion.

The single developer approach has shown some dividends. In practice, the main problem was prioritisation. There were often support issues needing urgent attention that arose in the areas where he/she is most experienced. This removed the focus from the porting work, which while very important, could never have a priority as urgent as keeping production operational.

A slightly more minor problem is the bottleneck introduced by having a single reviewer to sign off on the changes.

As the approach guidelines require pull requests to be merged after each step, this can lead to short delays. In practice, we worked around this by starting the next part of work from an unmerged branch. Then if any rework was required on the open pull request, that would be applied to the new branch (e.g., via git rebasing).

In the last 4 months, we have moved a second resource to this work to try and further speed things up.

We do not track the hours that each developer works on any given task, so there is no estimate of the total hours consumed by this effort.

## RESULTS

### Test Coverage and Rework

If we measure progress as “packages done”, then one of the issues that effectively delayed us, was rework. After porting package *A*, testing it and the downstream packages dependent on it, we would declare the package as “done”. However, when we started porting package *B*, which depended on package *A*, we would find a defect that needed to be fixed in package *A* again. This was generally because that part of package *A* was not properly covered by test cases. When we started exercising it under python3 in a different way, problems emerged.

This is a reason why good test coverage is very beneficial when undertaking a task such as porting. It can be seen as a type of refactoring - the functionality must remain unchanged, while some improvement is made to the code.

Another area where test coverage is especially important at the leaf nodes in the dependency graph. Here there are no further downstream packages to provide additional testing feedback. If the test coverage is low, then we have little confidence in the port, and must resort to manual testing (exercising the applications by hand). This is a risky strategy.

## Metrics

For each package we used our version control system history to extract the dates of the first and last commit related to the porting work. This excludes the rework mentioned in the previous section. Using the time elapsed between the first and last commits and the SLOC, we can derive useful metrics.

The rate (SLOC per week) to port a package as function of the package size (in SLOC) is shown in Fig. 2. We see no significant correlation. The time axis is not shown, but there was a factor of 4 difference in the rate for the first few packages (0.29 to 1.19 kSLOC code per week).

Figure 2: Package size versus rate of porting for all packages completed.

Considering the total SLOC in the codebase, minus the SLOC completed over time we can get a “burndown” chart, as in Fig. 3. There have been significant variations in the rate of work, but overall the trend is linear. Unfortunately, after almost 3 years of part-time work, we are only half way. Extrapolating this line, we predict an end date around January 2025. We need to decide if progressing with this porting project is worthwhile, as there will only be a one or two years of MeerKAT’s operational life remaining. Alternatively, we need to find a much more rapid way of progressing.

Figure 3: Lines of code remaining to be ported versus time. With completion date projected using a straight line regression.

## CONCLUSION

We have discussed our motivation and the various strategies available for porting our codebase from Python 2 to Python 3. We showed how the dependency graph drove the approach, and provided a detailed procedure. The various missteps and challenges associated with human resources and project prioritisation were described.

The results section indicate the disappointing progress we have made thus far. We will need to re-evaluate the porting project to see how we can change our approach. If we had

done such close analysis of the data a year or more ago we may have adjusted sooner.

We have not yet worked on legacy and proprietary packages that may be difficult or impossible to port, as these are in an unreachable leaf node. Nevertheless, our plan is separate out the parts that are too hard to port, and run them in containers that still have the old dependencies.

The porting of a codebase is a significant undertaking, and needs to be carefully managed. Prioritisation and dedicated resources are important, but success is not guaranteed.

# ALBA CONTROLS SYSTEM SOFTWARE STACK UPGRADE

G. Cuni, F. Becheri, S. Blanch-Torné, C. Falcon-Torres, C. Pascual-Izarra,  
Z. Reszela, S. Rubio-Manrique, ALBA-CELLS, Barcelona, Spain

## Abstract

ALBA, a 3rd Generation Synchrotron Light Source located near Barcelona in Spain, is in operation since 2012. During the last 10 years, the updates of ALBA's Control System were severely limited in order to prevent disruptions of production equipment, at the cost of having to deal with hardware and software obsolescence, elevating the effort of maintenance and enhancements. The construction of the second phase new beamlines accelerated the renewal of the software stack. In order to limit the number of supported platforms we also gradually upgraded the already operational subsystems. We are in the process of switching to the Debian OS, upgrading to the Tango 9 Control System framework including the Tango Archiving System to HDB++, migrating our code to Python 3, and migrating our GUIs to PyQt5 and PyQtGraph, etc. In order to ensure the project quality and to facilitate future upgrades, we try to automate testing, packaging, and configuration management with CI/CD pipelines using, among others, the following tools: pytest, Docker, GitLab-CI and Salt. In this paper, we present our strategy in this project, the current status of different upgrades and we share the lessons learnt.

## ALBA CONTROLS SYSTEM DEVELOPMENT AND EARLY OPERATION

When building ALBA controls system, the main goal from the software (and hardware) point of view was to use standard tools and be as homogeneous as possible in order to ease development, training, and troubleshooting. Beamlines and accelerators have the same software structure and use the same applications wherever it is possible, for example, vacuum or motion control.

### Controls Software Stack Overview

ALBA controls system uses Tango as middleware, a distributed control system framework based on CORBA [1]. It is characterized by a client-server architecture, its object-oriented design, and the use of the database as a broker and name service. The ALBA Controls Group chose Python as the main programming language and strongly invested in developing and supporting PyTango, a Python binding to C++ Tango library [2].

The vast majority of GUIs at ALBA are developed using Taurus [3], a library for building desktop applications in PyQt. Taurus was initially connecting only to Tango models but over years its architecture evolved towards a highly modular and data source agnostic solution broadly used in numerous scientific installations.

Apart from Taurus, other generic and transversal services, initially implemented as Tango device servers interfaced from GUIs, gradually evolved into projects used not only at ALBA beamlines and accelerators but also at many other institutes of the Tango community. These are, among others:

- Sardana, a scientific SCADA suite [4], which consists of Taurus-based widgets for experiment control and IPython based CLI called Spock on the client-side, and a powerful sequencer called MacroServer and Device Pool for interfacing with the hardware on the server-side.
- Panic, an IEC62682 compliant Alarm Handling suite (Alarm Handling Panic GUI and PyAlarm) [5] capable of messaging and automated execution of control system actions.
- Generic tools and device servers (Tango import/export scripts, calculation device servers, vacuum controllers, diagnostics tools) [6]

Apart from the generic services and user interfaces, every sub-system has its specific applications, e.g. MX-CuBE control application for macromolecular crystallography experiments used at BL13, TXM control application for tomography experiments used at BL09, or the accelerator timing system controls stack (Linux drivers, Tango device servers and GUIs).

The ALBA Controls Group used to manage all the software under maintenance with the “bliss” system. The bliss system, developed by the ESRF, is an rpm-based packaging and Software Configuration Management (SCM) tool. It comprises two applications: the blissbuilder and the blissinstaller, both offering intuitive to “non-packaging experts” graphical way of defining and creating packages, and installing them, at the same time being limited in terms of automatic package creation and deployment.

The different pieces of software run on diskless compact PCI (only for the accelerators) and industrial PCs, distributed in the service area or experimental hall with direct access to the hardware devices. The boot servers, archiving, Tango databases, CCD data acquisition, and various other services run on VMs centralized in the computing room. Most of the controls hosts run a standard Linux distribution which at the beginning was openSUSE but there are also some Windows hosts, mainly workstations for data analysis.

## ALBA CONTROLS SYSTEM SOFTWARE OBSOLESCENCE

A control system for a scientific facility such as ALBA is not a static system: new hardware needs to be supported.

ted, scientific software introduces requirements for up-to-date libraries and other dependencies, etc. Similarly, the different components of the system are heavily interconnected, which makes that, very often, the upgrade of a component requires similar upgrades in other related components.

While the initial stack of technologies and strategic decisions proved successful in the first stage of building the ALBA controls system and first years of commissioning and operation, they inevitably needed to be reviewed and updated after more than a decade of use and in the new stage of operation.

### *Operating System*

Most of the control machines (and also the generic IT servers and even personal desktop machines) installed during the first years of ALBA were running OpenSUSE 11.1, which had already reached its end-of-life in 2011, even before ALBA entered into operation. This imposed many limitations on the support for new software and hardware, due to being tied to core libraries and modules (e.g. libc, Python, numpy, PyQt4,...) that dated back to 2008. As this situation became increasingly problematic, some selected machines, typically those accessed by end-users, were upgraded to newer SuSE versions (mostly OpenSUSE 12.1, but also up to OpenSUSE 13.1), which alleviated some specific issues but increased the maintenance effort due to the larger number of platforms being supported.

Operating systems security updates became scarce after some years in operation, we had a big dependence on 32 bits systems that were not already supported with a lack of hardware drivers for evolving these systems into more up-to-date platforms. This situation was not sustainable, and by 2015 a task force was constituted to evaluate the different options for a general upgrade of the OS of control system machines and also on the workflows for simplifying future upgrades. As a result, in 2018 ALBA started replacing OpenSUSE with Debian in the control system machines (see more details in the "ALBA Controls System Software Upgrade" section).

### *Packaging System*

From the beginning, it was decided that all the software should be packaged in order to be deployed on a control system machine. This included software that was directly developed by ALBA's control group but also any other software that needed to be installed and which was not available for our OS as a system package from official or third-party repositories. Furthermore, it was decided to separate the management of the software that was installed as part of the control system from that related to the "general operating system". To that effect, and in order to facilitate the packaging tasks, the "bliss" system from the ESRF was selected and custom-adapted to ALBA's own conventions. While the packages produced and managed by bliss were of the same type (RPMs) as those of the system, they were different in that they were unpacked into non-standard paths and did not follow

the same quality rules (e.g. the dependency declaration was managed by bliss and was very limited in comparison with that of the system packages). This decision made more sense in the early times of ALBA, when the standard package build and management tools from the Linux distributions were much less user friendly, but it introduced several limitations that recommended its reconsideration:

- the separation between "general system" and "control system" was often not clear (e.g. in the case of generic libraries such as hdf5 which were also dependencies of control system packages, or the case of custom kernel drivers necessary for hardware support, or system daemons which were hard to manage by bliss).
- it was difficult to have a clear view of the whole stack of software required for a given purpose since its management was splitted into different tools (standard ones for the general system and bliss for the control system)
- the custom nature of the bliss packages prevented us from collaborating with other facilities in the packaging of software (even for software developed in collaboration, such as e.g. Tango)
- while bliss had a very gentle learning curve, it being a custom solution often required using workarounds to several of its limitations, which were not properly documented but passed as "group-lore"
- with the advent of containerization, the use of a custom packaging system made it very difficult to benefit from standard container images
- the maintenance of the bliss packaging system itself was a burden for the control system group

Because of these reasons, it was decided to move towards using the native package system for the host OS and standard package management tools as part of the change to an updated OS.

### *Python*

Most of the software developed and maintained at ALBA is based on Python. Because of our dependency on old OpenSuse 11.1 we were forced to support Python 2.6 this disincentivated the adoption of Python 3 within the ALBA controls team even after 12 years of its release in 2008. As a consequence, in 2021, after Python 2 reached its end-of-life we still have a considerable part of our software depending on Python 2. This is especially problematic because most of the core modules on which we depend had actively stopped supporting Python 2 and current Linux distributions already stopped providing them, making a gradual transition more difficult and forcing us to keep whole systems outdated because of it.

A lot of effort is being put on adapting our software to Python 3, starting in 2019 when Taurus started supporting it (with a common code base that also supported Python2), and following with Sardana, some GUIs, Tango

Device Servers, etc. mostly associated to the OS update of machines in the Control Room and Beamlines.

## Tango

The development of ALBA Control System was initiated using Tango 5 on OpenSUSE 10.2 platform. Prior to starting operation it already evolved to Tango 6 over OpenSUSE 11.1 and later to Tango 7, enhancing the performance of the system and providing what has been our stable platform for 10 years. Despite of the success on the development of the control system, several limitations generated recurrent issues, especially the dependence on outdated Java packages due to old OS and the lack of performance of the OmniNotify event system (notifd), that limited the event throughput causing continuous incidences and blocking the evolution to a full event-based architecture.

An initial upgrade project was started for several ALBA beamlines, for which a hybrid Tango 7/Tango 8 system was deployed. Tango 8 introduced ZMQ as a new event system, thus increasing the theoretical performance of the control system and eliminating the need for a permanent daemon dedicated to event dispatching, which was a recurrent cause of memory leaks and event bottlenecks. This hybrid system performed poorly, due to the usage of already obsolete operating systems and the (unknown at the time) incompatibility between different versions of ZMQ. Finally, a full Tango 8 based approach was adopted for those upgraded control systems. This required the deployment of multiple Jenkins servers in order to automatically recompile all existing Tango Device Servers for every new release of Tango.

Although Tango 8 was finally discarded as an alternative for the main Accelerators Control System (due to the legacy OS 32 bit dependency), all the work done on CI for the Tango 8 upgrade became the base for the current CI/CD workflow, which allowed a much smoother upgrade of both OS and Tango to the latest versions (Tango 9.3.4 over Debian 9), which solved all the previous performance issues and allowed a successful migration of all control systems at ALBA. The experience during the migration process also triggered the Tango Community to move from short-term releases to Long Term Supported (LTS) releases, a move that benefited the whole community in terms of development stability and larger reusability of software stack throughout the community.

## PyQt and PyQwt

Taurus, and as a consequence most GUIs at ALBA, was originally based on PyQt4 [7] for its general widgets and on PyQwt5 [8] for its plot widgets. PyQt4 reached its end of life in 2018 and PyQwt5 was by then already unmaintained (its latest release from 2011) and was never ported to PyQt5 or Python 3.

As with Python, the need to run the control GUIs on an obsolete OS shipping outdated versions of PyQt slowed the porting of our own software. Taurus started supporting PyQt5 in 2019 and switched to it as its default binding in

2020. It also started implementing alternative plotting widgets based on PyQtgraph [9] in 2017 but these only became ready to replace the old PyQwt5 ones in 2020.

After that, some GUIs (mostly the most modern ones which were already based on Taurus >= 4) could be ported with little effort, but many remain unported because they still use Qt APIs that were already deprecated in 2013. These are being gradually migrated as part of the effort to update the OS of machines in the Control Room and Beamlines.

## ALBA CONTROLS SYSTEM SOFTWARE UPGRADE

### New Operating System Selection

In 2015 a task force involving various members of the controls group in coordination with the IT infrastructure group started evaluating the various candidates to replace the old OpenSUSE 11 and 12 machines. One key decision was to decouple the choice of the OS for control system machines from that for generic IT systems because it became evident that, apart from a common requirement for robustness and long term maintainability, the requirements were not compatible: in the case of the control system we stressed the availability of scientific software and the support of scientific instrumentation and varied hardware platforms, while for generic IT systems the focus was on vendor support and network and filesystem robustness. As a result, OpenSUSE Leap and Debian were shortlisted as the candidates for the control system, while the IT systems moved towards CentOS.

During two years we conducted an in-depth evaluation of OpenSUSE (using versions 13.1 and 42.1) and Debian (with versions 8 and 9). The main aspects being evaluated were:

- life cycle and duration of supported updates
- amount of available software relevant for ALBA (i.e., mostly science-related). In order of preference we considered packages already included in the distribution, then those officially packaged for the distribution by its authors and then those packaged unofficially by some third-party
- usage in other similar facilities, specially within the Tango Collaboration
- relevant hardware platforms supported. In order of priority: amd64, i386 and arm
- quality of the documentation and community support
- quality of native package build and management tools

These aspects were not just evaluated from theoretical research, but also tested in practice by deploying both systems during more than a year to production environments (a relatively simple beamline and a support lab) for which we had to package and deploy a full basic stack of control system software, ranging from hardware kernel drivers to taurus-based GUIs and including also a Tango system with several device servers.

This selection process has been constrained by our needs to evolve our stack of technologies, the feasibility of porting existing devices, drivers, and applications from 32 to 64 bits hardware keeping consistency between the new and legacy control systems as well as the necessity to keep our CI/CD workflows in-house to avoid dependency from external services. To be able to recompile and test all the software stack onto new platforms, multiple Jenkins servers were configured for all our existing OS at ALBA (SuSE 11/12/42 and Debian 8/9 in 32/64 bits), including physical hardware machines to test and evaluate hardware drivers compatibility and performance. It allowed to test all platforms and confirmed the necessity to keep 32 bits support for the next 5 years.

Both distributions showed that they were fit for the task, but Debian performed a bit better in most of the aspects being evaluated and had better support to all our hardware platforms, to the point that it was enough to overcome the main advantage of OpenSUSE which was that it involved less change with respect to the old system. As a consequence, Debian was chosen and, in 2018 the migration started with the upgrade of the Control Room machines to Debian 9, and followed by the machines dedicated to Sardana in the beamlines (at the moment of writing all but two). Once this is done, other systems will be gradually updated, leaving only some legacy systems out of the upgrade.

## Packaging

As mentioned in the "ALBA Controls System Software Obsolescence" section, an important conclusion for the OS update was to also switch from our custom packaging system (bliss) to using standard system tools for both building and managing the control system packages.

As part of the new OS evaluation, we evaluated the "OpenSuse Build Service" [10] and the Debian packaging toolchain. Of both systems, we valued that the packaging could be managed with a workflow involving a version control system: a domain-specific one inspired in CVS in the case of OpenSUSE or git in the case of Debian [11].

Once Debian was chosen as our new OS for controls, we produced a step-by-step guide, a set of examples, and a Docker image with the whole Debian packaging toolchain in order to facilitate the transition from bliss to the standard Debian packaging workflow. We provided training to the whole group of controls developers, including hand-on sessions in which we collectively packaged the whole software stack required for the upgrading the Control Room machines.

On a first stage, the packaging workflow was done manually using the mentioned Docker image but, with the introduction of "salsa" service by Debian [12], we extended the Debian CI pipeline to automate the process [13]. Currently, the whole packaging process is done by a Gitlab CI pipeline triggered by pushing a version tag to the packaging repository and resulting in the package being automatically built for various distributions, tested and uploaded to a staging package repository. User intervention is required only for adjusting the package configuration du-

ring the creation of the first version of the package, or when the package configuration needs to be modified (e.g., for updating a dependency). These interventions can be entirely done using the web interface of Gitlab, eliminating the need of locally installing the packaging toolchain. The same toolchain is also capable of promoting the package to a production repository if the user confirms that it is ready after testing it using the staging repository.

The packages produced using this pipeline need to pass the same automated quality assurance tests used for the official Debian packages, resulting in much better quality packages than those that were created with bliss.

## GUIs for Accelerators Operation

The upgrade of Graphical User Interfaces (GUI) for operation has been a critical procedure, as it has been performed gradually without interrupting the operation of the accelerator. A gradual replacement of Control Room consoles has been performed over a 2 years period, in which all legacy OpenSUSE machines have been replaced by Debian, upgrading from Taurus 3 to Taurus 4 and Tango 9 in the process.

Paradoxically, the performance increase provided by Tango 9 caused several issues on old applications, due to the higher event throughput on those applications not properly designed to manage high update rates. Replacement of old applications by newer versions was performed on various stages, following a strict schedule in which users were informed and allowed to test each application prior to its deployment in production. Several applications required changes in its management of attribute updates. Having all applications built on top of a common framework (Taurus) helped to implement the solutions required on Taurus itself, allowing the upgrade of multiple applications at once and allowing to solve issues once-for-all as they appeared providing flexibility at the application level to choose between polling or event-based refresh for each attribute.

In addition to the Tango upgrade, several other technologies were upgraded. Qt4 and Qwt libraries were replaced by Qt5 and PyQtGraph, and the database backend for both Tango database and Archiving System was upgraded from MySQL 5.0 to MariaDB 10.0 the newest event-based Tango Archiving System [14]. The adoption of Taurus 4 on Qt5, which was profoundly refactored, required to modify existing applications to use new Qt style signals, and the migration to PyQtGraph of archiving visualization tools is still an ongoing project, for which new Python 3 database extractors have been developed capable of online decimation of the incoming data from the high-performance event system.

The usage of Taurus framework for developing all custom applications required for day-to-day operation allowed to do a transparent upgrade of those applications developed using only generic Taurus widgets[3][15], allowing to upgrade dozens of applications without only minor modifications, mostly on unit visualization

(managed by Pint on Taurus 4) and attribute values formatting.

### *Tango Device Servers Upgrade*

Upgrading device servers to new technologies have become one of the most difficult processes, due to the dependency on old hardware and the lack of drivers for newer operating systems. Industrial PC's devoted to hardware testing have been deployed on several ALBA laboratories for testing every upgraded device server prior to its deployment in production. Drivers have been updated whenever open source code was available, and several projects have been started to migrate DAQ acquisition cards to newer platforms.

In the meantime, most of the hardware-based control systems are still kept on legacy control system, while only ethernet-based hardware (PLCs [16], cameras, scopes) have been migrated to newer platforms using virtualized hosts. We are in the process of migrating all serial-line based device servers using serial-to-ethernet adapters, thus eliminating the need for Industrial PC's for most vacuum systems, and a new 32 bit Debian 9 image is under development to replace most of our legacy control systems. We expect to migrate two thirds of our legacy control system to Debian during the next year, but assuming that still many hardware dedicated IOCs will have to be kept on legacy versions waiting for a future hardware replacement.

For those devices already running on Debian 9 and all our purely software-based devices (database extractors, data processors, calculation and simulation devices, alarm systems) we started a project to migrate them to Python 3. The project started with the migration of the common-shared libraries (fandango [17], panic [5], pytangoarchiving) and the adoption of the new Python HL Tango API for every new development, which provides fully Python 3 compatible code.

### *Sardana Python 3*

Sardana is used by various European institutes, mainly synchrotrons, and at ALBA it is used at the beamlines, accelerator, and auxiliary laboratories. Due to the software stack obsolescence at ALBA, the Sardana codebase was required to maintain compatibility with Python 2.6, Tango 7, PyQt4, etc. for a long time. Even if the Sardana community was well aware of the Python 2 EoL the Sardana codebase migration to Python 3 was always being delayed in favor of other developments. This changed when the ESRF announced that after its accelerator upgrade program they would like to use Sardana with Python 3.

Sardana is a final application, not a library, and it followed a different migration approach than the Taurus project. Sardana codebase was migrated to Python 3 without supporting Python 2 at the same time. Sardana users highly demand new feature requests and bug fixes that are continuously being released. So, it was in the interest of both users and developers that the setups were upgraded to use the new Python 3 compatible version ASAP. The

upgrade process required the end users to migrate their Sardana plugins to Python 3 as well.

In the case of ALBA, the Sardana upgrade to Python 3 required upgrading the OS to Debian 9, Tango to version 9, and Taurus to version 4. The project scope was limited to upgrade only the strictly necessary part of the controls system to provide to the users the Sardana service running with Python 3. As a consequence, the coexistence of different software versions in different sub-systems was assumed. A transversal workforce of nine controls engineers was formed to work on the software migration to Python 3, packaging, testing, and commissioning.

The upgrade process consisted of two phases, first, the Tango database service was upgraded to Tango 9. In this process, the TANGO\_HOST configuration was changed to use a DNS network alias, in order to facilitate eventual rollbacks and future upgrades. Here, two problems appeared: the Tango 7 event system started to suffer memory leaks in certain conditions and the Tango Java event system stopped working. In the second phase, the Sardana Tango servers were moved to dedicated VMs and a new workstation was prepared to run the Sardana client applications. Here, appeared problems with the Tango 9 causing deadlocks and hangs of the experiment procedures.

The upgrade process required from the users a thorough testing process, nevertheless, rollbacks were not avoided. In order to advance in the upgrade, immediate workarounds were applied and issues were escalated to the Tango community, which was always very helpful in debugging and solving problems. In the current state, all, but two ALBA first phase beamlines were successfully migrated and all the second phase beamlines were built using Sardana Python 3. Other institutes in the Sardana community are also very well advanced in the upgrade process.

### *Following Debian updates*

The selection of Debian as a new OS for the control system was never considered as a one-time upgrade effort but was more a commitment to try to follow future Debian releases according to the needs and capabilities of the ALBA Controls Group. New Debian releases happen every two years, are supported by three years by the Debian organization, and later receives an additional two years of Long Term Support. During the three years of support, the release is updated once in a while with security fixes and fixes for important bugs. Those updates are called "point releases".

All the control system Debian hosts at ALBA, unless explicitly excluded, are upgraded to point releases during short shutdowns (several times per year). This upgrades only the non-control-system packages and the whole process is highly automated using the Software Configuration Management tool.

Due to the still not fully automated packaging creation for the current and future Debian releases, the upgrade to Debian 10 could not start as soon as it was available. Since the packaging infrastructure is now ready, soon we will start a project of upgrading the Sardana service to use De-

bian 10, which will open new possibilities in the project development thanks to the updated dependency stack. This will be a minor effort thanks to the automatic packaging and isolation of the Sardana Tango device servers on a dedicated VM.

Debian 11 was released in August 2021 and upgrading to it instead of Debian 10 has been discussed and is still an option, but the decision is strongly conditioned by the fact that Debian 11 does not provide a full Python 2 stack nor PyQt4 and therefore all software running on it needs to be ported to Python 3 and PyQt5 (or alternatively, run on virtual environments or containers).

## APPLIED PRACTICES AND TOOLS

Each author should submit the PDF file and all source files (text and figures) to enable the paper to be reconstructed if there are processing difficulties.

### Testing

Testing plays a very important role in the control system upgrade process, and testing strategy must be tailored to the nature and development status of each of the projects.

The SEP5 [18] introduced the first conventions for developing automatic tests with unittest module (part of the Python standard library) for Sardana and Taurus on the unit and integration level. Setting up Continuous Integration (CI) jobs for running those tests provided valuable feedback and let us avoid many new bugs and regressions before the upgrades in the production setups. Since the testing coverage is still not satisfactory manual tests are performed before every major release. Recently we decided to switch from unittest to PyTest [19] for developing automatic tests because this second one provides a better programming interface and many useful features available out-of-the-box e.g. fixtures, parameterization of tests, code patching, temporary resources context managers.

Developing automatic tests for the Tango control system requires setting up necessary resources for the needs of the tests. Our initial approach was to set up a disposable container running a Tango database with prepared instances of the Tango devices and starting and stopping Tango device servers for different classes of tests. Recently, in some tests, we started employing a different approach and use the PyTango (Multi)DeviceTestContext which allows better test control and isolation.

Automatic tests for the controls software can either interface with the real hardware or with simulators [20]. Currently, we employ this second strategy, for example, in the case of Sardana all the possible controller types e.g. motors or experimental channels are available in a simulation mode and are used during the tests. Similarly, in the case of the PyIcePAP, a Python library for interfacing the IcePAP motion control, simulated hardware is used during the tests. Furthermore, in the near future, we plan to employ automatic tests with the real hardware equipment located in our computing laboratory into our CI and in addition run nightly stress tests to

discover non-easily reproducible bugs and performance degradations.

### Automation and Reproducibility

The advantages of using Continuous Integration for the testing of both Taurus and Sardana have already been described in the previous section. Our experience in these cases has been unequivocally positive, because the use of CI not only improved the overall quality of the code but also enabled a much more agile collaboration as a consequence of the reduced risk of regressions. We will certainly promote the use of CI in other developments.

The use of Continuous Integration for software packaging in ALBA has also been discussed above. It is important to note that our current pipeline enables going one step further towards using a Continuous Delivery approach. Also, the fact that the packages are now artifacts of a fully reproducible pipeline whose logs are always available for inspection, has also facilitated the collaboration and support in the packaging process.

Additionally to the use of CI/CD for the packaging of our internal developments, we are also using it for publishing some of our software to PyPI, to Conda-Forge and other Anaconda Cloud channels, and even to salsa for inclusion in the official Debian distribution. This greatly improves the visibility and usability of our code outside ALBA.

Finally, it is also interesting to mention another area in which we found automation to be very helpful: the generation of documentation for our projects. In the case of Taurus and Sardana, we originally started by generating the documentation of the Taurus and Sardana projects using sphinx, and soon we automated it thanks to the ReadTheDocs service which we found excellent. However, we eventually decided to move the documentation build to the same CI system that we used for the code (first, Travis CI and now Gitlab CI [21]) in order to unify the CI. Apart from these projects, we also use Gitlab CI for autogenerating documentation of internal software and deploy it automatically.

### Configuration

The ALBA Controls Group uses Salt [17] to configure and manage software on remote nodes. We are moving to the central Salt Master the following tasks: the installation of Debian packages, the clones of Git repositories, the installations with Pip, and the installation and configuration of the Conda environments. We define a catalog of ALBA Services e.g.: Tango, Sardana, Taurus, Icepapcms, Archiving, etc. The application of the Salt recipes allows us to automate the installation and configuration of the same Services in parallel in different machines and in a reproducible way. Each remote node is configured through Salt Grains that specify which Services should be installed in that node.

We are still in the process to fully adapt the Salt solution to ALBA controls system and we have some open points, like the best use of version control of the services,

the proper workflow for testing a new version, or the use of a graphical user interface.

One particularly problematic point is how to manage rollbacks: the Salt recipes express the changes to be done in the target machine, which is not exactly equivalent to specify the state of the system. It is easy to conceive a situation in which reverting a salt change leaves the system in a state which is not identical to that previous to the original application. For the moment, the use of "snapshots" in the case of Virtual Machines seems the best workaround.

### *Control Room Scheduled Updates*

The upgrade of existing applications at ALBA Control Room required a careful approach, as it needed to guarantee maximum availability and stability for the operation of ALBA Accelerators. It required careful testing of every application, including hardware interaction, before applying any update to the main operator consoles. The need for hardware tests also forced us to integrate the testing procedures with the Accelerators Operation calendar, thus constraining the CI/CD workflow and defining our Control Room Update Flow states:

- Testing prior to deployment: Developers perform tests of GUI applications and device servers under development (from git or staging repositories) on a dedicated machine, only during machine maintenance periods (8-9 dedicated weeks per year).
- Testing on production: Packages are deployed on a machine available to machine operators that can be used to validate the latest releases (staging) of each software package prior to its propagation to the Control Room operators consoles. Applications are kept on this stage for at least a machine-run period (4 to 5 weeks) prior to their promotion to the production environment (only after validation by users).
- Production: Finally, validated applications available in the production repository are deployed into the 10 operator consoles in the Control Room for its use by all operators. Prior to the update, all previous stable versions of packages are deployed into an "old\_stable" machine, available as a backup in case a bug appears on operation despite all the previous testing.

This workflow implies a delay of 5-6 weeks before a development reaches its production status, a conservative approach in order to guarantee the maximum stability of the system. In the case hot-fixes are required, a special mechanism to perform updates during machine days is enabled (once per week), which requires a notification to affected users via an Accelerator Interventions ticketing system and an update of the configuration system (Salt recipes), which is managed by a git repository thus providing a register of changes.

### *Containerization*

Up to now our use of (Docker) containers has been mainly limited to the context of software development as, e.g.:

- providing the environments for the CI jobs
- providing a pre-configured a clean environment for manual testing or packaging of software
- developing or debugging in a reproducible environment

However, we are also considering the use of containers for deploying the control system in ALBA. In particular, we are currently evaluating how to deploy our typical beamline stack of applications as microservices in a Kubernetes cluster. Some of the expected potential advantages of this approach are:

- it could facilitate upgrades, thanks to the increased isolation of each component
- rollbacks would be much easier since the whole system can be re-deployed from scratch from a version-controlled configuration
- it would simplify the debugging thanks to the possibility of running clones of a given deployment

## **TOWARDS ALBA II**

The recently approved ALBA II project will consist of an upgrade of our installation to the 4th generation class of synchrotron light source and is planned to happen in 2028. The new accelerator will provide lower emittance and higher brilliance beam to the beamlines and new challenges to the control system. The ALBA Computing Division started preparing for the future requirements by analyzing the lessons learnt from the ALBA construction and operation as well as identifying and over-viewing cutting-edge solutions at similar facilities. In the following years, it is planned to start exploratory projects to acquire the necessary expertise, at least, in the following mainstream technologies which if applied could ensure long-term maintainability of the ALBA II control system. First, isolation of the controls software stack from the host OS, by use of containers or isolated environments e.g. conda. Second, use of web technologies for operators GUIs, which in comparison to desktop applications are cross-platform compatible and more manageable (isolation is done on the server placing minimal requirements on the end-user workstation). We also look forward to the upcoming Tango 10 version release, which code will be refactored/re-written in order to make it immune to the obsolescence of libraries and technologies e.g. CORBA.

In parallel, some more specific projects for the ALBA II control system have already been started. Here we would like to mention a joint effort between BESSY, DESY, and ALBA in the development of the third harmonic cavity with the DLLRF at 1.5GHz. From the side of controls, accelerators provides us with interface information to the FPGA they program. We have developed a Python binding using cython to access this FPGA and the rest of the cards of the MicroTCA used for

this system. This binding is used to simplify their development as well as to prepare an Agent in the DCS to represent this card. The interface of registers provided by accelerators is described in the csv file and this file is used as a source for an auto-generation tool capable to build not only the Tango device server but also the Taurus GUI, based on conda environments using Python 3.9. The current development is installed in an autonomous rack to be moved to even another facility to be used. In the installation, there is a pair of containers with the Tango frontend and the MariaDB backend, and the Tango control and the Taurus GUI work on their own conda environments.

## CONCLUSIONS

Decisions from the ALBA control system development, commissioning and early operation were successful in terms of the selected technologies e.g.: Tango, Python, PyQt, Tango, etc. From the perspective of time, we believe that it is crucial to keep the OS updated. In our case, the lack of update in the OS conditioned many other updates and, in the long term, generated more efforts in workarounds than the effort of keeping it up to date. Also, it generated a huge effort when it had to be finally updated. The big turnover in the team composition when transitioning from the development into the operation phase was probably decisive in postponing this effort.

Keeping the controls system up-to-date is a collective responsibility of the whole team. Decisions at different levels, from day-to-day to strategic, should be taken considering the long-term maintainability of the control system. Last but not least, it is highly recommended to continuously follow and explore emerging technologies in order to propose improvements, feel self-confident and determined in proposing and conducting upgrade projects.

## ACKNOWLEDGMENTS

All the work presented in this paper is an effort of the ALBA Control Seccion members. We would like to mention here: Jordi Andreu, Manuel Broseta [on leave], Tiago Coutinho [on leave], Roberto Homs, Gabriel Jover [on leave], Jairo Moldes, Daniel Roldan [on leave], and Marc Rosanes [on leave]. The upgrade projects would not be possible without support from other sections of the Computing Division, mainly IT Systems Section, here we would like to acknowledge Sergi Puso for his support in multiple fields and Marc Rodriguez [on leave] for sharing his expertise with us about Salt, and the MIS Section, here we would like to acknowledge Daniel Sanchez for his support in the GitLab administration. The ALBA Accelerators and Beamlines Divisions, as users of the control system, played an important role in the controls system upgrade projects by performing acceptance tests and provided valuable feedback. We would like to recognize the help provided by the Tango Controls Community members (a list of whom would be too large to fit into this paper). Finally, we would like to acknowledge the help from the Debian Science Team, and

especially Frederic Picca in guiding us in the process of adopting the Debian packaging policies.

# UCAP: A FRAMEWORK FOR ACCELERATOR CONTROLS DATA PROCESSING @ CERN

L. Cseppentő\*, M. Büttner, CERN, Geneva, Switzerland

## Abstract

The Unified Controls Acquisition and Processing (UCAP) framework provides a means to facilitate and streamline data processing in the CERN Accelerator Control System. UCAP's generic structure is capable of tackling classic "Acquisition - Transformation - Publishing/Presentation" use cases, ranging from simple aggregations to complex machine reports and pre-processing of software interlock conditions.

In addition to enabling end-users to develop data transformations in Java or Python and maximising integration with other controls sub-systems, UCAP puts an emphasis on offering self-service capabilities for deployment, operation and monitoring. This ensures that accelerator operators and equipment experts can focus on developing domain-specific transformation algorithms, without having to pay attention to typical IT tasks, such as process management and system monitoring.

UCAP is already used by Linac4, PSB and SPS operations and will be used by most CERN accelerators, including LHC by the end of 2021.

This contribution presents the UCAP framework and gives an insight into how we have productively combined modern agile development with conservative technical choices.

## INTRODUCTION

The Unified Controls Acquisition and Processing (UCAP) Framework is a recent product in the CERN Controls Software & Services (CSS) group's portfolio. This generic, self-service online Controls data processing platform, enables clients to easily implement and run Controls Device data acquisition and processing in Java or Python.

The main objective of the project is to provide a common approach to solve problems where:

1. data is acquired and grouped from several sources (*Acquisition*),
2. based on these inputs, and optionally internal state, a result is calculated (*Transformation*),
3. the result is made available to clients (*Publishing/Presentation*).

Such "Acquisition - Transformation - Publishing/Presentation" problems are regularly featured in many Controls products, such as data concentrators, software interlocks, logging adaptations and autopilot-style Controls software.

At CERN, Controls software development responsibilities are often split between the CSS group (mainly computing engineers providing frameworks and generic services), and

equipment and operations groups (typically experts in their specialised domains). Experience showed that in order to effectively tackle certain problems, collaboration of teams with different backgrounds is essential, as the expertise of Controls framework libraries and accelerator domain knowledge are distributed. The UCAP service aims to streamline development and maintenance by splitting responsibilities:

- the UCAP team provides infrastructure, tools, training and support for development, testing and deployment of transformations,
- while the transformation code and configuration stays under the responsibility of the end-user (typically a domain expert).

This *self-service* model enables end-users to focus on realising their business logic, while the service takes care of secondary tasks, such as process management and monitoring. It is also *scalable*: as service usage increases, only new machines and UCAP nodes need to be added to the system.

Nevertheless, this set up brings other challenges, such as isolating user groups on shared hardware, ensuring dynamic server-side code loading, providing substantial documentation and user-friendly access. At this scale, a high level of *automation* is essential

The "UCAP-idea" originates from 2016, with a first prototype started in 2018. During this phase, the first use case was satisfied, providing transformations on approximately 1000 data streams. The following year, in the beginning of Long Shutdown 2, development started on the operational product – in close collaboration with stakeholders. A few months later, still in early 2019, the system went to production while iterative development continued. As of 2021 Q3, the UCAP service is composed of 105 nodes (isolated deployment units), running on 6 physical servers, performing around 20 000 data transformations.

## UCAP IN A NUTSHELL

The UCAP service is a *multitenant* system. *Nodes* are assigned to client groups or use cases for isolation purposes. All nodes are fully functional data processing services, differing only in basic configuration parameters, such as name, description and responsible. The layered architecture, presented in Fig. 1, mirrors the "Acquisition - Transformation - Publishing/Presentation" chain – each layer being responsible for dealing with one aspect of data processing. UCAP complies with this model on the architecture level, avoiding the introduction of any new structural elements in the data representation.

The CERN Control System uses the *Device-Property model* [1], meaning that all endpoints providing data are

\* lajos.cseppento@cern.ch

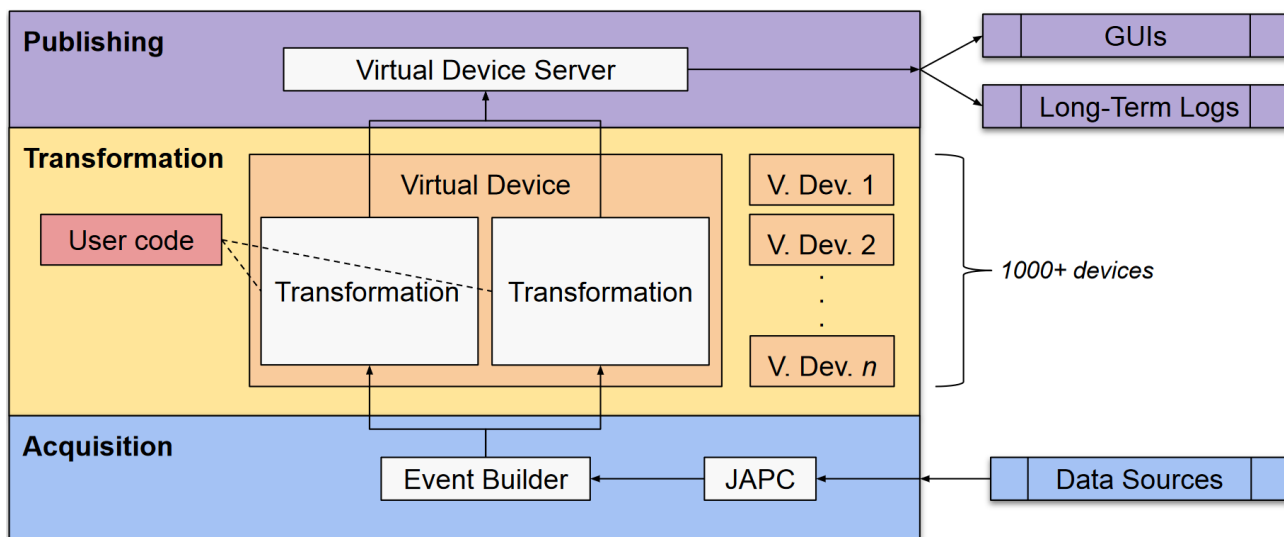

Figure 1: UCAP Node Architecture.

expressed in a `DEVICE_NAME/PropertyName` format, to which data is published as a map of key-value pairs.

### Acquisition Layer

This layer is responsible for *acquiring inputs* from data sources. This is carried out using JAPC<sup>1</sup> [2], a CERN standard library for reading inputs from individual Controls Devices. As JAPC is an abstraction layer over communication protocols, a wide range of inputs are supported, including UCAP itself (i.e., chaining of transformations).

In many cases, it is required to group inputs from several Controls Devices, for which *UCAP Event Builders* are provided. These data acquisition algorithms are the driving force for transformations. At the time of writing, 10 event builder implementations are provided, ready to be selected and configured by end-users.

A basic example of an event builder definition is shown in Listing 1, expressed in JSON format.

Listing 1: Basic Event Builder Definition

```
{
  "type":
    "GroupTriggeredCycleStampGrouped",
  "triggerGroup": {
    "subscriptions": [
      { "parameter": "MAGNET_1/Acq" },
      { "parameter": "MAGNET_2/Acq" }
    ],
    "timeoutMs": 1000
  }
}
```

This code snippet instructs UCAP to instantiate an event builder, grouping data from two sources based on their time stamps. The `type` field identifies the name of the acquisition logic, which also decides the rest of the configuration layout.

<sup>1</sup> Java API for Parameter Controls

In this case the `triggerGroup` declares how event creation shall be handled: the `subscriptions` list contains the name of the inputs and the `timeoutMs` field specifies how long to wait for them – this is notably useful when one of the sources is not available, since processing can move with the inputs that were available when the timeout was reached.

Community feedback highlighted how powerful event builders are. End-users can express acquisition logic in a declarative manner, instead of they themselves having to create subscription handles, to start monitoring threads and to implement combination logic.

Each event created contains the data received from all sources and it is passed to the Transformation Layer for processing.

### Transformation Layer

The Transformation Layer is responsible for carrying out the actual data processing. Transformations are instances of *converter* algorithms, which are configurable and can be implemented in Java or Python (Python with C/C++ bindings is also supported and used by the community). UCAP currently provides and maintains 20+ so called *standard converters*, which implement commonly required algorithms in a generic manner. Examples include merging homogeneous data from several sources; splitting multiplexed data prior to long-term logging. This enables a part of our user community to benefit from UCAP without having to write any code.

In addition, *custom converters* are also supported. For each event created, a transformation may create one or more results or choose to skip the input. Plus, if there is a need for a stateful transformation, the internal state of the transformation is preserved between events. Apart from these aspects, it is up to the end-user's creativity how they implement their business logic. An example of a Python converter structure can be seen in Listing 2: this particular code re-publishes the sum of two incoming values.

#### Listing 2: Example Python Converter Structure

```
def convert(event):
    log = logging.getLogger(__name__)

    result = AcquiredParameterValue(
        published_parameter_name,
        event.trigger_value.header
    )

    v1 = event.get_plain_value('BLM1')
    v2 = event.get_plain_value('BLM2')

    result.update_value(
        "result",
        v1 + v2
    )

    log.info("Input:_%s", event)
    log.info("Output:_%s", result)

    return FailSafeParameterValue(
        result
    )
```

For converter development we recommend using our in-house standards, CBNG [3] for Java and Acc-Py [4] for Python, however, it is also possible without those.

#### Publishing Layer

In order to make the transformation results visible to consumers, UCAP nodes encapsulate an RDA3<sup>2</sup> Device Server [5] [6] (the same communication protocol used by FESA<sup>3</sup> [7]). The user interface of the Publishing Layer is a simple return statement. Internally, the UCAP RDA3 Virtual Device Server takes care of managing client subscriptions. The results can be consumed with C++, Java and Python clients. Results can also be directly logged in the NXCALs<sup>4</sup> [8] time-series data logging system.

#### Other Notable Features

Apart from “doing the job”, UCAP provides several other Controls features, notably:

- FESA-style alarms, which can be integrated e. g., with LASER<sup>5</sup> [9],
- access to previously logged data from NXCALs,
- transparent rolling updates of user code without data loss,
- language-agnostic, RBAC<sup>6</sup>-protected [10] REST API for inspection and management and

- development, testing, monitoring and troubleshooting utilities.

## USER EXPERIENCE

User experience is crucial to ensure customer productivity and satisfaction. Good user experience also reduces the support load of the service provider team.

To facilitate development, all Java public API are annotated with javadoc and all UCAP Python public API are decorated with docstrings and MyPy type hints. Sample definitions and converter code are provided in both languages. UCAP includes testing utilities to aid users in writing unit test for converters, inspecting event builders or even running UCAP nodes locally either, directly from Java or using the UCAP Docker image.

When a user wants to start using UCAP, the UCAP team prepares and assigns two nodes for the use case:

- a PRO node for operational purposes,
- a TEST node for verification prior to deployment of transformations in operation.

A rich command line tool, *UCAP-CLI* (see Fig. 2), is provided to facilitate node management and introspection. It has an extensive TAB-based auto-completion feature, which aids users with displaying commands, Device, transformation and package names on pressing the TAB key. The CLI is also used extensively by the UCAP team for maintenance and support purposes. UCAP-CLI is available on all developer and control room machines, and it can connect to PRO, TEST and local UCAP nodes. The development and maintenance costs of this tool are also low compared to a fully featured GUI.

Out-of-the-box, service monitoring is provided to end-users in the form of Grafana dashboards [11] (example in Fig. 3). These dashboards are automatically created for each node and Device added to the UCAP service, and include subscription (data input) status, conversion errors and input/output rates. These dashboards are quite convenient as in case of failures (e. g., control room display is blank) they make *fault isolation* quick (e. g., inputs are down).

## TRAINING AND SUPPORT

Training for end-users is an essential element of the UCAP service. In the early stages of the service, focus was given to close stakeholder collaboration, frequent pair-programming sessions and an emphasis on written documentation. As the user base expanded, effort was put into public presentations (training lectures and product demos) which were recorded and made available online. Since publishing such materials, a correlation with a drop in the number of support requests from new users has been observed.

Communication channels comprise a traditional e-mail list and a Mattermost Channel for instant messaging. Mattermost has shown to be efficient in tackling quick questions. These channels are completed with periodic UCAP Technical Meetings which include demos and hands-on training.

233

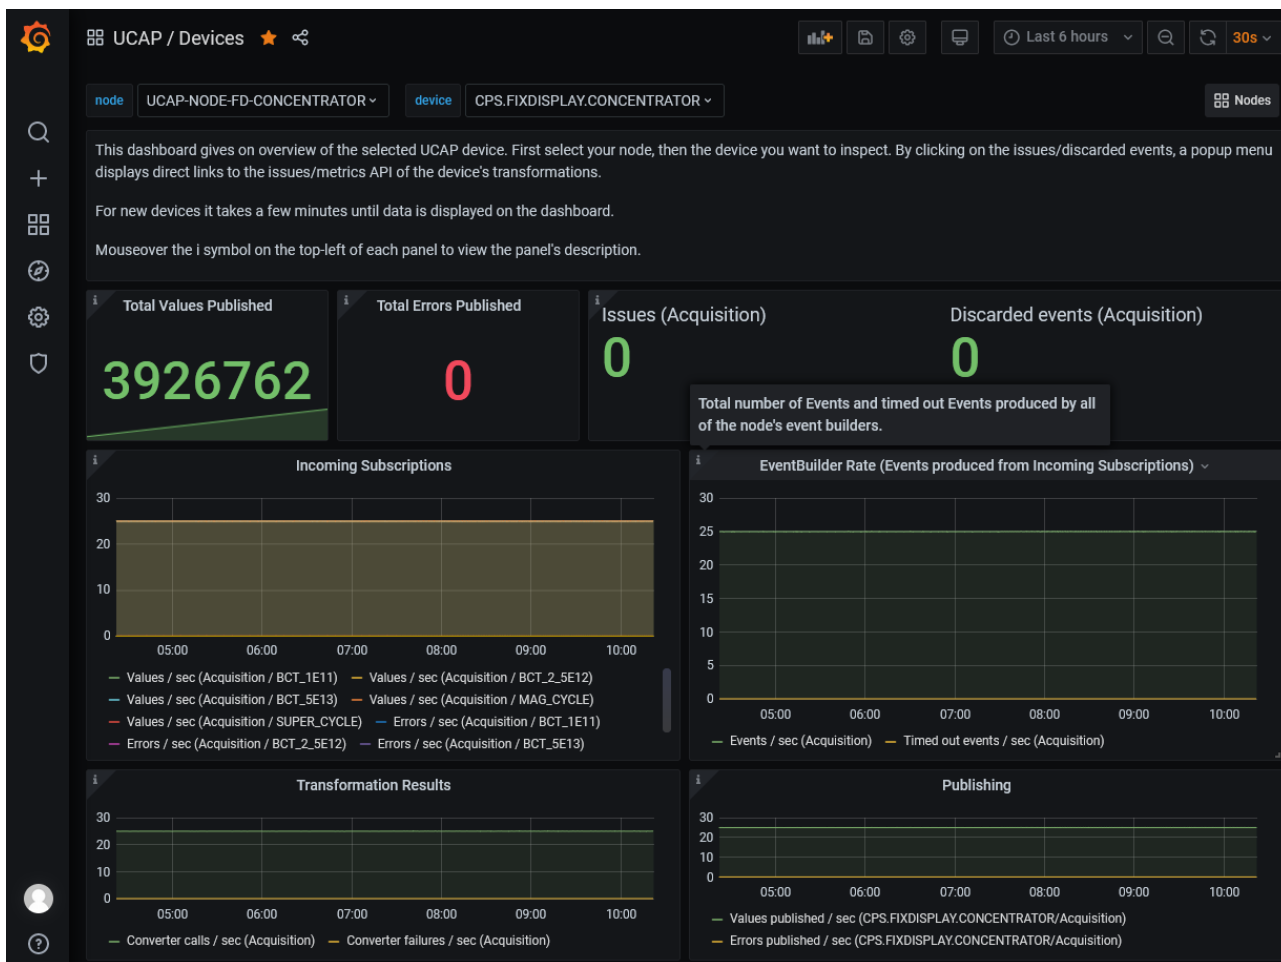

Figure 3: Grafana Dashboard of an Operational Device.

For code collaboration we leveraged GitLab. Highly automated testing is executed by a CI/CD pipeline on unit, integration and system test levels. Overall monitoring is based on the well-integrated Prometheus/Alertmanager/Grafana [15] [11] stack, with JMX used for some expert interventions. Node maintenance is carried out based on UCAP-specific YAML files, while UCAP tooling takes care of tackling deployment and process management. This has proven to be a cost-effective solution.

The documentation is based on *Mkdocs Material* [16], adhering to the CERN design guide, encapsulating both Java and Python API documentations. As the last step of the development tasks and one of the least rewarding engineering tasks, focus was given to making documentation easy to write: the documentation source is hosted with the UCAP source code, thus documentation can be reviewed in the same Git merge request.

## FUTURE WORK

In the first half of 2021, an extensive review of UCAP was conducted in order to reflect on the development and user experience gained so far and identify the next objectives. A tighter integration with the Controls Configuration

Service [17] and support for real-time processing were important aspects identified from the review. From a UCAP service provider perspective, redundant middleware and availability of a computing cluster are key aspects that could lead to an even better UCAP service.

## CONCLUSION

Used in Linac4 [18], PSB, PS, SPS and LHC – UCAP has been rapidly adopted across the CERN accelerator complex. The user community continues to grow, which is a clear indication of the success of the product. The high-quality standards followed during development have contributed to scarce bug reports and no service outage thus far. At the same time, UCAP has facilitated the removal of a significant number of custom and complex standalone systems, thus fulfilling the objective of providing a truly “Unified” Controls Acquisition and Processing platform.

## ACKNOWLEDGEMENTS

The authors would like to express special acknowledgements to early adopters of the service. Their feedback contributed a lot to the product.

# INTRODUCING PYTHON AS A SUPPORTED LANGUAGE FOR ACCELERATOR CONTROLS AT CERN

P. Elson, C. Baldi, I. Sinkarenko, CERN, Geneva, Switzerland

## Abstract

In 2019, Python was adopted as an officially supported language for interacting with CERN's accelerator controls. In practice, this change of status was as much pragmatic as it was progressive - Python has been available as part of the underlying operating system for over a decade and unofficial Python interfaces to controls have existed since at least 2015. So one might ask: what really changed when Python adoption became official?

This paper will discuss what it takes to officially support Python in a controls environment and will focus on the cultural and technological shifts involved in running Python operationally. It will highlight some of the infrastructure that has been put in place at CERN to facilitate a stable and user-friendly Python platform, as well as some of the key decisions that have led to Python thriving in CERN's accelerator controls domain. Given its general nature, it is hoped that the approach presented in this paper can serve as a reference for other scientific organisations from a broad range of fields who are considering the adoption of Python in an operational context.

## INTRODUCTION

The Python language, and specifically the cPython implementation for which this paper concerns itself, has one of the largest and fastest growing developer communities of any programming language [1]. It has been jokingly described as “the second best programming language for anything” [2] on the basis of its ability to adapt to a broad array of problems, including domains of particular interest to accelerator controls such as system automation, data analytics & machine learning, web services, and graphical user interfaces (GUIs). This flexibility comes less from the “batteries included” Python standard library, and is more a reflection of a rich suite of third-party packages available from the Python Package Index (PyPI).

CERN's Accelerator & Technology sector, referred to as simply “accelerator sector” in this paper, is responsible for the operation and exploitation of the whole accelerator complex, including the LHC, and for the development of new projects and technologies [3]. Python has been in use in the accelerator sector for a number of years, solving a diverse set of problems including fundamental physics simulations, gathering and analysis of data for machine development (MD) studies, rapid prototyping of services, GUI applications, and much more. For high-level operational accelerator controls at CERN, Java was the only supported programming language until the adoption of Python in 2019. The growth of Python has meant that more people are joining CERN with prior Python experience, and the simplicity of the language is compelling for

the large user base of domain specialists for whom software development is a tool to achieve a specific task rather than being the main focus of their work.

Promotion of Python to “supported” status includes the provision of a software infrastructure to allow the operational 24/7 running of Python for mission-critical high-level accelerator controls, as well as infrastructure, such as tooling and a support service, to aid with effective development of such applications & services. Much inspiration was drawn from the existing Java service for accelerator controls, though to directly emulate the Java experience in Python would be to suffer the worst of both worlds and to risk missing the advantages of Python adoption. Therefore, a key objective was to preserve the spirit of Python in the service provided.

The objectives of this paper are to outline some common practices observed before the adoption of Python; to highlight some of the idiomatic Python practices that should be preserved; and at a high level, to present some of the infrastructure put in place to facilitate the use of Python in the accelerator sector at CERN. With this, it is hoped that other scientific organisations may be able to identify existing practices and potential areas of improvement in their own journey to bring Python into an operational context.

As a reflection of the computers in use for high-level controls in the accelerator sector, this paper predominantly focuses on x86-64 architecture, variants of Linux operating systems (OS) such as CentOS, and bare-metal deployments to machines which are often multi-purpose and multi-user.

## A TYPICAL PYTHON STARTING POINT

### *Python Already in Use for Many Years*

Python isn't new, and is almost certainly in use in most medium to large scientific organisations today. Typically installed by default in Linux-based operating systems, the barrier to first use of Python is relatively low – scripts can be executed directly by the Python interpreter for a rapid and iterative development experience. As they develop, re-use of functions and other definitions by gathering scripts together into a library of modules becomes desirable. Historically, this was achieved by setting the PYTHONPATH environment variable to point to a directory of packages for consideration in the Python import machinery. At the same time, it is common to want to make use of the rich set of 3<sup>rd</sup> party, open-source software (OSS) Python packages. On a machine dedicated to a particular task, it is likely that the OS package manager will suffice for the most popular libraries, but eventually

it is inevitable that one or more of the 300,000+ packages on the Python Package Index (PyPI) [4] is not available, at which point using the Package Installer for Python (pip) becomes essential.

A common solution to minimise the need for user installations is to provide a dedicated, feature complete, software stack, such as the Anaconda Python distribution [5]. Indeed, in the CERN accelerator sector a number of such distributions existed, yet the need to augment the environment with extra packages using pip remained.

### *Pip and Virtual Environments*

Whilst pip is not part of the standard library, it is considered the de-facto package manager for Python and is the basis for a number of other popular Python tools such as tox, venv and poetry. This effectively makes pip an essential tool for everyday Python development.

The pip package provides a command-line tool from which other packages may be installed. The default file location used by pip when installing packages is the same location as where pip itself is installed. As a result, by default the installation of a package using pip requires user permissions of at least those of the user who installed pip in the first place. For Python & pip installed through the OS package manager, it is common, yet highly discouraged [6], to see the use of “sudo pip install” to grant pip sufficient privilege to install the packages into the system prefix. A common alternative solution is to request that pip installs packages into the “user site-packages” location found in the user’s home directory. This location is typically included in Python’s import search path, therefore both solutions result in packages being made globally available by default for all subsequent Python invocations. This means that the behaviour of an entirely independent Python application or service can be accidentally changed, without it itself having been modified. At CERN, since user home directories are on network mounted filesystems, the user site-packages location can impact applications running on different machines under the same user, and this in particular was found to be a common source of application instability.

The popular approach to avoid the global effect of pip installation is to use a virtual environment. Virtual environments can be created with the standard library “venv” package. A virtual environment is a prefix directory containing a link back to a “base” Python executable, and into which Python packages can be installed. In this way it is possible to have many virtual environments for a single base Python installation. When pip is installed in a virtual environment, packages can be installed without a global effect upon other Python invocations, and the environment is therefore considered “isolated”. By design, it is possible for virtual environments to be created by users who do not have permission to write to the base prefix, thereby giving a clear path to allow a centralised base Python installation which can be extended by users through the use of virtual environments.

## **RUNNING PYTHON OPERATIONALLY**

### *Advantages of Modules over Scripts*

Whilst Python is an interpreted language, and Python script execution is undoubtedly the simplest way of running Python code, there are a number of advantages of running modules rather than executing scripts. When running a script:

- The directory containing the script is put on the Python path, with a higher precedence than any other directory, including that of the standard library. This can easily result in “name shadowing” and accidentally replacing parts of the standard library and third-party packages.
- There is no standard mechanism for sharing scripts (e.g. they can’t be installed with pip), and no mechanism for declaring their dependencies.

A further observation is that scripts tend to encourage big blocks of linear code, with little factorisation and limited code reuse. For example, it is common to see a large directory of unmanaged scripts which each have subtle variations of one another. One desirable aspect of reuse, beyond the obvious ability to maintain functionality in a single place, is the ability to systematically test functionality through tools such as pytest. Whilst possible to write modules with exactly the same limitations as scripts, there is a much clearer consensus that Python modules should avoid the import-time behaviour in this way [7], and as a result, modules gathered into packages tend to be better equipped for effective code re-use.

As part of the guidelines developed for Python in the accelerator sector it was therefore recommended that the creation of packages, which are a collection of modules under a namespace, be favoured over the creation of collections of scripts. The immediate benefit to the user is that code can be easily re-used and tested, with declared dependencies being automatically installed alongside the code. Structurally, it enables relative imports in order to access sibling modules, and it avoids the need for later migration to a package structure as the code evolves.

The efficacy of this recommendation is hard to quantify in general, and strictly enforcing such a policy would be to the detriment of the flexibility that Python brings. Despite this, all known operational Python applications used in the CERN accelerator control room are deployed and run as packages in this way.

### *The Acc-Py Base Environment*

A single, common, software stack containing all Python packages suffers with the problem that the software cannot be updated for one project without risking it breaking for another. When managing such a software stack, either the whole stack must be versioned such that newer iterations can be released without changing existing releases, or packages can be added but practically never removed

nor updated. From a developer perspective, the delay to have packages added to the stack inhibits productivity, and as a result, a mechanism to extend the stack locally is essential.

Since virtual environments have become a fundamental part of everyday Python development, they were the preferred approach in the accelerator sector in order to enable pip-based installation of both user-developed and third-party packages.

With the ability to extend a Python distribution through pip, choosing which packages should be in the base distribution is brought into focus. Providing a package in the base distribution has the advantage of guaranteeing that all applications use a consistent version and thereby increasing the chance that tools are able to interoperate. It was concluded that in general this advantage did not guarantee consistency in practice, and that the additional cost of maintaining an extensive base distribution was not justified. As a result, in the accelerator sector base distribution, also known as the Acc-Py base, the decision to include as few packages as possible was made. The packages provided today are limited to those which are hard to pip install in an effective manner, either because they need machine-specific optimisations or specific compilation options. There are currently just two such packages in the Acc-Py base distribution: numpy and PyQt5.

CERN's accelerator operating schedule, typically a 3-4 year physics run followed by a 2-3 year shutdown, requires relatively long periods of stability between upgrade periods. The lifetime of a particular Python version is defined at a maximum of 5 years [8], meaning that a Python version ready to be used from the end of a shutdown period is likely to reach end-of-life before the end of an operational run. This is a key consideration for exposed services, such as web applications, which must, as a result, be re-released on a frequent basis in order to pick up security patches of Python and third-party libraries. The majority of Python usage in CERN's accelerator sector, however, is related to data analysis and GUI applications. For these cases, the biggest impact of Python's end-of-life is that key third-party dependencies will gradually phase out their own support for ageing Python versions, for example Numpy Enhancement Proposal 29 [9] makes clear the intention to limit support within fundamental libraries such as numpy, matplotlib and scikit-learn for older versions of Python. This paints a clear picture that Python is a tool which can be useful for its ease and speed of development, but that there is an additional maintenance cost to be considered over the time frame of CERN's accelerator schedule to ensure that an application or service is adapted as new versions of Python and third-party libraries are released.

In order to facilitate this adaptation to newer Python versions, the Acc-Py base distribution has been designed to allow side-by-side installation with other Acc-Py base versions. Only at the end of an accelerator run will older versions be deprecated and removed, thereby giving ap-

plication owners the freedom to choose the most appropriate time to adapt their code to a later version. Since no old versions are removed during a run, it can be guaranteed that a correctly isolated application which works at the start of an operational run will continue to work until the end of a run, but no such guarantees can be made for applications across multiple runs.

Whilst possible to install the base distribution on individual machines, the primary mechanism to deliver the distribution to all machines in the accelerator sector is via a shared network mounted disk. One major advantage of this approach is that deployed distributions are the same on all machines, and that updates are instantly available. When compared to a traditional local disk installation, downsides include that the network disk is a single point of failure, and that the added network latency could impact Python start-up time detrimentally. In practice, it has been found that having a single network location is a pragmatic approach and that the consistency across machines is particularly useful.

### *Tracing Python Startup*

To provide an overview of how the various Python distributions are being used, Python start-up logging has been added to the Acc-Py base distributions. For each Python invocation, a centralised log entry is generated containing essential information including username and start-up time, as well as the packages installed in the environment. Currently up to 40,000 logs are received per day, providing a vital window into Python usage, supplying invaluable information when providing support, and highlighting areas of potential improvement to the underlying service.

Adding tracing to an existing service is generally seen unfavourably due to natural fears of an invasion of privacy. Doing so also introduces extra work in the Python startup, this fact also limits what can be reasonably traced. Therefore the general advice for those wishing to add Python startup tracing such as this, is to plan on providing the capability early in the adoption process.

### *An Internal Package Index and PyPI Proxy*

When relying on pip for important work, it is considered good practice to run a PyPI proxy in order to ensure that any downtime of PyPI does not result in loss of productivity, or a loss in ability to deploy applications and services at key moments [10]. Furthermore, the computer network used for accelerator control at CERN prohibits internet access, providing extra motivation for having an internal PyPI proxy. As well as the ability to install public packages from PyPI, it is desirable to allow the installation of internal packages through pip. To solve both of these requirements, a Sonatype Nexus instance was installed. A package repository dedicated to internal releases and a PyPI proxy repository were created. These were then grouped together to form a single user-facing virtual repository.

The fact that Python packages share a single global namespace is a cause of increasingly obscure and often comical package names on PyPI. Whilst the addition of a concept similar to Maven's groupId would help alleviate this, the algorithm used to group together two repositories into one is an important detail not to be overlooked from both a usability and security perspective [11]. In this specific detail, the Python Packaging Authority's devpi package is considered to be the reference implementation, against which Nexus has been found to fall short [12]. This is further exacerbated by the fact that pip itself is able to group together multiple repositories, but does so in an undefined and unexpected manner [13].

Once the package index is set up, pip can be pre-configured to use the package index with no need for further user intervention. For the Acc-Py base distribution and subsequently created virtual environments, configuration is done on a per-installation basis. One subtle and unexpected source of behaviour relating to this is that a suitably configured base distribution does not result in an equivalently configured virtual environment [14]. A patch of venv, the standard library package for virtual environment creation, in the Acc-Py base distribution was needed in order ensure that the configuration was copied into newly created virtual environments.

Along a similar line, the version of pip installed in the base distribution is not the determining factor for the version of pip in a newly created virtual environment. Instead, the version is encoded into the "ensurepip" standard library package, which is fixed at Python release time. Again, further patching of the Acc-Py base distribution was essential to ensure that modern versions of pip are being used in virtual environments.

### *Development and Deployment Tooling*

In order to help users work efficiently and adopt best practice in Python development, a suite of development tools were created. This includes a tool to quickly set up a new Python package, with a well-defined project structure, and a placeholder for tests, sphinx-based documentation and GitLab-based continuous integration configuration.

In addition to the development tooling, a tool to deploy Python applications in a consistent and repeatable manner was developed. The tool, named acc-py-deploy, is comparable to pipx [15] in that applications are considered to be an extension of a Python package which can be installed into isolated virtual environments for later execution. Much like the poetry package [16], acc-py-deploy provides a mechanism to "lock" floating dependency versions into fixed versions. In the case of acc-py-deploy, this includes special behaviour to lock transient Java dependencies being used through JPype [17] such that an application may be deployed consistently as a virtual environment without the risk of dependencies differing between development and production. Deployed applications are run in full isolation mode, with both home-dir-

ectory-based user site-packages and PYTHONPATH disabled. A unique feature of acc-py-deploy is its integrated ability to elevate to a dedicated service user for the purposes of deployment to a centralised network mounted location. In this way it is possible to have a common application deployment repository, with individuals able to manage the deployment of their own applications, but without needing to grant users direct write access to the installation directory. These features provide a strong guarantee that the application is deployed repeatably and consistently, and that the execution of an application is run in a way which avoids common user or environmental configuration issues.

The uptake of acc-py-deploy has been strong, with over 50 deployed applications in production in its first 12 months. The previously common issue relating to unpredictable application deployment and execution has been eradicated and has been replaced by a reliable and user-friendly operational experience.

## **PYTHON ADOPTION PRACTICALITIES**

### *Fostering and Supporting a Community*

The adoption and centralisation of Python for accelerator controls presents an opportunity to bring together a broad community with a common interest in the Python language and associated tooling. Regular community meetings are therefore arranged in order to provide a space to share news, knowledge and experiences relating to Python. Although the effort to coordinate contributions is relatively high, these meetings have been an invaluable medium for dissemination of key information, and they are an effective way to enhance Python skill across the accelerator sector.

The addition of a centralised support service is a fundamental part of officially adopting Python in the accelerator sector. Support includes resolving operational issues quickly and efficiently, as well as providing guidance to users developing software with Python. Prior experience has shown that providing first-rate and highly individualised guidance through a Python support channel can lead to requests reaching above-and-beyond the scope and capacity of a centralised support service. In an effort to foster a greater sense of community, and to mitigate against over individualising support, a community-centric chat space was created, into which questions and discussion is encouraged. Although a simple solution, the uptake has been excellent, and the sense of an active community comes across strongly. Indeed, it has often been the case that the community have been able to efficiently support one-another directly.

### *Centralisation of Pre-existing Functionality*

When a community of users lack the tools needed to achieve a particular task, and there exists no service from which to request such tools be developed, it is common to see domain-specific solutions being created by users.

Whilst these tools are typically not designed for general purpose use, they provide invaluable insight into specific use cases.

In some cases, these solutions become popular amongst users and should be adopted for centralised support and maintenance. In the accelerator sector, one such tool, PyJapc, was developed by domain specialists in order to conveniently interact with the accelerator control system during machine development (MD) studies. The library is technically interesting as it directly bridges to the Java API for Parameter Control (JAPC) library, yet provides a less general API well-adapted for the use case at hand.

The centralisation of such tooling faces the risk of losing the strong user focus and potentially disenfranchising the original authors if the adoption is not done sensitively and pragmatically. In the case of PyJapc, whilst neither perfect nor general, priority was given to ensuring the existing behaviour was well-maintained, tested, and documented. Only after becoming extremely familiar with the code through bug-fixing and minor enhancements did larger API redesigns become a focus of effort. In turn this respect for what already exists buys credibility when proposing future changes, and it is hoped that this will ultimately lead to improved user uptake of future solutions.

### *Building-Out New Functionality Quickly*

The breadth and depth of existing Java infrastructure for accelerator controls made Python adoption all the trickier, as replicating the infrastructure developed over decades of effort was neither practical nor efficient for the adoption of Python. Instead, emphasis was given to creating packages which bridge to existing implementations written in other languages.

For simple RESTful APIs with OpenAPI or Swagger definitions, openapi-generator was used to generate Python bindings. Some post-processing of generated code was added in order to improve code layout and to programmatically inject type annotations for an improved static analysis experience. Whilst runtime bindings would have been possible due to Python's highly dynamic runtime, it was found that the well-defined types from generated code result in a superior API, with support for convenient static analysis and auto-completion in an integrated development environment (IDE).

When exposing existing Java libraries, the binding technology chosen was the JPy package [17]. JPy integrates tightly with the Java Native Interface (JNI) to start a Java Virtual Machine (JVM) in the same process as the Python interpreter. As a result, data can be passed between Java and Python efficiently without the need to copy data. To improve the developer experience, a tool named stubgenj was created to generate Python type annotations for Java libraries. As a result, it is possible to run static analysis tools and IDE auto-completion when interacting with Java libraries through Python and JPy.

The other binding technology used to build-out capability quickly was PyBind11 [18]. The tool generates Python bindings to C++ libraries, based upon C++ declarations of the desired interface. These declarations can be relatively easily crafted to form intuitive and idiomatic Python APIs. The results of creating bindings through PyBind11 are compiled shared-object modules. In order to maximise compatibility of these modules and to allow installation on multiple Linux operating systems, the manylinux2014 [19] standard was used when publishing Python wheels [20].

## CONCLUSION

The formal adoption of Python for accelerator controls at CERN was, on the surface, smooth and relatively seamless. Despite this outward appearance some significant culture shifts were introduced, including the removal of one-size-fits-all Python distributions in favour of virtual environments, the discouragement of script writing in favour of Python package creation, and the introduction of a community-focussed culture through user meetings and a collaborative chat space.

In the accelerator sector Acc-Py has been well-received, and as a result the use of Python is growing, users now have more flexibility to pick the best tools for their job, and most critically of all, the operational stability of Python applications and services has been ensured.

Python and its associated ecosystem are fundamentally open-source, and whilst costing more in the short-term, an effort has been made to report and fix bugs identified with the tools being used. In the long-term this strategy pays off, as it minimises the need for local patches and software bifurcation, and eases the future adoption of newer versions. A by-product of this is better software for all, including for other organisations following their own Python adoption story.

Some of the concepts presented around acc-py-deploy, particularly with regards to stability of execution and repeatability of deployment, can be reasonably compared to the benefits of containerisation. It is considered that the deploy concept from acc-py-deploy will work well as a build step for a container image, and that stable execution could then be handled by the container runtime. This is one particular area of potential future work for Acc-Py.

With key infrastructure in place, the Python adoption phase has now been replaced by a growth phase. Growth of the Python community in terms of number of users and the collective Python skill, and growth in terms of the quality & extent of the libraries provided to interact with CERN's accelerator control system.

# MODERNISATION OF THE TOOLCHAIN AND CONTINUOUS INTEGRATION OF FRONT-END COMPUTER SOFTWARE AT CERN

P. Manton<sup>†</sup>, S. Deghaye, L. Fiszer, F.Irannejad, J. Lauener, M. Voelkle  
CERN, 1211 Geneva 23, Switzerland

## Abstract

Building C++ software for low-level computers requires carefully tested frameworks and libraries. The major difficulties in building C++ software are to ensure that the artifacts are compatible with the target system's (OS, Application Binary Interface), and to ensure that transitive dependency libraries are compatible when linked together. Thus developers/maintainers must be provided with efficient tooling for friction-less workflows: standardisation of the project description and build, automatic CI, flexible development environment. The open-source community with services like Github and Gitlab have set high expectations with regards to developer user experience. This paper describes how we leveraged Conan and CMake to standardise the build of C++ projects, avoid the "dependency hell" and provide an easy way to distribute C++ packages. A CI system orchestrated by Jenkins and based on automatic job definition and in-source, versioned, configuration has been implemented. The developer experience is further enhanced by wrapping the common flows (compile, test, release) into a command line tool, which also helps transitioning from the legacy build system (legacy makefiles, SVN).

## INTRODUCTION

### *Front-End Computer Software Development at CERN*

CERN's Front-End Computers (FECs) are disk-less computer crates which host electronic cards connected on a back-plane. The software running on these computers typically uses a framework such as Front-End Software Architecture (FESA) [1,2] to interface with:

- The upper layer of the control system (settings management, timing, network (Remote Device Access (RDA3) protocol [3]), logging, post-mortem, machine protection, etc.)
- The cards' driver (C library) to drive the equipment.
- The OS (Linux, CentOS 7 with RT kernel) and framework (FESA) are designed to provide near real-time execution of the tasks through scheduling, thread priorities, and optimisation: this is a strong reason (amongst others), for using a performance-oriented language like C++ to build the software.

The production FECs run on CentOS 7, so the software must be built for that target, ensuring compatibility with the system's libraries (especially libc) and ABI (changes in ABI for C++11 support).

Software built using the FESA framework consists of an executable that is statically linked against the

<sup>†</sup>pierre.manton@cern.ch

framework's libraries (versioned headers and .a archive files). The framework libraries themselves depend on a collection of middleware libraries provided by different teams across different groups.

The FESA framework is mostly used by equipment developers who are not full-time software engineers. As such, the framework providers aim to offer tooling that promotes best practices (e.g. source code versioning, releasing, tagging) and minimises human errors.

## NEED FOR MODERNISATION

After almost two decades of building C++ software with Makefiles, a well-deserved modernisation was needed. A Continuous-Integration (CI) solution, based on a shared central Bamboo Server instance, was put in place almost ten years ago. A general move away from Bamboo to Jenkins or Gitlab CI for Controls software also needed to be taken into consideration. Additional objectives were to ensure that the new solution provides a better dependency management and ensure a smooth transition for our users.

### *Dependency and Toolchain Management*

The correct execution of FEC software requires the binaries to be built using consistent versions of the dependencies. At the lowest level, this means that versions of the dependent libraries should be both binary and functionally compatible. However, a complex dependency graph means it is not easy to ensure, especially if no compilation/linking errors are raised at build time. Dependency management entails two aspects:

1. Knowing where to find/store artifacts (header / library files) from the build system.
2. Being able to check the consistency of dependencies and versions in the dependency graph.

Beyond ensuring production software is built correctly, strong dependency management is very useful to the developer. When working with local copies of a sub-set of a dependency graph, developers are one step away from so-called "dependency hell". Without automatic dependency management developers need to ensure that all libraries used locally are compatible, which entails editing makefiles and building/rebuilding lots of dependencies before having a working setup. Compilation time in such cases is not negligible. The process is also error prone, often requiring to re-build several dependencies after each correction. Figure 1 highlights the difficulty of modifying dependencies by hand by showing the complexity of the dependency graph for a representative example of FEC software.

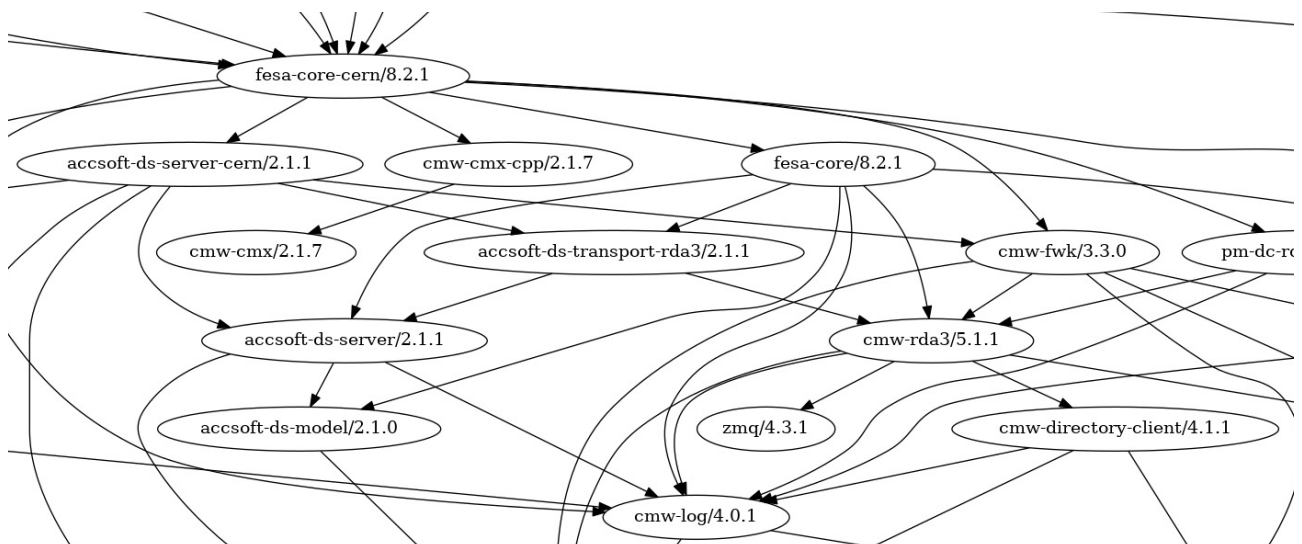

Figure 1: example of dependency graph for a FEC software (cropped)

Binary compatibility of the dependency libraries requires building all dependencies with compatible toolchains (compiler tools and settings, including libc and C++11 ABI [4]). The archive file (.a) artifacts of dependencies can be used by the software that is including them without many checks regarding compatibility.

New C++ standards require more recent compilers, but the ABI must still be compatible with the runtime environment. The CentOS7 toolchain (gcc 4.8, "old" ABI [4]) is the current standard at CERN, but production software can also be released using a more recent compiler (gcc 7). Since CentOS 7 was released several years ago (2014) a transition to a new supported toolchain must be anticipated to ease equipment groups migration efforts and ensure smooth operations.

The rest of this paper will describe how Conan [5] and CMake [6] can be leveraged to meet the aforementioned challenges and objectives, and improve developer experience.

### Introduction of CMake as a Modern Build Tool

While Make is still a standard way of building software, it is a fairly low-level tool. CMake brings deeper domain knowledge of C/C++ projects, is extremely popular and very well supported by IDEs, and has a permissive BSD license.

*"CMake is an open-source, cross-platform family of tools designed to build, test and package software. CMake is used to control the software compilation process using simple platform and compiler independent configuration files, and generate native makefiles and workspaces that can be used in the compiler environment of your choice."*  
– <https://cmake.org>

As a standard tool with good public documentation, CMake is favourable over the legacy in-house makefile hierarchy for a multitude of reasons:

- Better public documentation means less user support for FESA framework providers.

- Better integration with modern and powerful IDEs such as CLion increases developer productivity and satisfaction.
- The experience gained working with CMake is more valuable for trainees and developers in terms of transferable skills beyond CERN.

### A Command-Line Helper

Although aiming to increase the ease and quality of development, transitioning to new tools like CMake and Conan represents a challenge, especially for part-time developers, where adaptation and practice are required to master the new tools. To minimise this challenge a command line (CLI) tool, named Codeine is provided to simplify and standardise workflows e.g:

- Create a new project with a standard file layout.
- Wrap complex commands.
- Provide safe defaults (CentOS 7 compiler toolchain).
- enforce a consistent release flow (versioning, build, tag VCS, release location, structure of released artifacts).

As such, Codeine can help the transition to a new compiler toolchain by providing setting profiles and migration helpers.

### Renovation of the CI / Testbed

Tooling that can ensure a correct and reproducible build by design does nothing to help avoid functional failures. Testing the software is critical and making the test feedback loop as short as possible increases development efficiency. Having convenient tooling to setup and run tests helps ensure that tests are written, ran and results checked. Continuous Integration (CI) has been a standard practice in software development for a long time, and supporting tooling for it is evolving.

CERN's front-end software is well tested by an extensive collection of tests built over years, automatically executed from an ageing Bamboo platform [7]. Besides obsolescence of this platform (licence renewal, end of life support from Atlassian [8]), new

paradigms such as storing test job configuration together with the versioned source code have appeared and make developers' lives easier, by automating the configuration of the test plans / jobs. This approach saves thousands of clicks in the Bamboo interface to configure the dozens of CI jobs.

## MODERNIZATION OF THE DEVELOPMENT ENVIRONMENT

### Legacy Environment

The FEC software development environment at CERN (Figure 2) is tightly coupled to a Network File System (NFS) and to Virtual Machines (VPCs) that are setup for FEC development. The typical developer connects to their VPC and runs a dedicated distribution of the Eclipse IDE to develop. The NFS is mounted automatically on the developer VPCs. The development tools and dependencies (IDE, makefiles, dependent libraries) are either hosted on NFS, or depend on data or binaries hosted there.

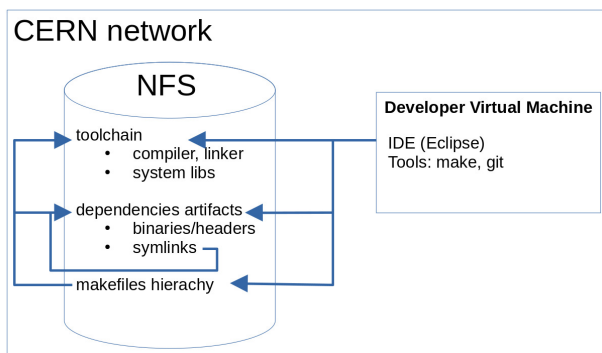

Figure 2: High-level view of the legacy development environment

The in-house makefiles provide build and release functionality, which is possible by knowing the layout of the dependency artifacts and the toolchain location on NFS. It knows the base path for artifacts (headers/libs) at build time, as well as where to store an artifact upon release. There is no enforcement of dependency consistency, nor of toolchain/compiler settings. As it predates Git, it only supports SVN.

This setup makes it easy to provide a functional development environment to the developer, but at the cost of flexibility:

- The development machine requires access to NFS, which is accessible only from the CERN network.
- Connecting to the development VPC is inconvenient (VNC, ssh -X), especially when the network access is with reduced bandwidth (e.g. teleworking), or when using multiple screens (VNC limitations).
- The custom layout of the dependencies folder on NFS makes it incompatible with most standard tools (IDEs, build systems) without extra integration work and project metadata duplication.

- The need to access NFS makes offline development or CI on the cloud either impossible or very inefficient.
- The Eclipse IDE for C++ is falling behind other C++ IDEs in terms of features and ergonomics (e.g. CLion, QtCreator, VSCode)

Modernizing the developer's experience entails keeping the ease of access of the development environment, while ensuring the continuity and quality of production artifacts. Regarding the development tools, that means providing more flexibility (e.g. offline work, local toolchain, choice of modern IDE, etc.). On the CI side, it means an easy initial setup and no redundant configuration tasks, as well as support for modern development workflows based on branches and merge requests.

### Modernization of the Development Tools

Replacing the makefile hierarchy with CMake brings standardisation to what was an in-house custom project structure. Moreover most C++ IDEs have good support for CMake projects, thus enabling much better IDE support out of the box.

Alongside CMake, Conan is used to alleviate other pain points of the legacy setup.

*"Conan is a MIT-licensed, Open Source package manager for C and C++ development, allowing development teams to easily and efficiently manage their packages and dependencies across platforms and build systems."* - <https://conan.io>

- Conan describes package dependencies precisely in its recipe file (a text or python file called '*conanfile.txt/py*'), and is able to check the consistency of the versions in the dependency graph, thus avoiding the "dependency hell".
- Conan enforces strong but configurable versioning of binary packages. The binary package's ID includes a hash of compiler settings to ensure binary compatibility of the produced artifacts
- Through the given metadata, Conan provides convenient ways to either fail a build if a dependency cannot be satisfied (wrong version, wrong toolchain/compiler settings), or build the dependency from source
- Conan can package binary artifacts and share them through Conan repositories. Binary packages can be downloaded and build artifacts uploaded via HTTP(S) with appropriate authentication and authorization. Conan repositories are implemented by various products, including Artifactory, Gitlab, Conan-server, Nexus. With no need for NFS access anymore, cloud and offline builds are much easier.
- Setting up a local build environment for a project with arbitrary dependencies is as simple as running "conan install"

### Renovation of the CI and Testbed

The decision to move away from Bamboo was triggered by the need to migrate to a newer version, and to

renew the licenses. Migration would have been a significant effort that already justified considering other platforms. Two options were evaluated, both already used at CERN and both without extra license fees: Jenkins (open-source) and Gitlab CI (deployed globally by the CERN IT department).

The legacy version of Bamboo in use so far required many slow interactions with the user interface to configure jobs and it had limited support for merge requests and branches. Therefore, the renovation was also an occasion to benefit from features brought by more modern tools. Below is a list of features expected from a CI platform:

- In-code configuration (.gitlab-ci.yml / JenkinsFile) and auto-configuration (zero-click) of the CI jobs
- Support for complex pipelines (serial and parallel stages, optional stages)
- Automatic support for branches and merge requests
- Support for triggers (an upstream jobs triggers the build of a downstream dependent job)
- Support for custom agents/executors
- Access rights management, integration with CERN's SSO
- Support for branch heavy workflows (e.g. libA on branch b1 will automatically pick up dependencies on the b1 branch if it exists)

## IMPLEMENTATION STORIES, LESSONS LEARNT

### *The Bamboo to Jenkins Story*

In terms of features, both Gitlab CI and Jenkins offer all basic features of a CI platform. What tipped the balance in favour of Jenkins was the fact that it is open-source, and not dependent on licenses from Gitlab. By using an open-source product we limit the risk of having features moved behind a higher-priced licence tier in the future. However, deploying dedicated Jenkins instances means additional work to build and maintain them versus the IT-managed Gitlab CI platform. Gitlab integrates vertically a lot of features that could be useful but which increase vendor lock-in (e.g. docker/Conan registries). The documentation of Gitlab is more complete and much better structured than that of Jenkins, especially regarding the domain specific language (DSL) to define pipelines. The Jenkins ecosystem is made of a lot of plugins. Support, documentation and compatibility of plugins can be a challenge. In practice, these are not blocking points, since most configuration is done once, and experience is shared within the team. Additionally it was decided to keep most of the CI jobs as simple shell command invocations, which is very portable across CI systems in case it is needed to migrate again in the future. This reduces vendor lock-in, and facilitates running jobs manually for testing or debugging.

The Jenkins master is deployed as an OpenShift pod, whose configuration is completely described as code. Deployment on OpenShift means no need to

deploy/maintain hardware. Configuration as code mitigates the lack of durability of pods on OpenShift, as well as making it easy to reuse (e.g. for another project/team) and easy to bring back up in case of major failure. The main challenge here was to find how to serialize the configuration (Configuration as Code) of Jenkins and its plugins, because the format and commands to use are barely documented, requiring long searches for help on the internet/stackoverflow [9], as well as a lot of trial and error.

Beyond the basic Jenkins installation, the most important plugin is the Gitlab Branch Source plugin [10] that allows to simply point to a Gitlab folder from Jenkins, and auto-configures the CI jobs for all repositories, branches and merge requests in that Gitlab folder.

### *Codeine: CLI helper*

Codeine (a play on words between "code" and the painkiller drug) is an idea to make development painless, especially considering two types of software developers:

- Framework and tooling providers
- Equipment developers

The distinction is often blurred depending if the focus of the team is on software engineering or more direct operational commitments. The goal with Codeine is to make the former's life easier, while letting the latter benefit from technical improvements with no/minimal impact to their work. Considering the ageing makefile-based build framework, the original idea behind Codeine was to wrap and abstract the steps of software development in the tool (create empty project, build, test, release) to be able to evolve the underlying implementation bricks with no impact on developer's workflow and habits. Codeine is based on a file describing the project, called '*product.xml*' which, in a first approach, contains metadata about the project: name, version, VCS repository, type (library or executable).

The first Codeine implementation re-used the custom makefiles to perform operations on the project (e.g. build, release). This approach helped consolidate the knowledge about existing workflows: inputs, outputs, dependencies. It also facilitated the migration of repositories from SVN to Git, based on the metadata of the '*product.xml*'. By implementing Git repository support in Codeine, the risky and complicated task of adding sub-par Git support to the legacy makefiles was avoided. After working on implementing the artifact release flow in Codeine, further metadata was added to the '*product.xml*' to structure the released artifacts (e.g. does the artifact require extra files beyond the binary to be delivered? symbolic links defined?). Metadata identifying the dependencies of the product were also added to '*product.xml*' in anticipation of better and/or automated dependency management. In summary, this version of Codeine fully supported the legacy makefiles framework, additional support for Git repositories, and a structured release process.

## A First Proof-of-Concept

Building on the Codeine base described above, a proof of concept was launched to integrate modern tools into the development workflow and validate the feasibility of using Conan to manage dependencies and CMake as a more modern build system.

From the outset Codeine was intended to support the transition between the makefile-based build system to a more modern one. It was anticipated that the existing '*product.xml*' content should be sufficient, or require only minor adaptation, however it was soon discovered that this was not the case. The first '*product.xml*' change required was to include an element to tell Codeine which build system it should use. This was considered a necessary hole in the abstraction layer of Codeine.

Having decided on trying out Conan to manage dependencies, the proof of concept used Conan through Codeine to build most of the framework development team's libraries. The first step was learning about Conan usage, while the second milestone was letting Conan know about Codeine's metadata, by using Conan's mechanism to extend python conanfiles.

Since Conan is not a build system for C++, but rather generates configuration for one, and CMake, among other advantages, has good support from Conan, it was decided to use CMake from Conan to build libraries. This makes for a complex flow: Codeine calls Conan, which uses a Codeine extension (python) to understand the '*product.xml*', and generate files for CMake, which in-turn is used to build the library.

Although complex, this proof of concept already brought several advantages:

- Strong dependency and toolchain management thanks to Conan.
- Standard dependency declaration
- Standard artifact packaging, ready to be consumed by a downstream project (using Conan).
- Conan's remote features to upload/fetch packages from an artifact repository, in turn enabling jobs isolated from the legacy NFS repository to fetch artifacts through HTTP.

However this proof of concept also showed that abstracting over both a loose legacy system and a stricter modern one is very hard. Several complications to Codeine were implemented to support both systems, in an imperfect way. Furthermore, the generated CMake files were complex and did not provide the extensive IDE support expected (e.g. QtCreator supports CMake based projects, but was not able to parse the generated CMake files satisfactorily)

### Lessons learnt:

- A floating period transitioning back and forth between the legacy and new system is to be avoided
- Good abstractions are hard, especially over vast and/or vague domains such as "developer experience"
- Retaining legacy compatibility takes a lot of effort, with little reward

- Conan brings a lot of structure to a project with its strict dependency management, however, this does not fit nicely with the loose structure of the legacy makefiles, which harmed the goal of Codeine being a perfect abstraction over the build system.
- More abstraction layers make debugging harder (why/where did a build fail: in Codeine? in CMake? in Conan?)

## Looking Forward: Second Proof-of-Concept

Given the experience of the Conan + Codeine + CMake proof-of-concept, a next iteration is foreseen, with aims to reduce complexity, and avoid the leaky abstraction problem posed by Codeine's '*product.xml*'.

Instead of Codeine being a complete wrapper over the development workflow, it will be re-focused on the parts missing from other tools: creation of new empty projects, and managing the release process (e.g. ensuring code is committed, pushed, that the code repository is tagged with the release version, etc.). This reduced scope of Codeine will allow to simplify the usage of tools like Conan and CMake, making the most of them without being limited by the incomplete abstraction that Codeine's '*product.xml*' tried to be. The advantage of using publicly available and documented tools instead of Codeine-as-a-wrapper are:

- More flexibility to the developer.
- Less support for the providers of Codeine.
- More publicly available support for the tools (e.g. Conan's and CMake's documentation, experts on StackOverflow [9]).

## CONCLUSION

Software engineering best practices evolve and improve with time, as do automation and tooling to support developers. Embracing such evolution in CERN's FEC software development environment brings added value, but given the variety of constraints, the modernisation is both technically and organisationally challenging. Forced migrations such as the CI/Testbed are a good opportunity for improvements. Modernisation is a continuous iterative process, and while changes are disruptive and require stakeholder buy-in, a flexible architecture allows for iterative changes to be rolled-out progressively.

Beyond developer productivity and satisfaction, having a modern development environment is also more attractive to potential candidates, for whom experience with industry standard tools is more valuable.

# PLCverif: STATUS OF A FORMAL VERIFICATION TOOL FOR PROGRAMMABLE LOGIC CONTROLLER

I. D. Lopez-Miguel\*, J-C. Tournier, B. Fernandez, CERN, Geneva, Switzerland

## Abstract

Programmable Logic Controllers (PLC) are widely used for industrial automation including safety systems at CERN. The incorrect behaviour of the PLC control system logic can cause significant financial losses by damage of property or the environment or even injuries in some cases. Therefore ensuring their correct behaviour is essential. While testing has been for many years the traditional way of validating the PLC control system logic, CERN developed a model checking platform to go one step further and formally verify PLC logic. This platform, called PLCverif, was first released internally for CERN usage in 2019, is now available to anyone since September 2020 via an open source licence. In this paper, we will first give an overview of the PLCverif platform capabilities before focusing on the improvements done since 2019 such as the larger support coverage of the Siemens PLC programming languages, the better support of the C Bounded Model Checker backend (CBMC) and the process of releasing PLCverif as an open-source software.

## INTRODUCTION

Programmable Logic Controllers (PLC) are widely used for industrial automation including safety systems at CERN. The incorrect behaviour of the PLC control system logic can cause significant financial losses by damage of property or the environment or even injuries in some cases. Therefore ensuring their correct behaviour is essential. While testing has been for many years the traditional way of validating the PLC control system logic, it is often not sufficient as the sole verification method: testing, even when automated, can not be exhaustive, thus can not guarantee the correctness of a logic. Some types of requirements, such as safety (i.e. an unsafe state can never be reached) or invariant (formulas which shall be true over all possible system runs), can be very difficult, if not impossible, to test. Model checking is a formal verification technique which complements the testing activities in order to fully validate and verify a PLC control system logic. Model checking assesses the satisfaction of a formalised requirement on a mathematical model of the system under analysis. It checks the requirement's satisfaction with every input combination, with every possible execution trace. In addition, if a violation is found, a trace leading to the violated requirement is provided. The main hurdle to the widespread usage of model checking within the PLC community is twofold: (1) the mathematical model representing the system under analysis can be difficult to write and requires in-depth understanding of the model checking tools; and (2) many real-life PLC logics are too complex and face the state-space explosion problem, i.e. the number of

possible input combinations and execution traces is too big to be exhaustively explored.

In 2019 CERN developed the PLCverif platform with the goals of easing the usage of model checking tools for the PLC developers community by automating the translation of the PLC programs to their mathematical models and to implement several abstraction algorithms to limit the state-space explosion problem. Since September 2020, the platform has been released under an open source license to foster the usage and the development of the tool within the PLC community. The objective of this paper is to give a status of the PLCverif platform focusing on the latest developments improving the usability and performance of the tool.

The rest of the paper is organized as follows: Section *PLCverif Overview* gives an overview of PLCverif to better understand the scope and the architecture of the platform. Section *Open Source Release* focuses on the open source release of PLCverif by describing the process of releasing the source code and presenting the code organization. Finally sections *Latest developments* and *On-going Challenges and Developments* present respectively the latest and ongoing developments.

## PLCverif OVERVIEW

This section gives an overview of the PLCverif platform [1] before presenting the latest developments.

### Verification Workflow

Out of the box, PLCverif offers a model checking workflow for the analysis of PLC programs. The verification workflow is shown in Fig. 1 and it has the following main steps:

1. **PLC program parsing.** PLCverif parses the PLC program (located in one or several files) to be analysed. By choosing the entry point of the verification, the analysis can be limited to a part of the program. The parsed PLC program is automatically translated into a mathematical, control flow-based representation, producing so-called Control Flow Automata (CFA). This precise description will serve as the basis for the analysis.
2. **Requirement representation.** The user should describe the precise requirement to be checked. This, however, does not mean that the user needs to describe the requirement using mathematical formulae. Currently, two requirement description methods are supported:

- Assertion-based requirements: special comments in the source code (e.g. `//#ASSERT On<>Off`)

\* ignacio.david.lopez.miguel@cern.ch

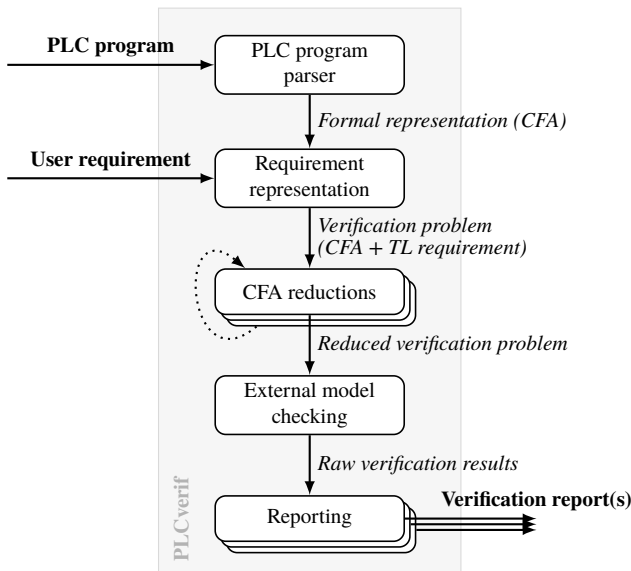

Figure 1: Formal verification workflow of PLCverif

can describe expressions (invariants) which are expected to be always satisfied at a given location of the program. The verification job will then check if the violation of any of the selected assertions is possible.

- **Pattern-based requirements:** the user chooses a requirement pattern that is a precisely-phrased plain text sentence with some placeholders, e.g. “If  $\alpha$  is true at the end of the PLC cycle, then  $\beta$  should always be true at the end of the same cycle.”. The gaps in the requirement pattern ( $\alpha$  and  $\beta$  in the previous example) shall be filled with expressions over the PLC variables. For each requirement pattern, a defined temporal logic representation is defined which will be used in the next steps.

If needed, new types of requirement representations can be defined, adapted to the specific needs.

3. **CFA reductions.** The formal, precise CFA representation of the program, including also the requirement, may need to be reduced in order to make the verification feasible and efficient. These reductions will not change the verification result for the given requirement; however, they may remove parts of the program which do not influence the result of the currently checked requirement [2].
4. **External model checking.** The model checking itself is performed by widely used model checker tools. In this step, (i) the reduced CFA is translated into the input syntax of the chosen model checker tool, (ii) the model checker tool is executed, and (iii) its output, notably the counterexample if available, is parsed to PLCverif’s internal representation.

Currently the following external model checkers are supported: NuSMV [3], nuXmv [4], Theta [5] and

CBMC [6]. These model checkers have different strengths and weaknesses. In addition, not every feature is supported by every model checker.

5. **Reporting.** The last step of the formal verification workflow is to produce verification reports. Some of these reports are in human-readable form and target the user of PLCverif. Other reports are machine-readable and serve as descriptions for the execution environment or as artifacts for later summary reports.

## OPEN SOURCE RELEASE

PLCverif is available publicly since September 2020 along with its source code under an EPL-2.0<sup>1</sup> license on GitLab<sup>2</sup>. This section presents the reasons for open sourcing PLCverif, as well as the process to choose the open source license and the code organization as found in the GitLab repository.

### Motivations

PLCverif has been entirely developed at CERN and therefore fits CERN’s needs. Nevertheless, the platform could be beneficial to two different communities outside CERN: the PLC developers community and the model checker community. For PLC developers, PLCverif could be used out of the box if the language used is among the ones already supported, i.e. Siemens Statement List (STL) and Siemens Structure Control Language (SCL). The current coverage<sup>3</sup> of Siemens STL and SCL in PLCverif is currently at 66% and 40%, respectively, for S7-300/400 PLCs, and at 55% and 25%, respectively, for S7-1200/1500 PLCs. This covers most of the functionalities of PLC programs developed at CERN as the instructions implemented represent the core of those languages. However, support for a missing instruction could be easily added if needed. Similarly, the support of a new programming language could also be developed taking as a reference the current implementation for the Siemens languages. For the model checking community, PLCverif offers the possibility to be integrated in a platform verifying real-life PLC code: it is a great opportunity for this community to test new algorithms or improvements of existing model checkers.

### License Selection

From the different open source licenses available, the choice has been made to release the PLCverif platform source code under the Eclipse Public License 2.0 (EPL<sup>4</sup>). This license is similar to the GNU General Public License (GPL<sup>5</sup>) but allows to link the code to proprietary applications: it then allows to use and extend the tool, even for

<sup>1</sup> <https://www.eclipse.org/legal/epl-2.0/>

<sup>2</sup> <https://gitlab.com/plcverif-oss>

<sup>3</sup> Coverage was calculated as the number of instructions that are implemented in PLCverif vs. the number of instructions in a given grammar for a given PLC. Binary arithmetic operations like addition or subtraction, and binary logic operations like conjunction or disjunction are not taken into account when the coverage for SCL is calculated. That is the main reason why the figures for SCL are much lower than for STL.

<sup>4</sup> See footnote 1.

<sup>5</sup> <https://www.gnu.org/licenses/gpl-3.0.en.html>

commercial purposes. The reason for choosing the EPL-2.0 license was driven by the fact that is a weak copyleft license, but also that most of the components used by PLCverif are already under the EPL-2.0 (more details in [1]).

### GitLab Repository

The PLCverif platform has been developed within the Eclipse ecosystem: it is mainly written in Java (Java 11), Xtend and Xtext. The modularity is assured via the split of the code among several distinct projects and Eclipse plugins. The main projects of the platform are:

- PLCverif Backend<sup>6</sup> is the core of the PLCverif platform and is responsible for all the CFA manipulations represented in Fig. 1. It is also responsible for interacting with the external model checkers via dedicated Eclipse plugins.
- Siemens Support<sup>7</sup> is responsible for the parsing of the Siemens STL and SCL code, i.e. transforms the PLC user code into the PLCverif internal CFA representation.
- PLCverif Frontends<sup>8,9</sup> are the visible parts from a user point of view. The GUI project provides a graphical application embedding a PLC code editor, a specification requirement editor and a report visualization part. The CLI project is the way to execute the PLCverif workflow via the command line allowing the execution of headless verification jobs such as in a CI/CD (Continuous Integration / Continuous Deployment) pipeline for PLC code.

## LATEST DEVELOPMENTS

Since the publication of [1] in 2019, several improvements have been made. Some of them are summarized below:

- The C code used to run CBMC was originally produced directly converting the intermediate model to a C code using *goto* instructions. CBMC is however not efficient with this kind of programs since it is not able to find loops. This method has been changed in order to produce a structured C code without *gotos*, being able to efficiently use the option *-partial-loops* of CBMC. With this option, CBMC will execute loops only partially. The disadvantage of this option is that the counterexample might be spurious.
- In order to confirm the feasibility of a counterexample produced by PLCverif when a property is violated, it is common to try to reproduce that situation in a real PLC or via simulation. In order to automate this process, it is now possible to automatically generate a file with the

values of all the variables that can be used as an input to the simulator or to the real PLC.

- Safety programs in Siemens are written in function block diagram (FBD) language. After exporting them with *OpennessScripter*<sup>10</sup>, an XML file is produced. A new feature in PLCverif has been developed in order to import those XML files into PLCverif translating them into STL code.
- The coverage of Siemens programs was increased both for STL and SCL. More built-in functions from TIA portal were included.
- Support of latest Theta version was included. Theta is being actively developed and new releases have been launched. In order to keep up with the latest improvements, PLCverif has been adapted to correctly parse Theta output. Currently, PLCverif supports Theta v2.21.0.
- The intermediate model Control Flow Instance had the limitation that it could not be used with dynamic indexing arrays. However, Theta supports this feature and PLCverif has been adapted to generate Theta programs with dynamic indexes.
- The grammar implemented in PLCverif to parse Siemens PLC programs has been extended to include partial support of Schneider PLC programs.
- Upgrade to Java 11. PLCverif was originally developed in Java 8. However, in order not to lose support and to be able to run the latest versions of some model checkers (Theta), it was needed to upgrade to Java 11.

## ON-GOING CHALLENGES AND DEVELOPMENTS

### Simplification of Numeric Variables

As observed in the large code base of CERN industrial PLC systems, one of the main challenges to perform PLC model checking is the state-space explosion originated by the inclusion of numeric variables. PLCverif represents input variables as non-deterministic in the intermediate model. This means that a 16-bit integer is going to have  $2^{16} \approx 7 \cdot 10^4$  possible values that the model checker needs to explore.

There exist some techniques to handle this type of variables, such as counterexample-guided-abstraction refinement (CEGAR) [7] or Satisfiability Modulo Theories (SMT). However, other approaches to directly simplify the PLCverif intermediate model are under investigation, highly improving the performance of the NuSMV model checker [8].

### Iterative Verification

It is common practice to have different modules within PLC projects (see [9] for an example). Some of these projects

<sup>6</sup> <https://gitlab.com/plcverif-oss/cern.plcverif>

<sup>7</sup> <https://gitlab.com/plcverif-oss/cern.plcverif.plc.step7>

<sup>8</sup> <https://gitlab.com/plcverif-oss/cern.plcverif.gui>

<sup>9</sup> <https://gitlab.com/plcverif-oss/cern.plcverif.cli>

<sup>10</sup> TIA Portal Openness API.

are too large to be verified by PLCverif yet. However, if the program is split into parts, the verification cases are smaller and can be successfully executed. If it would be possible to combine all the results together, it would be feasible to verify these large programs. To this end, different compositional verification approaches have been analysed but no generic method has been found yet to be applied to PLC projects.

Nonetheless, other abstraction techniques are under consideration, such as abstracting away the different modules. With this approach, a verification case is executed with all the functions abstracted away (all their outputs are going to be non-deterministic). If the property is satisfied, the original program satisfies that property too. On the other hand, if it is violated, one needs to check if the abstracted functions can produce the outputs leading to the violation. If it is not possible, a function is concretized (it comes back to its original form) and a new verification case is executed. This process is continued until a feasible counterexample is found or until all functions are concretized (coming back to the original program). Different strategies and improvements can be investigated for this method.

### Counterexample Analysis

When a program is verified and the result is a violation of the property, a counterexample is given by PLCverif. If the program is composed of several variables and they interact with each other (see [9] for an example), the counterexample is going to be large. Therefore, it will be difficult to analyse what part of the code made the property fail.

Some investigations have been done in this direction in order to point the user to possible locations in the code that have an impact on the final assertion. This way, the user would not need to go through all the code but just focus on the highlighted parts.

### Other

Since the release of PLCverif, there has been some progress in the development of more efficient model checkers. As already explained previously, the latest version of Theta has been integrated into PLCverif. However, although CBMC is efficient, it is a SAT-based model checker that uses few abstraction techniques. Therefore, an SMT-based model checker like ESBMC [10] could improve the performance of CBMC.

## CONCLUSION

This paper presented the latest developments of the PLCverif platform to formally verify PLC programs. The developments can be grouped into two main lines of work:

- Promoting and easing the use of PLCverif by making it open source, by supporting more PLC manufacturers (i.e. Schneider Electric), and by guiding the user to the root cause of an issue when a property is violated (counterexample analysis).

- Improving the performance of the verification time by simplifying numerical variables without losing meaningful information and by implementing an iterative verification process allowing to verify even more complex applications.

All the different developments presented in this paper are in different stages of maturity and are in the pipeline to be included into PLCverif. In addition some new developments will be carried on to support Schneider safety programs and to integrate new model checkers such as ESBMC.

# CERN CONTROLS CONFIGURATION SERVICE – EVENT-BASED PROCESSING OF CONTROLS CHANGES

B. Urbaniec, L. Burdzanowski, CERN, Geneva, Switzerland

## Abstract

The Controls Configuration Service (CCS) is a core component of the data-driven Control System at CERN. Built around a central database, the CCS provides a range of client APIs and graphical user interfaces (GUI) to enable efficient and user-friendly configuration of Controls. As the entry point for all the modifications to Controls system configurations, the CCS provides the means to ensure global data coherency and propagation of changes across the distributed Controls sub-systems and services. With the aim of achieving global data coherency in the most efficient manner, the need for an advanced data integrator emerged.

The “Controls Configuration Data Lifecycle manager” (CCDL) is the core integration bridge between the distributed Controls sub-systems. It aims to ensure consistent, reliable, and efficient exchange of information and triggering of workflow actions based on events representing Controls configuration changes. The CCDL implements and incorporates cutting-edge technologies used successfully in the IT industry. This paper describes the CCDL architecture, design and technology choices made, as well as the tangible benefits that have been realised since its introduction.

## INTRODUCTION

The Controls Configuration Service (CCS) is a core component of CERN’s Control system, serving as a central point for the configuration of all Controls sub-domains. CCS ensures that the data provided to other services is done in a coherent and consistent way. CCS is used by a diversified group of users, including installation teams (configuring Controls hardware), equipment experts (configuring processes and applications), and Accelerator operators. All CCS users interact with the service at various points in time, to verify or define appropriate configurations.

The service is built around a centralised Oracle database server. To minimise downtime of the system and risks of negative impact to the users, the server is deployed in a cluster as 2 redundant nodes, providing 99.9% availability. The data stored in the CCS database (CCDB) may be accessed via a dedicated high level web-based editor - Controls Configuration Data Editor (CCDE) [1]. At the same time the service also provides advanced Java and Python REST APIs which allow users to efficiently configure, modify and maintain configuration data in a programmatic way.

The CCS service has been an integral part of the Controls system for many years. The first version was created in the late 80s, during operations of the Large Hadron Collider’s predecessor - The Large Electron-Positron Collider (LEP). Since that time the service has evolved and been consolidated multiple times. The last renovation started 4 years ago [2] to match the CCS technology stack with technologies widely used in the software industry. All CCS components are based on Java (currently version 11) and the Spring framework. From the Spring framework, Spring Boot has been selected as a solution to establish a common architecture among all the applications in a simplified and unified way. As mentioned, CCS also provides a high-level web interface - CCDE. The CCDE is based on the AngularJS framework (provided by Google) and is augmented with a web components framework developed in-house and encapsulating common functionality and integration with CERN services such as SSO. Communication between the Java back-end and the AngularJS front-end is implemented using the REST architectural pattern.

## CERN CONTROLS CONFIGURATION SERVICE

As a core Controls service, the CCS must exhibit a high level of availability. Even though CCS downtime does not directly impact beam operation, it severely limits the means to verify or modify core system configurations. To provide the highest possible availability and quality of service, each CCS component is implemented with some degree of redundancy. For example service-side processes are stateless and deployed in a multi-node set-up. In the rare case of a failure for one of the nodes, the system remains operational without impacting users. Advanced monitoring and notification mechanisms continuously check the consistency and status of all service components and send alerts in case of any abnormality. This allows service managers to react before the CCS becomes unavailable.

Since its inception, the CCS has evolved regularly, in-synch with the significant evolution of CERN’s accelerator complex and multiple sub-systems. During the last 30 years, new advanced accelerators and major upgrades have triggered a need for a more sophisticated and powerful configuration platform. The global Controls architecture is realised as a layered system, reflected in CCS configuration domains, which can be simplified as follows:

- Low-level aspects covering kernel driver configurations and hardware types.
- Front-End Computers (FEC) with their modules (of hardware types, mentioned above), on which,

different acquisition and configuration processes are running.

- Software processes which represent physical Devices deployed in specific Accelerators, together with definitions of their interfaces, known as “Device Classes”.
- Role-based authorisation schemes, both for access to the aforementioned Device processes and to high-level applications.
- Configuration of Device data acquisitions and logging, to have data available for further analysis.

## CONTROLS CHANGES

Every change to Controls configuration, no matter how small, may impact one or more other Control system components. Due to the overall Controls complexity, manual adaptations in related sub-systems to account for changes, are highly time consuming and error prone, and risk to result in discrepancies between different Controls sub-systems. It is therefore crucial, to capture changes, notify related services, and even trigger specific actions, in an automatic way.

To ensure that changes are accepted and parsed correctly, they are treated as named events which may occur during the configuration lifecycle. Each such event may be acknowledged, analysed, and propagated to appropriate services to trigger necessary actions. Once such operations are complete, the user that triggered the change event should be notified of the outcome such as success or failure (including relevant details). The behaviour described above falls into the software architecture paradigm known as an “Event Driven Architecture” and aims to address all implications provoked by change requests.

The evolution of physical Controls hardware requires corresponding adaptations at various layers of the Control system. One example is the meta-data describing the programmatic interface of the equipment (“Device Classes”, mentioned above) which must naturally evolve following the hardware. This process of a Device changing Class is called “migration”. It is a critical event in the Controls configuration life-cycle, as it may impact a number of core Controls sub-systems such as LSA[3] (for settings management), NXCALS[4] (for time-series data logging), UCAP (for data processing), and end-user applications. To control this impact and minimise risks of inadvertent changes, the “Controls Configuration Data Lifecycle manager” (CCDL) is used.

A typical example of such a change, would be an evolution of a hardware component, such that the meta-data describing the component’s properties needs to be updated with respect to its data type (e.g. from a *scalar integer* to a *double array*). Such a change needs to be properly propagated to other Controls sub-systems to assure operational continuity e.g. consistent application of settings or data acquisition. The window within which such

changes are carried out (both in terms of underlying hardware and software) is normally limited to either Accelerator technical stops or shutdown periods.

To ensure the correct propagation of changes within the CCS and across related Controls sub-systems, a sub-component of CCDL, the migration “orchestrator” is employed. The orchestration engine reacts to the named configuration change events and processes them by orchestrating the corresponding changes in all related Controls sub-systems. This processing must be done in a logical order, reflecting how the sub-systems depend on one another. End-users are provided with live insights into the event processing and are also notified about any problems. The outcome of each distinct step in the migration processing chain is recorded as a status event. Status events are also injected back into the processing system for use by the orchestrator for optional conditional processing. This solution is deployed in production and Table 1 shows the number of processed events in 2020.

Table 1: 2020 Events Generated Based on User Actions

TabEvent	Occurrences
Device migration (change of Class)	21k
Device attribute changed	280k
Device added	100k
Device deleted	90k
NXCALS subscription changed	250k
NXCALS subscription added	360k
NXCALS subscription deleted	130k

Considering the long history of the CCS and the need to cope with the complexity of the Accelerator Controls domain, the CCS architecture and design are tailored to solve a wide variety of possible problems in a configurable and data-driven manner. Below, the core CCS components are described, together with specific examples of an event-based definition of business use-cases as seen from the perspective of Controls users.

## ARCHITECTURE

The main component of the event-based processing of changes in the system is the CCDL - Controls Configuration Data Lifecycle manager. The manager acts as an orchestration and integration point amongst core CCS components (CCDA – Controls Configuration Data API, CCDE – Controls Configuration Data Editor) and a limited number of clients using direct database access with dedicated schemas or PL/SQL APIs. The CCDL is composed of two main components: CCLC (the Lifecycle

manager) and the so-called “integrated Device migrator”. Supporting components of the architecture include:

- Apache Kafka – a distributed data store optimised for ingesting and processing streaming data in real-time.
- Oracle AQ (Advanced Queuing) – a proprietary feature of Oracle databases, which delivers database-integrated message queuing functionality.
- System events – representing configuration changes, are modelled as simple tuple objects, generated at the persistency (database) layer.

System events, modelled as data tuples, consist of meta-data such as operation types, timestamps, aggregation topics (i.e. database transaction ID), as well as the event data (i.e. configuration value before and after the change). The events are designed to be sufficiently rich for the processing system to minimise the need for querying additional data. At the database level the events are stored in log tables, structured with attention to data partitioning and indexing. In normal operations of the system, events are processed continuously which minimises the number of physical reads at the level of the database, thus contributing to overall performance operation of the system. In case when historical events need to be processed, indexing and table partitioning at the level of event type and creation timestamp lowers latency when accessing the data.

The decision to use Apache Kafka was driven by a frequent need for a loosely coupled integration of 3<sup>rd</sup> party clients with CCS (e.g. other Controls sub-systems). System events are fed to Kafka and made readily available to all subscribed clients, including internal clients like CCLC. This solution enabled a plug-and-play model (see Fig. 1), where external clients may integrate only at the level of Kafka data-objects (key-value pair tuples or JSON objects), or if necessary use a complete CCLC client API, tailored to a specific client domain (e.g. NXCALS or UCAP).

## CONCLUSIONS

Before CCDL was put in place, many of the configuration updates described above needed to be performed manually by a limited number of system experts. The manual nature meant that users had to request changes well in advance, such that experts of each of the possibly impacted Controls sub-systems had sufficient time to internally verify what would be the impact, and if necessary, prepare appropriate steps to mitigate risks and ensure a global consistency of the distributed configuration elements. This situation required careful planning and coordination to minimise errors and discrepancies between Controls sub-systems.

The introduction of CCDL helped to considerably reduce support and manual interventions. All changes can now be executed directly by the users, at any moment, without a need for specific actions from the various Controls sub-system experts. Feedback gathered during the last 3 years since the automatic Device migration process has been in place, shows that the work of the users has been simplified and became more efficient. At the same time, thanks to the fully automated process, the time when the global Control system configuration is in an inconsistent state, has been reduced to a minimum.

Reduction of the support and automatization of the configuration process is an example of a continuous evolution of the system. The increasingly dynamic nature of the CERN Accelerator Controls manifested by a growing number of data-driven components, indicates a need for software solutions which in place of customised use-case specific code, rely on more abstract and agile solutions. One possible solution is to deliver a platform which allows users to define complex high-level events based on atomic events generated by the system. While the atomic events represent fundamental changes occurring in the system (e.g. a new Device created), the complex event may be used to indicate patterns of behaviour. For

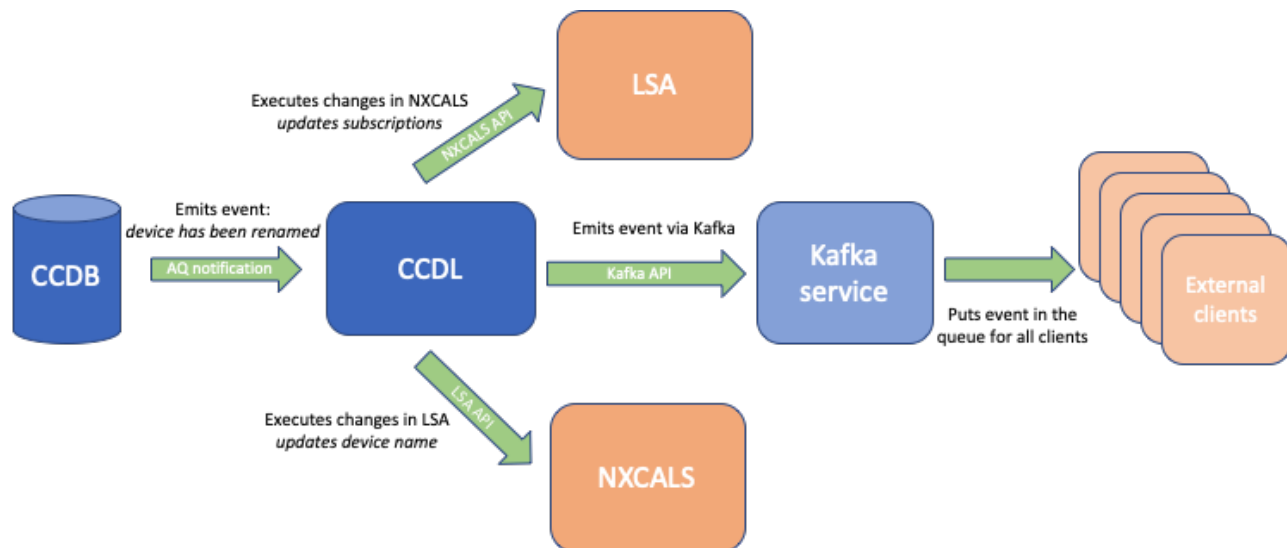

Figure 1: Diagram of event processing with CCDL.

example, a consecutive set of new Device created and Device renamed events may represent a complex event such as swapping of Devices by name while retaining their associated configuration intact. Discovery of such patterns may be achieved with Complex Event Processing engines, for example using Esper CEP framework [5]. The CEP approach provides users with a high degree of freedom in covering different use cases, including dynamic injection of new types of events, without noticeably increasing the amount of support needed from various related Controls sub-system experts.

In the mid-term perspective we plan to integrate ESPER CEP engine with CCDL and consequently expose means to define complex events and EPL (Event Processing Language) queries through a high-level graphical user interface as a part of CCDE. This will provide all the users of the Controls system configuration the means to define new events and give a possibility to look for patterns of events occurring in the system. With such extensions as well as described earlier stream processing engine like Apache Kafka and high-level API like CCDA, we aim to establish practical means to realise a business intelligence solution tailored to the needs of the CERN Accelerator controls and its users, while remaining agnostic to the CERN specific concepts.

# LESSONS LEARNED MOVING FROM PHARLAP TO LINUX RT

Cédric Charrondiere, Odd Oyvind Andreassen, Diego Sierra Maillo Martinez, Joseph Tagg, Thomas Zilliox, CERN, Geneva, Switzerland

## Abstract

The start of the Advanced Proton Driven Plasma Wakefield Acceleration Experiment (AWAKE) [1] facility at CERN in 2016 came with the need for a continuous image acquisition system. The international scientific collaboration responsible for this project requested low and high resolution acquisition at a capture rate of 10Hz and 1 Hz respectively. To match these requirements, GigE digital cameras were connected to a PXI system running PharLap, a real-time operating system, using dual port 1Gbps network cards. With new requirements for a faster acquisition with higher resolution, it was decided to add 10Gbps network cards and a Network Attached Storage (NAS) directly connected to the PXI system to avoid saturating the network. There was also a request to acquire high-resolution images on several cameras during a limited duration, typically 30 seconds, in a burst acquisition mode. To comply with these new requirements PharLap had to be abandoned and replaced with NI Linux RT.

This paper describes the limitation of the PharLap system, and the lessons learned during the transition to NI Linux RT. We will show the improvement of CPU stability and data throughput reached.

## INTRODUCTION

A plasma wakefield is a type of wave generated by particles travelling through a plasma. By harnessing these wakefields, accelerating gradients hundreds of times higher than those produced in current radiofrequency cavities can be achieved [2], allowing for more compact accelerators. AWAKE is a proof of principle experiment that aims to demonstrate this in a scalable way, sending proton beams through plasma cells to generate these fields, which subsequently accelerate electrons to high energy over a short distance.

One important observable is the shape and position of the proton beam halo along the beamline, that must be acquired in real-time. To handle the 10Hz image acquisition on 10 cameras simultaneously it was decided to use a PXI running PharLap.

Due to the lack of supported drivers, issues with timing and performance, the system was later upgraded to NI Linux RT to benefit from its flexibility.

## Motivation

The cameras are positioned along the beam line for several purposes (Fig. 1). The cameras that are on the virtual laser diagnostic line are used to measure the characteristics of the laser used to initiate the plasma. Other cameras are used to image the path of the laser and proton beams to align them in the plasma cell. Finally, some cameras are

positioned to visualize the low energy electron beam at different points of its path before it is accelerated by the proton generated wakefield in the plasma cell.

Figure 1: Camera locations in the Awake Experimental Area.

## HARDWARE TOPOLOGY

The AWAKE camera acquisition system acquires images from ethernet based, digital GigE cameras. The system publishes resampled images (resampling factor 5x5) at 10 Hz and publishes the full-size images on an SPS extraction event (once per AWAKE cycle). The basic system topology is shown below (Fig. 2)

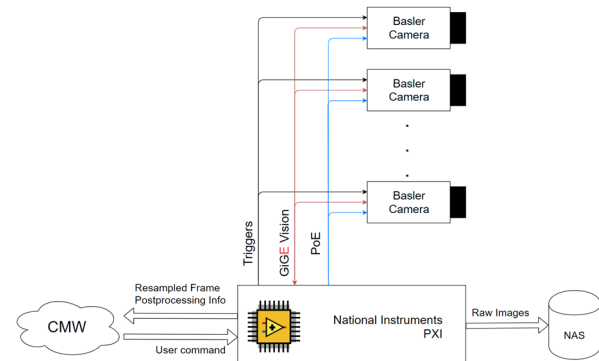

Figure 2: System topology.

Each camera is connected to the PXI system and powered by a PoE (Power over Ethernet) module. The triggering is handled through the FPGA as shown in the hardware architecture (Fig. 3)

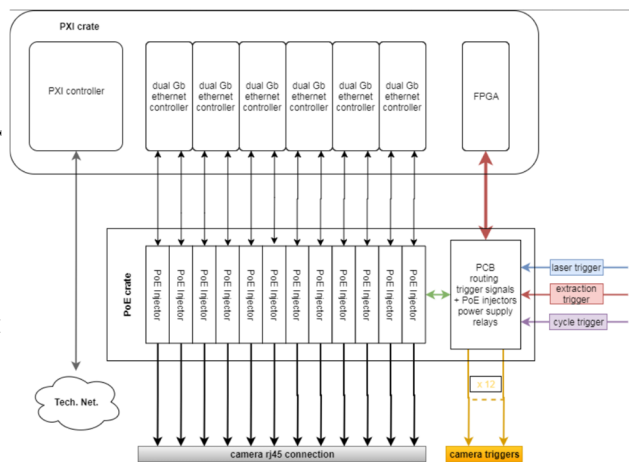

Figure 3: Hardware architecture.

## Performance

Two OSes support the new 10Gbps card: NI Linux RT and Windows. We compared the CPU usage on both, using CPUs with relatively close performances, a NI PXIe-8840 for Windows and a NI PXIe-8861 for NI Linux RT. The CPU usage in Windows was around 50% at idle due to th Windows and CERN services running in the background. In production, with cameras acquiring, the PXI was oscillating between 97-99%, resulting in multiple frame losses. With NI Linux RT, the usage of the CPU is around 0% at idle and between 50 to 70%, depending on the number of cameras plugged into the PXI. This increase in available CPU power drastically reduced the frame losses and increased the stability of the system.

## Network Attached Storage (NAS)

Publishing the raw images on the CERN network is not possible as its bandwidth is 1 Gbps and the current setup would require 4 Gbps. To allow the AWAKE team to acquire raw images at that rate in the specified amount of time (referred to as burst acquisition) a NAS is directly linked to the PXI's 10 Gbps card. The NAS used is a HP PROLIANT DL380 GEN9 running Linux.

## OPERATING SYSTEM

### PharLap

The main advantage of PharLap is that it is a lightweight RTOS (Real Time Operating System) with few software layers, which makes it robust and stable while maintaining determinism. This advantage is also a weak point in terms of debugging because when a RT application crashes, the whole OS stops responding, and a reboot of the device is required. In addition, because it does not implement memory virtualization, very little can be fixed at runtime without rebooting, requiring careful memory management. National Instruments will stop its support of PharLap in 2025 [3] with some new modules already not supported on this platform, forcing the community to stop using it for new projects or major upgrades.

In the case of AWAKE, a PXIe-8238 10Gbps ethernet card was required to log data to a NAS at high speed. This card is not supported by PharLap, which motivated us to change the OS.

Another issue is the timing synchronization daemon, SNTP 1.2, based on SNTP (Simple Network Time Protocol), that does not work properly on PharLap. When SNTP is synched, we measure a continuous oscillation of about  $\pm 0.02$  seconds around the correct time. After a few hours (2 to 20+), we measure an abrupt offset of about 4 minutes, followed by oscillations of  $\pm 0.2$  seconds.

### Linux RT

As the CERN accelerator complex infrastructure is UNIX based, having an acquisition system based on a NI Linux RT distribution makes its integration into existing services and databases easier. Contrary to PharLap, NI Linux RT (based on the OpenEmbedded platform) ships with built in tools for compiling, debugging, administrating and monitoring our device by default. The behaviour of the built-in NTP timing service works, and debugging via ssh (secure shell) is more convenient since this can be done while the system is running.

Remote access and troubleshooting are relevant to most of our projects as they often are installed in inaccessible areas. As an added bonus, other languages such as Python are also available, opening new possibilities.

In the AWAKE application, we were wary of potential performance issues due to a saturation of the network bandwidth but were not able to measure it. Thanks to the default monitoring tools available in the NI Linux RT distribution, we were finally able to quantify it and fix one of the major issues of the system, which was caused by too many clients connected to the system simultaneously.

In addition to the different monitoring tools, we also benefit from all the different native logging systems. The ethernet logger allowed us to quantify the behaviour of each camera's communication, especially when they were exposed to too much radiation.

The main drawback of NI Linux RT is its backward compatibility; some drivers are not, and may never be, supported.

## INTEGRATION

### Timing

The different timestamps from the camera's driver, such as the frame arrival timestamp, are based directly on the PXI clock. Because PharLap does not have a trustworthy built-in NTP daemon, there is a permanent clock drift, which requires every timestamp to be corrected. NI Linux RT's NTP client on the other hand works well, which helps with camera timestamping.

With regards to the PXI time, Linux RT is more user-friendly than PharLap. While it is possible to correct in PharLap, Linux RT freed us from this constraint.

## Triggering

To sync the image acquisition with the AWAKE laser and other SPS events, a trigger is generated by the AWAKE timing system. It is wired to a CERN central timing receiver card (CTRp) [4] [5], an FPGA-based custom timing card manufactured at CERN. This card allows us to subscribe to every timing event of a specific accelerator, in our case the SPS, and to forward a specific event trigger to all the cameras.

On the early version of the NI Linux RT (up to version 20.6) some VISA functions were not working properly with the CTRp card, such as the subscribe to PXI event (Enable\_PXI\_VISA\_event.vi). We should therefore not take for granted that custom PXI cards that work on PharLap will work out of the box on NI Linux RT.

## Vendor Libraries

In general, when using hardware, software and firmware from NI, compatibility and maintenance is not an issue. However, as the years have passed, and PharLap has gone from being a mature to an obsolete platform, even vendor specific compatible drivers have become difficult to find. For the NI Linux RT based systems, the opposite has been the case. Here many of the libraries and drivers have either been ported to the platform in the last few years, or are in the process of being implemented. This poses a challenge for the end user when maintaining the system, leaving you in a situation where some hardware is supported in one environment and not the other. Many of the major hardware families have equivalent replacements available, but they are often not “plug-in” replacements, and might require different signal converters and cables, running at different voltages. This has led to some caution when upgrading systems procured in the 2015 to 2021 timeframe, carefully having to anticipate whether the hardware would have compatible libraries both on PharLap and Linux RT when designing new control system.

In the case of the AWAKE camera acquisition system, the choice was driven by the necessity of higher throughput to cover additional cameras, and a higher level of stability in terms of time drift. The “Lessons learned” moving to NI Linux RT, has been that not everything is a drop-in replacement from the vendor side, and sometimes small hardware changes or features introduced in newer versions, can impact the whole system and should be carefully studied.

## 3<sup>rd</sup> Party Libraries

Most libraries on NI based systems are installed using a specialized tool called MAX (Measurement and Automation Explorer). This is the case both for PharLap and NI Linux RT, however the underlying technology for the two platforms is significantly different.

For PharLap, the installation is done simply by formatting the target, priming it with a base operating system and installing drivers by copying them to the right location on disk. There are no convenient ways to keep track of what is installed on which target. To upgrade a driver you need to install the appropriate driver bundle on your

development system, which is often versioned differently from what you see on the target. This often leads to confusion and maintenance overhead. To keep track of the libraries installed on the target, it is necessary to document every action taken during the course of development.

For NI Linux RT, the environment is based on UNIX, and in addition to the standard toolchain distributed via a dedicated package manager (OPKG for NI Linux RT), NI have added a management tool called SaltStack, that takes care of monitoring what is installed and if there are upgrades available. In addition, multi-target support has been added, so one can now distribute upgrades to multiple targets in parallel.

This means that system replication is easier for smaller systems on PharLap, but large-scale system administration is by far simpler on NI Linux RT. For third party libraries, this is a huge advantage, allowing custom developed code to be managed side by side with the vendor’s own drivers.

## Network Booting

One of the main requirements for systems installed in and around the accelerators at CERN, is the ability to remotely recover and re-install the system in case of failure. This was typically done via PXE (Pre-eXecution Environment), however in the later years UEFI (Unified Extensible Firmware Interface) has become more common.

For PharLap, NI uses traditional PXE boot while NI Linux RT NI uses UEFI [6]. Both technologies can be deployed at CERN, but UEFI has more modern capabilities and integrates better into the current infrastructure.

## Compilation Process, Debugging and Error Management

When developing 3<sup>rd</sup> party drivers and libraries such as the CERN middleware and timing libraries, the ability to test and validate the implementation is imperative.

In PharLap, because it is based on an older Windows NT kernel, all custom development requires the Visual Studio development environment, and a PharLap-compatible runtime.

To debug libraries, you first have to test the library under Windows and then rigorously test all functionality on PharLap. The problem is that PharLap does not have any proper debugging tools, and the error messages it produces are often obscure or too generic, forcing you to add extensive debug information as part of the implementation (such as printing information along the execution of the code).

On NI Linux RT, you have all the standard GCC and UNIX tool chains available, and debugging can easily be done in a comfortable way, saving both development and maintenance time.

## Compilation Tools

As mentioned, PharLap relies on the Visual Studio toolchain to compile 3<sup>rd</sup> party software. Unfortunately, the development of a dedicated Visual Studio runtime for PharLap was stopped at version 2010, and Microsoft, the

owner of Visual Studio stopped its support for the runtime in its development environment in 2020 (official EOL was 2015 but extended EOL was pushed back to 2020). Furthermore, Visual Studio 2010 is not compatible with Windows 10 and beyond, making compilation of source code for PharLap based systems even more complicated [7].

For NI Linux RT, the standard gcc or g++ toolchain can be used, even on the target itself, and both development and validation is straight forward. If in addition you leverage automated builds through continuous integration and modern DevOps solutions (such as those provided by GitLab), any upstream change to a dependent source can be caught, compiled, and tested immediately as it is released. This has proven to be a huge time saver in terms of consolidation and maintenance.

## CONCLUSION

Switching from PharLap to NI Linux RT brought performance improvements, reducing both the general resource and CPU usage. The UNIX environment simplified library and system administration. It also allowed features that were missing from PharLap such as the 10 Gbps network drivers and the NAS.

The next challenges will be to increase the image post-processing speed in order to increase the resolution of the cameras. As a result of the operating system change, we can now benefit from newer FPGA cards dedicated to vision analysis, allowing us to offload some calculations from the CPU.

# DATA-CENTRIC WEB INFRASTRUCTURE FOR CERN RADIATION AND ENVIRONMENTAL PROTECTION MONITORING

Adrien Ledeul\*, Catalina Cristina Chiriac, Gonzalo de la Cruz, Gustavo Segura, Jan Sznajd  
CERN, Geneva, Switzerland

## Abstract

Supervision, Control and Data Acquisition (SCADA) systems generate large amounts of data over time. Analyzing collected data is essential to discover useful information, prevent failures, and generate reports. Facilitating access to data is of utmost importance to exploit the information generated by SCADA systems.

CERN's occupational Health & Safety and Environmental protection (HSE) Unit operates a web infrastructure allowing users of the Radiation and Environment Monitoring Unified Supervision (REMUS) to visualize and extract near-real-time and historical data from desktop and mobile devices. This application, REMUS Web, collects and combines data from multiple sources and presents it to the users in a format suitable for analysis.

The web application and the SCADA system can operate independently thanks to a data-centric, loosely coupled architecture. They are connected through common data sources such as the open-source streaming platform Apache Kafka and Oracle Rdb. This paper describes the benefits of providing a feature-rich web application as a complement to control systems. Moreover, it details the underlying architecture of the solution and its capabilities.

## INTRODUCTION

Radiation protection and environmental monitoring are fundamental aspects of the CERN Safety Policy. CERN's occupational Health & Safety and Environmental protection (HSE) Unit conducts a program in charge of monitoring the radiological and environmental impact of the organization. The aim is to ensure workplace safety for CERN employees and visitors, minimize the environmental impact of CERN, and provide regulatory authorities with comprehensive reports.

In order to achieve these objectives, a geographically distributed and heterogeneous set of instruments is continuously measuring the nature and quantity of ionizing radiations produced by the accelerators, possible contamination as well as conventional environmental parameters.

Radiation and Environment Monitoring Unified Supervision (REMUS) [1], based on WinCC Open Architecture (WinCC OA) [2] is the Supervision, Control And Data Acquisition (SCADA) system controlling this infrastructure. It is accessed from various control rooms across the Organization and has more than 200 active users.

At the time of writing, REMUS is interfacing 86 different types of devices. It contains 850 000 tags, manages 120 000

alarms and handles a throughput of 25 000 Input/Output operations per second. REMUS archives roughly 80 billion measurements per year.

One of the main challenges of such a system is to provide comprehensive yet accessible means to extract and exploit the data. REMUS itself allows users to display a large variety of synoptic views and control panels designed for the operation in control rooms. However, such user interfaces are not the most suitable for data extraction at a higher level of abstraction, and typically require physical access to terminals in a protected network.

Two use cases are particularly challenging to handle. The first one is that CERN radiation and environmental protection experts are in charge of transforming the data generated by REMUS system into business-specific reports. Such reports are used for further internal analysis and to consolidate CERN's communication with the host states and with the general public. The second one is to provide the CERN's Fire and Rescue service and other emergency response teams with access to near-real-time data on remote terminals. This is particularly useful at CERN, where installations for environmental monitoring are geographically scattered. The installation of dedicated monitoring screens is not always possible at the location where the access to the data is needed.

This paper describes the approach taken to make radiation and environmental monitoring data accessible to third party applications as well as why web technologies were chosen for the presentation of this data.

## A DATA-CENTRIC APPROACH

This section introduces the approach taken for the consolidation and homogenization of the data layer.

### *The Data-Centric Manifesto*

The data-centric mindset, as opposed to the application-centric one, considers the data to be the permanent assets, and the applications the temporary ones. The key principles, as expressed in the Data-Centric Manifesto [3], can be summarized as follows:

- Data is the key asset.
- Data is self-describing.
- Data is stored in non-proprietary formats.
- Data access control and security is the responsibility of the data layer itself.

This approach suits well REMUS use case, as radiation and environmental protection data must be kept for an indefinite amount of time, as requested by regulatory authorities. On the other hand, the applications publishing

\* adrien.ledeul@cern.ch

and consuming the data change regularly, driven by technological evolution.

The key point is to think and design the data-set before designing the applications fulfilling the requirements. The concepts of a data-centric mindset applied to the CERN Radiological and Environmental Monitoring System are illustrated in Fig. 1.

Figure 1: Data-Centric principles applied to REMUS. The center of the diagram represents all the data associated with radiation and environmental protection monitoring at CERN. The external blocks represents applications consuming and producing data through APIs.

The first steps taken in REMUS towards a data-centric approach were to consolidate and complete the data layer, as well as to unify the applications access to the multiple data sources of the control system through a common API.

## REMUS DATA PIPELINE

This section describes the REMUS data flow, from the instruments to the data layer used by visualization tools.

### Overview

REMUS is in charge of the data acquisition of over 5500 measurement channels, generating about 2600 data points per second in total. The acquired data is processed in parallel in two different ways, following the Lambda architecture [4]. On the one hand, data is processed in batch for long-term archiving. On the other hand, data is processed as a stream to allow immediate and continued exploitation [5]. The aim is to provide a data layer that can be homogeneously accessed through a data access API for historical and near-real-time data queries. The full data pipeline is illustrated in Fig. 2.

Figure 2: REMUS Data Pipeline. Applications consume data aggregated by the data access API. Data is fetched from various data sources with different latencies and time resolutions. Oracle and NXCALs are used for historical data; Kafka and InfluxDB for near-real-time data.

### Batch Processing

REMUS fetches the data buffered in instruments' internal memories at a configurable polling interval. This data is written into files that are then injected in Oracle Rdb's partitioned tables using SQL\*Loader [6] processes. A subset of the data is then transferred to the Next CERN Accelerator Logging Service (NXCALs) [7], based on Hadoop [8], where it is kept indefinitely at the highest resolution. The data stored in Oracle Rdb is reduced after two weeks, in order to guarantee low latency access.

### Stream Processing

In parallel to the batch processing, REMUS receives continuous data streams from the instrumentation. The streams are transformed by the SCADA and published to a dedicated Kafka [9] topic using an open-source WinCC OA Kafka Driver [10], developed and maintained by CERN's HSE Unit. The topic is then filtered using Kafka Streams [11] to eliminate potential malformed messages. The processed stream is then sent to InfluxDB [12] via Kafka Connect [13] for temporary data retention.

### Data Access API

Environment and Radiation Unified Data Integration Service (ERUDIS) is a data access API. ERUDIS provides high-level abstraction of the data sources that can be consumed by third party applications. The architecture of this API is based on Akka, an actor concurrency model framework, and the Alpakka [14] library, designed for handling data streams. These tools simplify the creation of interfaces for unifying heterogeneous data sources, as well as provide means for interactive management of data streams, such as buffering, advanced error handling and automatic redundancy mechanisms.

## REMUS WEB

This section introduces REMUS Web, a web infrastructure that allows users to visualize and extract near-real-time and historical data from desktop and mobile devices. REMUS Web takes advantage of the data pipeline introduced in the previous section to present the data to the user in a format suitable for analysis.

### *Rationale of the Approach*

**Web Applications** Since its invention at CERN, the World-Wide Web [15] has evolved from a hosting platform for simple and static hypermedia documents to an infrastructure for the execution of complex applications [16]. In the last decades web applications became a popular and widespread solution in the software industry due to the advantages they present over standalone applications.

From the user's point of view, web applications are more accessible. They can be reached through the web browser and do not require complex installation processes or specific hardware configurations. Web applications work on any device capable of running a simple web browser, offering greater portability and cross-platform access. Furthermore, the requirements that end-user workstations must satisfy to run the applications are minimal, since computationally expensive tasks are delegated to the server.

From the developer's point of view, maintenance and update processes of web applications are simpler compared to standalone applications, since the application only needs to be deployed on the servers and no intervention is required on the end-user workstations. Web technologies are the most widely used and the most mature for the development of graphical user interfaces (GUI), which facilitates and speeds up development thanks to the large ecosystem, plugins and community around web development. In addition, web technologies are widely spread in the IT industry and it is easier to recruit professionals with web development skills than with SCADA and control systems skills. According to the 2021 Stack Overflow Developer Survey [17], web developer roles are the most popular on the market.

**Progressive Web Applications** In recent years the importance and impact of the web has been increasing. Most modern software companies base their business models on offering services through the web. This has meant the consolidation of the web as a service platform and the emergence of new web technologies that have made the line between web applications and native applications increasingly thin. In this model, cross-platform compatibility (desktop, mobile, and tablets) is essential to maximize the reach of the application and to provide the best user experience.

Progressive Web Applications (PWA) [18] provide users an experience on par with native applications. PWAs are a type of web applications that are intended to work on any platform using a standard-compliant browser, including both desktop and mobile devices. PWAs take advantage of recent

advancements in web browser technologies such as service workers [19], web app manifests [20], and caching to bring features usually associated with native apps. These features include installability, responsiveness, network independence, re-engageability, and enhanced security. PWAs offer similar features to native and hybrid [21] applications, with a smaller bundle size and fast loading times [22]. Using PWA can significantly reduce the costs and resources required for the development and maintenance of a multi-platform application, since all platforms share the same codebase.

**Data Accessibility** The aforementioned features solve several of the challenges posed by accessibility of control systems' data. The use of a web application facilitates remote access to the data generated by the SCADA from any desktop or mobile device with a standard-compliant web browser. This is especially useful when operators must carry out interventions in remote facilities where there is no access to the control system terminals. Furthermore, REMUS Web is built as a PWA, allowing operators to access the data generated by every equipment from their mobile device. REMUS Web provides QR codes for every instrument connected to REMUS, which can be printed and attached to the instruments. In this way, when operators need to intervene on an instrument, they can access the instrument data in real time by scanning its QR code. This mechanism also allows operators in the field to access data from devices that do not have any integrated display.

### *Technological Stack*

The technologies and tools used in the development of REMUS Web are listed below. These technologies have facilitated and accelerated the development of the tool, as well as improved its maintainability and scalability.

**Front-end** HTML, CSS and JavaScript are the standard technologies used for the development and design of web applications and therefore are the base technologies on which REMUS Web front-end is built. Additionally, high-level tools and libraries facilitate application development.

Most modern web applications are built on JavaScript frameworks for GUI development, which simplify the application development and maintenance processes. Currently, there are three major JavaScript frameworks that dominate the market: React [23], Angular [24], and Vue.js [25]. These frameworks have different characteristics and the decision of which one is the best option will depend largely on the circumstances of the project to be developed [26].

In the case of REMUS Web, we considered React to be the preferred option. React is a free and open-source JavaScript library for building GUIs which is developed and maintained by Facebook. React is flexible, efficient and declarative. According to the 2021 Stack Overflow Developer Survey [17], React is the most commonly used web framework and the most wanted by developers. At the performance level, React is fast and light. It offers a similar

performance to that of its direct competitors [27]. Since React is a UI library and not a complete framework, it offers a lot of flexibility and freedom to decide the architecture, tools and libraries used to build the application. Unlike other frameworks that use their own directives and templating languages, React's code is essentially pure JavaScript, which makes the learning curve shorter.

React has built-in functionalities for state management that are suitable for simple projects. However, the need for a more sophisticated state management solution arises as the complexity of the application increases and it becomes necessary to share state between different components. Redux [28] is the most widespread solution and the one used in REMUS Web. Redux is a predictable state container for JavaScript applications based on the Flux [29] architectural pattern.

Since one of the main goals of REMUS Web is to facilitate the study and analysis of the measured data, the use of a powerful and flexible charting library is of utmost importance. To this end, REMUS Web uses Highcharts [30]. Highcharts is a consolidated JavaScript SVG-based multi-platform charting library. It is flexible, well adapted to desktop and mobile devices and offers a wide variety of charts.

Real-time access to SCADA data away from the central control room is vital to assess and intervene quickly in critical situations. REMUS Web uses the WebSocket protocol [31] to establish a full-duplex real-time communication channel between the client and the server. In this way, the new data generated by the SCADA system is streamed to the client with a very low latency.

**Back-end** REMUS Web back-end is based on Java [32] and Spring Boot [33]. Spring Boot is an open source, microservice-based Java web framework. It is an extension of the well known Spring Framework [34], simplifying the set-up and configuration of standalone Spring applications and taking an opinionated view of the Spring platform and third party libraries to facilitate the development process.

## Architecture

Figure 3 shows the architecture of REMUS Web. The application is deployed on the CERN Platform-as-a-Service (PaaS) infrastructure, based on RedHat OpenShift [35]. OpenShift is a container orchestration platform optimized for web applications. It allows building, testing and deploying web applications without provisioning and maintaining dedicated servers for each application. OpenShift runs the applications in Docker [36] containers.

The front-end of the application runs on the users' web browser and communicates with the back-end in two different ways depending on the nature of the information to be transmitted. WebSockets are used for the transmission of real-time data such as measurements or alarms. They are also used to send commands from the client to the server in order to start, stop or modify the parameters of the transmitted

data flow. The rest of the communication between the client and the server is done through HTTP [37] requests.

The back-end of the application follows a classic three-layer architecture. The presentation layer exposes the REST and WebSocket APIs that the front-end consumes to interact with the back-end. The business layer contains the domain logic that drives the core functionalities of the application. Finally, the data layer is responsible for interacting with different data sources in order to persist and fetch data.

The data layer is based on Spring Data and ERUDIS. Spring Data is used to access and modify the data that is strictly owned by REMUS Web, such as reports, dashboards, or user preferences. In addition, it is also used to access the metadata of the SCADA system. On the other hand, ERUDIS is used to access both the historical and near-real-time data of the instrumentation connected to REMUS.

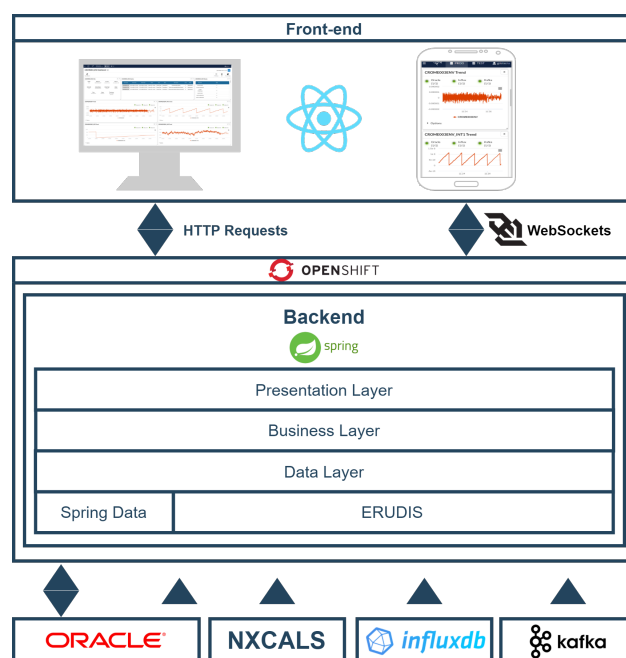

Figure 3: REMUS Web Architecture.

## Functionalities

This section introduces some of the most important functionalities that are included in REMUS Web.

**Notification Configuration** Users can configure personalized e-mail and SMS notifications based on events produced by the SCADA. Users can select the notification sources, the event that triggers the notification (e.g. an alarm goes on or off) and the notification lifetime.

**SCADA Monitoring** The application allows the generation of custom reports to monitor the current and past status of the SCADA system. It is especially useful for analyzing incidents and to carry out investigations.

**Near-real-time Alarm Screen** REMUS alarm screen is accessible directly from the web and displays the generated alarms in near-real-time. This eliminates the need to connect to the SCADA remote terminals in order to access the alarm screen, being accessible from any desktop or mobile device with internet access.

**Near-real-time Trends** REMUS Web allows to access and plot (see Fig. 4) both historical and near-real-time SCADA data. Users can fetch data from multiple data sources and define various parameters on the data to select. These parameters include time period, data resolution, and filters based on the alarm and fault status or the working mode of the instrument that generated the measurements.

Figure 4: REMUS Web Trends.

**Domain-specific reports** REMUS users require domain-specific reports for radiation and environmental protection. Such reports are used for internal analysis and to report to CERN's host states authorities. REMUS Web includes tools to generate these reports. Use cases include the extraction of aggregated radiation data and generation of the hyetographs (see Fig. 5).

Figure 5: REMUS Web Reports. This screenshot shows a generated hyetograph, allowing experts to analyse the impact of rain on water flow rates.

**Dashboards** REMUS Web includes a powerful tool for creating and visualizing dashboards. The tool makes a wide variety of widgets available to users. Users can compose their own custom dashboards by combining different types of widgets. The layout and size of the widgets can be modified using a drag-and-drop interface. In addition, REMUS Web automatically generates a dashboard for each of the instruments connected to REMUS. Such dashboards show

real-time data from this particular instrument, its alarms, and its parameters, as shown in Fig. 6.

Figure 6: REMUS Web Dashboards.

**Metadata Statistics** REMUS Web allows access to the complete inventory of REMUS entities such as measurement channels, instruments, and events. Users can filter the data using multiple criteria and perform data aggregations to extract statistics and charts, as shown in Fig. 7.

Figure 7: REMUS Web Statistics.

## CONCLUSION

Control Systems' Human-Machine-Interface went a long way, from push buttons and wired lamps to modern SCADA graphical user interfaces. The fast evolution of data architectures and web technologies is an opportunity to go one step further in the accessibility of SCADA's presentation layer.

CERN's Radiation and Environmental protection SCADA extended its data extraction and analysis capabilities, exploiting a modern data-centric architecture and web technologies.

## ACKNOWLEDGMENT

We would like to thank all the members, past and present, of the REMUS Project team as well as colleagues from Radiation Protection, Environment, Beams and Information Technology groups for their fundamental contribution to the success of the REMUS Web project.

# UPGRADING ORACLE APEX APPLICATIONS AT THE NATIONAL IGNITION FACILITY

A. Bhasker, R. D. Clark, R.N. Fallejo  
Lawrence Livermore National Lab, CA, USA

## Abstract

As with all experimental physics facilities, NIF has software applications that must persist on a multi-decade timescale. They must be kept up to date for viability and sustainability. We present the steps and challenges involved in a major Oracle APEX application upgrade project from Oracle APEX version 5 to Oracle APEX version 19.2. This upgrade involved jumping over 2 major versions and a total of 5 releases of Oracle APEX. Some applications - that depended on now legacy Oracle APEX constructs required rearchitecting, while others that broke due to custom JavaScript needed to be updated with compatible code. This upgrade project, undertaken by the NIF Shot Data Systems (SDS) team at Lawrence Livermore National Laboratory (LLNL), involved reverse-engineering functional requirements for applications that were then redesigned using the latest APEX out-of-the-box functionality, as well as identifying changes made in the newer Oracle APEX built-in “plumbing” to update custom-built functionality for compatibility with the newer Oracle APEX version. As NIF enters into its second decade of operations, this upgrade allows for these aging Oracle APEX applications to function in a more sustainable way, while enhancing user experience with a more modernized GUI for existing and future Oracle APEX webpages.

## INTRODUCTION

The National Ignition Facility (NIF) made history when it first fired all 192 of its laser beams at a single point inside the vast, spherical target chamber in 2009. Now, over 10 years and more than 2,700 shots later, NIF still dominates the world of high-energy lasers by a factor of 10 and continues to help the Laboratory achieve its mission objectives, offering unparalleled laser performance and precision [1]. As NIF enters into its second decade of operations, it must continue to maintain its various software applications in a sustainable and viable way. Two such applications that the Software Data Systems (SDS) team at NIF recently upgraded are the *Production Optics Reporting and Tracking* and the *Shot Planner* applications. At the time of this undertaking, these applications were running on Oracle APEX version 5.0. Oracle APEX is a web-application development tool for the Oracle databases [2], that supports utilization of JavaScript and JQuery components as well. In this paper, we discuss the steps involved in upgrading these NIF applications from Oracle APEX version 5.0 to Oracle APEX version 19.2 – a jump spanning 2 major versions and a total of 5 releases of Oracle APEX.

### The Oracle APEX Applications

The original *Production Optics Reporting and Tracking* (PORT) and the *Shot Planner* applications were developed

in very early versions of Oracle APEX when NIF was in the process of being built, over a decade ago. The PORT application covers a wide domain of capabilities – ranging from reporting and analysis to task-scheduling and optics installation. The Shot Planner application functions as a scheduling app, providing reports and forms to plan the sequencing of shots on NIF. At the time of the Oracle APEX upgrade, both these applications were running on legacy Oracle APEX themes and utilizing certain Oracle APEX constructs (such as AnyChart/Flash Charts [3]) that are no longer supported by the latest Oracle APEX versions.

## METHODOLOGY

The PORT application comprised of ~500 application pages, and the Shot Planner application comprised of ~200 application pages at the time of this upgrade. The following are the steps that the team undertook as a part of the Oracle APEX upgrade for these applications (Figure 1).

1. Identify all Obsolete Application Pages
2. Set up an APEX 19.2 environment for testing
3. Fix Forward Incompatibility
4. Deploy Pre-Upgrade Fixes
5. Line Up Post-Upgrade Fixes
6. Oracle APEX Upgrade Utility Recommendations
7. Upgrade and Deploy Post-Upgrade Fixes

Figure 1: Methodology followed.

### Identify Obsolete Webpages

The SDS team worked with the various users to identify any application pages that were no longer used. Given the age of these applications, several application functionalities were no longer required as the program evolved with time. Identifying these application pages gave the team an opportunity to prune out the deprecated functionalities. To be sure that a functionality could be deprecated, all visits of the various application pages on these applications were recorded for a period of one year before beginning the actual upgrade. To achieve this, a new Oracle database table was created to record this information from the APEX\_WORKSPACE\_ACTIVITY\_LOG view [4].

### A Sandbox Environment with Oracle APEX 19.2

The next step was setting up a test environment with the target Oracle APEX version 19.2 installed. Copies of the application were imported into this *sandbox* environment. The team meticulously tested all the functionalities on each Oracle APEX application page and identified features that were no longer working in the new upgraded environment. This was done by comparing each application page in the

*sandbox* against the actual *production* version of the application page and documenting the results.

### Categorize/Fix Forward Incompatibility

The comparison test between the application pages on the *sandbox* v/s *production* environments helped identify whether a page could be upgraded to Oracle APEX version 19.2 as-is, or if some additional work needed to be done to bring it to a functioning state. Broadly speaking, the comparison test resulted in pages falling in one of the following three categories:

- The application page could be upgraded as is, i.e., no additional work required.
- The application page rendered initially but some smaller functionalities no longer worked. Example: List of Values (LoV) now require both an explicit return and display value while they did offer backward compatibility for only defining one value to be used for both display and return.
- The application page did not render at all due to some browser incompatibility. This typically meant a JavaScript or JQuery error.

Fortunately, the majority of the application pages belonged to the first category, where the pages could be upgraded as is. However, there were still many high impact application pages on both the applications that needed to be fixed before the *production* environment could be upgraded to Oracle APEX 19.2. At this point, *two* important determinations need to be made. First, determining the cause behind the application pages not behaving exactly the same as they did in the old environment. We found that the cause was one of the two (Figure 2):

- The application page had an Oracle APEX feature implemented that was deprecated and no longer compatible with version 19.2. These were typically minor fixes that mostly required small changes in code.
- Or, there was custom JavaScript/JQuery either embedded in the application page itself or in a custom plugin used by that application page. The fixes for these ran the full gamut, from being small code fixes like updating the *html/css* class names being referred to in JavaScript code, to reverse engineering and redesigning an entire application functionality using the latest Oracle APEX 19.2 constructs like Interactive Grids.

Second, determining whether the fix can be applied in the current *production* environment version *before* upgrading to the new version (Figure 3). For instance, fixes involving certain unsupported APEX features could be made in the current version. An example would be rewriting the List of Values (LoV) definitions to include both return and display values. An example where the fix could not be applied before upgrading would be an application page using complex custom Javascript that is not compatible with the Javascript versions native to the latest Oracle APEX version and was redesigned using the latest Oracle APEX 19.2 out-of-the-box constructs.

By the end of this step, the *sandbox* environment had been used to develop mitigations for all types of broken

application pages, and the *sandbox* environment was a functional equivalent of the *production* environment.

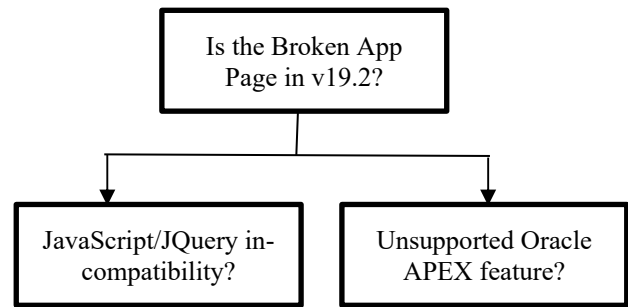

Figure 2: Page forward incompatibility causes.

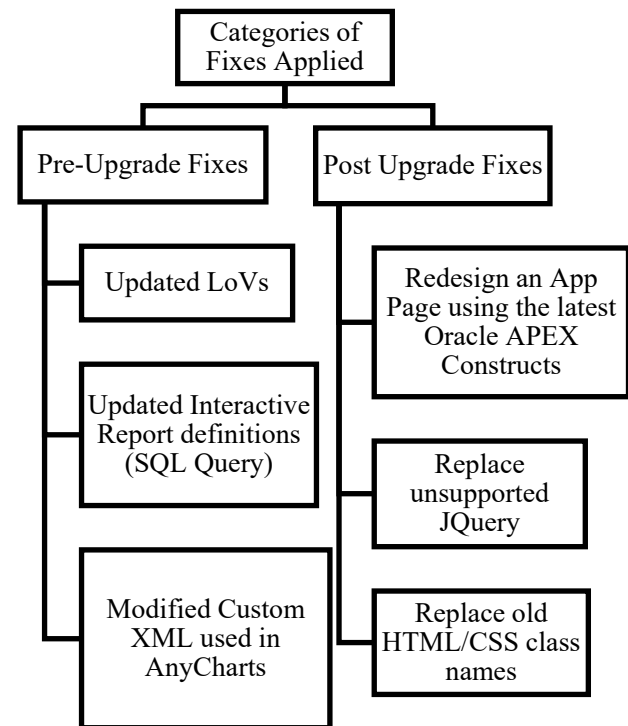

Figure 3: Examples of fixes for a smooth upgrade.

### Apply Pre-Upgrade Fixes

Any identified fix that could be applied to the APEX 5.0 version environment was deployed, and the applications were once again imported to the *sandbox* environment. A second round of testing confirmed that the specific pages with the pre-applied fixes now worked correctly in the Oracle APEX 19.2 environment.

### Export the Post-Upgrade Fixes

Any re-architected pages using new Oracle APEX constructs like Interactive Grids or Oracle JET charts were exported from the *sandbox* environment and applied as a software release immediately after upgrading the *production* environment to Oracle APEX 19.2. Another example of a post-upgrade fix includes several pieces of custom JavaScript code and plugins that use the *html/css* class names to add custom features to regular Oracle APEX constructs like Interactive Reports and Classic Reports. For instance,

the APEX Interactive Report class is now called 'a-IRR-table' in APEX 19.2; previously this was called 'apexir\_WORKSHEET\_DATA'.

### Upgrade Utility

Oracle APEX has an in-built 'Upgrade Application' Utility which makes recommendations for individual features in pages that can be upgraded. Figure 4 below shows an example of some upgrade categories it auto-suggests. The team also tested the specific application pages listed under these upgrade categories after accepting these upgrades in the sandbox. Some of these upgrades do not result in functional equivalents of the original page. For example, accepting the upgrades to upgrade Tabular Forms (which are still compatible with Oracle APEX 19.2) to Interactive Grids did not result in functioning pages, and required further re-design of the page. Such upgrades were selectively applied during this phase of the upgrade. Other upgrades, such as 'Enable Group By for Interactive Reports' or 'Enable Save Public Reports' were accepted using this utility, as they only enhanced the features on the page.

### Upgrade and Deployment

With all the fixes identified, applied and user-tested over the course of several weeks in the upgraded sandbox environment, the upgrade was successfully performed in the production environment, followed by the deployment of the post-release fixes, and then accepting the pre-tested page-wise upgrades from the APEX Upgrade Utility. The entire effort took around 4 months, which including meticulous testing, identifying the causes for various incompatibilities and any redesign efforts.

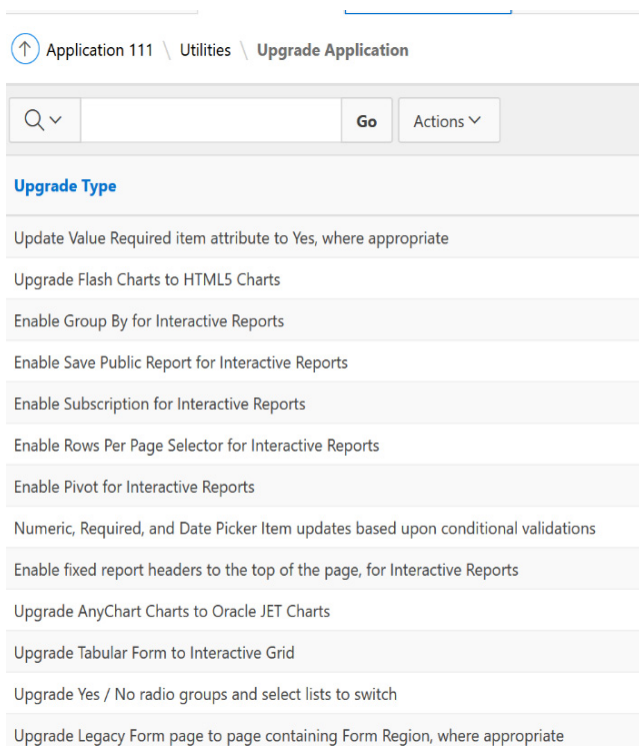

Figure 4: APEX upgrade utility.

## NOTABLE LESSONS LEARNED

Some issues encountered in the upgrade that are worth mentioning:

- There were several cases of JQuery incompatibility when running the same application page on the same browser, but on the two different versions of APEX. Example: replacing “\$.browser.msie” with “navigator.appname” got several pages working again.
- Oracle APEX has changed the CSS class names of some of its more popular constructs like Interactive Reports. Legacy custom code as well as plug-ins often utilize these.
- Some functionalities were redesigned using Interactive Grid instead of applying complex custom JavaScript to Interactive Reports to implement some *Form* functionalities in older versions of APEX. It was discovered that while the Interactive Grids in Oracle APEX allowed users to save Private and Public reports (same as Interactive Reports do), these saved reports are not exported as a part of an application page export. This is significant because this may impact the Oracle APEX administrator’s ability to maintain individual application backups containing all saved reports. Fortunately, the full application export does in fact contain the saved reports.
- The APEX\_PLUGIN.GET AJAX\_IDENTIFIER() function can sometimes include hyphens in the unique AJAX-ID generated in the upgraded Oracle APEX version. Some browsers may have compatibility issues with this and throw console errors.
- Some LoVs had invalid values that could only be viewed in the *Page Component View* in Oracle.
- APEX 5.0. The LoV’s values could not be viewed in Oracle APEX 19.2’s *Page Designer* view at all. These LoV definitions were updated as part of the pre-upgrade fixes as the *Page Component* view is not available in Oracle APEX 19.2.
- Interactive Reports with SQL query definitions of the format *select \* from <object>* needed redefinition with explicit column names in the select clause. This was for niche cases where the backend definitions had been updated since the application page was created, and the page accommodated for this in APEX 5.0. However, when ported to the APEX 19.2 environment, it generated errors because it was looking for fields that did not exist in the source object anymore.

## CURRENT STATUS AND FUTURE WORK

The upgrade project of the Production Optics Reporting and Tracking and the Shot Planner applications from Oracle APEX version 5.0 to Oracle APEX 19.2 was the first phase of an overarching project to keep it in an easily maintainable state, following recommendations from Oracle on best practices with Oracle APEX. The next phase of the project includes upgrading the Oracle APEX Theme for the two applications to the Oracle recommended Universal Theme. This upgrade to Oracle APEX 19.2 allows for these aging Oracle APEX applications to function in a more

sustainable and secure way, while enhancing user experience with a more modernized GUI for existing and future Oracle APEX webpages.

## Abstract

As part of the MACH-B (Multipole Accelerator Codes for Hadron Beams) project, Reservoir Labs has developed a Fast Multipole Method (FMM [1–7])-based tool for higher fidelity modeling of particle accelerators for high-energy physics within Fermilab's Synergia [8, 9] simulation package. We present results from our implementations with a focus on studying the difference between tune depression estimates obtained using PIC codes for computing the particle interactions versus those obtained using FMM-based algorithms integrated within Synergia. In simulating the self-interactions and macroparticle actions necessary for accurate simulations, we present a newly-developed kernel inside of a kernel-independent FMM, where near-field kernels are modified to incorporate smoothing while still maintaining consistency at the boundary of the far-field regime. Each simulation relies on Synergia with one major difference: the way in which particles interactions are computed. Specifically, following our integration of the FMM into Synergia, changes between PIC-based computations and FMM-based computations are made by simply selecting the desired method for near-field (and self) particle interactions.

## INTRODUCTION

The majority of numerical approaches for accelerator multiparticle-tracking solve the macroscale problem by employing Particle-In-Cell (PIC) methods [8–14]. These methods incorporate an Eulerian method for solving the necessary equations and Lagrangian techniques to advect particles through the domain (e.g., see Fig. 1).

Figure 1: PIC-based Hockney solver. Given a cloud of charged particles, iterate (1) Grid charge deposition; (2) Compute potential; (3) Compute forces at grid points; (4) Compute forces at particle locations.

Since space-charge modeling in high-intensity hadron beams for the accelerator physics community requires scal-

able and high-fidelity algorithmic approaches, all new computational approaches must (1) be inherently multiscale, (2) exploit locality, (3) reduce expense of non-locality while handling accuracy, (4) guarantee high accuracy when needed, and (5) handle a variety of complex geometries.

Reservoir Labs' MACH-B (Multipole Accelerator Codes for Hadron Beams) project addresses the above five key elements, maintaining the strengths of PIC codes and approaches while further improving upon some of their weaknesses, allowing domain experts to evaluate and optimize various scenarios for complex high-energy physics experiments. The MACH-B technology is based on both existing and novel mathematical frameworks, providing scalable, high-performance algorithms that will assist in accurately and rapidly computing a variety of complex particle accelerator simulations; specifically, (1) **Fast Multipole Methods (FMM)** and (2) **Boundary Integral Solvers (BIS)**.

## Introduction to Fast Multipole Methods

FMM approaches achieve linear scaling by separating near- and far-field interactions (e.g., see Fig. 2) on a spatial hierarchy using tree data structures. As they achieve arbitrary precision at modest cost with straightforward error estimates [1, 2, 4–6, 15–20], FMM techniques are well-suited for problems requiring high accuracy at large scales, such as in particle accelerator simulations.

Figure 2: (Left): A naive  $O(N^2)$  approach for computing the interactions between well-separated sources and targets. (Right): Using multipole and local expansions to reduce far-field costs, based on refinement.

FMMs are **inherently multiscale**, separating a regular domain into disjoint sets, using a tree structure to **exploit locality** as well as **reduce the expense of non-locality** through low-rank approximation multipole expansions [1, 4]. FMMs compute the total field at a domain  $B$  as the sum of (a) the field due to the sources contained in its near field  $\mathcal{N}^B$  and (b) its far field  $\mathcal{F}^B$ . Contributions from  $\mathcal{N}^B$  are computed using direct, dense summations, while contributions from  $\mathcal{F}^B$  are obtained by evaluating approximating expansion coefficients, constructed to achieve far-field low-rank approximations at computationally-efficient and provably-accurate levels of accuracy. Through two parameters ((1) for points per smallest grid in the hierarchy and (2) for number of coefficients in the expansions), **high accuracy is guaranteed** [2, 3, 21].

\* This work was supported by the U.S. Department of Energy as part of the SBIR Phase I Project DE-SC0020934.

<sup>†</sup> langston@reservoir.com

The FMM uses *upward* and *downward passes* on a hierarchical tree structure, employing multiple operators for converting expansion (multipole and local) coefficients to **achieve optimal  $O(n)$  complexity** (See Fig. 3 from [4]).

Figure 3: Local to Local (L2L), Multipole to Multipole (M2M) and Multipole to Local (M2L) operators translate coefficients efficiently throughout the FMM algorithm.

## INTEGRATING FMM INTO SYNERGIA

In this work, we focus on MACH-B's effort in integrating the FMM algorithm [1, 20] into Synergia [8, 9] for computing particle interactions as compared to existing PIC-based methods. We rely on the STKFMM from [15], itself a generalization of the highly-efficient PVFMM [6] implementation of the kernel-independent FMM [3–5, 19]. We chose this particular implementation of the FMM for two main reasons:

1. *Kernel-Independence*: rather than applying only to the Laplace kernel ( $1/r$ ), this version is kernel independent (in particular, it can handle any elliptic kernel).
2. *Computational Performance*: both the theory and implementation of this version are among the most performant currently existing.

Prior to the introduction of the FMM, Synergia offered two ways of computing interactions, both based on the Particle-In-Cell (PIC) method: `space_charge_2d_open_hockney()` and `space_charge_3d_open_hockney()`. All rely on Hockney's method (as seen in Fig. 1) and can be summarized as follows: given a cloud of charged particles,

1. *Grid Charge Deposition*: for each cloud particle, "deposit"/interpolate its charge on a regular uniform grid.
2. *Compute Potential*: compute the potential generated by charges from a grid point at all other grid points using the FFT (convolution with electrostatic kernel  $1/r$ ).
3. *Compute Forces at Grid Points*: compute 3D forces at each grid point using finite differences.
4. *Compute Forces at Particles*: interpolate force values from the uniform grid to the particle locations.

The FMM was integrated into Synergia such that changes from native PIC-based routines to FMM-routines are performed with minimal effort; currently, switching between methods requires merely changing one word in the name of the aforementioned functions to: `space_charge_2d_open_fmm()` and `space_charge_3d_open_fmm()`, respectively.

## Verifying Correctness of FMM in Synergia

To verify correctness and performance of each implementation, we perform to three different sets of experiments:

- *Test 1*: Compare Synergia's 3D Hockney uniform grid routine potential computations with a naive approach.
- *Test 2*: Compare 3D FMM routine potential computations with a naive approach (same grid as Test 1).
- *Test 3*: Compare 3D FMM, 3D Hockney (Synergia) and naive force computations on arbitrary point clouds.

The first two tests verify the correctness of each implementation, positioning random charges at uniform grid points. The potential at each grid point is computed using a naive ( $O(N^2)$ ) method and constitutes the ground truth against which we compare solutions. We limit ourselves to 32 points per dimension since computations through the naive method become to onerous beyond this point. Because particles are located at grid points, no interpolation is necessary for the PIC codes; hence, expected numerical accuracy for PIC-based methods matches that of the FFT itself (i.e.,  $\epsilon \approx 10^{-15}$  in double precision) as seen in Table 1.

Table 1: Test 1: Compare Synergia's 3D Hockney routine potential computations with naive approach on uniform grid. The PIC-based routine behaves as expected.

$G_{pts}$ per dim	Total $G_{pts}$	Rel. Err.
8	512	$4.56 \cdot 10^{-16}$
16	4096	$1.36 \cdot 10^{-15}$
32	32768	$3.78 \cdot 10^{-15}$

Test 2 is analogous to Test 1, except we employ the FMM for computing particle interactions rather than Synergia's PIC-based methods. The FMM is oblivious to charges abeing located at gridpoints. The FMM parameter,  $p$ , dictates its accuracy and computational costs; single precision can be expected with  $p \approx 8$  and double precision with  $p \approx 12$  while the latter takes about twice as long as the former. Table 2, shows results for different values of  $p$ , where it is observed that the FMM behaves as expected.

Table 2: Test 2: Compare 3D STKFMM routine potential computations with naive approach on uniform grid (same grid as Test 1). The FMM-based routine behaves as expected with higher accuracy as  $p$  is increased.

$G_{pts}$ per dim	Total $G_{pts}$	Rel. Err. ( $p=8$ )	Rel. Err. ( $p=12$ )
8	512	$4.95 \cdot 10^{-9}$	$1.91 \cdot 10^{-11}$
16	4096	$2.95 \cdot 10^{-9}$	$9.72 \cdot 10^{-12}$
32	32768	$2.97 \cdot 10^{-9}$	$5.16 \cdot 10^{-12}$

Test 3 compares the accuracy of Synergia's PIC-based methods and the FMM in a general case: a cloud of charged particles. For this purpose, we generate a 3D ensemble of

charges (positive/protons) containing up to 32768 particles and then compare to the naive solutions in Table 3. The FMM ( $p = 8$ ) achieves full (single) precision while the PIC-based method suffers from significantly lower accuracy due to interpolations and finite difference steps (Step 1, Step 3 and Step 4 from Fig. 1) associated with PIC codes. When particles, are not at grid points (as in Test 1) and forces must be computed, the error resulting from these steps becomes dominant.

Table 3: Test 3: Compare 3D STKFMM, 3D Hockney (Synergia) and Naive force computations on arbitrary point clouds. The FMM preserves its accuracy regardless of the particle distribution, whereas the PIC-based methods suffers from significant numerical errors associated with interpolation and finite differences.

$N_{particles}$	Param. ( $M/p$ )	Rel. Err. (PIC/FMM)
4096	32/8	0.228 / $1.28 \cdot 10^{-7}$
16384	32/8	0.166 / $2.07 \cdot 10^{-7}$
32768	32/8	0.141 / $2.66 \cdot 10^{-7}$
4096	64/8	0.180 / $1.28 \cdot 10^{-7}$
16384	64/8	0.141 / $2.07 \cdot 10^{-7}$
32768	64/8	0.123 / $2.66 \cdot 10^{-7}$
4096	128/8	0.116 / $1.28 \cdot 10^{-7}$
16384	128/8	0.106 / $2.07 \cdot 10^{-7}$
32768	128/8	0.0992 / $2.66 \cdot 10^{-7}$
4096	256/8	0.0587 / $1.28 \cdot 10^{-7}$
16384	256/8	0.0640 / $2.07 \cdot 10^{-7}$
32768	256/8	0.0656 / $2.66 \cdot 10^{-7}$

To these results, we note the following observations:

1. In the most general case (e.g., arbitrary particle clouds), the FMM offers greater accuracy and speed compared with PIC-based methods.
2. In special cases, including the case where the underlying solution is smooth (e.g., as the number of particles goes to infinity, i.e., Vlasov), PIC methods may exhibit higher accuracy (see tune depression case below), although such conditions may be difficult to verify.

## TUNE DEPRESSION SIMULATIONS

The ( $x/y$ ) *tune* of a particle is defined as the number of ( $x/y$ ) transverse oscillations a particle experiences per revolution around a closed-loop accelerator. Tune is heavily-dependent upon the nature of the accelerator lattice, but also depends strongly on the interactions between the particles (self-energy). For instance, researchers at Fermi Lab have shown an interesting relationship between the transverse ( $x/y$ ) offset of a particle's original position within a Gaussian bunch and its tune. Figure 4 shows the computation of the tune for particles with initial offset between  $0\sigma$  and  $5\sigma$  (measured in number of bunch transverse standard deviations:  $\sigma$ ) In particular, this figure shows the importance of self-interactions. Indeed, no changes in the tune are observed

Figure 4: Tune depression (Hz; x-transverse oscillations per turn) vs initial x offset. Results obtained using Synergia PIC routine for computing particle interactions.

when the interactions are neglected, while an interesting relationship is present when they are. This demonstrates the importance of particle-particle interactions in this context and, more generally, for accelerator simulations.

In the context of MACH-B, we study the difference between tune depression estimates obtained in Synergia from PIC versus FMM, adopting the following methodology: first, create a Gaussian bunch of size approximately  $10^{-5} \times 10^{-5} \times 10^4$  mm centered at the origin and containing approximately  $10^{10}$  physical particles (protons) and between  $10^4$  and  $10^7$  macroparticles depending on the situation (see below for more information about macroparticles). Each macroparticle is randomly assigned a position and momentum following a Gaussian distribution with mean 0 and covariance matrix specific to the lattice, chosen so that the overall shape of the bunch remains constant at each iteration. We introduce “spectator particles” with specific initial offsets to monitor the tune as a function of offset.

After initializing the particle bunch, we set the particles in motion and record the transverse position of each spectator particles after each turn (50 to 500 with  $10^1$  to  $10^2$  time steps per simulation). We extract the tune as a function of offset by taking the Fourier transform of the  $x/y$  transverse position as function of turn. The estimate for the tune is taken to be the dominant frequency identified using the resulting spectrum. Finally, we plot the relationship between the estimated tune and the original offset.

We reproduce the results obtained using PIC codes by using an FMM in its stead. Important differences are observed, however, and this leads to multiple key observations:

1. FMMs can reproduce observed results from PIC codes in the context of tune depression computations.
  - (a) FMMs faithfully capture the physical interactions between particles up to numerical accuracy, while PIC methods introduce a large degree of regularization (often desirable).

Figure 5: Tune depression (Hz; x-transverse oscillations per turn) vs initial x offset. Results obtained using FMM integrated within Synergia for computing particle interactions. PIC routines introduce more regularization than the FMM resulting in smoother (less noisy) estimates.

2. It is computationally necessary to use macroparticles to represent a particle bunch as the number of particles needed to capture the full dynamics ( $> 10^{12}$ ).
  - (a) The use of macroparticles requires the user to use a modified Laplace kernel for representing interactions with the FMM.
  - (b) The number of macroparticles and type of modified kernel affects results; i.e., regularization of the singularity at the origin has the largest effects.

These observations are important for understanding the advantages and disadvantages of using FMMs for particle accelerator simulations as detailed below.

### FMM vs. Tune Depression Simulations

As previously mentioned and shown in Fig. 5, we successfully reproduced the relationship between tune depression and initial particle offset within a Gaussian bunch using Synergia with an FMMs replacing PIC. However, results obtained using the FMM tend to be more noisy than those obtained using Synergia's native PIC methods.

This phenomenon is mostly due to the inherent regularization associated with PIC methods; the key for computational efficiency here is the use of the FFT, which leads to an  $O(N \log(N))$  scaling ( $N$  being the number of grid points) rather than a prohibitive  $O(N^2)$  scaling in the case of a naive computation. The use of the FFT, although efficient, comes at a cost: the use of a uniform (DFT) grid. The need to go between charges in an arbitrary configuration to (proxy) charges on a regular grid entails the use of interpolation (deposition) further introducing artificial regularization. Indeed, after deposition, two particles that were originally close to each other, and that would thus have exerted large forces upon each other, now find themselves much farther apart and thus exerting much weaker forces.

By contrast, the FMM can compute all interactions between particles with high numerical accuracy without the need for deposition, interpolation, or a regular grid or finite differences, thus avoiding regularization. In addition to preserving high accuracy, FMM costs remains low (i.e.,  $O(M)$  for  $M$  particles). It turns out, however, that this absence of regularization may not always be beneficial.

Indeed, in this specific case (Gaussian bunch), regularization proved beneficial as seen from the qualitative differences between the smoother curve in Fig. 5 and noisier one in Fig. 5. The main reason behind this is that the underlying true (asymptotic as the number of particles goes to infinity) solution for this particular problem is itself smooth. In this context, regularization can capture the underlying physics (one does not lose information by smoothing/regularizing since the solution is already smooth). By contrast, the FMM suffers from strong fluctuations due to small local charge density inhomogeneities that are negligibly small in the asymptotic solution (e.g., Debye screening).

While PIC-based regularization may be advantageous in certain contexts, it is, however, not always appropriate since its success ultimately relies on strong un-verifiable hypotheses regarding the underlying physics. Instead, the FMM offers a fast alternate approach to computing particle interactions without the need for such strong assumptions. While a potential introduction of noise in the estimated solution is possible, this noise can be controlled through the use of macroparticles and modified interaction kernels.

When the charge density is not homogeneous, or when the interactions between multiple bunches are considered, PIC methods are further disadvantageous: the rectangular domain covered by the regular grid needed must contain all particles present in a PIC simulation. However, for an inhomogeneous density, this results in potentially more grid points than particles (many having zero charge), and therefore an FFT cost (proportional to number of gridpoints) much higher than that of the FMM (proportional to the number of particles).

### Macroparticles and Incorporation into FMMs

Despite significant advantages of FMMs over PIC methods, it necessary to use macroparticles for large simulations purposes. *Macroparticle* is an all-encompassing term for a family of heuristics, by which the number of particles in a simulation is significantly reduced compared with the number of physical particles.<sup>1</sup> In Synergia, macroparticles are created through a smaller number of particles with larger charges. For instance, to perform a PIC-based simulations in Synergia using  $10^{12}$  physical particles of charge  $e$ , but only  $10^7$  macroparticles, one would simply create a simulation with  $10^7$  particles having charge  $\frac{10^{12}}{10^7} e = 10^5 e$ .

Although often appropriate, such simple macroparticles may not always capture physical phenomena appropriately. In this sense, a more suitable way of creating macroparticles

<sup>1</sup> Given their fewer numbers, the interactions between macroparticles *must* be modified if the solution is to represent a larger number of particles.

Figure 6: Tune depression ( $x$ ) vs original  $x$  offset for modified interaction kernel ( $1/(r+\delta)$ ) using simulations with  $6.4 \cdot 10^6$  physical particles and  $6.4 \cdot 10^4$  macroparticles. In Fig. 5,  $\delta = 10^{-2}$  was set while here, we set  $\delta = 10^{-5}$ . Note how less regularization leads to a much noisier outcome.

is through the use of a *modified interaction kernel*. Modifying the interaction kernel (electrostatic potential  $1/r$ ) by reducing the strength of the singularity at the origin, can be used to introduce regularization as well as to emulate the behavior of the particles in the asymptotic limit (e.g., local averaging, Debye screening, etc.). In MACH-B, we modify this kernel by adding a small positive quantity to the radius, so that the interaction kernel now takes the form:  $1/(r+\delta)$ , for some  $\delta > 0$ , mollifying the strong forces at the origin (responsible for noise) while behaving like a regular electrostatic potential far from the origin.

The parameter  $\delta$  can have a significant impact on the qualitative behavior of the solution for computing the tune depression in the previous section as shown in Fig. 6 as compared to Fig. 5. These figures show computations of the tune depression using the same bunch but with two different interaction kernel  $\delta$  values. Figure 6 effectively approaches the unregularized case, whereas Fig. 5 represents macroparticles that interact like point particles when far away, but produce much smaller forces when close by. In particular, note the how much smoother the results are when using even a minimal ( $\delta = 10^{-2}$ ) amount of regularization.

Macroparticles are not merely for computational convenience; their appropriate modeling is *necessary* for capturing the physics. For instance, for the tune depression simulations described in the previous section, one could simply try to reduce the number of physical particles rather introducing macroparticles. This, however, fails to generate the desired outcome as shown in Fig. 7 because a bunch with significantly fewer particles will behave significantly differently than a dense bunch. A dense bunch, however, cannot be simulated directly because too many physical particles are required.

Figure 7: Tune depression ( $x$ ) vs original  $x$  offset for a varying number of physical and macroparticles. In Fig. 6,  $N_{\text{physical}} = 6.4 \cdot 10^6$ ,  $N_{\text{macro}} = 6.4 \cdot 10^6$ , whereas here  $N_{\text{physical}} = N_{\text{macro}} = 6.4 \cdot 10^4$ . Note how using too few physical particles (or inappropriate macroparticles) fails to capture the appropriate behavior.

## CONCLUSIONS AND FUTURE WORK

In MACH-B, we have successfully integrated FMMs into the Synergia particle accelerator simulation software suite and have shown the correctness of our implementation and have provided information favoring the use of FMM in many cases, especially when higher accuracy is needed or when the underlying solution may exhibit strong variations.

In our tune depression studies, the advantages of the FMM in this case are salient. Indeed, our FMM algorithm is constructed in such a way that it can handle a much larger family of macro-particle interaction kernels than can PIC codes, allowing the user to introduce various kinds of regularization when appropriate, or to simply do away with any sort of regularization without loss of accuracy. By contrast, PIC codes *always* introduce a significant amount of regularization which nature is quite rigid and difficult to modify. The FMM also offers better scalings than PIC codes in many cases (e.g., multiple bunches).

As we continue to modify our kernels and incorporate them into additional PIC-related codes, we anticipate the FMM libraries will become powerful tools for domain scientists and researchers for study and cross-verification, largely due to their ease of use and modification.

## ACKNOWLEDGMENT

Thank you to Drs. Eric Stern and Qiming Lu at Fermilab for helpful conversations and guiding us through Synergia as well as Drs. Robert Ryne and Jean-Luc Vay at LBNL for many very fruitful discussions.

# STANDARDIZING A PYTHON DEVELOPMENT ENVIRONMENT FOR LARGE CONTROLS SYSTEMS \*

S. Clark, P. Dyer, S. Nemesure, BNL, Upton, NY 11973, U.S.A.

## Abstract

Python provides broad design freedom to programmers and a low barrier of entry for new software developers. These aspects have proven that unless standardized, a Python codebase will tend to diverge from a common style and architecture, becoming unmaintainable across the scope of a large controls system. Mitigating these effects requires a set of tools, standards, and procedures developed to assert boundaries on certain aspects of Python development — namely project organization, version management, and deployment procedures. Common tools like Git, GitLab, and virtual environments form a basis for development, with in-house utilities presenting their capabilities in a clear, developer-focused way. This paper describes the necessary constraints needed for development and deployment of large-scale Python applications, the function of the tools which comprise the development environment, and how these tools are leveraged to create simple and effective procedures to guide development.

## GOALS

Python has grown in popularity since its 1991 inception, with wide use in scientific and analytic applications. The myriad libraries released to simplify complex tasks — such as Numpy and SciPy for scientific calculations, and the PyQt5 user interface toolkit for application development — have driven increased adoption within the Collider-Accelerator Department (C-AD) Controls Group at BNL. As this adoption began, many developers created simple scripts scattered across the filesystem, which grew into operation-critical applications over many years. Long-term maintenance of these scripts is difficult for future developers who must now not only learn the codebase, but also the unique project structure and procedures of dozens of disparate programs. The primary goal of the Python development environment is to alleviate the manageability issues described above.

## PYTHON DISTRIBUTION

An essential requirement for Python usage in a large complex must be to establish a common base across all workstations. The Anaconda Python distribution provides exactly this, with each version containing a specific set of Python binaries and packages. Additionally, Anaconda is well-supported with first- and third-party tools to ease maintenance and deployment of distribution upgrades.

Initially, the Anaconda distribution was installed to a network mount which was globally available to all hosts, and any necessary packages (in addition to the standard set) were

installed directly upon request. However, two primary issues were encountered with this method: performance and maintainability. Performance issues appeared shortly after the adoption, which manifested in slow application launch times. Latency and bandwidth limitations over the network were discovered as the probable cause. Maintainability was further impacted by cascades of package upgrades triggered by new package installations, leading to previously-working scripts and programs breaking due to backwards incompatibilities unless careful intervention was taken during the process.

The deployment philosophy for the Anaconda distribution was changed to account for both issues. As mentioned above, inhibited performance was found to stem from network latency. During investigation, locally-installed copies of the Anaconda distribution showed a marked decrease in application launch time. Resulting from the discovery, the Anaconda distribution was moved from the network share to local disk on each host requiring Python. The tool `conda-pack` [1] facilitates this by allowing system administrators to create a portable clone of the Anaconda distribution which then can be extracted and installed locally on machines for use.

On a yearly schedule, the Anaconda distribution is rebuilt and redistributed. This provides an opportunity for Python and package upgrades, base package additions, as well as other general maintenance of the distribution. The newest distribution is constructed on a machine, tested for general compatibility, and finally deployed to all machines using the `conda-pack` tool as described above. Two local copies of Anaconda are maintained upon release of a new distribution — the new version and the prior version — guaranteeing Applications two years of first-class support, allowing developers to migrate to newer Anaconda releases at their own pace. Distributions prior to the two locally-kept copies are available on the network share. This limits the local disk usage by Anaconda versions, but reintroduced issues with network latency. This, however, should be mitigated if applications are regularly maintained and released using the latest available distribution.

## PROJECT CREATION & ORGANIZATION

A unified project architecture is key for ongoing maintainability and standardization of development procedures. The details of how projects are structured at the file level are equally important as aspects of development such as a standard package base, ensuring that developed procedures work equally across any project created within the development environment.

\* Work supported by Brookhaven Science Associates, LLC under Contract No. DE-SC0012704 with the U.S. Department of Energy

A custom utility, caddy, was created to ensure all projects follow a unified layout. Caddy is based on the open source Python package CookieCutter, which allows for the development of project templates consisting of boilerplate files and code for a project. The templates utilize a syntax which allows developers to insert values into the boilerplate based on input received when creating the initial project; these values, which may include the project name, author, and options to Git-version the project, modify both file names and contents to suit the new project. In addition to the basic project structure and contents, the templates may also optionally include a script to be run when a project is initially created. The development at C-AD heavily relies on Python virtual environments, so this post-creation script automatically spins up a virtual environment and installs base requirements upon project creation, as well as sets up a Git repository for the new project. Templates have been defined for several types of project bases — such as graphical user interfaces, command line applications, web applications — and placed into Git repositories for later reuse.

The templates used by Caddy were designed to conform to the Python Packaging User Guide (PyPUG). Following PyPUG allows all applications and packages to be installed into virtual environments; this simplifies development and deployment as is discussed later, and prevents potential lock-in that a nonstandard packaging system would introduce. Additionally, in-house packages which may benefit the broader community can easily be shared on package hosts like the Python Package Index.

The process of creating a project from a template has been automated by the Caddy script to ease barriers to entry and to minimize user error. The creation process consists of two parts: selecting a template, and defining values. The user is given a list of available templates obtained from GitLab, and makes a numerical selection for the desired project type. Then Caddy prompts the user for each variable used within the template and ensures valid values are given for each. Once complete, Caddy clones the template into a new directory specified at the prior prompt, performs template variable substitution, and runs the post-generation script associated with the template. At this point, the user is informed of the new project location and may begin development. The automation afforded by setting up projects through Caddy allows developers to focus less on project setup and boilerplate, and more on the business logic of the application. Refer to Fig. 1 for a demonstration of this process.

## VERSION MANAGEMENT

Version management is another critical piece of Python development given the speed at which programs evolve. When compared to other version control systems (VCS) such as ClearCase, Git provides three main benefits: free software, mature and complete implementations, and broad community support. These aspects make Git a modern, well-known, and cost-effective choice for development. Git offers a relatively simple set of core features which can be expanded

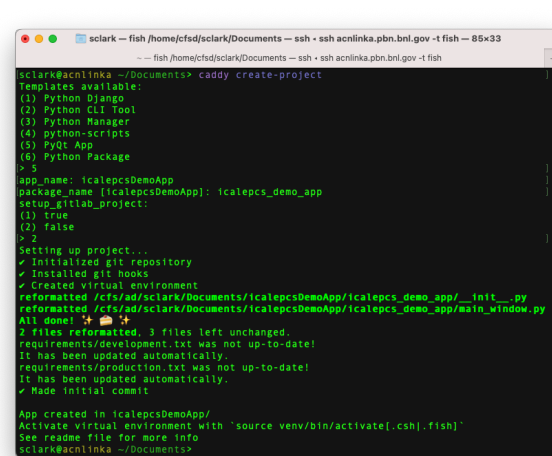

Figure 1: Use of caddy to create project, include template selection & variable definition.

upon over time, easing the learning curve for those new to Git.

A platform to host source code and version information is also required. Many solutions exist for Git-based repositories, and GitLab was chosen out of the offerings due to the availability of a free, self-hosted version of the platform, as well as additional project management features included in the platform. The self-hosted option offers greater control of the installation and data storage, while still allowing flexibility to migrate to an enterprise tier with additional features and commercial support. GitLab's primary feature, aside from version control, is a robust continuous integration and deployment (CI/CD) system. At C-AD, this has been leveraged to automate the building and deployment of Python packages and applications; this is further discussed below.

From a conceptual standpoint, a coherent version numbering system is necessary to facilitate tracking and upgrading various packages and applications within the development environment. The Semantic Versioning Specification (SemVer) was used, which operates under the principle that version numbers contain intrinsic meaning by defining major, minor, and patch revisions. For example, a package version v3.21.5 is known to be the 3<sup>rd</sup> major revision, 21<sup>st</sup> minor revision, and 5<sup>th</sup> patch revision. When used as defined in the specification, a change in the major revision indicates that the new release breaks backwards compatibility. Changes in minor or patch revisions must maintain backwards compatibility however, and either add new features or fix existing bugs, respectively. This standard allows developers to be aware of changes they may encounter when upgrading dependencies for a project, and also ensures the smooth installation of packages into virtual environments as is defined by the PEP440 specification used by Python. [2]

## DEVELOPMENT & DISTRIBUTION

### Applications

Applications created in the development environment must explicitly disallow untracked modification of released executables. Releasing Python source files directly to a writeable directory was initially viable; however, as programs increased in complexity, multi-file applications became unmanageable and prone to untracked changes. The following requirements for a Python application build system were identified: performance must be responsive for user-facing applications; all necessary files and any package dependencies must be bundled with the application; and changes to released applications must be made through version control to ensure all version history is tracked.

Various solutions were considered to bundle applications, including Python's native ZipApp module, Facebook's XAR technology, Pants build system's PEX, and LinkedIn's Shiv tool. ZipApp was ruled out as its limitations on inclusion of C-extension module created a cumbersome caveat for developers. [3] XAR showed initial promise in its ability to bundle all source files and dependencies, but was found inadequate due to the overhead of cutting-edge, OS-level dependencies which are unsupported by less recent Linux distributions. A significant trial was performed with PEX, but despite having all features necessary, launching of bundled executables was not performant enough for user-facing tasks due to reliance on the `pkg_resources` library. [4] Finally, Shiv was found marketed as a performance-optimized tool with all features offered by Pex. After many weeks of testing, Shiv was found to satisfy all feature and performance criteria.

Shiv allows applications to be released as pseudo-binary files, whereby all source code and dependencies are bundled into a ZIP file containing a specific syntax to allow execution by the Python interpreter. Since all contents are contained within a single archive, modification of released applications is more difficult than helpful; one would need to extract the archive, make changes, re-archive with the correct Python-specific syntax, and copy over the existing binary. This obfuscation enforces developers' use of version control for projects.

Further, since all applications bundle dependencies within the binary, different applications may rely on differing package versions. This gives developers additional flexibility to upgrade dependencies (or not), irrespective to the underlying Python distribution. Some larger dependencies, such as PyQt5, would greatly increase disk usage by executables if they were to be included in each archive, so often-used packages are included as a part of the Anaconda distribution so any application can access those packages without bundling them in the archive.

### Packages

Initial Python modules developed were released directly as source into a common directory on the `PYTHONPATH`, making the modules accessible to Python scripts system wide. This mode of development was easy, as no special setup was

needed to use them. But, as some breaking changes were introduced to these common modules, any dependent script or application broke immediately with no procedure to revert to a prior version. So a method to version custom packages — just as is done through the Python Package Index (PyPI) — was necessary.

The development environment, as mentioned previously, specifies that packages must be structured to conform to the Python Packaging User Guide. An effect of this is that packages are able to be built by the `setuptools` module into `tar.gz` archives for later installation. Using this capability, in-house packages are bundled into versioned archives when released; these act as snapshots of the package at release time. These bundles are then placed into a common directory and can be installed into other projects indefinitely, regardless of any future development or releases of the package. Pip, the Python package manager, was configured globally to search this common directory for packages when a user makes an installation request. Developers wishing to use first-party packages can install them into a project's virtual environment just as they would with any third-party package available through PyPI in order to enforce strict versioning, as opposed to making them available as a part of the Anaconda distribution.

cadpip compile --help
cadpip sync --help
cadpip switch --help

Options:
--help Show this message and exit.

Commands:
check      + Show list of outdated CAD packages in given setup.
compile    + Compile a setup, but do not switch to it.
index      - Show list of all available CAD packages.
info       - Show documentation in a browser for a CAD package or module.
install    + Add new package to requirements and switch to setup.
show       - Show list of installed CAD packages.
switch     + Compile a setup and switch to it.
sync       + Synchronize the environment to a setup.
uninstall  + Add new package to requirements and switch to setup.
versions   - Show all available versions of a CAD package.
scark@acnlminka: ~/D/icalpecsdemoApp (master)>
```

Figure 2: Various cadpip options for managing project packages.

Python's default Pip provides a very simple package management interface, but lacks any higher-level functions such as version conflict resolution or the notion of multiple package sets, such as for development and release. Various tools were considered for this task, such as Poetry and Pipenv, but were either immature or lacking in recent development at the time of investigation. So, a custom script `cadpip` was created to handle version resolution and package set management. Package requirements are defined in two files: `requirements/production.in` and `requirements/development.in`. Packages listed here can either be loose or pinned, meaning any version may be used or a specific version is required, respectively. Running the `cadpip switch {p,d}` command updates pack-

ages to the latest available versions which satisfy the constraints in the `production.in` and `development.in` files, respectively. It then uses `piptools` to bring the current virtual environment into sync with the selected package by adding, updating, and removing packages as necessary. The final set of package versions which were installed are then written to the files `requirements/production.txt` and `requirements/development.txt` depending on which package set a user chose; these files always contained pinned packages, and are used to exactly recreate the virtual environment when a project is either cloned or built. Refer to Fig. 2 for a sample of the tool's capabilities.

## RELEASING PROJECTS

GitLab's CI/CD feature is leveraged during the release process, as mentioned in the Version Control section, which hooks into Git procedures to trigger predefined actions on a remote server. The actions performed when a project is released include: optional unit testing with PyTest, building projects using either Shiv or `setuptools` (described above), and releasing the build artifacts to appropriate locations for use.

The benefits of using CI/CD as opposed to building and releasing locally are two-fold. First, projects being built are guaranteed to be in an unmodified environment. If a user were to build a project locally, modifications to the Python environment may impact the end product, such as packages installed in the home directory or changes to the `PYTHONPATH` environment variable. CI/CD ensures that the build environment is unchanged by running builds in a sandboxed virtual environment under a dedicated account which maintains the default settings. So, if tests pass and a package builds, it can reasonably be expected that the application or package will work on any machine setup with the Anaconda distribution used for the build. Additionally, by executing all build and release procedures from a dedicated account, the paths applications and packages are released to may remain read-only to other users to prevent any modifications.

Bringing together semantic versioning with the CI/CD process is a lightweight shell script, `git release` (as shown

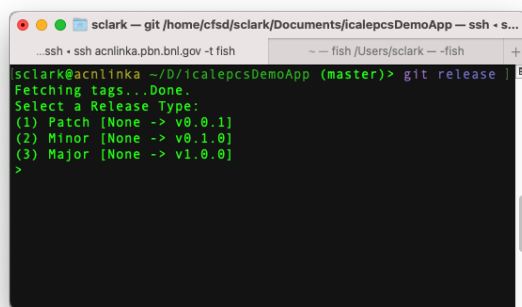

Figure 3: `git release` prompting for version selection prior to releasing software.

in Fig. 3). `git release` makes the release process as simple as a prompt for users. It parses the Git history to find the most recent release number, and calculates new version numbers for major, minor, and patch releases. The user may select one of the three, which `git release` then tags the most recent commit with and pushes to GitLab. This formally kicks off the release process, at which point `git release` displays a progress bar tracking the build process from GitLab. If any errors occur, they are also printed to the console for inspection.

# DevOps AND CI/CD FOR WinCC OPEN ARCHITECTURE APPLICATIONS AND FRAMEWORKS

R. P. I. Silvola, CERN, Geneva, Switzerland

L. Sargsyan, A. Alikhanyan National Laboratory (former YerPhI), Yerevan, Armenia

## Abstract

This paper presents the Continuous Integration and Continuous Deployment (CI/CD) tool chain for WinCC Open Architecture applications and frameworks developed at CERN, enabling a DevOps oriented approach of working. By identifying common patterns and time consuming procedures, and by agreeing on standard repository structures, naming conventions and tooling, we have gained a turnkey solution which automates the compilation of binaries and generation of documentation, thus guaranteeing they are up to date and match the source code in the repository. The pipelines generate deployment-ready software releases, which pass through both static code analysis and unit tests before automatically being deployed to short and long-term repositories.

The tool chain leverages industry standard technologies, such as GitLab, Docker and Nexus. The technologies chosen for the tool chain are well understood and have a long, solid track record, reducing the effort in maintenance and potential long term risk. The setup has reduced the expert time needed for testing and releases, while improving the release quality.

## INTRODUCTION

The CERN Industrial Control Systems Group of the Beams Department (CERN BE/ICS) [1] provides support and software solutions to the SIMATIC WinCC Open Architecture (WinCC OA) [2] community for setting up SCADA applications. This includes general infrastructure (cryogenics, electricity, radiation protection, etc) as well as controls for the experiments, and associated institutes. The group provides a CERN specific distribution of WinCC OA, repackaging the software released by ETM Professional Control, a Siemens AG subsidiary. In addition, the group develops and maintains WinCC OA applications, as well as frameworks for building such applications, and for connecting them to the CERN IT infrastructure.

The WinCC OA software catalogue supported by the group spans hundreds of applications and two frameworks composed of a large set of components, totalling up to millions of lines of source code written in multiple languages, including C++, PL/SQL, CTRL – which is a WinCC OA proprietary scripting language, and others. Many of these projects are required to run on both Linux and Windows, increasing their complexity.

While the code itself has always been kept in a central repository, the procedures for building a release, including compilation, packaging and deployment to our package repositories, were left to the developer in charge of each individual project. This approach meant that each component was built in a different way, and releases were only possi-

ble to be done when the expert was present. Much of this was standardized by the introduction of ARES [3], yet the approach taken was in a way upside down, requiring many manual steps for releases, leading to automated commits to the repository. This required developers to change contexts each time a release was to be prepared, be it for validation or for production, and the automated commits resulted in unnecessary pollution of the commit log, making it hard to read.

While ARES greatly simplified and automated releases, there was a disconnect between development and releases. The tools used for the release infrastructure were based on technologies poorly understood by framework developers, which lead to recurrent delays while debugging issues as the ARES expert intervention was required. The tooling, while advanced, was designed with Java projects in mind, which differ radically from WinCC OA and Frameworks development.

To alleviate these issues, a deep look was taken into the development processes, and based on it, a new set of tooling was designed and put in place. The resulting DevOps processes and CI/CD infrastructure are described in the next sections.

## WORKFLOW

Deciding on a workflow (see Fig. 1) for development with git, the industry “standard” git flow was adopted, later morphing closer to the GitHub flow [4]. For any given project the master branch is considered stable, yet not necessarily production quality. There is no development branch, simply bug fix and feature branches, all of which tend to be short-lived. The frequent merges promote targeted and granular development, reducing the occurrence and probability of complicated and time-consuming merge conflicts.

To start development for a bug fix or a feature, the developer manually creates a ticket in the ticketing system. The name of that ticket is then used as the branch name. On that branch each commit produces a release that can be passed on for validation by users. Once a merge request is created, unit tests are automatically run, and each subsequent push will trigger a new set of tests to be executed. After a review and with the tests successful, the branch is merged into master, resulting in a snapshot build. A tag produces a release that is automatically deployed into an array of repositories. All the steps of the process can be performed either from the command line interface, or from a single browser tab.

For a developer this is a natural workflow, while GitLab [5] allows for less technically minded people to create releases as well, after a short training session.

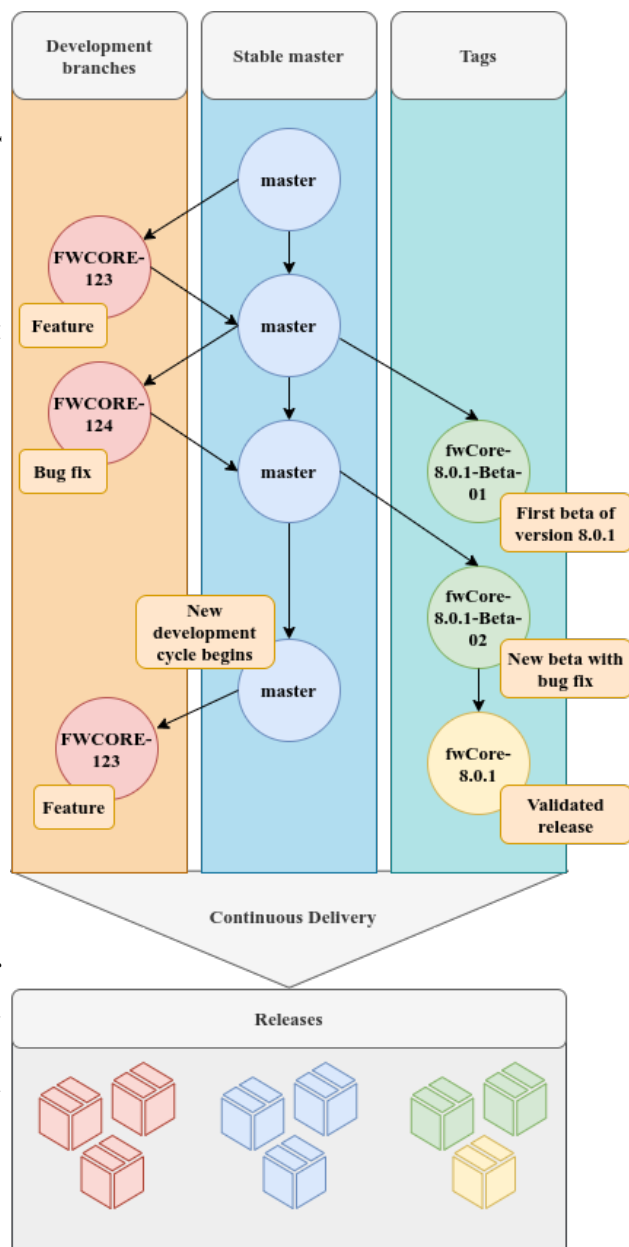

Figure 1: Example of the workflow.

## RELEASE GENERATION

**RELEASE GENERATION** The automation of the processes is achieved by use of GitLab Pipelines, executing jobs on private hosts with Docker [6] executors, which run custom Linux images loaded with WinCC OA and a set of custom tooling. For certain quality assurance tasks other images are used to leverage newer tools. These images themselves are produced also with GitLab on the very same runners, as explained below.

### CERN WinCC Open Architecture

The CERN WinCC OA Service repackages WinCC OA for Windows and Linux, in order to add in certain CERN-wide customizations – including in house license fulfilment

and Oracle Database integration. This repackaged distribution is provided to the CERN WinCC OA community. As a future part of critical infrastructure, each release must be thoroughly validated to meet the highest QA standards. For this, the software package is installed on a clean production-like system, and specific common operations are executed, including creating applications and running processes. The validation has been completely automated for Linux with the use of containers, and as a final product of each automated release pipeline, a set of development and test container images are released. These are then used to compile executables developed at CERN, build components, and test further integrations.

### CERN WinCC OA Framework Components

The compilation and packaging process of WinCC OA Framework components often requires careful setting up of environments, making it close to impossible without the component expert present. This problem was furthermore difficult to tackle since in the past the binaries were all stored in the version control system.

As a part of the migration to git and GitLab, all binaries were stripped from the repositories and their compilation was shifted to the release pipeline, utilizing the standard development container image. Any libraries and other build time dependencies thus must be pulled in automatically during the build, removing dependency on a single developer's environment, or their knowledge on how to recreate it.

Building the binaries from source just prior to packaging ensures they match the source code in the repository, and that no local changes make it to any component or framework release. Each release is tagged with the git revision hash, and the source code is publicly available.

After compilation, the release pipeline (see Fig. 2) passes on to the build stage, where the tooling generates documentation and manuals, updates the component XML specification used for installing them, and packages it all into a zip file. Passing into the test stage, several QA jobs are run to find issues earlier in the development cycle, producing a stable and well tested set of components for deployment.

### Kobe

Kobe is the tool built to automate framework and component releases. It was originally envisioned as a leaner version of ARES, allowing for continuous builds either on GitLab or locally on the developer's system. It is built on common, historically stable and commonly used GNU/Linux tools and bases its logic on information available in the repository and in the pipeline. It has since its conception grown to do much more, including generation of Online Qt documentation integrated into WinCC OA, as well as rich PDF manuals, using  $\text{\LaTeX}$  templates, and Markdown.

Kobe produces fully framework compatible components with a guaranteed unique version number for each branch, tag and revision. Releases follow a specific format with the component or framework name, the version number and an optional beta or release candidate suffix. The lack of either

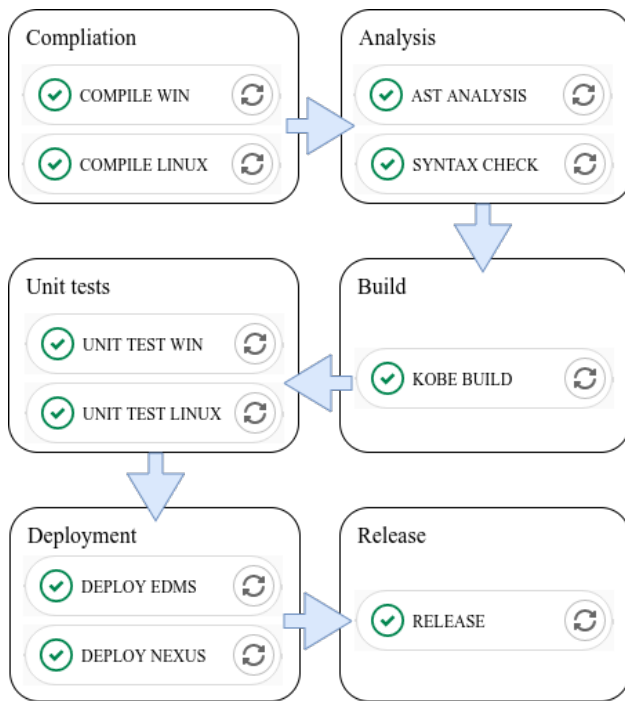

Figure 2: Example of a release pipeline.

suffix indicates a final release of that version, leading to the packages of components from these pipelines getting labelled accordingly, and to be released in to the appropriate repositories – after having passed through automated tests. These unique versions and suffixes allow dependable identification of deployed versions, thus reducing the ambiguity what has been deployed.

### CERN WinCC OA Frameworks

Frameworks are built in very much the same way, simply as a collection of components. The collections are specified with a configuration file and Kobe automatically pulls the the components from the appropriate repositories. This could be from a GitLab job, a Nexus [7] repository or from EDMS [8].

During active development, the latest snapshot builds are included into the framework snapshot distributions, which are triggered at the end of each component snapshot pipeline. To ensure the possibility to generate new versions of the full framework at any time in the future, the versions included for framework beta and final releases are locked and pulled from mid- or long-term repositories.

## QUALITY ASSURANCE

Quality assurance is an integral part of the CI/CD pipeline, and includes both static analysis as well as unit tests. For C++, abstract syntax trees are analysed against thousands of carefully selected rules from publicly available rule sets, including MISRA [9], HIC++ [10] and Fuchsia [11], among others, and a report is produced and made available in a centralized reporting tool. This allows us to identify hidden bugs and vulnerabilities, as well as code duplication and smells, all with historical trends. As abstract syntax trees are

only possible with compiled languages, a different approach is taken for CTRL by analysing it with WinCC OA's own syntax checker. The results are transformed into standards compliant reports, visible with details directly in the GitLab Pipeline UI. In the future it is planned to have these also integrated into centralized reporting tool.

Unit tests implemented according to specifications drawn up together with the component responsible and users' feedback are included in weekly containerized component tests, daily full stack integration tests on physical machines as well as triggered full framework tests of the JCOP framework [12] and the Unified Industrial Control System and Continuous Process Control framework (UNICOS-CPC) [13]. A CERN custom interface to WinCC OA and a framework unit test component are used to automate the tests. A clean application is instantiated in a container, with the set of components to be tested. The test results generated by the unit test component are likewise in standards compliant format and thus visualized directly on GitLab Pipeline UI. They are also fed into the centralized reporting tool, improving their visibility.

## DEPLOYMENT

Once packaged and tested, components and frameworks are deployed to repositories. Each repository serves its own purpose, and depending on the type of release, it is routed to a different one, completely automatically.

### GitLab

For active development, GitLab job artifacts act as the short-term repository. With GitLab API [14] they can be pulled programmatically either to a project, or to build a framework. Based on Amazon S3 [14] compatible object storage, the releases are quickly available, and are stored generally for a week. The artefacts of the latest job are stored indefinitely, as are the artefacts of tags – i.e. betas, release candidates and final releases.

### Nexus

All betas, release candidates and final releases are automatically deployed to Sonatype Nexus repositories. We do not take advantage of staging repositories, as that purpose is served by GitLab's object storage. Nexus repository is a mid-term repository and is available in parts of the CERN network, but not outside of it, nor is it available in the experiment networks. Thus, it is mainly used for validation and pre-production tests.

### EDMS

Final releases are deployed to EDMS, our most long term document repository ( more than 30 years ). It is also the most accessible one, available in all CERN networks – experiments included – and outside of CERN. The ARES EDMS client is used for the deployments to EDMS, as it greatly simplifies the tasks needed to follow EDMS release workflows. Improvements to the tool have been made to allow

better diagnostics of deployments and the document statuses, increasing its robustness.

## NFS

According to previously mentioned requirements we will now provide details about hardware used and specifications.

## INFRASTRUCTURE

GitLab, provided as a service by CERN IT Department, is used as the backbone of the CI/CD infrastructure as illustrated on Fig. 3. The integrated container registry is used to store container images, and the UI is used to configure all of it. CERN GitLab Service also provides public runners, which are sufficient for most jobs. WinCC OA development and testing however have very specific requirements, necessitating the use of private runners.

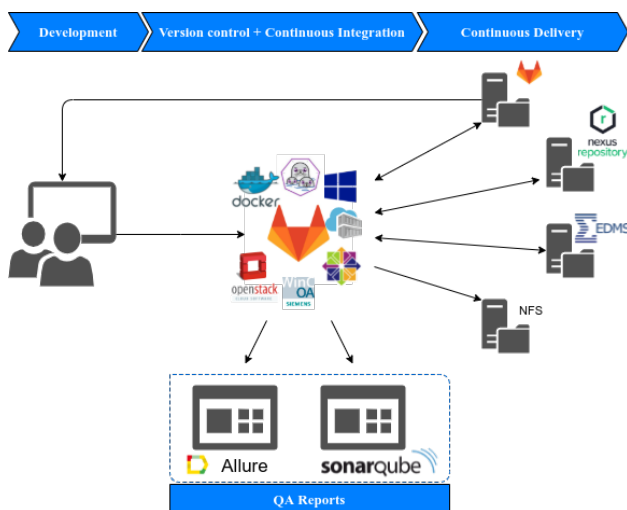

Figure 3: CI/CD infrastructure.

For lightweight jobs, OpenStack [16] Linux and Windows virtual machines are used. Setting up private runners on them guarantees availability for our frequent jobs as well as optimizes the pulling of containers – which are fairly large when loaded with WinCC OA. This has also allowed exploratory work towards alternative container based custom executors which will be necessary for the future operating systems.

For heavier tasks bare metal servers are necessary. Repackaging of WinCC OA distributions for Windows and Linux are I/O heavy processes that take over an hour on virtual machines, yet happen in just minutes on dedicated hosts. Our full stack integration tests benefits as well from their dedicated bare metal runner, as the tests require a full production-like system with connected devices, including PLCs, to run tests on multiple levels, from low-level front-ends to middle-ware and SCADA integration.

Exposing a bare metal system with a shell runner to a common GitLab instance is a compromise in security, and great care is taken to strictly restrict their access.

## CONCLUSION

Approximately twenty-five thousand framework snap-shot releases, triggered by a matching twenty-five thousand component snapshot releases, and hundreds of thousands of more development releases have been produced since we started deploying Kobe build infrastructure in the late summer of 2018; not counting hundreds of betas, release candidates and production releases of component and frameworks. All of these releases have passed automatic tests in containers running the latest releases of WinCC OA, which themselves were generated and tested automatically by our CI/CD tooling.

This is an increase of two orders of magnitude from the old automatic release service, while reducing the effort for the developers to close to zero, saving thousands of hours of work only in releases, not to mention the increase in quality of the software. What used to be an error prone and complicated procedure involving multiple different web applications, now takes all of writing ‘git tag’ and pushing the tag to GitLab. For snapshot and development builds, pushing the sources to GitLab is all there is to it, making it a natural part of development.

The developers thus benefit from a more natural, development-oriented workflow, while the users gain more frequent releases, shorter lead times and simply a better tested end product, all with publicly available reports and up to date documentation.

The quality of support has also improved as we can guarantee version uniqueness, as well as provide instant test releases for any bug fixes, to be validated in production-like environments, while being clearly tagged as development releases. Trusted users can even create merge requests, which will immediately provide them with a usable release of the component.

The added control and improved quality assurance of the strict and replicable release flow also improve the operational safety and security on the organizational level, while further security tooling can now be easily integrated.

With conventions and templates, we have arrived at a highly standardized and unified system. This is not to say everything is the same, and that there are no exceptions.

Most compilations are configured with qmake, on Windows and Linux, yet some developers have preferred to stay with pure make or CMake builds. This knowledge of build system is however abstracted away by scripts and templated pipelines, and while debugging a failing compilation might require expert knowledge, most development can be done by junior developers with limited experience.

Further customizations are also made available through environment variables, allowing for custom repository structures and non-standard naming conventions, among other things. While we approach near complete unification of our conventions in the group, as the tool is being adopted by experiments and application groups around CERN, legacy structures and conventions need to be supported, and as with any software, further improvements will always be needed.

The success of the project hinged on the continuous involvement of the entire team. Their contributions ensured the fit for our needs, and what was seen was a true integration of new and existing tooling and processes. The team's involvement also ensured the project's adoption, and its ever-continuing improvement.

# DEVELOPMENT OF A SINGLE CAVITY REGULATION BASED ON MicroTCA.4 FOR SAPS-TP

W. Long<sup>†</sup>, X. Li, Y. Liu, S. H. Liu

Institute of High Energy Physics Dongguan Campus, Chinese Academy of Sciences, Dongguan, China

## Abstract

A domestic hardware platform based on MTCA.4 is developed for a single cavity regulation in Southern Advanced Photon Source Test Platform (SAPS-TP). A multi-function digital processing Advanced Mezzanine Card (AMC) works as the core function module of the whole system, it implements high speed data processing, Low-Level Radio Frequency (LLRF) control algorithms and an interlock system. Its core data processing chip is a Xilinx ZYNQ SOC, which is embedded an ARM CPU to implement EPICS IOC under embedded Linux. A down-conversion and up-conversion RTM for cavity probes sensing and high-power RF source driver can communicate with AMC module by a ZONE3 connector. A hosted tuning control FPGA Mezzanine Card (FMC) combines both the piezo controlling and step-motor controlling functions for independent external drive devices. The design of the hardware and software of the platform electronics and some test results are described in this paper. Further test and optimization is under way.

## INTRODUCTION

The SAPS-TP is next to the China Spallation Neutron Source (CSNS) which is located at Dongguan City, Guangdong Province in China. It is an innovative research platform for advanced accelerator and X-ray technologies serving Southern Advanced Photon Source (SAPS) which will be built as a 4th generation light source based on diffraction limit storage ring, and the CSNS II which is the upgrade of the CSNS. It is mainly composed of a superconducting RF hall, an optical experiment hall, a low temperature hall, a high-accuracy measurement hall and a comprehensive laboratory [1].

The superconducting RF hall is about 3500 m<sup>2</sup>. It has 2 vertical test pits and a horizon test station can be applied for assembling and test of the 324 MHz spoke cavity, 648 MHz elliptical cavity, 500 MHz elliptical cavity and 1.3 GHz elliptical cavity, etc.

The function of the single cavity regulation includes amplitude and phase stabilization controlling of cavity field, resonance controlling, continue waveform (CW) or pulse mode conversion and fast interlocking, etc.

MTCA.4 system is the new generation embedded digital hardware platform specifically for high energy physics applications. It is a modular, open standard architecture with high reliability, which is becoming more and more popular, and widely used in European X-ray Free Electron Laser (XFEL), European Spallation Source (ESS) and Stanford Linear Accelerator Center (SLAC), and so on.

A domestic hardware platform based on MTCA.4 is developed for SAPS-TP single cavity regulation. The system

architecture and the development of hardware platform based on MTCA.4 are described in this paper.

## SYSTEM ARCHITECTURE

The single cavity regulation for SAPS-TP is mainly used to control to RF field and the resonance frequency of the cavity. The block diagram of the system design is shown in Fig. 1.

Dedicated RF power source (klystrons or solid-state amplifier (SSA)) is used to feed the cavity with required input power. In the RTM module, the forward and reflected power signals, the cavity pick-up signal and the reference RF signal are down-converted to intermediate frequency signals using analog mixers driven by local oscillator signal (LO).

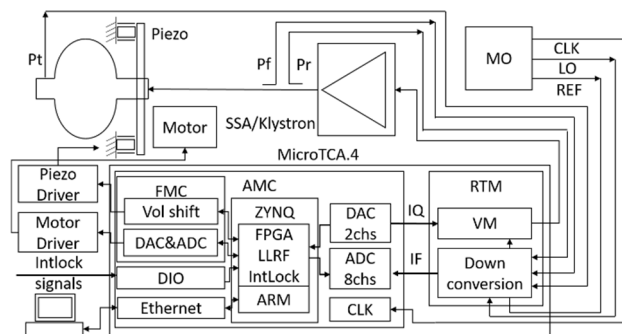

Figure 1: Design of single cavity regulation for SAPS-TP.

The LLRF system implements the cavity RF field controlling feedback loop to keep the RF field amplitude and phase stability [2, 3].

The master oscillator provides RF synchronization signals, such as the reference signal (REF), LO signal and the clock (CLK). In the AMC module, the intermediate frequency signals are sampled by ADCs with the frequency of CLK. Next, the raw data are demodulated to in-phase (I) components and quadrature (Q) components with the IQ or no-IQ algorithm. Errors between setpoint values and detected values are sent to PI controller. The digital I/Q output of PI controller are sent to DACs and are converted to analog I/Q signals. The baseband I/Q signals are then mixed with the in-phase and quadrature-phase components of a REF signal whose frequency is located at the required RF frequency to generate final RF excitation signal. This process is called up-converted which implemented by the vector modulator device of the RTM module.

The superconducting cavity is very susceptible to small changes in dimension, because of its very narrow RF resonance bandwidth. The equipped mechanical tuners can tune the cavity to a resonance frequency. There are two types of tuners, the slow tuners are based on step motors, and the fast tuners are based on piezo elements. The LLRF

system implement the cavity resonance frequency controlling feedback loop to compensate the cavity detuning caused by reasons such as Lorentz force and microphonics and so on. The digital frequency control output is composed of step motor control signals and piezo control signals. In FMC card, the digital step motor control signals from AMC module are converted to 5 V pulse signals which be sent to step motor driver, and the digital piezo control signals are converted to 0~10V analog signals by ADCs which be sent to piezo driver.

The LLRF system also implement cavity quench detection. The others interlock signals are connected to the digital IO port of the AMC module front panel such as arc, vacuum, temperature, water flow, etc. All the interlock signals are connected to the interlock system which also implemented by the FPGA of the AMC module for fast protection. The RF excitation can be turn off quickly, and the output interlock signal will switch off the RF switchers of the RTM module to cut off the excitation quickly too.

The hardware platform based on MTCA.4 is being developed. It mainly composed of the following devices :

- A domestic AMC module.
- A Module Management Controller (MMC) mezzanine Card.
- A tuning control FMC card.
- A down-conversion and up-conversion RTM module.
- A domestic MTCA.4 chassis including the two 1.6 kW power modules (one for redundancy) and 2 Cooling Unit (CU) modules.

The first version AMC module and the MMC mezzanine card have been produced and tested. The Design of the tuning control FMC card has been finished and is going to be produced. It is based on low speed and high precision DACs and ADCs, and level shift and voltage translation circuit. The RTM module has 8 down-conversion channels and 1 up-conversion channel. It has been developed and produced by the colleagues in the project group. The designed down-conversion RF frequency range is from 300 MHz to 4 GHz, IF frequency range is from 5 MHz to 100 MHz, and up-conversion RF frequency range is from 200 MHz to 4 GHz. Now, its test and optimization of the RTM module is under way. A domestic MTCA.4 chassis including two 1.6 kW power modules and 2 CU modules has been produced by our cooperation manufacturer. Its functional test is finished and the power ripple index need to be improved.

## DEVELOPMENT OF AMC MODULE

We developed a domestic multifunctional digital processing AMC module which is shown in Fig. 2. It is expected to be used for vertical and horizontal tests of RF cavity in SAPS-TP, and can also meet the requirements of different systems in CSNS II and SAPS, such as RF system & Control system & Beam diagnostic system.

The AMC module has good compatibility. It is conforming to MTCA.4 standard and the zone3 IO connector assignment class A1.1 CO with double-width mid-size dimensions. The AMC module provide 4-lane PCI Express Gen3 interface connected to port 4~7 of the backplane to

realize high speed data transmission with other AMC modules. It also realizes 1GbE Ethernet interfaces (Port 0~1), point-to-point link interfaces (Port 12~15), M-LVDS interfaces (Port 17~20), TCLKA, TCLKB and FCLKA which conform to standard MTCA.4 backplane topology. So, it can work very well as part of a large system based on MTCA.4. What makes it special is that we designed the AMC module and expected that all the digital functions of a single cavity regulation can be finished by one AMC module. So, there is no need to communicate through high-speed serial buses, and the delay of control system is reduced.

Figure 2: Domestic digital processing AMC module.

It has 8 channels ADCs and 2 channels DACs. The Analog Devices AD9268 ADC chip with maximum sampling rate up to 125 MHz and 16-bit resolution is chosen for IF signals sampling. Its analog input bandwidth is 650 MHz, which enable this ADC chips can also be used for 324 MHz or even up to 648 MHz direct sampling applications. A compatible analog front end is designed to adapt to different applications. All the ADC input channels can be configured to AC coupled or DC coupled which be routed to the different differential pairs (TF or PA) of the Zone3 connector conforming to DESY Zone3 class A1.1 CO assignment.

The DAC chip is Analog Devices AD9783. Its dual DA architecture facilitates easy interface to common quadrature modulators. Its sampling rate is up to 500 MHz, and has 16-bit resolution. This chip is widely used in CSNS RCS RF system and its performance and stability has been tested.

Because the ZYNQ SOC IO resources is very limited, all the digital interface of AD and DA chip are DDR LVDS interface, so 2 channels can share a group of IO pins.

The core data processing chip is a Xilinx Zynq-7000 SOC system-on-chip. The ZYNQ SOC combines a dual core ARM processor, with a traditional FPGA logic fabric. The single silicon chip can be used to implement the function of an entire system rather than several different physical chips being required. In the single cavity regulation, an EPICS IOC runs in PS part of the SOC which is the ARM processor for remote control, and a LLRF algorithm and interlock system runs in PL part of the SOC which is the FPGA. The data communication between FPGA and ARM

processor is carried out through AXI bus inside the ZYNQ SOC chip. It simplifies the architecture of hardware greatly, and saves the PCB space which is important to AMC module, because it is not very big.

The Ethernet interface connected to ARM CPU is used for network communications such as remote control and monitoring.

The clock tree is designed to realize the synchronization of signals on board. The clock source can be chosen from the internal crystal oscillator or external input clock signal. There are three input methods for the external clock:

- The front panel clock input.
- The RTM\_CLK clock signal from RTM module.
- The TCLKA/TCLKB clock signal from backplane.

The AMC module is designed with ultra-low clock jitter. We expect that the phase error will be smaller than  $0.1^{\circ}$ , if a 648 MHz direct sampling application based on it.

A 12-channel jitter attenuator SI5394 is used to perform jitter attenuation, and two LTC6950 frequency synthesizer are used for clock distribution. The total theoretical clock jitter is about 170 fs RMS, but not yet be tested due to the unfinished adapter RTM module.

An FMC connector is provided which fully compatible with the FMC Low Pin Count (LPC) standard. It is mainly designed for multi-channel step motor controlling and piezo controlling, and maximally compatibles with commercial FMC boards such as DFMC-AD16 and DFMC-MD22, etc. It is also extended with 3 additional high-speed serial ports of High Pin Count (HPC). So, the interface can also compatible with some usual 4 channel fiber communication FMC card.

The front panel digital IO on LEMO 00 connector has 10 pins and conform to 3.3 V LVTTTL standard which can be used for external trigger and interlock signals.

A 4 channels QSFP cage is provided in front panel. And each channel can be used separately for timing, timestamp, interlock signals and optical fiber communication.

This AMC module has 2 GB DDR3 memory size (1 GB memory connected to ARM CPU, 1 GB memory connected to FPGA).

The block diagram of the AMC module is shown in Fig. 3.

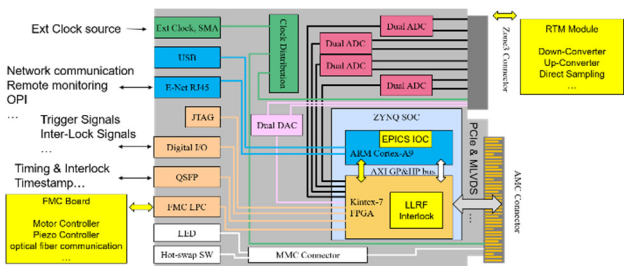

Figure 3: The block diagram of the AMC module.

Because the RTM module is being tested and optimized yet, performance of the AMC module is tested with the compatible signal conditioning input card SIS8900 RTM module and a developed adapter RTM module.

The Fast Fourier Transform (FFT) spectrum of the ADC is shown in Fig. 4.

Figure 4: FFT spectrum of ADC.

The results of Signal-To-Noise Ratio (SNR) measurement are from 75.9 dBFS to 76.2 dBFS, and the results of (Spurious-Free Dynamic Range) SFDR measurement are from 86.2 dBFS to 92.1 dBFS.

To test channel isolations, we feed IF signals with different frequencies into the two adjacent channels, and the FFT spectrum of a channel is observed by spectrum analyser. The cross talk signal from the adjacent channel can be observed. The results of the isolation test is shown in Table 1.

Table 1: The Results of Isolation Test

[dB]	Ch0	Ch1	Ch2	Ch3	Ch4	Ch5	Ch6	Ch7
Ch0	-	76.0	-	-	-	-	-	-
Ch1	84.3	-	80.9	-	-	-	-	-
Ch2	-	75.2	-	77.1	-	-	-	-
Ch3	-	-	82.2	-	80.8	-	-	-
Ch4	-	-	-	87.3	-	79.5	-	-
Ch5	-	-	-	-	78.9	-	85.6	-
Ch6	-	-	-	-	-	94.8	-	85.1
Ch7	-	-	-	-	-	-	78.1	-

We also tested the performance of DAC. The result of SNR measurement is 78.1dB, but there are some bigger harmonic components. The analog circuit behind the DAC output is going to be optimized.

MMC MEZZANINE CARD

The MTCA.4 system provided a remote and centralized health management service for the modules in chassis which is based on the Intelligent Platform Management Interface (IPMI) specification. The MicroTCA management architecture is mainly realized by a MicroTCA Carrier Management Controller (MCMC) and MMC controllers which connect each AMC module to Intelligent Platform Management Bus (IPMB) based on I<sup>2</sup>C. MMC controller is a very important part of the AMC module. Without the MMC controller, AMC module will not be detected and identified by MicroTCA system, and the payload power will never be provided for it.

We developed, based on N.A.T NAMC-MMC-Reference Design, a MMC controller mezzanine card for our AMC module. It can be connected to the AMC module by a 40 pins connector. Considering the difficulty and the development time. There are 3 phases of our development:

- Firstly, both the hardware and software are based on the reference design.

- Secondly, we had developed our own MMC controller software.
- Thirdly, we'll going to design and develop our own MMC controller including all the hardware and software.

We test the MMC controller with the nVent 3U commercial MTCA.4 chassis and NAT-MCH-PHYS80 MTCA Carrier Hub (MCH). Module operational state management, hot swap management, Light-Emitting Diode (LED) management have been tested, and all these functions work very well. The AMC module can be detected and fed with payload power normally. And we also did the voltage sensors and temperature sensors reading test and the temperature threshold event test, all these functions work well too.

The design of MMC controller software is divided to three layers. At the bottom, there is the driver layer including I<sup>2</sup>C drivers, voltage sensor drivers and temperature sensor drivers. All the values of sensors are periodically read into a pool which is a list of arrays. The middle layer implements the state machines for module status switching, hot swap management, LED management and threshold event management, etc. The top layer is in charge of IPMI communications including protocol packet parsing and building. This design of software architecture provides many conveniences for debugging and maintenance. So, for MMC testing, a fake temperature threshold event IPMI package can be easily built and send to MCH which will control CU module to increase speed of fans to decrease the AMC module temperature.

The MMC mezzanine card and its test bench are shown in Fig. 5.

Figure 5: MMC mezzanine card and its test bench.

## SOFTWARE DEVELOPMENT

An embedded Linux is developed for the Zynq7045 SOC chip based on open-source Linux kernel source and the Xilinx PetaLinux tools. The experimental physics and industrial control system (EPICS) Input/Output controller (IOC) application Demon is also developed and tested. The

Demo of EPICS IOC has 3 types of Process Variables (PVs) which are used to test reading and writing of FPGA registers and reading of waveforms respectively. The data of waveform PV is transferred from FPGA via Direct Memory Access (DMA). A Xilinx AXI DMA intellectual property (IP) core manages and controls the high-speed transmission the data from FPGA to ARM. It be configured to simple mode to fetch data from a FIFO. A user defined IP is developed to control the AXI DMA timing and provide the interface between user data and the Xilinx AXI DMA. The Linux DMA driver for Xilinx AXI DMA is developed based on Xilinx DMA proxy driver which is an open source code and can be download from Xilinx web site. The device support waveform PV realizes the user space operation of DMA based on the Linux DMA kernel module. The entire system including the EPICS IOC demo is no more than 100 MB and can be loaded via a Secure Digital Memory (SD) card for convenient debugging.

## SUMMARY

This paper mainly describes the system architecture of the single cavity regulation for SAPS-TP which will be build based on MTCA.4 hardware platform, the hardware and software design and development of platform electronics. The hardware platform has good compatibility and extensible. The developed domestic AMC module provides rich functions and standard extension interface. It is expected to constitute a complete single cavity regulation control system including RF field controlling, resonance frequency controlling and interlock system with the tuning control FMC card and a down-conversion and up-conversion RTM module. There is no need to communicate through high speed serial buses, the system architecture is simplified and the delay of control system is reduced.

# R&D STUDIES FOR THE ATLAS TILE CALORIMETER DAUGHTERBOARD \* †

Eduardo Valdes Santurio<sup>‡</sup>, Samuel Silverstein, Christian Bohm,  
Suhyun Lee, Katherine Dunne, Holger Motzkau  
Stockholm University, Stockholm, Sweden

## Abstract

The ATLAS Hadronic Calorimeter DaughterBoard interfaces the on-detector with the off-detector electronics. The DaughterBoard features two 4.6 Gbps downlinks and two pairs of 9.6 Gbps uplinks powered by four SFP+ Optical transceivers. The downlinks receive configuration commands and LHC timing to be propagated to the front-end, and the uplinks transmit continuous high-speed readout of digitized PMT samples, detector control system and monitoring data. The design minimizes single points of failure and mitigates radiation damage by means of a double-redundant scheme. To mitigate Single Event Upset rates, Xilinx Soft Error Mitigation and Triple Mode Redundancy are used. Reliability in the high speed links is achieved by adopting Cyclic Redundancy Check in the uplinks and Forward Error Correction in the downlinks. The DaughterBoard features a dedicated Single Event Latch-up protection circuitry that power-cycles the board in the case of any over-current event avoiding any possible hardware damages.

We present a summary of the studies performed to verify the reliability of the performance of the DaughterBoard revision 6, and the radiation qualification tests of the components used for the design.

## INTRODUCTION

The instantaneous luminosity at HL-LHC will be increased by a factor of five compared to the LHC. Consequently, the read-out systems of the ATLAS detector [1] will be exposed to higher radiation levels and increased rates of pileup. The current electronics for the read-out system of the ATLAS Tile Calorimeter (TileCal) will not be able to handle the new requirements imposed by the HL-LHC. R&D work is ongoing to upgrade the TileCal electronics with a new design that will provide continuous digital read-out of all the calorimeter cells with better energy resolution, improved timing and less sensitivity to out-of-time pileup [2]. The upgrade R&D work requires Total Ionizing Dose (TID), Non Ionizing Energy Loss (NIEL) and Single Event Effects (SEE) tests to be performed on the upgraded on-detector electronics, to qualify the design as reliable for the HL-LHC radiation environment.

## ATLAS TILE CALORIMETER

TileCal is a sampling calorimeter with plastic scintillator tiles and steel plates as active and absorber materials, respectively. TileCal is longitudinally divided into four cylindrical barrels (Fig. 1b) each comprising 64 wedge-shaped modules (Fig. 1c). Scintillator light is collected on each side of a pseudo-projective cell by wavelength shifting fibers and read out by a pair of PMTs.

Figure 1: (a) The ATLAS detector. (b) A TileCal barrel. (c) Depiction of a TileCal wedge-shaped module.

## THE TILECAL HL-LHC UPGRADE SYSTEM

The TileCal HL-LHC upgrade on-detector electronics will continuously sample data from all TileCal PMTs at 40 MHz by means of 896 independent modules, so-called MiniDrawers (MD). Each MD servicing up to six pairs of

PMT channels, each pair sampling the light coming from the same TileCal cell. Each PMT signal is conditioned, shaped and fed into amplifiers with low- and high-gain by a Front-end electronics (FENICS) card, before they are digitized by a MainBoard (MB, Fig. 2). A read-out link and control DaughterBoard (DB) receives and propagates LHC synchronized timing, control and configuration to the front-end, while transmitting continuous read-out of the MB channels to the off-detector systems. Each MD is independently powered by radiation tolerant Low Voltage Power Supplies (LVPS) sitting on-detector and designed to withstand the radiation requirements of the HL-LHC.

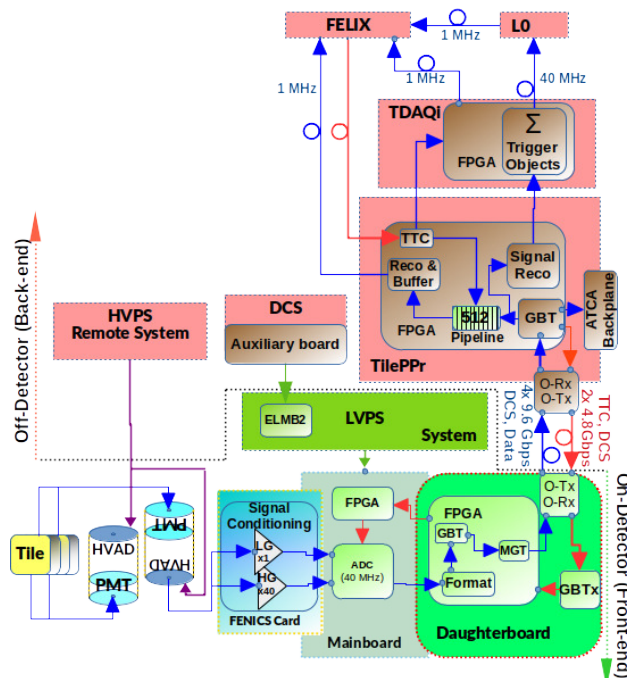

Figure 2: Block diagram for the On-Detector and Off-Detector electronics.

On the off-detector, Tile Processors (TilePPrs) receive the PMT digitized data and store it in pipelines (Fig. 2). The TilePPr will send all the digitized data to the Level 0 (LO) trigger system through the Trigger and DAQ interface (TDAQi) at 40 MHz, and the Front-End Link eXchange (FELIX) system will read-out data stored in the TilePPr pipelines at 1 MHz if a trigger decision is made. The power will be controlled, monitored and distributed to the on-detector electronics by the Detector Control System (DCS) interfaced LVPS, while the High Voltage Power Supply (HVPS) remote system will provide high voltage to the High Voltage Active Dividers (HVAD) sitting the PMTs.

The front-end electronics of TileCal include multiple, complementary test and calibration systems. These are the charge injection system (CIS), the laser calibration system and the Caesium (Cs) source calibration system. The CIS sends electronic pulses with configurable amplitude can be injected into the system in order to test the behaviour of

the digitization and read-out chain of each channel over its full dynamic range. The LASER system distributes short, controlled light pulses over optical fibres to the light mixers of the PMT blocks to allow measurements of individual PMT gains of each PMT in the absence of collisions. The Cesium system uses radioactive  $^{137}\text{Cs}$   $\gamma$  sources that are moved hydraulically through water-filled tubes that pass through each scintillating tile in the calorimeter, producing strong, slow signals read by a separate read-out path is implemented with a slow integrator circuit read-out by ADCs sitting in the FENICS cards.

## THE DAUGHTERBOARD REVISION 6

The DB Revision 6 (DB6, Fig. 3) design aims to solve the radiation tolerance issues found in the previous revision while incorporating a more robust timing design and extra features that will allow minimizing single points of failure one step further. The DB6 consists in a radiation tolerant and electrically redundant board that serves as a hub that interconnects the on-detector and off-detector electronics of the HL-LHC TileCal Upgrade System by means of four Small Form-Factor Pluggable+ (SFP+) modules and a 400 FPGA Mezzanine Card (FMC) connector. A block diagram for the design of the DB6 is shown in Fig. 4. The design consists in equal and electrically independent halves, each capable of servicing the six PMT channels that correspond to the half of the MD interfaced with the DB.

Two CERN radiation-hard GBTx ASICs will receive two GBT-FEC protected 4.8 Gbps downlinks with LHC synchronized clocks and configuration commands. Each GBTx recovers two 160 MHz good quality LHC synchronized clocks in order to drive the GTH transceivers of both FPGAs, two 40 MHz Trigger, Timing and Control (TTC) synchronous clocks to drive the relevant logic of the KU FPGAs, and four 40 MHz TTC phase configurable clocks to drive the digitizing blocks and calibration signals on each MD quadrant. Two Xilinx KU XCKU035 FPGAs powered by TMR capable firmware provide continuous GBT-CRC protected words to the four 9.6 Gbps uplinks with all the Detector Control System (DCS) and PMT digitized data. The DB6 design allows nominal running with at least one working downlink and two working uplinks. By means of the FMC connector interface, the KU FPGAs send all the front-end configuration commands and phase-configurable LHC synchronized clocks and receive MB power monitoring information, data from slow current integrator ADCs that sit in the FENICS cards, and samples of two-gains of the signals coming from each PMT digitized by fast ADCs sitting on the MB. Additionally, two buses will allow communication between FPGAs from both halves of the DB, a slow bus (CommBUS) powered by IDDR/ODDR IOs and a high speed 9.6 Gbps bus powered by interconnected GTH transceivers (GTHBUS), allowing signal monitoring, in addition to trigger commands and data interchange between both FPGAs. The DB6 features two Microsemi ProASIC FPGAs to control the remote KU FPGA resets, manage the

Figure 3: The DaughterBoard revision 6.

Figure 4: The DaughterBoard revision 6 block diagram.

initialization of the GBTxs and the KU FPGAs, and buffer the JTAG interface signals received from the off-detector by the GBTx that allow remote reconfiguration of the KU FPGAs and their attached FLASH memories. Additionally, the DB6 design includes an xADC header per FPGA for extra analogue sensor monitoring capabilities, and digital ID serial chips for unique MD half identification.

The firmware of the KU FPGAs are in charge of reading out the dual-gain PMT digitized data and formatting it into GBT-CRC protected words. The firmware has a complex clock and timing scheme with multiple clock inputs from various sources such as the two GBTxs, an oscillator and the six ADCs sitting on a MB half. Some of these clocks are being asynchronously multiplexed depending on the availability of the GBTx links. The DB6 design routing was optimized to take advantage of the Ultrascale dedicated XYPHY BITSlice byte groups architecture [3]. The bit and flame clocks, and high-gain and low-gain serial data signals coming from each ADC channel will be routed

to the same byte XYPHY BITSlice group. The byte groups used for each specific are 1 or 2, since they contain the dedicated Global Clock Capable IO pins (GCIO) that allow direct access to the Phase Locked Loops (PLLs) and the Mixed-Mode Clock Manager (MMCM) of the bank, and assures that there is no congestion with more than 6 clocks driving IO loads on any half bank. Figure 5 shows the scheme followed for the clock input distribution and the routing of signals of the ADCs and other relevant time-dependent data paths to the different banks. This scheme makes sure that successful timing-closure is easier to achieve during firmware implementation. The DB6 firmware has been under development and extensive testing has taken place in different testbenches and a test beam by interfacing DB6 prototypes to various prototype versions of the TileCal HL-LHC Upgrade system. The experience accumulated from the previous revisions and prototypes of

Figure 5: Distribution of clocks, ADC read-out pins (bit\_clock, frame\_clock, hg\_data and lg\_data), GTH transceiver signals, Configuration BUS (configbus) interface, TTC phase configurable clocks to drive the digitizing blocks and calibration signals on each MB quadrant (ttc\_clock, tpl/tpb) and other clock dependent modules for the DB6 Xilinx KU XCKU035 FPGA.

the DB was used as a baseline guide for the DB6 firmware that is currently in active development. Core functionalities have been successfully implemented in the firmware such as stable 4.6 Gbps downlinks and 9.6 Gbps uplinks interface with the TilePpr, ADC read-out, CIS signals, slow ADC Integrator system readout and front-end configurations.

## RADIATION TOLERANCE STUDIES FOR THE DAUGHTERBOARD 6 DESIGN

Previous revisions of the DB were tested for TID, NIEL and SEE to verify the radiation tolerance of each iteration for the HL-LHC era. The main driver for selecting the components to us in the board are the Xilinx FPGAs because of their importance in the functionalities of the design and weight in the end-price of the production of the boards. Three generations of the Xilinx Kintex family were studied. The fourth revision of the DB (DB4) was powered by 28 nm planar Kintex 7 (K7) FPGAs, the fifth revision by 16 nm FinFET Kintex Ultrascale+ (KU+) FPGAs, and DB6 by 20 nm planar KU FPGAs. The strategy followed for Single Event Upset (SEU) appearances in Xilinx FPGAs rests in using the Xilinx Soft Error Mitigation (SEM) IP Core in the firmware implementation. The Xilinx SEM detects,

classifies and corrects SEUs for the configuration memory. Not all the SEUs can be corrected, those classified by the SEM as uncorrectable are planned to be mitigated by using Triple Mode Redundancy (TMR) and partial reconfiguration whenever possible in the firmware, and where none of the previous solutions is possible an FPGA total re-configuration from the attached FLASH memory will be triggered. The K7 FPGAs were sufficient for the radiation requirements of the TileCal for the HL-LHC with manageable SEU rates where manageable with the fluences simulated at the time when the tests were performed [4]. However, there was a need to migrate to a different transceiver architecture because of the bandwidth gap present in the K7 GTX transceivers. It was expected that migrating to smaller feature size such as the ones of KU and KU+ would reduce the cross section for the Single Event Upsets (SEUs) of the FPGA chosen.

The KU+ FPGAs present in the DB5 feature GTY transceivers that allow 9.6 Gbps communication with full compatibility with the LHC timing [5]. The DB5 design proved to withstand up to 20 kRad of TID, being enough to qualify it for the HL-LHC lifetime within the radiation doses simulated as reported in the ATLAS Tile Calorimeter Phase-II Upgrade Technical Design Report [2]. However,

Figure 6: Current monitoring data corresponding to SEL tests with protons at 226 MeV performed on two Trenz TE0841 micromodules (marked as Trenz KU FPGA 1 and Trenz KU FPGA 2), a Microsemi A3PE starter kit, and a Lattice ICEBLINK LP1K evaluation board. The irradiation took place over seven runs, each signalized in the red boxes with (\*x) followed the corresponding deposited TID dose. Note that values for the measured currents for TrenzTE0841\_VCCIOB, TrenzTE0841\_VCCIOC, and TrenzTE0841\_VCCIOD are quite close to the current values for the ICE40LP1K\_5V0. Therefore, the aforementioned channels are not visible in the plot [6]

new dose estimates were obtained by new simulation runs performed with updated geometry. The new values established that to qualify the DB5 design, new TID tests had to be performed up to either 72 kRad or to 14.4 kRad if the test included annealing. The SEU tests resulted in 4934 SEUs over a fluence of  $2.05 \times 10^{11}$  protons  $\text{cm}^{-2}$ , of which only 11 SEUs could not be corrected by the Xilinx SEM. The uncorrectable SEU rates predict that  $1.4 \pm 0.4$  uncorrectable errors are expected per DB per year. Between the Xilinx SEM and the TMR it is expected that correctable SEUs will not affect nominal runs. The DB5 SEE tests showed that the KU+ 16 nm FinFET technology is susceptible to Single Event Latch-ups (SEL) with SEL-fluence rate increased from  $2 \times 10^{-11}$  SEL-fluence rate at 58 MeV to  $2.36 \times 10^{-10}$  rate at 226 MeV protons [6]. The over-currents due to the latch-ups did not cause any noticeable damage, however SELs are highly undesirable. Hence, the solutions to mitigate SELs are to add an over-current protection to the design and migration to an SEL-resistant FPGA. Xilinx FPGAs require a specific power-on sequence and the implementation in DB5 was done by means of an RC circuit.

The KU FPGAs present in the DB6 design are powered by GTH transceivers, which are compatible with the 9.6 Gbps communication required by the TileCal HL-LHC Upgrade system. According to the published studies during the time, no SELs were seen in the 20 nm planar Xilinx FPGAs. Two Trenz TE0841 boards (each with the same KU FPGA used in the DB6 design), a Lattice ICE40LP FPGA and a ProASIC3E A3P31500 FPGA were irradiated with 226 MeV protons to verify for SEL sensitivity up to a target fluence of  $1.11 \times 10^{12}$  p/cm<sup>2</sup>, covering eight times the fluence simulated for 10-years of HL-LHC. During the test, all the currents of the FPGAs were monitored (Fig. 6) and no SELs were detected. The LCMXO2 CPLDs present in the TE0841

boards for buffering the JTAG chain used to configure the KU FPGAs failed due to TID effects. As a consequence only rough estimates of the SEUs could be obtained through the Xilinx SEM over two runs: 2 uncorrectable errors and 2333 correctable errors for a rate of 166 soft errors per  $10^9 \times \text{p/cm}^2$ .

In the case of the ProASIC3E A3P31500, the firmware started failing at around 57 kRad of TID or 75% of the total fluence with no recovery after power cycling. As reported by Actel, the firmware functionality was fully recovered after a long process of annealing and the VPUMP of the FPGA was permanently damaged making the reconfiguration of the chip permanently unavailable [7]. The Lattice ICE40LP FPGA firmware failed after approximately  $10^9 \text{p/cm}^2$  of the delivered fluence. The firmware functionality was recovered on-site by reconfiguring the FPGA from the attached FLASH memory after power-cycle.

Even though no SEL occurrences are expected in KU FPGAs, it was decided to integrate an SEL current limiting circuitry in the chain of DC-DC converters used in the power sequence scheme of DB6. This circuitry will power off the whole DC-DC converter chain of the half of the DB where one of the voltages gets a high current drain. This solution will increment the robustness of the board by avoiding potential damages to the FPGAs and other components on the presence of isolated unexpected SELs or overcurrents originated by any power failures. Additional radiation induced problems potentially caused by the use of large electrolytic capacitors at the DC-DC regulators used in previous revisions of the DB are being mitigated by the use of conductive polymer capacitors, which have been observed to be radiation tolerant with no impact to performance after 200 kRad at 500 rad per hour [8].

The KU FPGA offered a good compromise in SEU rates ranging between K7 and KU+ and no SEL sensitivity up to the HL-LHC simulated fluences. Therefore, two DB6 prototypes were produced to do TID tests to the full design. The two DB6s (DB6-1 and DB6-2) were irradiated by means of a  $^{60}\text{Co}$  source at the CERN CC60 facilities. Each of the DBs was exposed to different dose rates and different dose targets. DB6-1 was irradiated to 220 Gy at a “fast” rate of 3.37 Gy/h and DB6-2 was irradiated to 52.6 Gy at a “slow” rate of 0.33 Gy/h. The KU FPGAs and all the board currents were monitored for each of the voltages, putting special interest in detecting any failures on the eight Coretek SFP+, the four KU FPGAs, the four Microsemi ProASIC3 FPGAs and the reconfiguration FLASH memories. A baseline firmware was programmed in the ProASIC FPGAs and in the KU FPGA attached FLASH memories. After the irradiation period, both DBs were extensively tested in testbenches and none of the aforementioned components were damaged by the deposited TID.

Figure 7: DB6-1 Current monitoring during 220 Gy (22 kRad) of TID exposure at 3.37 Gy/h (0.337 kRad/h).

During the DB6-1 TID exposure (Fig. 7), it was discovered a strong correlations between temperature and current in 0.95 V. An increase in current was measured in the 0.95 V of both sides at around 140 Gy. During the setup a fan was situated to keep the temperatures of the FPGAs steady during the irradiation period. The fan active components started to fail at around 140 Gy, leading to the increase of temperature on the FPGA during the rest of the irradiation period. The 0.95 V supplies the VCCRAM and the VCCINT for the core of the KU FPGA, making the currents drawn

Figure 8: DB6-1 correlation between current and temperature for the 0.95 V channel of both DB halves fixed to a second polynomial degree regression.

from this voltage more sensitive to any temperature change in the FPGA.

A correlation between the 0.95 V current and the FPGA temperature was found by fitting the data to a second degree polynomial regression (Fig. 8). A convolution to the original data was done then to find the expected 0.95 V current behaviour for an exposure with constant temperature (Fig. 9). In each half the temperature value chosen for the convolution was the temperature measured on each FPGA when the test started.

In the case of DB6-2 (Fig. 10), all the currents and the temperatures were stable during the full run.

## CONCLUSIONS

The DaughterBoard is the read-out link and control board that interfaces a TileCal MD and the off-detector electronics. The current revision of the DaughterBoard (DB6) fulfills the radiation requirements for TID and SEE imposed by the HL-LHC. The DB6 improved the radiation tolerance of the previous designs that includes the SEL sensitivity issues of DB5, by migrating the design to the non-SEL sensitive 20 nm planar KU FPGA, adding extra protection to mitigate any overcurrent appearances and using conductive polymer capacitors. The studies performed on SEUs showed that even though the KU+ FPGAs offer a better SEU rates, the preliminary rates measured in the KU FPGAs are a good compromise for a design where SELs are unacceptable. To fully qualify the DB6 for the HL-LHC radiation requirements a dedicated SEU test and NIEL tests need to be conducted. Around 930 of the

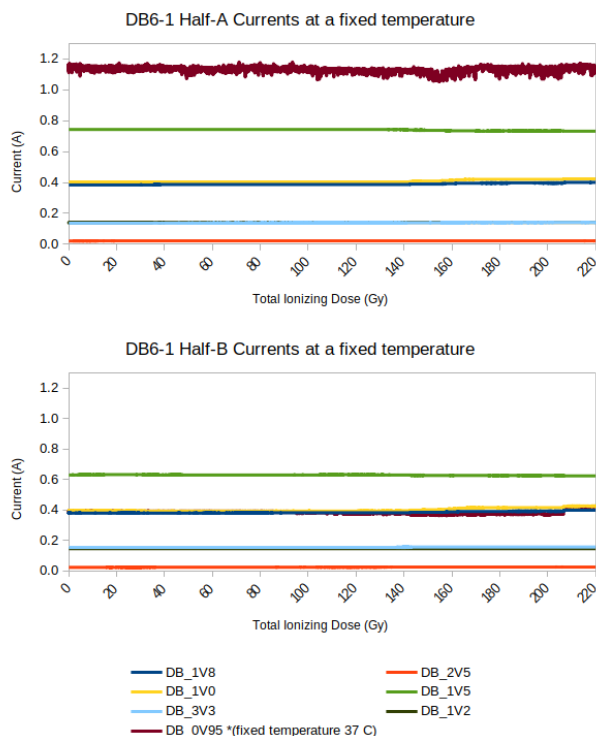

Figure 9: Expected DB6-1 Current monitoring during 220 Gy (22 kRad) of TID exposure at 3.37 Gy/h (0.337 kRad/h) with constant temperature. Only the current measurements for the 0.95 V voltages were corrected for temperature, the correction was done following the initial temperature value measured at the start of the test.

redesigned DaughterBoards will be produced for Phase-II as the contribution of Stockholm University to the the ATLAS Upgrade for the HL-LHC era.

## Abstract

As part of the Compact Muon Solenoid (CMS) experiment, the Electromagnetic Calorimeter (ECAL) Detector Control System (DCS) is undergoing a large software and hardware upgrade during the second long shutdown (LS2) of the CERN Large Hadron Collider (LHC). The DCS software running under the WinCC Open Architecture (OA) platform, required fundamental changes in the architecture as well as several other upgrades on the hardware side. The extension of the current long shutdown (2019-2021) is offering a unique opportunity to perform more updates, improve the detector safety and robustness during operations and achieve new control features with an increased modularity of the software architecture. Starting from the main activities of the ECAL DCS upgrade plan, we present the updated agenda for the LS2. This covers several aspects such as the different software migrations of the DCS, the consolidation of toolkits as well as some other improvements preceding the major ECAL upgrade foreseen for the next long shutdown (2025-2026).

## INTRODUCTION

The CMS (Compact Muon Solenoid) [1] experiment at the CERN Large Hadron Collider (LHC) is a general multi-purpose detector designed primarily to probe proton-proton and heavy ion collisions. The detector is built around a huge superconducting solenoid of 6m internal diameter providing a magnetic field of 3.8 T. A silicon pixel and strip tracker, a lead tungstate crystal electromagnetic calorimeter and a brass scintillator hadron calorimeter are located within the solenoid volume. Muon detectors are embedded in the steel flux-return yoke outside the solenoid.

The electromagnetic calorimeter consists of about 76,000 PbWO<sub>4</sub> scintillating crystals and a lead/silicon preshower. The detector is conventionally sub-divided in three main partitions: Barrel (EB), Endcaps (EE) and preshower (ES). The EB is organised in 36 super-modules forming a cylinder around the proton-proton interaction point. Each super-module contains 1700 crystals arranged in four modules. The EEs are the structures which close both ends of this cylinder with each of them formed by two half disks named DEEs and containing 3662 crystals. The ES consists of two circular structures placed in front of the EEs. More details on the CMS ECAL detector can be found in [2].

The challenging constraints on the design of the ECAL required the development of a complex sophisticated Detector Control System (DCS). The ECAL DCS has successfully supported ECAL operations since the commissioning phase of the detector contributing to an efficient data collection during Run 1 and Run 2 operations. Detector maintenance at CMS closely follows the LHC calendar with major upgrades postponed to special times, known as the Extended Year-End Technical Stops (EYETS) and the LHC Long Shutdowns (LS). We are currently in the second major long shutdown LS2 [3] since the start of the LHC. Initially planned to last two years until April 2021, due to the ongoing COVID-19 pandemic the LS2 was extended by one year. During the LS2 both hardware and software upgrades were performed, as described in [4]. In this paper we focus on the software upgrades, including the software migration which allowed the ECAL DCS to be up-to-date with the latest versions of the control platform and frameworks.

This paper is organized as follows. After describing the CMS ECAL DCS, we describe the software upgrade performed during LS2 where different upgrades are reported in four subsections. An additional section reports on the reorganization of the notification system of the ECAL DCS, which also took place during LS2. Finally, we summarize the contents in the last section.

## THE CMS ECAL DCS

The ECAL DCS was designed to ensure an autonomous control and monitoring of the working conditions of the ECAL detector and to guarantee the detector is properly powered and able to collect data when the LHC is operational. The ECAL DCS is organised according to the detector services it provides, where the latter can be categorized in four different groups: powering services, safety services, environmental monitoring services (humidity and temperature) and external services. The ECAL DCS architecture is schematically shown in Fig. 1.

The DCS software supervises the interaction among the different subgroups mentioned above and runs on three DELL blade servers installed with the Windows Server 2008 R2 operating system. A redundant software replica is also available in the event of a critical failure of the primary system. The DCS software is assembled via the commercial WinCC Open Architecture (WinCC OA) control system toolkit from ETM [5] along with CERN software frameworks known as JCOP Framework [6] and components developed by the Central CMS DCS team [7]. Industry standards, as OPC Data Access (OPC DA), Modbus and

\* on behalf of the CMS Collaboration

<sup>†</sup> luigi.marchese@cern.ch

S7 protocols for hardware communication are used. As part of such ECAL DCS migration described in this paper, the OPC DA servers have been migrated to OPC Unified Architecture (UA) servers.

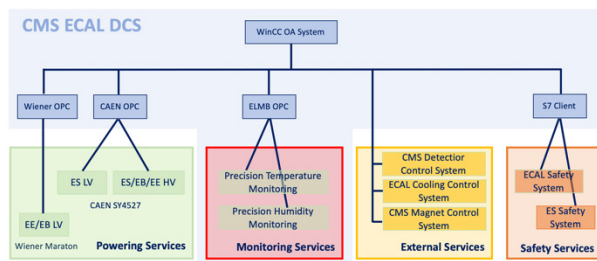

Figure 1: ECAL Detector Control System (DCS) architecture including its connection with other services. Inspired by [5].

Commands are sent to the ECAL subsystems via a Finite State Machine (FSM) [9], the core of each control system at the LHC. Thanks to a logical grouping of DCS subsystems into a hierarchical tree-like structure, the FSM enables a simplified representation of the DCS by introducing a set of defined states for each detector partition, for instance state ON/OFF for the ECAL EEs, and specific rules to move from one state to another. Within this architecture, the state of each sub-component is clearly summarized at higher level and high-level commands can be propagated down to individual ECAL partitions in a controlled way. This allows process variables to be summarized in a single-human-readable state and control commands to be implemented by a shifter in the CMS Control Room without a detailed expertise of the underlying hardware.

## SOFTWARE MIGRATION

During the current long shutdown, the ECAL DCS had to go through some software migrations which can be subdivided into three types: WinCC OA and JCOP control framework migration, OPC UA migration and control system migration. They are described in more detail in each of the subsections below. Following these migrations, an additional review of the DCS software was also needed, as reported in the final part of this section.

### *WinCC OA and JCOP Control Framework Migration*

This migration was centrally coordinated by the CMS DCS team, as part of a CMS-wide plan to accommodate all the CMS DCS software with the latest release of the control platforms. The plan was discussed and agreed internally in CMS in the first half of 2020. The final CMS migration took place in July 2021 with a few validation tests performed in April and June 2021 during a few days of ECAL operations.

The ECAL DCS was migrated from WinCC OA version 3.15 to version 3.16 and from the CERN JCOP control framework version 8.1.2 to version 8.4.0 [10]. WinCC OA migrations at CERN are common, as the software needs to be up to date with the latest versions ETM provides support for. Nevertheless, this specific migration required a major

effort as the new version of the platform only supports a specific encoding type forcing a migration from the old type.

**WinCC OA Migration.** While projects in WinCC OA versions lower than 3.16 were created using the ISO-8859-1 (Latin) encoding by default, the 3.16 version only supports Unicode UTF-8 encoded projects. This is part of an attempt by ISO and the Unicode Consortium to develop a coding for electronic text that includes every existing alphabetic symbol, since the ISO-8859-1 (Latin) encoding covers ASCII characters but doesn't include several symbols frequently used in other languages different from American English or some of the most popular western European languages. Compared to the ISO-8859-1 encoding, where each symbol is represented by a single byte (character data type), in the UTF-8 project each character is represented by a multibyte encoding with 1-4 bytes. Since only a sub-set of the Unicode UTF-8 encoding is backwards compatible with the previous encoding, the ECAL DCS project required a review of all the codes to check if they were compatible with such a change. ECAL DCS source files were checked looking for non-compatible characters. Automatic tools were implemented to detect and update pieces of codes. As a result, only 11 of the 304 ECAL DCS files required such changes. They were often code comments written by international developers using special characters from languages different from American English.

While analysing the ECAL DCS codes, a special care was devoted to some strings which needed to be treated as arrays of characters for some applications. Since individual characters of these arrays must be processed as such for a proper functioning, a search for these specific arrays of characters through the ECAL DCS codes was required. A program has been developed searching for these special character-type situations, like character-type declarations or arrays of characters, allowing the discovery of pieces of codes which would have failed otherwise.

An additional effort was performed to develop a new set of Unicode standard functions, which were also ASCII-compatible. In total, the code was updated to accommodate the introduction of 11 new types of functions in the ECAL DCS project. In order to reduce transitioning periods between the two WinCC OA versions, all the ECAL DCS components were upgraded already in the legacy system 3.15 so that the development proceeded in parallel for both versions.

With respect to user's interface, special characters in the panels might not be displayed correctly if the panels were written with ASCII-compatible characters. In large projects it happens often that some elements from old panels are copied and pasted into new panels. When importing pieces of code, such as buttons etc., from panels written with the ISO encoding into new panels written with the UTF encoding, some artefacts might be generated. ETM recommended that in order to convert existing panels to the new UTF format, a conversion to XML files should be performed. A new XML file format for storing purposes of

project panels has been adopted in WinCC OA version 3.16. Even though the previous file format could have been compatible, for consistency it was decided to convert all the existing files in the ECAL DCS system accordingly. Being the XML format also compatible with the previous WinCC OA version, an earlier deployment was already implemented in the previous WinCC OA 3.15 legacy system. As the conversion was completed, the converted panels were re-analysed via a set of tools to remove redundant declarations and correct for possible undetected conversions.

**JCOP Control Framework Migration.** The Joint Control Project JCOP is a collaboration between the CERN LHC experiments, the EP Department and the Industrial Group in the Beams Department at CERN aiming for a shared control system architecture used LHC-wide. As part of this mission, in 2003 the group released a common JCOP framework which allowed the configuration, the monitoring and the operation of different sub-detectors of the LHC experiments enabling communication with the Data Acquisition systems and the CERN infrastructure services, as well [11]. Updated versions are produced periodically. Following the new release of the WinCC OA platform, the JCOP group released a new version of the JCOP framework compatible with it. Thus, the ECAL DCS had to migrate the framework used in the legacy system version 8.1.2 to 8.4.0. In the previous JCOP framework versions most functions worked with no need for an explicit call of required libraries, as libraries and utilities were part of a global scope of WinCC OA. Due to performance purposes, this software design was abandoned starting from version 8.4.0 of the JCOP framework causing a review of all the source codes to explicitly call required framework libraries. This review affected not only the ECAL DCS system, but almost all the DCS systems implemented by the other CMS sub-detector groups. Given the large use of the past functionality, this required a major effort. Thus, the JCOP and CMS Central DCS teams provided the sub-detector DCS teams with specific tools for an automatic identification and modification of sources which required an update. As recommended by the JCOP framework team, the tool codePurger has been used to scan the entire ECAL DCS project searching for unresolved calls of functions and implementing automatic modifications. This resulted in the creation of a reference database which was later used for such identification and modification of sources requiring an explicit call for libraries. In total 240 code transformations were required, out of 120 source files analysed by the tool. For consistency the updated codes were also compared to previous versions proving the reliability of the tool and implemented updates.

### *OPC Unified Architecture Migration*

Since 1996 the OPC DA standard has been successfully allowing communications between any hardware regardless of its vendor. At CERN, OPC DA has been heavily used to control and monitor a large variety of devices, which are controlled by a SCADA layer provided by

WinCC OA. WinCC OA communicates via its built-in OPC driver - an OPC Client - to an OPC server, which communicates with the physical device. A schematic representation is shown in Fig. 2. Following the release by the OPC foundation of the OPC-UA specifications and implementations, CERN decided to migrate all the existing OPC DA servers to OPC UA [12]. Compared to the old OPC DA based on the deprecated Microsoft COM/DCOM, OPC UA is now based on modern industry standards making it a more compelling candidate for controlling and monitoring middleware between SCADA systems and hardware devices.

Some of the most important OPC UA highlights include:

- its platform independence being not tied anymore to Microsoft platforms,
- its improved security since it has a comprehensive security model built in securing channel client/server communication,
- its improved modelling since it has an extensive vocabulary for modelling purposes which allows to type components and express inter-component relationships.

Within the WinCC OA – OPC architecture described above, hardware addresses are encoded in the form of datapoints. Individual software components for each application are responsible for the final installation and configuration of datapoints related to that application.

The OPC UA migration in CMS took place in parallel with the WinCC OA/JCOP framework migration during summer 2021 with several validation tests performed in spring 2021. The ECAL DCS makes use of three different OPC servers to monitor and control the following devices:

1. Wiener Marathon power supplies for EE/EB Low Voltage (LV) via Wiener OPC,
2. CAEN power supplies for EE/EB High Voltage (HV) and ES LV and HV via CAEN OPC,
3. CERN-made module Embedded Local Monitor Boards (ELMBs) used for ES High Voltage monitoring, for EEs HV and for ECAL Precision Temperature Monitoring via CANOpen OPC.

The software components affected by this migration in ECAL DCS are reported in Fig. 2. Every component required a reconfiguration of the address space. This was done via an automatic tool released by the JCOP framework team for the different OPC servers. This migration also allowed for a conceptual change from a monolithic single-server configuration to a multiple-server paradigm resulting in a further splitting of the current OPC server's configuration. Benefiting from this, it was possible to anticipate some of the granularity changes which will be required for the LS3 upgrade, when the ES and EE detectors will be removed and so the related OPC UA servers. Having a more granular architecture already in place will simplify the removal operation expected for LS3.

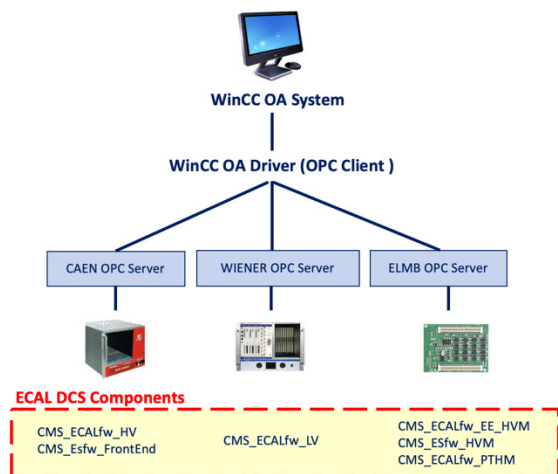

Figure 2: WinCC OA/OPC architecture used at CERN with the indication of the three different servers in use. For each type the ECAL DCS component, which had to undergo the OPC UA migration, is also indicated.

### Version-control-system Migration

After having been largely used during LHC Run 2 operations, the Apache Subversion system (SVN) [13] for versioning and revision control system was officially abandoned by CERN in 2018. This forced all the LHC experiments to migrate their SVN-based projects to the Git distributed version control system, hosted by the CERN GitLab service [14]. The ECAL DCS team took this opportunity to also implement some hierarchy reorganization of the project repositories. When moving to Git repositories, the original SVN repository was split into a hierarchy of individual repositories, which were structured according to their functionality. As a result, the ECAL DCS system moved from a single repository to a set of 35 different repositories.

### Additional Reviews

In this section we describe a few additional software reviews, which were needed following the migrations reported in the previous sub-sections.

When installing a specific component, some other components might be needed prior to the installation of the component in consideration. This is due to the dependency chain which must be respected for the component to be installed properly. The JCOP migration described in the previous section affected the dependency chain to be followed when installing a component. As for the other CMS DCS projects, the installation of the ECAL DCS components follows guidelines from the JCOP framework group. When installing a component, the component itself should provide all the required information respecting the needed dependencies. A specific toolkit, the ECAL DCS installation

toolkit, has been developed over the past years for such a purpose. Following the software migration and the introduction of new libraries, the toolkit has been reviewed and modified to meet some new requirements, such as the new configuration of OPC UA servers.

An additional software review was also needed regarding the new OPC UA configuration for Wiener OPC. Following a hardware replacement for ECAL LV (which took place during data-taking operations in August 2021), a type mismatch in the address configuration between OPC UA and WinCC OA has been discovered. After running some tests, the default type in WinCC OA was moved from bool32 to int32 solving the mismatch. This was not observed during the validation tests in spring 2021 and became clear only after the whole migration took place. It was also reported to the CERN OPC experts for future improvements.

## UPDATED NOTIFICATION SYSTEM

In parallel to the software migration, during the LS2 some work was also done to improve the current notification system. In the ECAL DCS project, components use a central tool developed by the Central DCS team for configuring alarm-based notifications. By using this tool, the system accesses the needed CERN e-group – the interface developed at CERN to manage groups – and import a list to distribute messages to its members. The ECAL DCS team has contributed to some improvements for a further e-group integration. While in the past the tool required periodic synchronizations to be fully operational, this is not needed anymore for the new version to operate. Specifically, in the past ECAL DCS notifications and recipients were part of groups – the notification groups – whose lists of recipients were also synchronized once or twice a day. Since the notification groups were used by different components to send messages, the previous centralized system allowed for multiple messages to be sent to the same group of users. During ECAL operations this might be problematic, as it becomes hard to monitor new alarms among several replicas of others. A reorganization of the notification system was designed in 2020. The new system is organised by application domains, with each of them used exclusively by a single component. This prevents the possibility of multiple messages to be sent by different components. Users can then subscribe/unsubscribe directly to an independent e-group for a specific notification domain simplifying the overall system.

## CONCLUSION

After several successful years during Run 2 operations at CMS, the CMS ECAL DCS project is undergoing major modifications during the current second-long shutdown at the LHC. During summer 2021, system codes have been reviewed and modified to accommodate several software migrations ongoing in CMS, such as the WinCC OA and JCOP control framework migrations. In parallel, OPC DA servers used by the ECAL DCS project have been migrated to the new OPC UA configuration. Taking advantage of the

long shutdown, additional upgrades were also performed. All the code repositories stored since the start of the ECAL DCS project have been moved to the CERN Gitlab version control system and the ECAL DCS notification system has been reorganised for a more efficient functionality. Some validation tests were performed in spring 2021, in preparation for the final migration which took place during summer 2021. The ECAL DCS system has been successfully migrated and will serve as the ECAL DCS legacy system for the Run 3 data-taking operations starting in March 2022.

## ACKNOWLEDGEMENTS

The ECAL DCS project is supported by the Swiss National Science Foundation, Switzerland. The authors would like to thank also the CMS Central DCS group and the CERN JCOP framework group for their support through several upgrades described in this paper.

# THE CONTROL SYSTEM OF THE LINAC-200 ELECTRON ACCELERATOR AT JINR

A. Trifonov\*, M. Gostkin, V. Kobets, M. Nozdrin, A. Zhemchugov, P. Zhuravlyov,  
Joint Institute for Nuclear Research, Dubna, Russia

## Abstract

The linear accelerator Linac-200 at JINR is constructed to provide electron test beams with energy up to 200 MeV to carry out particle detector R&D, to perform studies of advanced methods of beam diagnostics, and to work as an irradiation facility for applied research. While the accelerator largely reuses refurbished parts of the MEA accelerator from NIKHEF, the accelerator control system is completely redesigned. A new distributed control system has been developed using the Tango toolkit. The key subsystems of the accelerator (including focusing and steering magnets control, vacuum control system, synchronization system, electron gun control system, precise temperature regulation system) were redesigned or deeply modernized. This report presents the design and the current status of the control system of the Linac-200 machine.

## INTRODUCTION

Linear electron accelerator Linac-200 (Dzhelepov Laboratory of Nuclear Problems, JINR, Dubna, Russia) is a unique facility intended for scientific and methodological research in the field of accelerator physics and technology, elementary particles detectors research and development, as well as fundamental and applied research in the fields of materials science and radiobiology. It is based on the MEA linear electron accelerator which was transferred to JINR from NIKHEF in the end of 90s.

Main accelerator structure unit is a station. The injector station A00 includes the electron gun, chopper, prebuncher and buncher. First accelerator station A01 includes one accelerating section and a klystron, which also feeds the RF equipment of the A00 station. All the rest stations include two accelerating sections and a klystron each.

Current setup (Fig. 1) consists of 5 stations, A00–A04, and allows generation of the 200 MeV electron beam. In the future it is planned to increase the number of stations up to thirteen, and the energy will accordingly increase up to 800 MeV [1].

Almost all MEA equipment is in good condition and has reasonable operating resource. However, control systems hardware and software, as it is the most rapidly developing sphere, were mostly out-of-date already at the moment of accelerator transfer from NIKHEF to JINR. Therefore, two major accelerator control system upgrades took place. The

first one was continuous, when necessary control subsystems were developed when they were needed [2]. The second one started in 2018 when development of the new global control system began [3].

The global control system automatically collects, processes, stores and displays information about the operation of the accelerator, as well as about the state of the technological equipment involved in the operation of the accelerator. Also, the global control system provides the ability to automatically control individual accelerator subsystems.

The main requirements for the Linac-200 global control system is high reliability, safety, simplicity of software development, and ease of technical support. There should be an opportunity for future modifications and extensions. The software of the global control system should use standard interfaces for interaction between components and be able to use existing developments of the world community.

Tango Controls allows to create control systems that meet these requirements. It is also worth mentioning that the control system for the NICA collider at JINR is being developed using Tango [4]. Therefore, it was decided to implement a new global control system for the Linac-200 accelerator based on Tango.

## CONTROL SYSTEM CONCEPT

### *Tango Controls*

Tango Controls is a free open source device-oriented controls toolkit for controlling any kind of hardware or software and building supervisory control and data acquisition (SCADA) systems. The fundamental unit of Tango is a device, which is an abstraction hiding real equipment or program component behind the standard interface. Tango provides high level client application interface which has necessary programming classes to implement client-server communications – synchronously or asynchronously execute commands, read or write attributes, or use events to acquire the data from the Tango devices. Tango incorporates a number of tools to build efficient control system environment including centralized administration and monitoring, access control, logging system, data archiving and code generation for rapid development of the Tango device servers using C++, Java and Python [5].

\* trifonov@jinr.ru

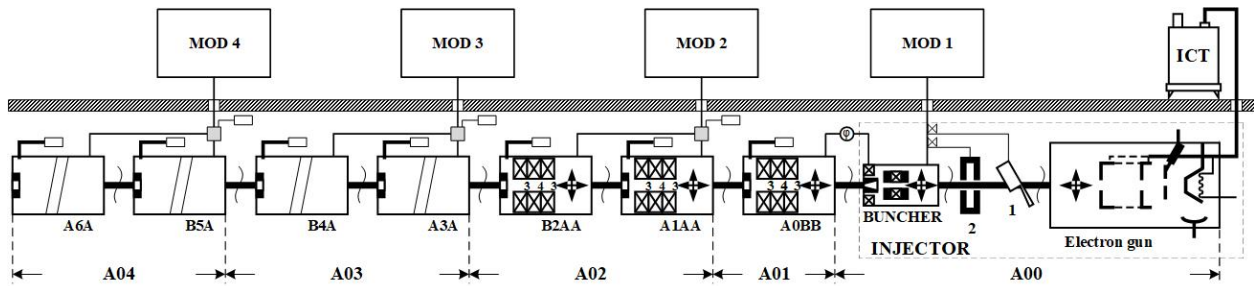

Figure 1: Linac-200 accelerator layout (1 – chopper, 2 – prebuncher).

## Control System Structure

Layout of the Linac-200 control system is shown in Fig. 2. The system is implemented as three levels: hardware access level, server level and client level.

At the hardware access level, digital and analog signals are collected and analog signals are converted to digital. This level also includes all equipment that needs to be controlled. The hardware access layer is connected to the server layer through a data transmission channels. Ethernet and RS-485 are used as data transmission interfaces.

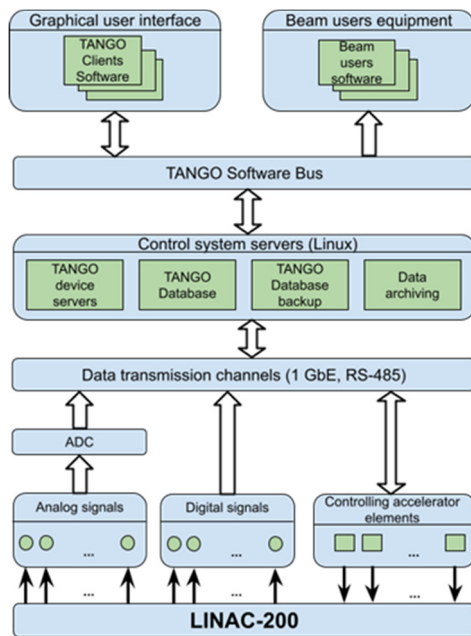

Figure 2: Linac-200 control system layout.

The server level is required for the effective centralized collection, processing and storage of data from the elements of the hardware access level, as well as for the implementation of subsystems control algorithms.

The server level provides a set of software components that are necessary for the effective functioning of the control system. These components include:

- Tango database (for which it is necessary to provide reliable backup methods, the ability to quickly transfer to another server).
- System of differentiation of access rights to the elements of the control system.
- A data archiving system that allows you to store data in a database for short-term or long-term storage.
- A data archiving system that allows you to store data in a database for short-term or long-term storage.

Supermicro [6] servers running Linux Debian are used as server computers. C++ and Python languages are used for server software development.

The client layer provides graphical user interface (GUI) for monitoring and controlling various parameters of the accelerator. At the moment, in the Linac-200 control system, client applications are developed in C++ using Qt5 and QTango [7]. For each subsystem (or, if there is such a need, for individual elements of the subsystem) there is a separate client application. In addition, there is a global client application that provides a graphical interface for launching client applications for individual subsystems (or their elements).

In the future, it is possible to use web clients, which can be implemented using the technology described in [8]. Also, the possibility of using Taurus [9] – a framework for creating both GUI and command-line applications with Python, seems promising.

## Network Infrastructure

The Linac-200 global control system is based on the interaction of components included in the Ethernet network, divided into a number of segments serving the main control room, accelerating stations, users control room and accelerator hall. The network infrastructure of the global control system is shown in Fig. 3.

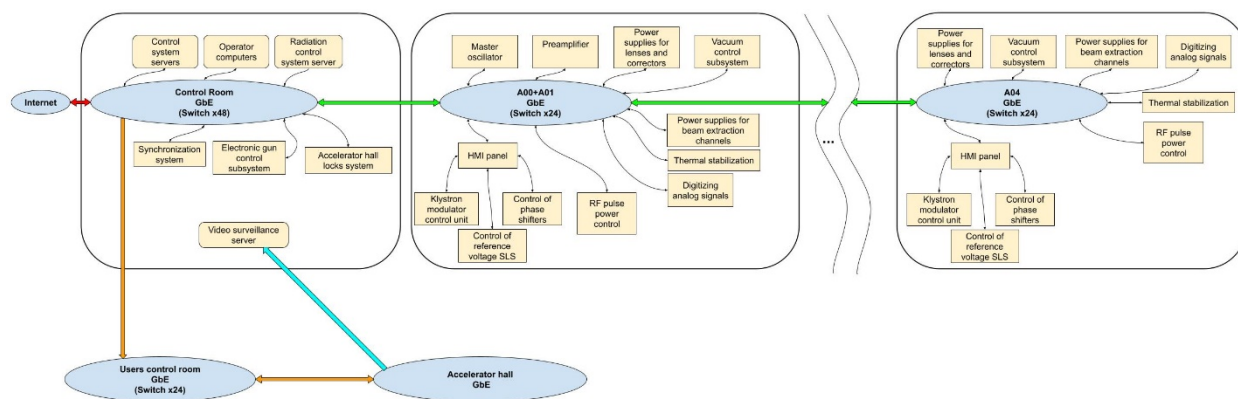

Figure 3: The network infrastructure of the Linac-200 global control system.

## Local Control

Local control is available for a number of subsystems and is done with the Weintek MT8071iP [10] operator panel.

In addition to displaying the local control graphical interface, the Weintek MT8071iP panel acts as a Modbus server. Slave devices are connected to the panel by means of RS-485 interface according to Modbus RTU protocol. Data is transmitted to the Tango-based global control system via Ethernet using Modbus TCP and Modbus RTU over TCP protocols.

## LINAC-200 CONTROL SYSTEM SUBSYSTEMS

### Electron Gun Control System

The beam is generated by the 400-kV DC triode-type electron gun with a thermionic cathode. As part of the development of a global Tango-based control system, new software for the electron gun control was developed.

More information about electron gun control system can be found in [11].

### Synchronization System Control

The new synchronization system is a multichannel generator that generates sync pulses to control the accelerating system and synchronize the accelerator subsystems. It consists of a master oscillator and a multichannel delayed pulse generator.

At the moment, a separate software running on a Windows computer is used to control the synchronization system. In the future, it is planned to integrate the synchronization system software into the global Tango-based control system. For this purpose, a corresponding Tango class will be implemented, as well as a client application with a graphical interface.

### Control of RF system elements

At the moment the following RF system elements are controlled:

- Master oscillator.
- Preamplifier.
- Klystrons modulator control units.

- Phase shifters.

**Master oscillator.** A high-frequency signal generator AKIP-7SG384 is used as a master oscillator. The interface for interaction with the control system is Ethernet. Data exchange via Ethernet is carried out using the Tango Socket device [12]. The control of the frequency and amplitude of the output signal is realized.

**Preamplifier.** A specially designed power amplifier DIALTEK UMP245-300 is used as a preamplifier of the RF system. The control of the output power and RF pulse width is realized. Data exchange between preamplifier and the control system is implemented using Modbus RTU over TCP protocol.

RTU over TCP provides a method to transmit RTU messages with a TCP/IP wrapper through a gateway onto Ethernet without changing any of the bytes in the message. Standard Modbus RTU is meant for transmission over serial lines. The message starts with a one byte Slave ID and ends with a two byte CRC (Cyclical Redundancy Checking). In RTU over TCP, the server does not have a slave ID and uses an IP address instead.

Since the existing Tango class [13] does not support this protocol, a new TangoPyModbus class to handle the Modbus protocol was implemented base on the PyModbus library [14].

**Klystrons modulator control units.** The solid state modulator consists of the special multicore pulse adding transformer and 40 PFN (Pulse Forming Network) units. Each of these units is a printed circuit board with a 2 kV line-type (50  $\mu$ s) modulator. Two units feed a primary of the pulse adding transformer [15]. Such a layout allows generation of pulses which amplitude can be changed by changing the number of active PFN units. This number is controlled by the special Weltek controllers. These controllers also provide information on the modulator status to the control system [16]. Interaction with global control system, as well as the local control is realized by means of Weintek MT8071iP operator panel.

**Phase shifters.** A specially designed mechanical phase shifter (Fig. 4) is used to control the phase shift of the klystron actuating signal of the Linac-200 accelerator station. It has a high resolution positioning of the sliding coaxial line along the length, due to the use of a stepper motor and high manufacturing precision of the ballscrew.

Figure 4: Mechanical phase shifter.

The phase shifter is controlled by means of a specially designed electronic board, the main elements of which are a microcontroller and a stepper motor drive.

Interaction with global control system, as well as the local control is realized by means of Weintek MT8071iP operator panel.

### Focusing and Steering Magnets Control

Magnetic elements are used to focus and steer the position of the beam, which are mainly required to reduce the loss of particles during acceleration. Focusing is carried out using solenoidal and quadrupole lenses. Steering magnets are used to adjust the position of the beam relative to the accelerator axis.

The magnetic elements are powered by the KORAD KA3005P and KA6003P power supplies. Modifications (KA3005P / 6003P) differ in the range of currents and voltages (0–30 V, 0–5 A and 0–60 V, 0–3 A, respectively) and are selected based on the power consumed by a particular element of the accelerator magnetic system. Remote control interfaces include USB and RS-232.

The integration of these power supplies into the global Tango-based control system is hampered by the fact that the USB and RS-232 interfaces are unsuitable for transmitting data to the control room of the accelerator (a distance of about fifty meters), and the built-in software of the power supplies does not allow each unit to be assigned a unique address for its unambiguous identification.

To solve this problem, intelligent interface modules KPI-11 were developed. Based on these modules, a control system for magnetic elements was developed (the diagram is shown in Fig. 5). This system allows to remotely and independently control the network of power supplies KORAD KA3005P / 6003P [17].

### Vacuum Control System

The diagram of the vacuum control system is shown in Fig. 6.

The vacuum system is controlled by the B&R Industrial Automation PLC model X20CP3584 [18]. The PLC software was developed in C in the B&R Automation Studio 4.5 integrated development environment. Interaction with the global control system is carried out through the Modbus TCP protocol.

### Precise Temperature Regulation System

Its planned to use the Unichiller 100-H circulators from Huber [19] for precise temperature regulation. A special Pilot ONE unit would be used to control the circulators. This

unit is equipped with a touch screen for local control and also supports remote control via Ethernet, which in turn makes it possible to integrate it into a global control system.

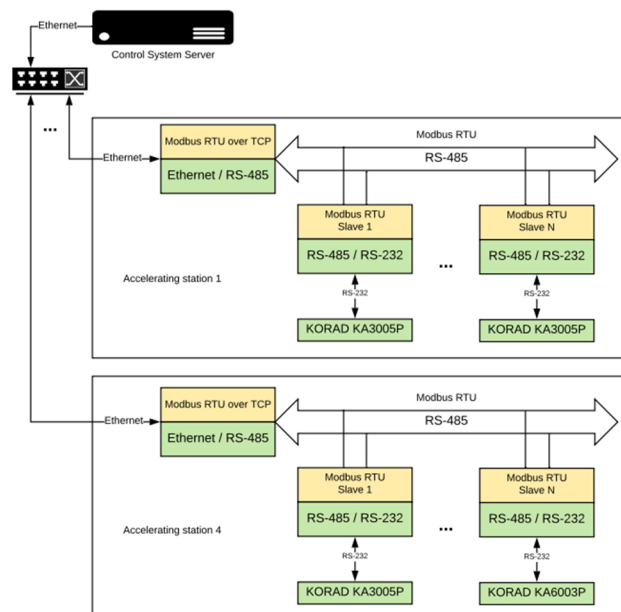

Figure 5: Magnetic element control system layout.

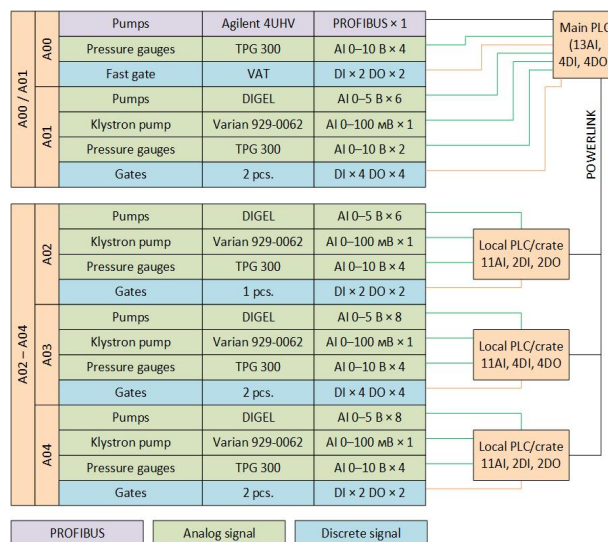

Figure 6: Vacuum control system layout.

## CONCLUSION

The general concept of the global control system which capable of providing launch and control of the main accelerator subsystems has been designed. Tango-based software for individual subsystems of the Linac-200 has been developed.

The accelerator building is undergoing major repairs. After the completion of the first phase of the repair, it is planned to launch the accelerator with a new control system.

## ACKNOWLEDGEMENTS

We are grateful to:

- G. Sedykh, E. Gorbachev, V. Elkin and D. Egorov for useful discussions about control system architecture and Tango-based software development advices.
- I. Shirikov, D. Donets and D. Ponkin for their valuable contributions to the Linac-200 hardware development.
- R. Pivin, A. Popov and R. Timonin for their valuable contributions to vacuum control system development.
- All Linac-200 engineers who participated in discussions and provided us with insightful comments and ideas.

# DISTRIBUTED CACHING AT CLOUD SCALE WITH APACHE IGNITE FOR THE C2MON FRAMEWORK

T. Oliveira\*, D. Martin Anido, M. Braeger, B. Copy, S Halastra, A. Papageorgiou Koufidis  
CERN, Geneva, Switzerland

## Abstract

The CERN Control and Monitoring platform (C2MON) [1] is an open-source platform for industrial controls data acquisition, monitoring, control and data publishing. Its high availability, fault tolerance and redundancy make it a perfect fit to handle the complex and critical systems present at CERN. C2MON must cope with the ever-increasing flows of data produced by the CERN technical infrastructure, such as cooling and ventilation or electrical distribution alarms, while maintaining integrity and availability. Distributed caching [2] is a common technique to dramatically increase the availability and fault tolerance of redundant systems. For C2MON we have replaced the existing legacy Terracotta [3] caching framework with Apache Ignite [4]. Ignite is an enterprise grade, distributed caching platform, with advanced cloud-native capabilities. It enables C2MON to handle high volumes of data with full transaction [5] support and makes C2MON ready to run in the cloud. This article first explains the challenges we met when integrating Apache Ignite into the C2MON framework, and then demonstrates how Ignite enhances the capabilities of a monitor and control system in an industrial controls environment.

## INTRODUCTION TO C2MON

C2MON is an open-source monitoring platform developed at CERN. C2MON acts as the backbone of the Technical Infrastructure Monitoring system (TIM) that is used to monitor and control CERN's technical services from the CERN Control Centre (CCC) [6]. The main function of TIM is to provide reliable and real-time data to CCC operators about the state of CERN's widely distributed technical infrastructure. To handle such a large volume of information while maintaining data integrity, C2MON uses Java Message Service (JMS) [7] technologies together with caching technologies. Caching involves storing information in a separate low-latency data-structure for a period of time to be reused and consequently minimizing the cost of re-accessing it [2]. The existing C2MON caching layer relied on a legacy Terracotta Ehcache framework [3]. Ehcache is a widely-used Java-based cache that is fast, lightweight and can be scalable through the use of a Terracotta Server that provides distributed caching capabilities [3].

C2MON uses a 3-tier architecture, as presented in Fig. 1, that composes a Data Acquisition (DAQ) Layer, the Server Layer and a Client Layer. The DAQ layer is responsible for acquiring data from specific sources and publishing it to the C2MON server tier. The Client layer provides various

Figure 1: C2MON Architectural Overview.

service classes that allow to interact with the server. The Server layer, which is the core part of C2MON, is responsible for receiving and handling the data.

Most of the information in C2MON is stored and used in the form of Tag which changes frequently as new data from the DAQ is received and evaluated by the system. In order to evaluate the correct and normal values of each Tag, C2MON provides an Alarm mechanism. The Alarm is a declaration associated with a Tag and contains a condition specifying the legal values of that Tag. If the new value received is outside the legal value range, the Alarm is activated and pushed to the client. Finally, the C2MON server layer also provides a rule engine with a set of operations, that allows expressing complex computations, comparisons and conditions.

## INTRODUCTION TO APACHE IGNITE

“Apache Ignite is an open-source memory-centric distributed database, caching and computing platform” [4].

Ignite provides a simple interface to work with large data sets in real time. It is written in pure Java, based on Spring and supports different technologies like Java, C# and C++. The main capabilities that Apache Ignite provides are

- Elasticity: The Ignite cluster can grow horizontally simply by adding new nodes over a TCP connection.
- Persistence: Cache entries can be persisted on a file system or in an RDBMS (Relational Database Management System).
- Distributed computing: Apache Ignite provides a set of APIs that facilitate the distribution of computation and data processing across the nodes in the cluster for better performance; it simplifies greatly the development of a microservice-based architecture.
- Streaming: Ignite allows the processing of continuous streams of data (which C2MON uses to receive cache events asynchronously through continuous queries).

Ignite includes the notion of client and server nodes, where a node is a single Ignite instance running in a JVM (Java Virtual Machine). In a client server architecture both client and server nodes are interconnected with each other. The server, which can be constituted by a single node or a group

\* tiago.marques.oliveira@cern.ch

of nodes forming a cluster, handles all the data storing processes and computing of data. The client node is usually embedded with the application code and acts as an interface to run operations in the cache like inserting or retrieving data, but can in some cases also participate in computing tasks [4]. Apache Ignite comprises a memory-centric architecture that can be used as an In-memory or distributed database. This memory-centric storage allows to store data and indexes both in-memory and in-disk with the same data structure and enables executing SQL queries in both with optimal performance.

## HOW CACHING WORKS IN C2MON

In such a fast paced environment as the one present at CERN where it is crucial to maintain the correct functionality of critical systems, it is essential to have a reliable monitoring platform capable of providing high availability and fault tolerance when dealing with the increasing flows of data produced by the CERN Technical Infrastructure. In order to achieve those requirements, C2MON relies on caching technologies. The cache in C2MON acts as a working memory that allows for stored information to be retrieved as fast as possible. The database is a persistent storage, and serves as a backup solution, that is responsible for storing long term data and to populate the cache when necessary.

C2MON uses a classic client/server cache with a distributed cluster. This caching layer serves as a middleware that reduces time-consuming operations of fetching data from the database by storing the objects that are most used. When the cache starts up, it must be warmed up : cache loaders in C2MON are responsible for converting the data loaded from the database to POJOs (Plain Old Java Objects) and storing them in the cache [8].

The infrastructure of C2MON heavily relies on the use of ActiveMQ [9] to transport data. ActiveMQ is an open source, Java Messaging Service (JMS) compliant, message-oriented middleware supported by the Apache Software Foundation. The number of messages that are received can reach up to a few millions per day, and C2MON has to process all of them in real-time while maintaining data consistency. This processing involves the evaluation of Tag values, activation or termination of Alarms, rule calculation and event propagation. The calculation of rules in C2MON is a very expensive process that involves many successive calculations and can even be recursive. As the rate is so fast, some sort of rapid access memory is necessary to store intermediate values. Since JMS is only responsible of receiving and passing data and does not allow the storage of data, a new component is needed to fulfill this requirement. This logic could also be implemented directly in the database layer, as C2MON uses a relational database like Oracle. But this would require business logic to be implemented outside the C2MON server core, it would require the use of Oracle-specific Procedural Language and would lead to a lot of latency when persisting all the intermediary values. The solution is the use of a

Figure 2: CAP theorem.

distributed working memory like Apache Ignite. This helps to achieve availability and consistency of data.

## ADVANTAGES OF APACHE IGNITE

The Apache Ignite architecture is flexible enough to be used in various architecture patterns and styles. One possible approach that facilitates local and integration tests is to run Ignite embedded with the application where the node runs on the same JVM with the application. In a production environment a better approach is to have the Apache Ignite server nodes in a separate JVM and client nodes that connect remotely to the servers. The great advantage of this approach is the increasing flexibility that allows Ignite servers to be taken down and restarted without harming the cluster or the correct functioning of the application they support [10]. Ignite also offers the possibility of using three approaches of caching topology, where each cache mode is individually configured for each cache. In C2MON, Apache Ignite was configured with a replicated caching topology in order to achieve the highest possible level of performance. In this approach, cached data is replicated to all members of the cluster so it is available immediate use without waiting and is thus providing the fastest read-access of all caching topologies. The main downside of this approach is that writing operations are very expensive since updating a replicated cache requires pushing the new version to all cluster nodes which may limit the scalability with high frequency of updates [10].

### CAP Theorem

There is a widely known idea that needs to be taken into account when dealing with distributed computing theory, which is the CAP Theorem introduced by Eric Brewer [11]. This theorem presents the fundamental trade-off between consistency, availability and partition tolerance. Figure 2 presents the graphical representation of the CAP Theorem where the three properties represent:

- Consistency that implies that all the nodes in the cluster have the same data.
- Availability of the system that should always answer the queries if possible.
- Partition Tolerance meaning that if a break in the communication occurs, the system will continue to work as expected.

Based on this theorem, Apache Ignite can be classified as a CP system, meaning that availability is sacrificed for consistency of data and partition-tolerance, since it is ACID (Atomicity, Consistency, Isolation, Durability) compliant,

supporting distributed transactions with partitioned tolerance [10]. Ignite can also be considered as an AP system, since it offers two types of transactional modes for cache operations: atomic or transactional. In atomic mode Ignite supports multiple atomic operations, successively, where each DML (Data Manipulation Language) operation will either succeed or fail without any data being locked, giving it a high performance. On the other hand, in transactional mode, the DML operations can be grouped in one transaction and the data will be locked [10]. This second approach is used by Ignite in C2MON, with CP prioritised, where the consistency of data is crucial.

## DIFFICULTIES AND CHALLENGES FACED

Having covered the background to this project and giving an overview of the caching system, the focus now shifts to the difficulties and challenges faced during the process of replacing the caching system.

### Code Rigidity

One major problem with the design of C2MON was the rigidity of its caching layer design. Rigidity is the tendency for software to be difficult to change and where every change can cause subsequent changes in dependent modules [12]. This was due to the tight coupling of C2MON to the current caching technology, so the change would involve refactoring a major part of the current architecture.

### Testing

It is crucial to have a good testing environment to ensure that the software is working as expected, and to detect and fix any eventual errors or bugs, when dealing with large and critical systems like C2MON. This should include not only unit tests to validate individual components but also integration tests to check the good behavior of those units interacting together. Integration testing environments should mimic production as much as possible, so that potential issues in production can be reproduced and resolved with certainty. This step becomes even more difficult with the increasing number of external dependencies like ActiveMQ, Oracle database and Apache Ignite, in the case of C2MON.

### Cloud Readiness

Over the past years, CERN has embraced cloud technology which presents significant advantages. It allows a more agile sharing of resources and it simplifies the reusing and duplication of entire groups of machines for testing purposes. Cloud-based deployment file systems are also usually transient and network interfaces are typically allocated on the fly with a randomly-generated hardware address and attached to a local, private and non-routable network. Furthermore, the life cycle of a cloud container hosting an application is linked directly to its main process, which must consequently be managed at level of the hosting cloud, as opposed to the host they are running on [13]. C2MON was initially designed

Figure 3: C2MON Cache Abstraction Class Diagram.

around 2009, when cloud technologies were not as ubiquitous as today, and its legacy architecture makes it impossible to take advantage of all the capabilities of a platform like Apache Ignite that is considered "cloud-ready". An example of this is the challenge node discovery in a cloud. Nodes in a cloud that wish to regroup in a cluster must usually employ broadcast messages, but this is disallowed at CERN for performance and security reasons. As a result, C2MON must rely on a fixed list of IP addresses, severely limiting how fast it can be deployed and reconfigured over new hardware or a dynamic cloud environment.

## SOLUTIONS

The remainder of the paper will describe the redesign of the C2MON platform caching layer, and how the design choices have helped to overcome these aforementioned challenges and achieve the goal of integrating Apache Ignite into the C2MON framework.

### Code Refactoring

In order to change the caching layer technology of C2MON, it was necessary to make a big code refactoring of various modules that were tightly coupled to it. To minimize the rigidity of C2MON's infrastructure, the caching layer was rebuilt depending completely on abstractions, decoupling it from the technology in place. Every dependency in the design should target an interface, or an abstract class, and never a concrete class that is much more prone to changes [12]. This approach has the disadvantage of losing some of the capabilities of Apache Ignite, but has the advantage of making it easier to change the caching technology in the future (if necessary), without major code changes. Figure 3 presents a snippet of the class diagram that corresponds to the new C2MON cache abstraction layer.

The C2monCache interface is the base of the entire C2MON caching layer, and contains all the necessary methods that interact with the cache, like inserting elements in the cache and retrieving them and querying elements in the cache, that was purposely implemented in a very simple way so that it could be implemented by any future alternative caching technology. This interface is implemented by an abstract class, AbstractCache, that hides the underlying implementation of the caching technology, and is also responsible for managing the caching update flow, the cache loaders and the cache listeners. The cache loaders are used to warm up the cache on startup and the cache listeners are used

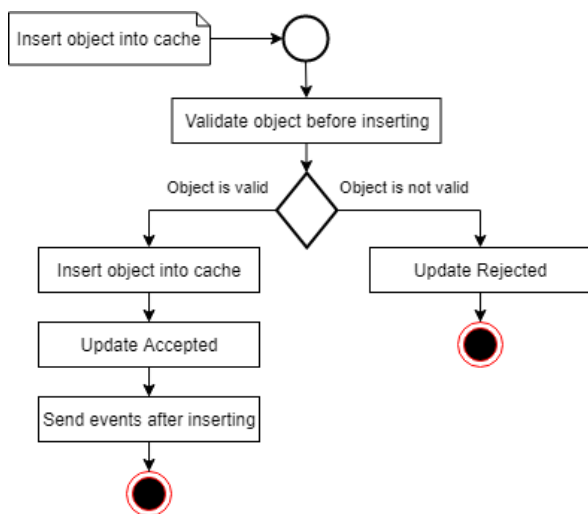

Figure 4: C2MON Cache Insertion flow.

to propagate all caching events. The `IgniteC2monCache` is the concrete class that contains the Apache Ignite implementation of `C2monCache`. Another implementation choice was the use of Java Generics throughout the whole caching implementation. Generics allows to abstract over types and the core idea is to express intent, and mark the respective objects as being restricted to contain a particular data type [14]. The `Cacheable` interface is implemented by all objects that reside in C2MON caches, creating another layer of abstraction and removing the possibility of run time errors during execution. Although Apache Ignite supports ACID transactions this might not be present in other caching technologies, and data consistency must be guaranteed for the good functioning of C2MON. Figure 4 displays an activity diagram of how the insertion in the cache is processed to respect cache consistency. When a new object is inserted in the cache it goes through a validation process first that guarantees that the object is complete and correct, and it is not older than the previous update, otherwise the update operation is discarded. In case the validation passes, the object is successfully inserted in the cache and corresponding events are propagated to any potential cache listeners.

## Testing

The lack of a proper testing environment, made it difficult to fully test the correct integration of C2MON with its various external dependencies. The alternative used to overcome this problem was the use of Testcontainers [15]. Testcontainers is a Java library that supports JUnit tests and that can execute those tests against instances of any software that can run in a Docker container. To use Testcontainers, all of C2MON components had to be "containerized" for the Docker container platform. Testcontainers encapsulate the management of the Docker images and spins up the required containers during the tests and tears them down once the test execution is finished. It provides a faster feedback loop for integration tests, as all the containers start with a clean and known state which increases the reliability of the tests.

## CONCLUSION

The usage of Apache Ignite has proven to be a robust and capable solution, that enhanced the capabilities of the C2MON framework. However, some of its capabilities could not be completely exploited at CERN because of the way C2MON is deployed. Although the main goal was to change the caching technology of C2MON and to integrate Apache Ignite, the opportunity was also taken to sanitize and refactor the entire caching layer. This was done following the best practices for software development and testing, employing newer features like the implementation of generics and the use of Java streams. Product testability proved to also be a very important factor that had to be improved to ensure that C2MON behaved the same way as before the Ignite integration : Docker technology (through Testcontainers) proved an effective and simple way to perform extensive, repeatable integration testing of the C2MON platform.

# IMPLEMENTING AN EVENT TRACING SOLUTION WITH CONSISTENTLY FORMATTED LOGS FOR THE SKA TELESCOPE CONTROL SYSTEM

S.N. Twum\*, W. Bode, A. F. Joubert, K. Madisa, P.S. Swart, A. J. Venter  
SARAO, Cape Town, South Africa  
A. Bridger, UKATC, Edinburgh; SKAO, Macclesfield

## Abstract

The SKA telescope control system comprises several devices working on different hierarchies on different sites to provide a running observatory. The importance of logs, whether in its simplest form or correlated, in this system as well as any other distributed system is critical to fault finding and bug tracing. The SKA logging system will collect logs produced by numerous networked kubernetes deployments of devices and processes running a combination off-the-shelf, derived and bespoke software. The many moving parts of this complex system are delivered and maintained by different agile teams on multiple SKA Agile Release Trains. To facilitate an orderly and correlated generation of events in the running telescope, we implement a logging architecture which enforces consistently formatted logs with event tracing capability. We discuss the details of the architecture design and implementation, ending off with the limitations of the tracing solution in the context of a multiprocessing environment

## PREVIEW TO THEORY AND SKA SYSTEM ARCHITECTURE

### *Observability and Monitoring in a Distributed System*

Logs have long been the de facto approach used to sample parts and peek into the internal state of a running program. Coupled with metrics, monitoring can be done across a system to understand its health at any given time. Inasmuch as this age old approach has been very beneficial to developers, especially for debugging purposes, it is limited in its diagnostic ability in distributed environments. Monolithic applications are easily observable using only logs and metrics. But in the dawn of the era of microservice architecture, logging alone is not adequate to debug and probe the internal state of such a system. Distributed systems with different services and multiple instances of these services need a correlated view of events to troubleshoot errors. It now requires the use of logs, metrics and traces, all together producing the emergent quality of this new buzz word, “observability”. J. Heather explains observability as inferring the internal state of a system from its external outputs. But it is not just the ability to see what is going on in your systems. It’s the ability to make sense of it all, to gather and analyze the information you need to prevent incidents from happening, and to trace

their path when they do happen, despite every safeguard, to make sure they don’t happen again[1]. Full observability of a distributed system is a function of three pillars [2], namely:

- Logs: a snapshot of an event in a running system.
- Metrics: measurement of activities on a running system, e.g. CPU load.
- Tracing: A trace is a representation of a series of causally related distributed events that encode the end-to-end request flow through a distributed system [2].

### *An Overview of the SKA Telescope Control System Architecture*

The SKA telescope control system will be a collection of software and services running from two sites which will be controlled from HQ in Jodrell Bank. The software consists of Tango Devices managing specific telescope hardware, and processes running all manner of software which are maintained by 17 or more teams on our Agile Release Trains (ARTs) [3]. The control system has a hierarchical structure to reduce complexity. The TANGO device is an abstraction hierarchy that has functional purpose at the top, and that goes down to physical form at the bottom. The frequency of intervention required at the different levels are different, increasing as you go downward the hierarchy (the Telescope Operator will exercise low frequency supervisory control, while at the lowest level you find real-time, closed loop feedback control) [4]. Control propagates downward (with fan-out) through this hierarchical structure. This is one source of causal path for events to propagate through the system. A specialisation of this hierarchical structure is that of the sub-array, an aggregation of telescope resources that are engaged for use in an observation [5]. Figure 1 illustrates the usage of sub-array nodes to control of the Mid telescopes.

During the lifetime of a running telescope, commands are triggered, events are fired, threads are spawned, several things are happening at the same time and it is not a trivial task to have end to end observability of the running system. This complex network exudes all the characteristics and challenges that are inherent in distributed systems. Though the various moving parts of the system are well tested, they are susceptible to faults and the ability to pin point a glitch to an exact root cause, following it through the various parts can only be provided in a distributed tracing system.

\* stwum@sarao.ac.za

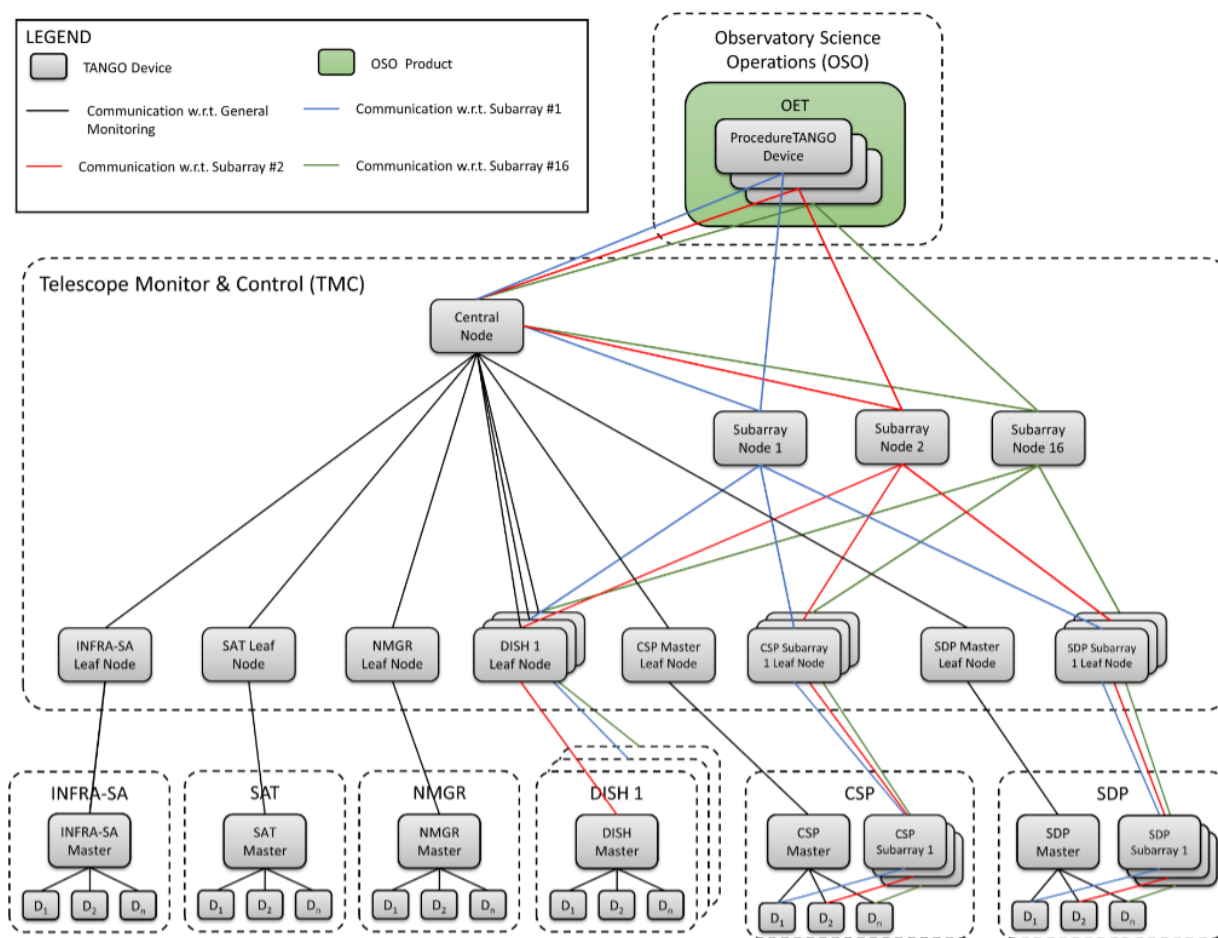

Figure 1: Hierarchy of tango devices demonstrating the control of the Mid telescopes using sub-array nodes [5].

In order to glean correlated debugging information for the SKA distributed services/devices architecture, we first adopted a standardised approach to logging across all packages maintained by the different teams and then, implemented a tracing solution in the form of transaction IDs to be used by Tango commands. The remaining sections discuss in detail the design decisions on our logging standard and the transaction IDs used to provision our tracing solution.

## HARMONISING APPROACHES TO LOGGING IN THE SKA SERVICES/DEVICES SYSTEM

The SKA logging system collects, stores and retrieves logs from derived, off-the-shelf and bespoke software. All these different logs sources are maintained in different packages by different teams on the SKA Agile Release Train. Prior to the harmonised logs, each team had their own logging standard. After a review of the different logging approaches used by the teams, we provided a reference logging implementation which implements a standard log format. The details about the standard log format follow in the next section.

### SKA Standard Log Format

The SKA log format ensure logs are emitted in a uniform manner to aid in troubleshooting and parsing. All processes executed inside a container log to stdout. For the emitted logs to be ingested into the logging system, they have to conform to the format below [6]:

```
VERSION"|"TIMESTAMP"|"SEVERITY"|" [THREAD-ID]"|
"[FUNCTION]"|" [LINE-LOC]"|" [TAGS]"|"MESSAGE LF
```

Example log in the ska log format is below:

```
1|2019-12-31T23:12:37.526Z|INFO||testpackage.
testmodule.TestDevice.test_fn|test.py#1|
tango-device:my/dev/name| Regular information
should be logged like this FYI
```

The log message format is not an extension of syslog/RFC5234 format. More on the SKA log message format can be found on the SKA Telescope Developer Portal <sup>1</sup>.

To aid in filtering, Table 1 below describes tags that have been adopted as standard tags which may be found in a log message.

<sup>1</sup> <https://developer.skatelescope.org/en/latest/tools/logging-format.html>

Table 1: SKA Standard Tags for Logs [6]

Tag Name	Description	Example
tango-device	An identifier string in the form:<facility> /<family> /<device>. This corresponds with a Tango device name. <ul style="list-style-type: none"> <li>facility: The TANGO facility encodes the specific telescope (LOW or MID) and the telescope sub-system (SaDT, TM, SDP, CSP, Dish, LFAA, INFRA)</li> <li>family: Family within facility</li> <li>device: TANGO device name</li> </ul>	MID-D0125/rx/controller <ul style="list-style-type: none"> <li>MID-D0125: where 0125 is the serial number of the Dish instance</li> <li>rx: The Single Pixel Feed Receiver of the Dish</li> <li>controller: The controller of the Single Pixel Feed Receiver</li> </ul>
subsystem	For software that are not TANGO devices, the name of the telescope sub-system.	SDP
transaction_id	Transaction ID to associate logs from different systems relating to a distributed activity	txn-t0001-20200928-000000010

## Design Motivation

The preliminary results gathered from analysing the code base of existing projects at the time drove the design of our current standard. We prioritised:

- Readability
- A sensible size of log length to provide useful information. The minimum required are:
  - timestamp
  - log level
  - extensible tags - a mechanism to specify arbitrary tags
  - the function in the source code where the log emanates from
  - the filename where the log call originates
  - the line number in the file
- Ability to parse the log message.

## The SKA Logging Configuration Library

The SKA logging format is hosted in the ska-telescope gitlab repository as a python package. The package allows developers to configure logging for any module to have all applications log in a consistent format [7]. The SKA tags defined in Table 1 above can be added to a tags filter available in the library among other configurations. All new ska projects in both the Observation and Management Control and Data Processing ARTs use this logging library as do the existing ones before the format and its library were implemented.

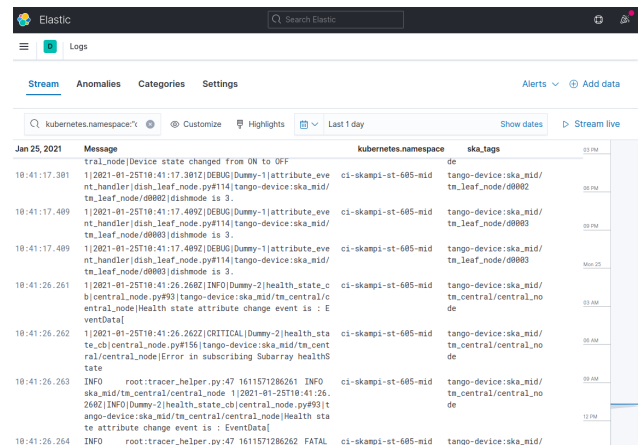

Figure 2: Kibana logs filtered using the value of the ska\_tags\_field.tango-device field [6].

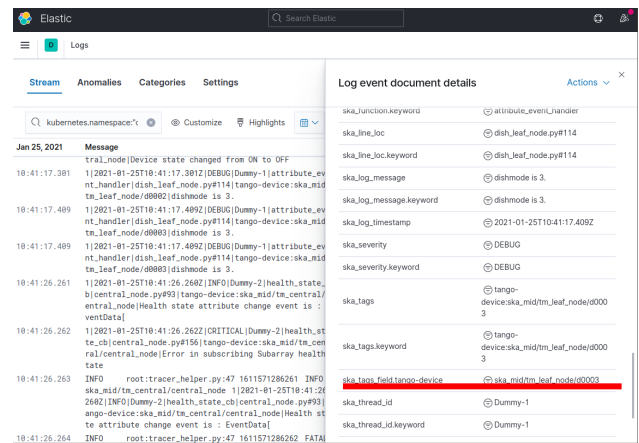

Figure 3: Kibana logs with only messages with the value ska\_mid/tm\_leaf\_node/d0003 for the ska\_tags\_field.tango-device field [6].

## TRACING EVENTS IN THE SKA CONTROL SYSTEM USING TRANSACTION IDS

The SKA control system churns out logs and aggregates metrics for system health monitoring; the missing piece to the full observability puzzle was the ability to obtain correlated log trails (tracing) of events. Tracing is the the only signal which explains the relationship between the different parts of the system which are managed by the different teams in our ARTs. It is nearly impossible to debug and discover patterns or correlations in the SKA control system searching through the gigantic logs being aggregated from the many services running in the kubernetes orchestrated environment. With the SKA formatted logs complete, it served as a scaffold to build the tracing solution by injecting a transaction ID in the logs. This design was driven by the snippet below:

```
with transaction('My Command') as txn_id:
    # do stuff
    ...
```

The idea in the snippet above is to ensure that any action performed within the context of the transaction will have record of an id for tracing. The transaction ID is cascaded down further requests until a trace is complete. In the SKA control system, the transaction context handler is implemented in a transactions python library <sup>2</sup> which relies on the SKA Logging <sup>3</sup> and SKA Unique Identifier (SKUID) <sup>4</sup> libraries.

### SKA Unique Identifier Library

The SKUID library does more than just generate unique ids for transactions. It generates scan ids, entity ids and transaction IDs for telescope operations [8]. The scan and entity ids are out of this discussion's context. The transaction ID is generated every time a transaction context block is initialised. It is a unique value served by a remote or local unique id generator (which can possibly generate a duplicate). The remote URL has a generator-id following right after the "txn" prefix (e.g. txn-t0001-20200914-123456789) while the local generator has "local" right after the "txn" prefix (e.g. txn-local-20200921-516590971).

### SKA Log Transactions Library

This library glues together the SKUID and logging packages to provide a transaction ID in a context handler which is injected into logs as a tag [9]. Within the context handler there is an enter and exit log entry which log the beginning and the end of a transaction using the generated transaction ID or a specified custom ID. In the event an exception occurs within the transaction, an exception log will be emitted with the transaction ID also. An example log on entry and exit of the transaction context in the ska log format looks like this:

```
1|2020-10-01T12:49:31.119Z|INFO|Thread-210|
log_entry|transactions.py#154||Transaction
[txn-local-20201001-981667980]: Enter[Command]
with parameters [{}] marker [52764]
```

```
1|2020-10-01T12:49:31.129Z|INFO|Thread-210
|log_exit|transactions.py#154||
Transaction[txn-local-20201001-981667980]:
Exit[Command] marker [52764]
```

To demonstrate the usage of the log-transaction library, a multi-level device has been added as an example in the ska-tango-examples <sup>5</sup> library. This multi-level device comprises a top-level device, four mid-level devices and one low-level device as depicted in Fig. 4.

The mid-level devices are triggered from commands in the top-level device and they in turn call the low-level device. During the interaction between these devices, the transaction ID generated at the top-level is propagated all the way to the low-level device and appears as tags in the logs as shown in Fig. 4. The rest of the logs are a combination of logs showing entry and exit into mid-level and low-level devices. When all mid-level devices with their associated low-level device triggers are finished, the trace ends with a log indicating an exit from the top-level device [10].

### Tracing in a Multithreaded Environment

Though the log transactions library has support for async code it does not support a multithreaded case at the moment. Consider the scenarios in the code snippets below:

```
# SCENARIO 1
class Device(Device):

    def function_that_logs(self):
        do_something()
        log.info("logging something") # The
        ↳ same thread, so this should log
        ↳ a transaction ID

    @command
    def some_command(self):
        with transaction("name", parameters,
        ↳ logger=ska_logger) as
        ↳ transaction_id:
            function_that_logs()
```

<sup>2</sup> <https://gitlab.com/ska-telescope/ska-ser-ska-ser-log-transactions>

<sup>3</sup> <https://gitlab.com/ska-telescope/ska-ser-logging>

<sup>4</sup> <https://gitlab.com/ska-telescope/ska-ser-skuid>

<sup>5</sup> A project that demonstrates how to structure an SKA project that provides some simple Tango devices coded in PyTango. See <https://gitlab.com/ska-telescope/ska-tango-examples>

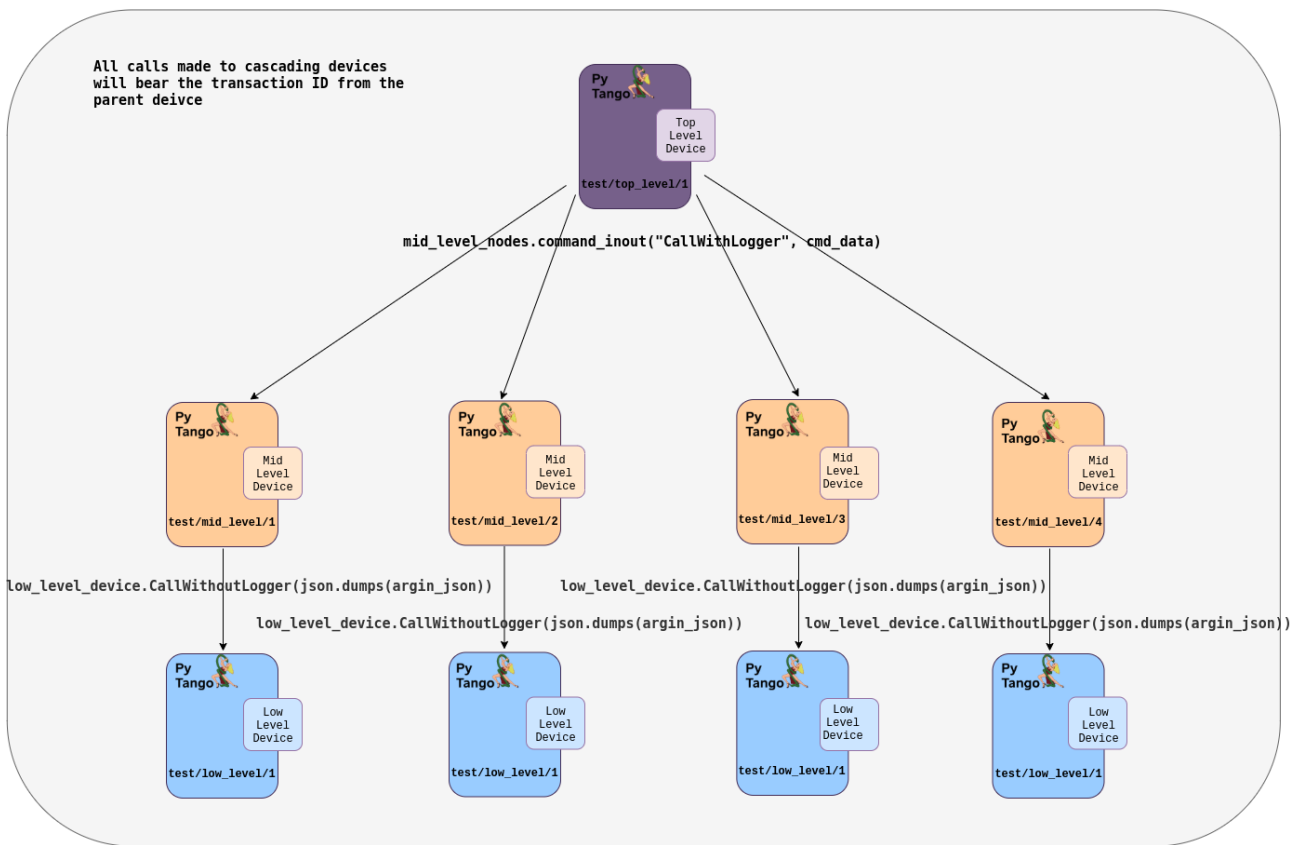

Figure 4: Diagrammatic illustration of the tango-example multi-level device and interaction among those devices.

```
# SCENARIO 2
class Device(Device):

    def function_that_logs(self):
        do_something()
        log.info("logging something") #
        ↳ This will not have a
        ↳ transaction ID

    @command
    def some_command(self):
        with transaction("name", parameters,
            ↳ logger=ska_logger) as
            ↳ transaction_id:
                t = threading.Thread(
                    target=function_that_logs,
                    ↳ args=(1,))
                t.start()
                t.join()
```

The code in SCENARIO 1 will produce a log just like in the example log above with the transaction ID in it but the log from SCENARIO 2 will not. The same is true for work passed off from a transaction to a thread managed by a thread pool. The thread lifetimes would exceed the transaction. This applies to code with or without async or event.

## FUTURE WORK

The enablers for the functioning of the SKA log transaction, namely SKA logging and SKA unique ID generator, do not have any left over features to be added except the local ID generation of the SKUID service to guarantee absolute uniqueness. This is trivial at the moment as the SKUID service URL is served up all the time in the integration environment. Having had all three pillars of distributed system implemented, the logical next step is to build the tooling we need to facilitate system diagnosis. The tooling will be available in all ART and will display to a user the flow of information and state across the MVP. At the time of implementing the log transaction, the SKA Telescope Control System is currently been demonstrated in an MVP and there is no clear evidence of that our troubleshooting would benefit from this feature. The need for it will be assessed and implemented as the project progresses, especially with AA0.5 release at hand.

## CONCLUSION

To fully understand a distributed system requires us to have distributed tracing. Tracing compares to a database join with the contributing tables being the different paths the event travels through and each event having an ID on which the join is performed [11]. The SKA Control System like every other distributed system poses a big observability challenge. To be able to infer the internal state of both low and mid telescope control systems, we have developed libraries to ensure running applications have consistently formatted logs with tracing. All the work done are available in public repositories under the ska-telescope organisation in: ska-ser-logging, ska-ser-skuid and ska-ser-log-transactions.

## ACKNOWLEDGEMENTS

We would like to acknowledge the National Research Foundation (NRF), the South African Radio Astronomy Observatory and the SKA Observatory for their support in carrying out this work under the Bridging Program and the SKA SFAFe program.

### Abstract

In 2019, the Tango Controls Collaboration decided to write down a formal specification of the existing Tango Controls protocol as Requests For Comments (RFC). The work resulted in a Markdown-formatted specification rendered in HTML and PDF on Readthedocs.io. The specification is already used as a reference during Tango Controls source code maintenance and for prototyping a new implementation. All collaborating institutes and several companies were involved in the work. In addition to providing the reference, the effort brought the Community more value: review and clarification of concepts and their implementation in the core libraries in C++, Java and Python. This paper summarizes the results, provides technical and organizational details about writing the RFCs for the existing protocol and presents the impact and benefits on future maintenance and development of Tango Controls.

### INTRODUCTION

The TANGO control system is a device-oriented controls toolkit for controlling any kind of hardware or software and building SCADA systems.

The first version of the Tango Controls was designed and developed more than 20 years ago [1]. Since then, it has evolved to follow technology progress and needs of new features and improve its quality. There are still some technical challenges that relate to the legacy of the source code and dependency.

One of the challenges is concerning the heart of TANGO, which use CORBA for all the client/server communication. This open architecture allows distributed objects to communicate with each other, which is a perfect match for a scientific and heterogeneous control system like Tango, considering each hardware as an object.

From its date of creation, CORBA has seen different support from big names in the industry, even being part of the standard library of programming languages like Java. This architecture was the seed of many other types of architecture like web services (JBoss).

### Motivation

Nowadays, CORBA is still used by very specific domains but not maintained to face the evolution of computer science. In 2013 the Tango Community mentioned for the first time a study for the replacement of CORBA.

The implementation reference of Tango written in C++ shows a real entanglement inside the source code, in which

OmniORB, the C++ CORBA library, is leaking in all the public API. Removing CORBA would mean refactoring the entire Tango C++ library by abstracting at many different levels.

Backward compatibility in Tango is essential, and the idea to replace the library would generate a lot of uncertainty regarding the fundamentals of Tango. Having a precise specification, an idea that emerged during the 2018 Tango kernel meeting in Krakow and lacking before the RFC project, would have been the best way to remove this risk.

**Implementation Agnostic** The Community works towards improving the maintainability of Tango Controls. The Collaboration proactively makes the framework immune to obsolescence of libraries and technologies (e.g. CORBA) it is based on. It is expected it may require rewriting all source code-base for a particular language.

**Knowledge sharing** Another factor to consider is the retirement of the initial Tango Developers. There is a risk of losing a deep knowledge of the Tango protocol implementation. Before the RFCs, the tango library source code was, in fact, the only specification. This could lead to losing the compatibility between versions of the Tango Controls or between libraries for different programming languages after bug fixes or features' implementations.

**Compatibility** The Community has found that formal documentation of the protocol and Tango Controls concepts is needed [2]. This assures that maintenance and development will not break compatibility.

### WRITING RFCS

Writing proper specifications, understandable by software developers and not influenced by the implementation, was not an exercise that the Tango community used to do.

The model of the specification was inspired by the process established by ZMQ [3] which is one of the protocols used by Tango with an open specification and very well documented process called Request For Comments (RFC).

After a presentation at the 2019 Tango Meeting (DESY, Hamburg 2019), it was decided to start writing the specification with the involvement of all major institutes and companies that use Tango Controls.

### The Process

The Tango RFC process is a clone of the ZMQ RFC one with a minor adaption to the Tango organisation. The scope

of this RFC was to collect the existing specifications of the Tango V9 in regards to the concepts and model, protocol behaviour and conventions.

The objective is to describe the expected behaviour when an operator interacts with the model of Tango and also to describe the communication and processes which allow two different implementations of Tango to communicate between each other. Contrary to ZMQ, the API is not part of the scope of specification for two reasons. First, the current C++ implementation uses CORBA object, which would make the specification very tight to the implementation. Secondly, the different implementations use specifics of the language implemented with, i.e. High-Level Device Servers, although they are trying hard to respect a similar API.

In the future, it would be interesting to fix the API into specification. But for practicalities, it was better to focus on the abstraction formed by the Tango Model and to test this new way of working.

The process of writing the specification is based on C4 and COSS, which are very similar to how the software developers work in a git environment.

**C4** which stand for Collective Code Construction Contract [4] is inspired by the Github-flow [5] but applied to documentation. This way of working ensures of the transparency of the edition by keeping track of:

- changes expected by the authors to the existing specification (logging issue),
- the different phases of building the new specification,
- the comments and the acceptance of the editors

This process allows anyone of the Tango Community to participate to the edition whatever the degree of membership. Only the editors roles was restricted to the representative of the Tango Consortium [6] to ensure a review from an experienced person.

**COSS** stands for Consensus-Oriented Specification System [7] is a lightweight process which describe the lifecycle of the specification. It aims at achieving small specification which are not necessary fully complete although accepted as the most useful description of the moment. Consensus-oriented means that all the participant have to find a common ground before to be validated. Further detailed specification can be achieved by iteration.

In the case of the Tango community, the knowledge has been spread over tens of different institutes which often use Tango their own way with their own semantic. COSS is important for the Tango Specification as it concentrates the point of view of many stakeholders by consensus. The lifecycle also describes what part of the specification is obsolete, also by consensus. The Tango v10 project will probably introduce deprecated feature which should be clearly stated. The complete set of state described in the COSS specification allows to cover the all lifecycle (Fig. 1).

## Tools

Creating a sustainable technical specification requires good tooling support. The Tango Control RFCs are the result of a collective effort of numerous contributors. The authoring process requires collaboration, involves many discussions, and ends with a peer review of the resulting document. These factors led to the adoption of the *Docs as Code* [8] philosophy and raised a need for a full-fledged DevOps platform that facilitates planning and tracking the work, provides a version control system, allows for code reviews and enables integration with external services to publish the documents. GitHub was selected as a platform offering all the required features. After migration in 2021 [9], all RFC development takes place on GitLab [10]. The RFC documents are published on the Read the Docs platform [11].

The RFC specifications are drafted using the Markdown markup language [12]. Markdown format was selected because of its close integration with the GitHub (and now GitLab) platform. The documents are stored in human-readable plain text files which makes them suitable for putting in a version control system. GitLab automatically renders Markdown as HTML which allows one to preview the modification during the development and provides instant feedback on how will the final document look like. The RFCs are taking advantage of the extensions offered by GitLab Flavored Markdown, including the *front matter* [13] which is used for embedding metadata like editor's name or document's status.

Some aspects of the Tango Controls specification like naming schemas must describe complex textual patterns. A well-defined formal notation is required to precisely describe the structure of such patterns. The RFC authors adopted the ABNF language [14] for this purpose. Listing 1 shows an excerpt from the Device Property specification using ABNF to specify the Property name.

Listing 1: Device Property name specification.

```
alphanum = ALPHA / DIGIT
underscore = %x5F
device_property_name =
    1*1ALPHA
    0*254(alphanum / underscore)
```

## THE RESULT

### Documents' Structure and Organisation

The project provides a template to prepare an RFC about a given part of the specification. Each topic to specify has its own document. Always starts with some metadata to help automatic processing followed by a short preamble that focus on the licensing of this documentation and the use of the ietf RFC2113. It is important then to collect the goals of the document and some user cases to describe what it is being to be specified.

The specification itself is the most agnostic as possible to the current implementations. The focus stay in describe

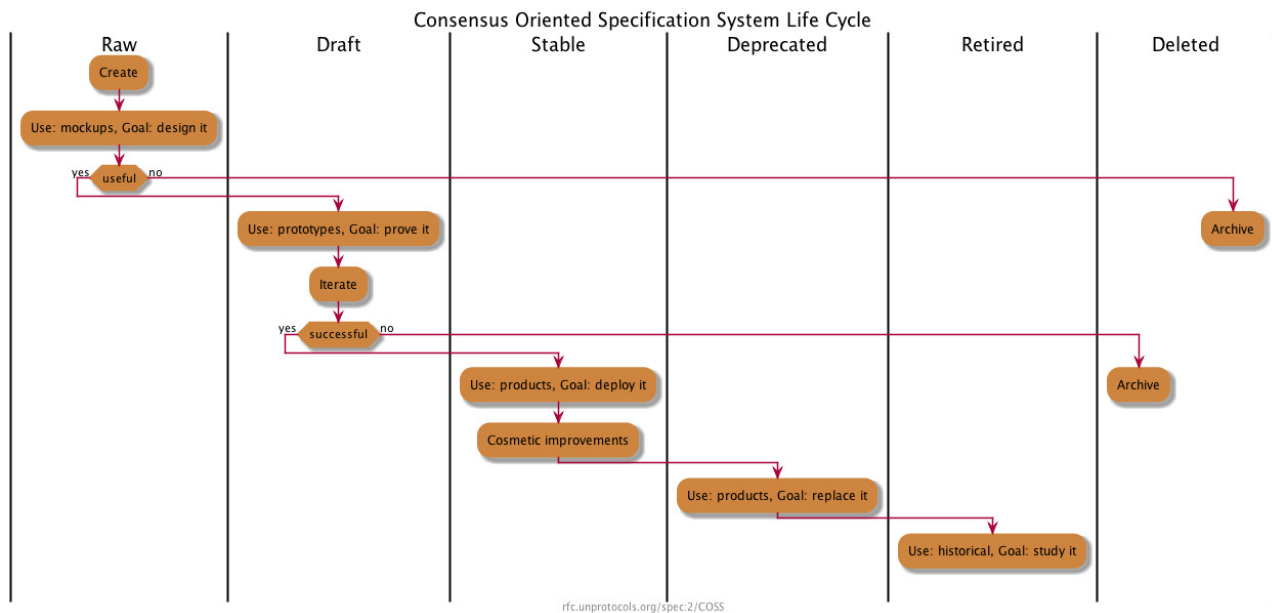

Figure 1: The complete COSS lifecycle.

and define the best way possible how things shall be made for interoperability and compatibility but giving enough freedom to avoid to be a rigid corset.

The topics in the tango-rfc are [15]:

1.Tango Control System	10.Request-Reply protocol
2.Device Object model	11.Request-Reply with CORBA
3.Command model	12.Publisher-Subscriber protocol
4.Attribute model	13.Publisher-Subscriber with ØMQ
5.Property model	14.Logging service
6.Database system	15.Dynamic Attrs & Cmds
7.Pipe model	16.Cache system
8.Server model	17.Memorized Attributes
9.Data types	18.Authorization system

## Publication

The RFCs are published on the ReadTheDocs.io service: <https://tango-controls.readthedocs.io/projects/rfc/en/latest/>. It is compiled from the Markdown sources with use of *Sphinx* [16] and *myst-pareser* [17] library and renderd to HTML and PDF formats.

The ReadtTheDocs supports versioning. The service can be configured to use Git tags and branches as sources for different versions of the documentation. This feature allows to relate the RFCs to a specific version of Tango Controls. The versioning is already exploited to pre-release RFC-10 *Request-Reply protocol* specification [18] which is well advanced in writing but still in-progress.

## USE OF THE RFCS

### Added Value

Writing formal specifications for the existing Tango 9 software had some interesting side benefits.

Trying to describe some Tango 9 features revealed some inconsistencies in the way they are currently implemented in the different languages. For instance, some code generated by POGO [19], the Tango code generator, is not always behaving the same way when generated in the different supported languages. The possibility to override a device property with a class property is currently not implemented the same way in the different languages [20]. This will be improved in a future version of POGO.

This exercise helped to spread the knowledge among the involved developers on some not so well known Tango features and also pointed out the parts of the documentation which required some improvements.

This work triggered as well interesting discussions to agree on a common vocabulary because different words were used in different institutes to name the same Tango concepts. For instance, the administration device is sometimes named “Management Device”, “Admin Device”, “DServer” or “Device Server” in different institutes [21].

Finally, this activity was a great opportunity to discuss new features [22], backwards compatibility of the future versions and to propose some improvements at the concepts level.

### Future Use

The RFC will play an essential role in the future development of a new major version of Tango. The model of Tango has proven to be a powerful concept for the last 20 years. Many existing and new projects have successfully

based their control system Tango and therefore need to ensure that new versions of Tango provide the same or compatible features. The RFCs describe the behaviour of Tango as it is today seen by clients and servers. The RFCs open the door to a new development of the Tango core with a new code base while ensuring that the features of Tango which are provided by the current LTS version (V9) are maintained. The RFCs can be seen as a specification for future versions of Tango. Having a clear specification agreed by all means new implementations are not required to implement all features of a full Tango-based system. Possible implementations could be made for only the server part or even micro-servers which implement only events for example. This approach allows a step-by-step approach to testing new ideas without taking a large risk that the new developments do not satisfy the needs of a typical Tango system.

The RFCs are also a guarantee that even if key members of the kernel team leave the behaviour of Tango has been captured and documented. This gives another guarantee that in the future of Tango could be entirely redeveloped without taking too much risk for existing installations even if source compatibility is not guaranteed.

## CONCLUSIONS

The most important Tango Controls concepts and protocol behaviour are formally documented now. The RFCs are published on ReadTheDocs: <https://tango-controls.readthedocs.io/projects/rfc/en/latest/>. These documents have status *draft*. This means one can use them as a specification for prototype development.

Final work is in progress for RFC-10/The Request-Reply Protocol [18]. The RFC-13/Publisher-Subscriber protocol implementation with ZMQ is waiting for review [23]. Three other RFCs:

- RFC-11/The Request-Reply protocol - CORBA implementation,
- RFC-17/Memorised attribute service,
- RFC-18/Authorisation system

are planned to be written if need.

Cache system specification is now part of RFC-10/Request-Reply, and it is not yet decided if it will be moved to RFC-16.

The Tango Community plans to organise a workshop for the final edition of the RFCs and plan the next steps.

The RFCs will be further developed to follow new or changed features of Tango Controls. As the Tango Community plans to build a prototype of Tango V10, the RFCs will be used and verified for completeness and any ambiguity. This will also trigger either supplementation or corrections of the specifications.

Following COSS, after verification by usage and when a new version of Tango Controls is ready, the documents will be marked as stable.

## ACKNOWLEDGEMENTS

The authors acknowledge the support of the Tango Controls Collaboration for funding and contributions. The RFCs were written with the engagement of all Tango Controls Community. Authors would like to thank all who contribute by writing, commenting, reviewing, discussing and encouraging to do the work, among others (in last name alphabetical order): Gwenaelle Abeillé (SOLEIL), Reynald Bourtembourg (ESRF), Thomas Braun (byte physics), Antoine Dupre (MAX-IV), David Erb (MAX-IV), Andrew Götz (ESRF), Igor Khokhriakov (IK), Olga Merkulova (IK), Sergi Rubio (ALBA), Graziano Scalamera (Elettra).

## CI-CD PRACTICES AT SKA

### Abstract

The Square Kilometre Array (SKA) is an international effort to build two radio interferometers in South Africa and Australia forming one Observatory monitored and controlled from global headquarters (GHQ) based in the United Kingdom at Jodrell Bank. SKA is highly focused on adopting CI/CD practices for its software development. CI/CD stands for Continuous Integration & Delivery and/or Deployment. Continuous Integration is the practice of merging all developers' local copies into the mainline frequently. Continuous Delivery is the approach of developing software in short cycles ensuring it can be released anytime, and Continuous Deployment is the approach of delivering the software into operational use frequently and automatically. This paper analyses the decisions taken by the Systems Team (a specialized agile team devoted to developing and maintaining the tools that allow continuous practices) to promote the CI/CD practices with the TANGO-controls framework.

### INTRODUCTION

When creating releases for end-users, every large software endeavour faces the problem of integrating different parts of their software solution and bring them to the production environment. When many parts of the project are developed independently for some time, an integration problem arises when merging them into the same branch, consuming more developer resources than originally planned. In a classic Waterfall Software Development process this is usual but also happens when following the classic Git Flow — also known as Feature-based Branching, which is when a branch is created for a feature. As an example, considering one hundred developers working in the same repository each of them creating one branch, merging can easily lead to conflicts becoming unmanageable, for a single developer to solve, thus introducing a delay in the releases (in literature this is called "merge hell"). This problem becomes evident especially working with over a hundred repositories with different underlying technologies. Therefore, it is essential to develop a standard set of tools and guidelines to systematically manage and control different phases of the software development life cycle throughout the organisation.

In the Square Kilometre Array (SKA) project, the selected development process is SAFe Agile (Scaled Agile framework) that is incremental and iterative with a specialized team (known as the Systems Team) devoted to supporting the Continuous Integration, Continuous Deployment, test automation and quality.

### Continuous Integration (CI)

CI refers to a set of practices requiring developers to integrate code into a shared repository often. Each commit is verified by an automated build, allowing teams to detect problems early in the process, giving feedback about the state of the integration. Martin Fowler [1] states various practices in this regard:

- maintain a single source repository for each system's component, favouring the use of a single branch;
- automate the build (possibly all in one command);
- automated test is run after build process for the software to be self-testing (this is crucial: all benefits of CI rely on the test suite being high quality);
- every commit should build on an integration machine: the more developers commit the better it is (common practice is at least once per day);
- frequent commits reduce potential conflicts: developer workflow is reconciled on short windows of change;
- main branch must always be stable;
- builds must be fast so that problems are found quickly;
- multi-stage deployment: every software build must be tested in different environments (testing, staging, etc);
- make it easy to get the latest version: all programmers should start the day by updating their local copies;
- Everyone can see what's happening: a testing environment with the latest software should be running.

### Continuous Delivery & Deployment (CD)

Continuous Delivery [2] refers to a CI extension focusing on sustainably automating the delivery of new software releases. Release frequency can be decided according to business requirements, but the greatest benefit is reached by releasing as quickly as possible. Deployment has to be predictable and sustainable, irrespective of whether it is a large-scale distributed system, complex production environment, embedded system, or app. Therefore the code must always be in a deployable state. Testing becomes the most important activity, needing to cover enough of the codebase.

Often, the unsupported fact that frequent deployment equals lower levels of stability and reliability, is assumed. For software, the golden rule should be "if it hurts, do it more often, and bring the pain forward" — [2], page 26.

There are many patterns around continuous deployment related to the DevOps culture [3], "the outcome of applying

the most trusted principles from the domain of physical manufacturing and leadership to the IT value stream. [...] The result is world-class quality, reliability, stability, and security at an ever lower cost and effort; and accelerated flow and reliability throughout the technology value stream, including Product Management, Development, QA, IT Operations, and Infosec". It fosters increased collaboration between development (requirements analysis, development and testing) and operations (deployment, operations and maintenance) within IT. In the era of mainframe applications was common to have the two areas managed by different teams resulting in a development team with low interest in the operational aspects (managed by a different team) and vice versa. Sharing responsibility means that development teams share the problems of operations by working together in automating deployment operations and maintenance, and in return, operations have a deeper understanding of the applications being supported. It is also very important that teams are autonomous: being empowered to deploy a change to production with no fear of failure. This is only possible by supplying the necessary testing/staging platform and required infrastructure tools for developers to engage with the platforms and by using applications and deployment processes that can be rolled out and reverted if required.

Automation is one of the key elements of a DevOps strategy. It allows teams to focus on what is valuable (code development, test results, etc.) instead of the deployment itself, reducing human errors. The importance of those practises is to reduce risks of integration issues, releasing new software and creating better software products. CD goes one step further, as every single commit to the software that passes all the stages of the build and test pipeline, is deployed into the production environment — preferably automatically.

## CONTAINERISATION

The *system engineering* development process was adopted in the initial design phase of the SKA project to reduce complexity by dividing the project into simpler elements. For every element, an initial architecture was developed, which comprises the software modules needed corresponding to a repository — each a component of the system.

Since all components need to be deployed and tested together, the first decision is how to package them. A container is a standard run-time unit of software that packages code and dependencies so that the component runs quickly and reliably across different computing environments. A *Docker* [4] *container image* is a lightweight, standalone, software package including everything needed to run an application: code, runtime, system tools, system libraries and settings.

One of the main dependencies in the SKA software is the TANGO-controls [5] framework, a middleware for connecting software processes mainly based on the CORBA standard (Common Object Request Broker Architecture). The standard defines how to expose the procedures of an object within a software process with the RPC protocol (Remote Procedure Call). TANGO extends the definition of an object

with the concept of a Device that represents a real or virtual device to control. This exposes commands (procedures), and attributes (i.e. state) allowing both synchronous and asynchronous communication with events generated from attributes. Fig.1 shows a module view of the framework.

Figure 1: TANGO-controls simplified data model.

The importance of containers becomes clear with dependencies. The entire framework is packaged onto a set of containers [6] so that the final product is a containerized application that will be run in a system for managing these applications. Specifically, there is a SKA repository *skatango-images* [6], encapsulating all its components in a set of container images. Fig. 2 shows a simplified diagram for this project. By extending one of them, TANGO-controls becomes a layer inside the base images of any SKA module solving the dependency once for all.

Figure 2: SKA-tango-images repository.

*Kubernetes (K8s)* [7] is used for container orchestration and *Helm Charts* [8] for declaring runtime dependencies for K8s applications. In K8s all deployment elements are resources abstracted away from the underlying infrastructure implementation. For example, a Service (network configuration), PersistentVolume (file-system type storage) or Pod (the smallest deployable unit of computing, consisting of containers). The resources reside in a cluster (a set of connected machines) and share a network, storage and other resources like computing power. Helm is a tool for managing K8s deployments with charts — a package of pre-configured K8s resources, tied to run-time instance configuration.

Namespaces create a logical separation of resources within a shared multi-tenant environment. A Namespace

enforces a separate network and set of access rights enabling a virtual private space for contained deployment.

*ska-tango-images* repository contains the definitions of two Helm Charts: *ska-tango-base* and *ska-tango-util*.

*ska-tango-base*: application Helm Chart defines the basic TANGO ecosystem with the following K8s services:

- *tangodb*: MySQL database used to store configuration data used at the startup of a device server;
- *databaseds*: device server providing configuration information to system's components, and runtime catalogue of the components/devices;
- *itango*: interactive TANGO client;
- *vnc*: Debian environment with x11 window system together with vnc [9] and noVNC [10] installed on it;
- *tangorest*: rest api [11] for TANGO eco-system;
- *tangotest*: TANGO test device server [12].

*ska-tango-util*: library chart helper for defining TANGO device servers on applications. Defines the following Helm templates:

- *multidevice-config*: K8s ConfigMap defining dsconfig JSON configuration file, bootstrap script for dsconfig, and python script for multi-class device server startup;
- *multidevice-job*: job for dsconfig application to apply a configuration JSON file set into the values file;
- *multidevice-sacc-role*: K8s service account, role and role binding that waits for configuration job to finish;
- *multidevice-svc*: K8s service and a K8s StatefulSet for a device server tag specified in the values file.

A Helm Chart contains at a minimum, information concerning the version of the container images and pull policy (image retrieval rule) for deployment. It also contains the necessary information to correctly initialize the TANGO database (device configuration) and how is exposed to other applications for discovery whitening the cluster.

Other SKA repositories *Makefiles* are selected as an abstraction and organisation layer eliminating language-specific scripts for building, testing, deployment and promoting ease of use in CI/CD. The use of a *Makefile* in each project simplifies containerisation work and automation of code building, testing and packaging processes, making it possible with a single command to compile the project, generate container images and test them by dynamically installing the related Helm Chart in a K8s environment.

The Makefile also enables publishing of container images and Helm Charts to SKA artefact repository and promotes reusability of the same build toolchain in different environments such as local development and CI/CD lifecycle.

## ARCHITECTURE FOR INTEGRATION

In the previous section, was highlighted how the SKA project can be seen as a set of elements composed by a set of software modules corresponding to a repository. For each repository, one or more container images are built and pushed into the artefact repository (Nexus [13] box shown in fig. 5) while for each element, a Helm Chart is published into the same storage solution.

Since a Helm Chart can be in a dependency relationship with another chart, this concept can be used for integrating the various SKA elements which comprise the SKA MVP Product Integration (SKAMPI [14]) in a composable way representing the bulk of the effort for integrating all SKA's software sub-systems. Fig.3 shows a simplistic view of this above concept and its hierarchy.

Figure 3: SKAMPI.

It is important to consider the operational aspects of the Helm dependencies which state that when Helm installs/updates a chart, the K8s resources from the chart and all its dependencies are aggregated into a single set, sorted by type followed by a name, and created/updated in that order. Due to this, a limit was imposed for single-level hierarchy with a parent chart, called the umbrella chart, which pulls together the charts of the hierarchy. While SKAMPI is the composition of the entire hierarchy, it is possible to think of different umbrella charts for other purposes like integration testing between a select few elements of the hierarchy. Fig. 4 shows the umbrella chart concept: the blue umbrella chart is the entire hierarchy while the red and green ones are for other purposes. This means that every SKA element can perform its integration testing by creating an umbrella chart with sub-elements needed for its integration.

Figure 4: The umbrella chart concept.

## SKA INFRASTRUCTURE

To support the integration's architecture an infrastructure was built consisting of a standard footprint of VPN/SSH JumpHost gateway (called Terminus), Monitoring, Logging, Storage and K8s services to support the GitLab [15] runner architecture, and MVP testing facilities as shown in Fig.5 used to support DevOps and Integration testing facilities.

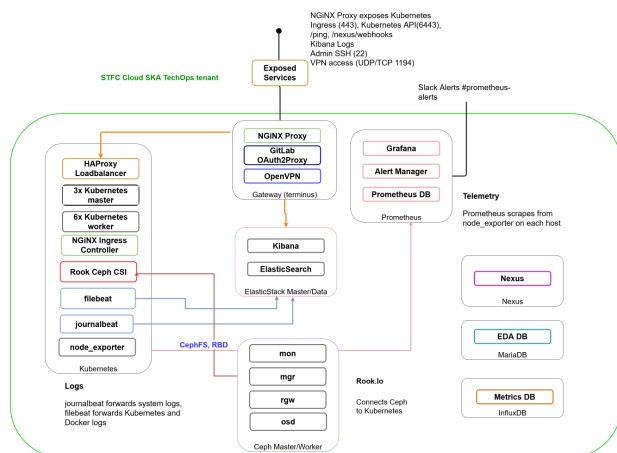

Figure 5: STFC cloud components.

A K8s cluster was deployed with 1 LoadBalancer, 3 Master, and 6 Worker configuration. Fig.6 illustrates how the LoadBalancer ties K8s services together exposing deployed applications to the outside world. The K8s API Server is exposed externally from Terminus using TCP pass-through, and NGiNX [16]'s Ingress Controller is SSL terminated for external access. These services are exposed using an NGiNX reverse proxy. Ingress access on port 443 is password protected using oauth2-proxy [17] integration with GitLab.

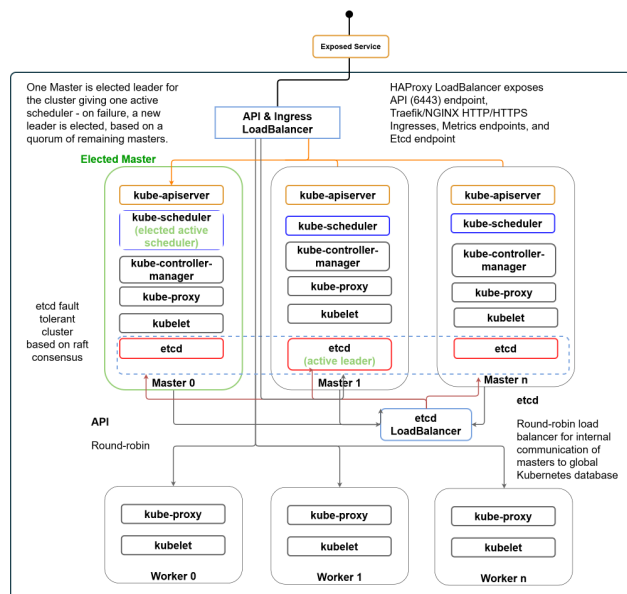

Figure 6: Kubernetes components.

In Fig.7 it is shown the K8s runner [18] works as a multiplexer receiving requests from GitLab for jobs and launching their respective Pods up to a configured scaling limit (15 currently). GitLab's runners use intermediate cache to speed up jobs by passing dependencies between them. This cache is based on Minio [19] with S3 [20] compatible buckets for storage.

Figure 7: GitLab runner.

## PIPELINE

To bring everything together for a complete CI/CD toolchain, GitLab [15] was selected. The data model for a generic SKA software is shown in Figure 8.

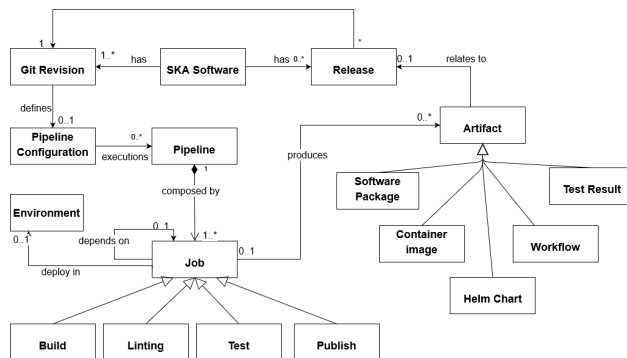

Figure 8: Pipeline definition data model.

The entry point of the diagram is the Pipeline box, composed of several jobs. This was standardised for each project regardless of its artefacts so that the same standardised steps for code/configuration and Helm Charts are followed:

- **linting:** code is analysed against sets of coding rules to check if it follows the agreed best practices;
- **build:** code is compiled and a container image created;
- **test:** compiled package (and image) are tested;
- **publish:** code artefacts are published;
- **pages:** test results are published (GitLab's naming).

The pipeline is respected as the main hub of software development in which code is built, tested, verified, published and integrated. These steps are used in local development (where the same shell scripts are available thanks to the *Makefile* targets), merge workflow, QA, integration and release. Also, having an almost identical platform environment

for different stages of the software lifecycle, significant differences between development and operations are eliminated.

Fig.9 shows a simplification of the run-time behaviour of the selected technologies working together. At the centre part, there is a K8s cluster defined for every project in SKA's telescope. Outside the K8s cluster, are GitLab code repositories and pages, Nexus Artifact repository [13] (store packaged code artefacts), ELK stack (Elasticsearch, Logstash and Kibana) [21] for logging, prometheus [22] for monitoring (metric collection) and Ceph [23] for distributed storage.

Inside the cluster, in an isolated K8s Namespace, are the GitLab runners related K8s resources, checking every 30 seconds if there are pending pipelines triggered manually or pulled by resources. If the runner finds a pipeline, it creates a K8s Pod for each job defined in the configuration file. Each created Pod is capable of deploying an umbrella chart needed for specific testing of the repository in an isolated Namespace. The installed deployment can then be tested and the job's result will be reported to GitLab producing artefacts, to be stored in the correct artefact repository.

During any stage of the pipeline, jobs can download required dependencies from the artefact repository. Depending on the type of job, the pipeline is used for deploying the permanently running version of SKAMPI or other resources needed. The K8s cluster is equipped with monitoring solutions to examine the cluster's health and performance and any resources that are deployed in it. Storage and logging solutions are integrated to provide a consistent logging and distributed storage framework for the resources. Finally, this architecture for creating temporal K8s resources for pipeline steps (testing, building, packaging, etc.) ensures that necessary environments for the jobs are always clean — i.e. not affected by previously run pipelines.

Figure 9: CICD at run time.

## TESTING

The most important in CI is testing, so we need to question ourselves how a generic component of the SKA can be tested with the above architecture. At the SKA, testing was split into two distinct types: pre-deployment and post-deployment. Deployment happens when a runner executes

a job with a GitLab environment keyword. By doing so, the job is linked to the K8s cluster through GitLab configuration. While pre-deployment tests (unit tests) are made without the real system online (using stubs and mocks), other tests (integration and system tests) need more than one live system component to be up and running as they will be using other services and applications. The SKA is composed of several distinct modules, each of them with its repository and different requirements for the components needed for integration and system testing. For each, an umbrella chart was introduced which enabled the specific component to be deployed together with its dependencies. Specifically, to enable the GitLab pipeline to deploy and test the chosen component each repository must:

- contains at least one Helm Chart;
- has an environment;
- has a Makefile for K8s testing.

A set of templates and standardized Makefiles was developed by the System Team, so it is only necessary to include them in the repository. The post-deployment test job is then composed of the following steps defined in those Makefiles:

- **install:** installs chart (and sub-charts) in the Namespace specified in the environment;
- **wait:** wait for every container to be running;
- **test:**
  - create container in the Namespace specified in the environment;
  - run PyTests inside this container;
  - return test results.
- **post test:** delete all resources allocated for tests.

The artefacts are the output of the tests, containing reports both in XML and JSON and other (i.e. PyTest's) output so that consequent pipeline steps (mostly packaging and releasing) can be run.

## DEVELOPMENT WORKFLOW

There are two important assumptions for understanding SKA's development workflow: the master branch shall always be stable, and branches shall be short-lived. Stable means that the master branch always compiles, and all automated tests run successfully. This also means that every time a master branch results in a condition of instability, reverting to a condition of stability shall have precedence over any other activity on the repository. As a result, the selected development workflow for SKA is the following:

- developer works on current code base's copy;
- work on a story starts on a new branch named after it;
- developer frequently commits changes to local git repo;

- developer creates unit tests to be run on local environment until they successfully pass;
- once tests pass, changes are pushed to a remote branch;
- CI server (GitLab):
  - checks out changes when they occur;
  - runs static code analysis providing feedback;
  - builds system and runs unit and integration tests on the branch;
  - provide feedback to developer about test status;
  - provide feedback about coverage metrics.
- once all branch's tests execute successfully, the developer opens a pull request (i.e. *GitLab's Merge Request*) for merging changes onto master;
- code is reviewed and approved by other developers;
- code is merged into the master branch;
- CI server (GitLab):
  - runs whole pipeline again including the tests on master branch;
  - releases deployable artefacts for testing (reports, code analysis, etc.);
  - assigns build label the code's version built (i.e. docker image version);
  - alerts team if build or tests fail for them to fix issue ASAP;
  - publishes the successful build artefacts to artefact repository.

## CI-CD AUTOMATION AND QUALITY

To verify if all best practices are followed, plugins and tasks were implemented to perform quality checks on GitLab's merge requests and artefacts published to Nexus. Fig.10 shows a module's view of the frameworks for those.

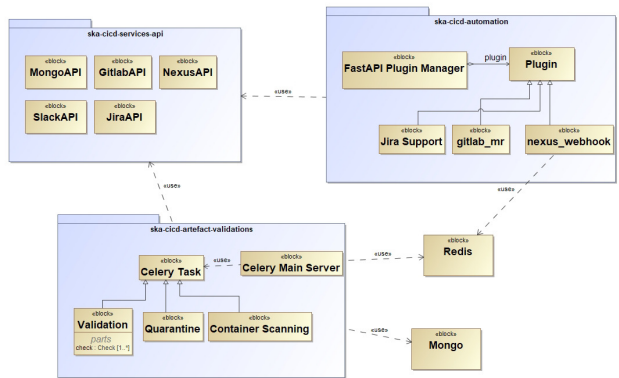

Figure 10: CI-CD automation framework.

The above diagram shows three main packages:

- **ska-cicd-services-api** [24] which includes all APIs that will be used in the other two packages. These APIs allow to communicate with GitLab (i.e merge request creation or for project information), Slack [25] (i.e. sending messages to channels), Jira [26] (i.e. project information) and Nexus (i.e. obtaining component information);
- **ska-cicd-automation** [27] which uses FastAPI [28] to build a Python web application with a plugin architecture. Three plugins have been created: **gitlab\_mr** used for merge request quality checks and providing feedback to developers directly on GitLab; **jira\_support** to handle jira operations and **nexus\_webhook** to trigger webhooks every time a new artefact is published;
- **ska-cicd-artefact-validations** [29] based on Celery [30] containing a main server pulling messages from Redis [31], transforming them into artifact validation tasks and storing the results into a MongoDB [32] database.

### Merge Request Quality Checks

To ensure that every developer follows the development workflow and best practices, automated checks are performed on Merge Requests. A webhook was added to the ska-telescope GitLab group, which triggers a service (fig. 10 *ska-cicd-automation* [27]) every time a new Merge Request is created. The quality checks will then verify if:

- the Merge Request Settings were set correctly;
- the branch name, the commit messages and the merge request have a Jira Ticket ID;
- the project has a proper license;
- the project as documentation on it and if it was updated;
- the project has pipelines with the needed jobs.

After performing the checks, their result is reported back to the developers on GitLab's main Merge Request page via a comment (see Fig. 11 for an example of the comment, including a table with the severity of the failed check, description about the check and mitigation strategy).

Type	Description	Mitigation Strategy
Missing Assignee	Missing Assignee	Please assign at least one person for the MR
Pipeline Checks	Pipeline Checks	Please add the following jobs: - ci-metrics - container-scanning
Missing Jira Ticket ID in Branch Name	Missing Jira Ticket ID in Branch Name	Branch name should start with a lowercase jira ticket id. Please close this MR, rename your branch and create a new MR.

Figure 11: Checks results table.

### Nexus Artefact Validation

There are many packaged code artefacts of multiple formats being created in the SKA project hosted on GitLab

and then published to the Nexus Artifact repository. Those should follow SKAO's conventions: Artefact names should be compliant with semantic versioning 2.0.0 [33] and must include associated metadata with the required information, such as who published it, from which GitLab repository is they originate from and other useful information.

To ensure that the guidelines and policies described are followed for consistent, compliant and robust artefact management, there are a series of automated validations in place at *ska-cicd-artefact-validations* [29]. If an artefact fails validation, it is moved to a quarantine state and the results of the checks are reported back to developers that triggered the pipeline that published it. This report is made by creating a new Merge Request where the developer is made assignee and its description contains a table composed of the failed validations and instructions on how to mitigate them.

The execution of artefact validations happens following the Celery architecture with a server that pulls messages from a queue (Redis) and creates tasks (processes) to perform the specific validation. Every task can then create other tasks as needed to perform other activities (i.e. quarantine the artefact or create merge request on GitLab). The result validation is stored in a MongoDB database.

When an artefact is published on the GitLab job the following tasks are performed:

- **validation:** performs the validation checks;
- **get metadata:** extract existing metadata from artefacts;
- **container scanning:** scans for container vulnerabilities using Trivy;
- **quarantine:** quarantine artefacts if any checks fail;
- **create MR:** create MR to report failures to developers;
- **insert DB:** insert metadata into MongoDB about the validation performed.

With the above tasks, it is possible to keep and maintain a clean and organized repository, where all artefacts follow the guidelines and policies defined on the project.

## CONCLUSION

The majority of decisions taken by the Systems Team follow the workflow described by the Continuous Integration process outlined in Martin Fowler's paper inspired by the state-of-the-art industry practices of [1–3]. In particular:

- for each component of the system, there is only one short-lived repository with minimal use of branching;
- artefact build, tests and publishing are automated with the use of few commands (Makefile targets);
- every commit triggers a build in a different machine;
- once artefacts are built, the SKAMPI will automatically create a new deployment of the system and more tests will be done at that level (i.e. system tests);

- having a common repository (Nexus and GitLab pages) for the code artefacts and test results simplifies downloading the latest changes from every team and for each component to enable fast development;
- the integration environment is accessible to all developers and deployed in a unique Namespace on the cluster.

In addition, every artefact is validated in terms of quality so that a common standard across the project is maintained.

## Abstract

In the field of Experimental Physics and Industrial Control Systems (EPICS) [1], the traditional tool to implement high level procedures is the Sequencer [1]. While this is a mature, fast, and well-proven software, it comes with some drawbacks. For example, it's based on a custom C-like programming language which may be unfamiliar to new users and it often results in complex, hard to read code. This paper presents pysmlib, a free and open source Python library developed as a simpler alternative to the EPICS Sequencer. The library exposes a simple interface to develop event-driven Finite State Machines (FSM), where the inputs are connected to Channel Access Process Variables (PV) thanks to the PyEpics [2] integration. Other features include parallel FSM with multi-threading support and input sharing, timers, and an integrated watchdog logic. The library offers a lower barrier to enter and greater extensibility thanks to the large ecosystem of scientific and engineering python libraries, making it a perfect fit for modern control system requirements. Pysmlib has been deployed in multiple projects at INFN Legnaro National Laboratories (LNL), proving its robustness and flexibility.

## INTRODUCTION

The Experimental Physics and Industrial Control Systems (EPICS) [1] is one of the most successful frameworks to develop control systems for physics facilities, being used at major laboratories and experiments all around the world. Its main feature is the implementation of the Channel Access (CA) (and the PV Access in newer versions), a standard protocol where the different parts of the control system can communicate. This provides a standard interface to access all the Process Variables (PV) and works as a hardware abstraction layer. Using this protocol, many components have been developed by the community to provide the core functionalities of a modern control system, like Phoebus [3] and React Automation Studio [4] for Graphical User Interfaces (GUI) or the Archiver Appliance [5] for historical data storage.

The sequencer is the tool proposed by the EPICS core developers to implement high level procedures and Finite State Machines (FSM) for process automation. This is an extension of the core software and was first proposed in 1991 in the EPICS paper [1] and originally developed at the Los Alamos National Laboratory. It defines a C-like language called State Notation Language to develop finite

Figure 1: Pysmlib logo.

state machines which is transcompiled to C code and then compiled to machine code. The user can define states and transitions, while the sequencer takes care of low-level details like the connection with the Channel Access, the event handling and concurrency. Finally, the code is usually run as part of a EPICS input output controller (IOC), which is the piece of software which defines and publishes the PVs on the Channel Access.

This software has proved valuable and has been widely adopted thanks to its good performance, seamless integration with the Channel Access and the IOC, and its programming model. Even so, some of its limitations have emerged over time. For example, being C-based was a great advantage at the beginning since it means that one could extend it with any C/C++ library. Today, higher level languages are preferred for this kind of high level tasks, and performance is no longer a limiting factor in most cases. For this reason Python has emerged as one of the most prominent languages for modern scientific and engineering computing, thanks to a large number of dedicated libraries. Also, Python appeals to a broader audience of less-technical programmers.

The PyEpics [2] python library, which wraps the original libca C library, became thus a popular alternative to communicate with the Channel Access. This can be used to write both simple scripts and full blown programs. Large experiments or collaborations used this, or similar wrappers, to build tightly integrated high level suites which handle automation and much more at facility level, such as ophyd and bluesky [6]. These are great solutions, but require a big investment into their design model, which could not be ideal for simple tasks or small independent laboratories. Also, at this level there is a lot of fragmentation in the community, with no default go-to solution but many different approaches tailored to the needs of specific laboratories.

\* [davide.marcato@lnl.infn.it](mailto:davide.marcato@lnl.infn.it), [www.davide.marcato.dev](http://www.davide.marcato.dev)

In the middle between vanilla PyEpics scripts and full experiment-wide software, there is still the need for a generic standalone solution to develop finite state machines, where the execution flow, event handling and connection with the channel access is provided. Pysmllib aims to recreate the sequencer programming model and its strengths, while taking advantage of the python language and focusing on ease of use.

This paper formally presents the library to the scientific community, describing its design and going into details on the implementation and execution flow. Then an overview of the user interface is presented and finally the current status of the project and some plans for the future are outlined.

## DESIGN PRINCIPLES

A Finite State Machine is a computational abstraction where the program behaviour depends on its current state and the input it receives. The machine can perform a transition to a different state in response to inputs. For example the schema in Fig. 2 represents a simple FSM with 3 states  $S_0$ ,  $S_1$ ,  $S_2$ ,  $S_3$  and 2 inputs  $x_0$ ,  $x_1$ . The execution starts from  $S_0$  and while  $x_0$  is 0 the current state does not change. When  $x_0$  becomes 1, the FSM executes a transition to  $S_1$ . Now the FSM follows the value of  $x_1$  by staying in  $S_1$  when its value is 0 and moving to  $S_2$  when it becomes 1. In  $S_2$  the FSM can go back to  $S_0$  if  $x_0$  becomes 0 or to  $S_1$  when  $x_1$  is 0.

Figure 2: Schematic representation of a FSM with 3 states and 2 inputs.

This kind of abstraction is extremely useful to design control system algorithms, where the controlled system can be described with states and transitions, and the control algorithm can be tuned for the current state.

Pysmllib aims to provide a simple way to describe Finite State Machine states and transitions, while handling all common tasks and minimizing the custom code required. Thus, it keeps track of the current state and executes it in response to events and takes care of connecting the FSM to the inputs, while providing the user some methods to access them. The term *input* is here used both for input (readable) and output (writable) signals. In fact, in pysmllib they are an abstraction of Channel Access PVs, even though the library is designed so that a future expansion to different types of inputs is relatively easy and requires as little updates to the user interface

as possible. On top of the methods to read and write PVs provided by PyEpics, the methods to detect rising and falling edges or changes are provided, which are particularly useful for the design of a FSM. Then, the user can implement the FSM states as methods of a class, which represents the FSM, with a specific naming convention and the library is able to automatically discover them. When performing a transition from one state to another, the user can decide to implement *entry* and *exit* methods for each state, which are executed only once during the transitions, as can be seen in Fig. 5.

Pysmllib is designed to maximize network efficiency and system responsiveness, in order to be able to react with minimum latency to input events. Thus, all the inputs are connected at startup time, and the connection is kept in memory during the whole execution. The current state is executed every time a channel access event is received, in a event driven way, without relying on a periodic loop. For example, when an input changes its value or its connection status, the current state is re-evaluated so that the FSM can react to the new value, while the state is never executed if no event is received. To optimize network usage, multiple FSMs can be loaded and run in multi-threading while sharing the connection to common PVs and a dispatcher is used to broadcast channel access events to each FSM. The user is expected to develop multiple FSMs, load them together on a single *daemon*, using the provided loader helper, and let it run continuously. This approach comes natural for always-on operations (eg: a feedback correction) but it is also the ideal execution flow for procedures that start from a user input or some external conditions: in these cases the FSM will wait on a *idle* state where no action is performed until the enable signal is received, execute its core procedure, and then come back to idle. This means that when the enable arrives, all the inputs are already connected and the user doesn't have to wait for the FSM startup and all the connection times.

To ensure consistency, the inputs should not change value or status during the execution of a state. For this reason a queue of events is used and they are evaluated in order one by one, where each event triggers one execution of the current state of all the FSMs connected to such input. Along with input events, the user can also set *timer* events, so that the current state is executed after a custom amount of time. This is useful to set timeouts or to execute periodic actions. Other features include logging methods to write FSM logs in a unified way, and a watchdog implementation. In fact, contrary to the sequencer where the code is usually executed on the same IOC that defines the PVs, here the FSM daemons can run everywhere on the channel access network, and most probably will run independently from the IOC and from the user interface. A method to assert if the FSM is online and running is thus needed, since the control system may rely on the FSM to work correctly. For this reason a watchdog is implemented, where the FSM will periodically write to an external PV. The PV is then configured to raise an alarm or an error when the write operation does not happen regularly.

Finally, pysmllib is developed as a generic library with no dependency on the task to perform, and aims to be useful

for a large audience of control system developers. It offers an online documentation and follows open source standards, where the users are encouraged to contribute.

## SOFTWARE ARCHITECTURE

In this section the internal architecture of the library is detailed, along with a description of the execution flow of a FSM. Figure 3 shows a summary of the main classes with their attributes and methods. These can be grouped into 4 modules, as highlighted by the color of the tables. Each module concerns with one of the main features of the library: access to the inputs (green), FSM execution (blue), timers (orange) and other smaller utilities (red). A complete description of each module follows.

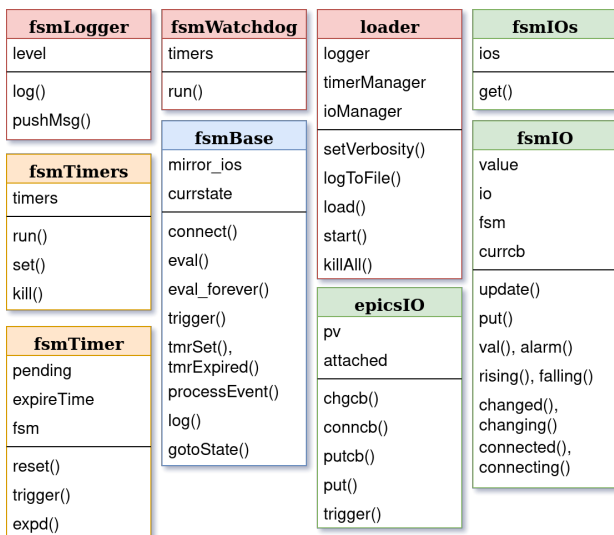

Figure 3: Diagram of the main classes and their most important attributes and methods.

### Input Management

The Channel Access defines some methods to access the Process Variables: it's possible to perform a `get` (read) or a `put` (write) operation, but also to `monitor` a PV, that is register to the IOC server to be notified about PV events. There are 3 types of events: *change* events are emitted when the PV has a new value, *connection* events when the connection status changes and *put complete* events when a put operation completes. With PyEpics it's possible to register a callback to be executed when one of these events occurs, so that the event can be processed.

PySmlib defines the `epicsIO` class which is responsible to keep the connection with a PyEpics PV object and registers the callbacks on the Channel Access events. When an event arrives a `trigger` method is executed, which will pass a copy of the event data to all the attached FSMs. Each FSM has a queue of events where this data is temporarily placed, while waiting to process it. All of this is done on the callback thread, while the queue consumption is done on the FSM execution thread, so the queues must be thread

safe. Furthermore, this class is also responsible to perform the `put` operations, which are directly executed by the FSM, since the Channel Access already implements a queuing system. The `epicsIO` class is instantiated when a FSM connects to a new PV. To avoid duplicating connections to the CA when different FSMs connect to the same PV, a helper class (`fsmIOs`) is used. This class keeps track of the available inputs and creates a new `epicsIO` instance only when required.

One important requirement is that an input does not change during the execution of a FSM state. To achieve this, every time a FSM connects to an input it creates a corresponding instance of `fsmIO`, a class which represents a local copy of an input to each FSM. The execution follows this pattern: first an event is removed from the queue, then the local copy of the corresponding input is updated using the event data and finally the current state is executed. This pattern is repeated until there are no more events in the queue and the thread waits idle for new ones. So each event brings the update of a single input and triggers a single execution of the current state. If the original IO changes during the state execution, the local copy is not affected.

Figure 4 shows an example of the FSM execution flow in response to a *change* event from an input. First, the registered callback is executed by the PyEpics library and all the FSMs connected to the corresponding input are triggered. Then, the event data is queued on the event queue and the thread of the callback (blue in the figure) completes its execution. Now, the FSM thread (green in the figure) awakes and consumes the available events one by one. In order to keep the instance of `fsmIO` synchronized with the original input, first the `reset()` method is called, which removes old data, and then the `update()` one which feed the new information. Finally, the current FSM state is executed by calling the user-defined methods.

In the code, the user can inspect the new received value thanks to the `fsmIO` class, which implements all the methods to read and write the value and metadata of the input. For example, it's possible to read the current value with `val()`,

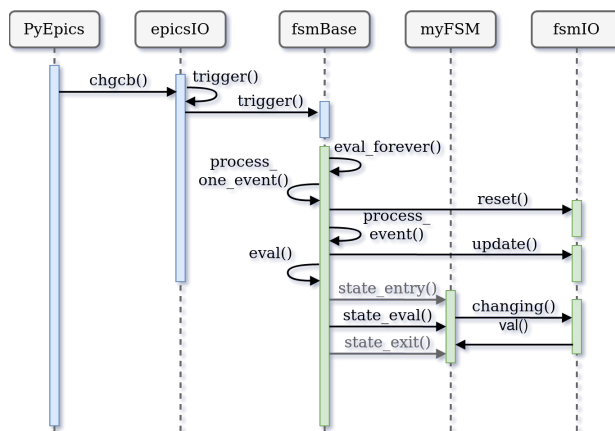

Figure 4: Execution flow of the FSM current state in response to an event from an input.

connection status with `connected()` and the alarm severity with `alarm()`, and to write the value with `put()`. Other methods allow to detect rising or falling edges, or other transient properties of the input. For example, we want that the `connecting()` method returns `True` only during the state execution that was triggered by the connection event, and not on the following ones. Conversely, the `connected()` method will continue to return `True` until the input disconnects. This is especially useful for the design of a FSM to perform some actions just once when a condition is met. To implement this, the type of the current event is used to understand what kind of event triggered the state execution. For example, an input is `changing()` when the current event is of `change` type, while it is `rising()` when the current event is of `change` type and the new value is greater than the preceding one.

### Finite State Machine Execution

The FSM execution flow is managed by the `fsmBase` class. The user is expected to derive from this class to implement his own specific FSM. In the constructor of the derived class the user will connect to all the inputs using the `connect()` method, and will specify the first state to execute. This can be done using the `gotoState()` method which accepts a string with the state name as argument. After that the user will implement the states as methods of the class. As illustrated in Fig. 5, for each state the user will implement a `eval` method and optionally the `entry` and `exit` methods which are executed only once during the state transitions. To be correctly recognized, the methods must be called by concatenating the state name to `_eval()`, `_entry()` or `_exit()`. For example, for a state called `idle`, the user must define the method `idle_eval()` and can optionally define the methods `idle_entry()` and `idle_exit()`.

Figure 5: Entry, eval and exit methods can be implemented for each FSM state.

The `fsmBase` defines a thread which runs the FSM states. This thread initially waits on the event queue for some events to populate it. When an event arrives, it is removed from the queue and processed in order to update the `fsmIO` instance of the corresponding input. Then the `eval()` method is called, which is responsible for the actual state execution. This method performs the following steps:

1. Perform a state transition if required. In this case it also executes the `_entry()` method of the new state, if it's defined.

2. Execute the `_eval()` method of the current state.
3. If the user requested a state transition, the `_exit()` method of the current state is executed. In this case go back to step 1 without processing a new event.

The user can call `gotoState(new_state_name)` inside the state `_eval()` method to perform a transition. In this case, the execution loop is restarted from step 1 without processing a new event, so that the new state is evaluated once without waiting. The `gotoState()` function simply saves the name of the next state and uses the `getattr` python function to find the methods with the corresponding names. The actual transition is executed in step 1 by updating the pointer to the current state.

Other methods of the `fsmBase` class can be used to check conditions on multiple inputs together or to retrieve the input responsible for the current execution of the state. Furthermore, the class is used as a single interface for timers and the logger, as explained in the following paragraphs.

### Timers

Timers are used to schedule internal events, where the current state is executed after a fixed amount of time. They can be used to perform asynchronous operations such as periodic writes or to enforce a timeout when waiting for an external condition to become true. The user can set a timer with the `tmrSet()` method of `fsmBase`, selecting an identifying name and an expiration time in seconds, while the methods `tmrExpired()` and `tmrExpiring()` can be used to verify if a timer has expired in the past or in the current event.

A single timer is represented by the class `fsmTimer`, which keeps track of the expiration status. The class `fsmTimers`, instead, is used to manage all the timers of all the FSMs. This is a thread which keeps a list of timers ordered by their expire time. When the FSM sets a timer, this is added to the list in the correct place. The thread schedules a waiting time equivalent to the remaining time of the first timer in the list, and then triggers the corresponding FSM by appending a *timer expired* event to its event queue. After that it removes the timer from the list and schedules a new waiting time. When the list is empty the thread waits idle until a new timer is set.

All the timers, inputs, and each FSM live on different threads, and thus create a complex multi-threading execution flow. With `pysmlib` this complexity is completely hidden from the user, which gets a well-tested core to build upon, without worrying about low level details.

### Utilities

On top of the core functionalities, the library offers useful utilities to simplify the user code on some common tasks. For example, the `loader` class provides methods to create a launcher file which executes many FSMs in parallel. In fact, after the development of the FSM classes, it's often useful to run different instances of the same FSM with different

parameters, or simply to launch together correlated FSMs to share common resources. The `loader` method of the `loader` class takes care of instantiating a FSM. It lets the user specify custom parameters to be passed to the constructor of the FSM, but it adds some system parameters used to share common resources. For example, a single instance of `fsmIOs` is created and passed to all loaded FSM in order to share the inputs. The same mechanism is used to share the timer manager thread.

The `loader` class is also used to configure log messages. In fact, the library provides an abstraction of a generic log facility which can be configured to send messages to different backends with a unified interface. At load time the user can specify to log to file (`logToFile()`) or standard output (default) and can set the verbosity level with the `setVerbosity()` method, choosing between *debug*, *info*, *warning* and *error* levels. Likewise, the `fsmBase` class provides the `logD()`, `logI()`, `logW()`, `logE()` methods that can be used to write log messages with the corresponding level. The logging facility is provided by the `fsmLogger` class, which is currently a custom class with few options, but can easily be expanded or replaced by the logging module of python without any changes to the user interface, thus minimizing the impact on the existing code.

Another shared resource is the `fsmWatchdog` class, which provides the ability to periodically write to an external PV while a FSM is running. This class is derived from `fsmBase` and implements a specific FSM which periodically writes the watchdog of all running, user-defined FSMs. The user can define an input of an FSM to be used as the watchdog PV by calling the `setWatchdog()` method of `fsmBase` on the constructor of each FSM, and this will be automatically passed to an instance of `fsmWatchdog` at load time. The user can also specify the interval and the value to be written for each watchdog, choosing between 0, 1 or an intermittent value. The external PV should be configured so that when a write operation does not occur after a specified time interval, it raises an alarm. This can easily be achieved with the `HIGH` field of a binary output PV.

## DEVELOPMENT TOOLS

The development of the library adheres to modern standards for python projects. The code is well formatted and documented, respecting the `pylint` indications. To ensure easier updates to the core library automated tests have been developed. These simulate the most common operations and check if the expected result is achieved, so that the developer can easily notice when an update or a new functionality introduces bugs. The tests were developed using the `pytest` [7] framework, and can be run directly with `pytest` or using `nox` [8], a tool to automate test executions in different environments. In fact, given a list of python versions, it takes care of creating a different conda environment for each version, install the dependencies and run the tests. This way, it's easy to verify that the code continues to run correctly on all supported versions of python. To simulate Channel Access

connectivity the `pcaspy` module is used, which helps running a PV server from python, without firing up a complete EPICS IOC. Finally, the `nox` tests are run automatically on the Gitlab CI [9] every time the code is pushed to the server, so that the developer can be alerted of failures.

Since the library was developed with a broad and generic audience in mind, it has also been published as free and open source code on Github [10] with a GPLv3 license, which is compatible with the EPICS open license. The library is packaged as a standard python module using `setuptools` and is available on the PyPI [11] python software repository, so that it can be installed with just one command. Version strings are managed using `versioneer` [12], a tool that helps defining automatically the current version based on the underlying git tag.

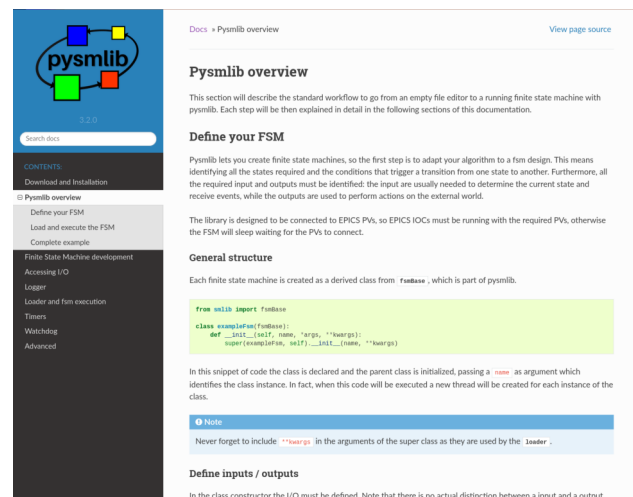

Figure 6: Pysmlib online documentation.

Web-based documentation was built using `sphinx`, which generates beautiful HTML pages from reStructuredText files. The resulting website can be seen in Fig. 6 and includes some examples, a tutorial, and the detailed API description. Finally, the HTML pages are hosted using Github Pages [13], so that they are always available online.

## USER EXPERIENCE

Pysmlib was first envisioned and developed for the radio frequency (RF) control system [14] of the ALPI linear accelerator at the INFN Legnaro National Laboratories (LNL). This system requires a lot of procedures to power up, tune and lock each cavity which were previously performed manually. With this library it was possible to automate lots of tasks, thus reducing the time and effort required to setup the accelerator for a run.

Given the success in its first use case, the original code was decoupled from the RF control system to create a general purpose library that could be easily used on different projects. Thus, version v2.0 introduced the *pysmlib* name and the library was published online, complete with documentation. Version 3 dropped the support for Python 2, which was being deprecated, and further consolidated the user interface,

adding methods to access the alarm state of an input and improving the automated tests.

The library has been integrated into multiple projects at Legnaro to automate different tasks, from simple ones like acquiring the spectre of the beam using a magnetic dipole to more sophisticated ones like online beam emittance measurement or BOLINA [15] beam trajectory optimization algorithm. Another common use case is to build simulators, where the FSM reacts to control PVs simulating the effect of a real object, which is useful to test the control system software. For example, a FSM was developed to simulate a wire scanner diagnostic complete with its handling motor. A FSM can also be used to build alarm handlers, like telegram-epics-bot [16] which sends a Telegram message to selected users when a PV enters the alarm state. In general pysmllib is useful whenever it is necessary to develop programs which are not executed one-shot, but are always running waiting for the correct condition to execute their task. In fact, the ability to detect edges on the PV values is extremely useful for this scenario and with this library it is provided by default.

In listing 1 an example of a minimal complete FSM is provided, where the FSM is expected to copy the value of a *counter* PV to a *mirror* one, when the *enable* PV is non-zero.

```

1  #! /usr/bin/python
2  from smllib import fsmBase, loader
3
4  # FSM definition
5  class exampleFsm(fsmBase):
6      def __init__(self, name, *args, **kwargs):
7          super().__init__(name, **kwargs)
8          self.counter = self.connect("counter_pv_name")
9          self.mirror = self.connect("mirror_pv_name")
10         self.enable = self.connect("enable_pv_name")
11         self.gotoState('idle')
12
13     # idle state
14     def idle_eval(self):
15         if self.enable.rising():
16             self.gotoState("mirroring")
17
18     # mirroring state
19     def mirroring_eval(self):
20         if self.enable.falling():
21             self.gotoState("idle")
22         elif self.counter.changing():
23             readValue = self.counter.val()
24             self.mirror.put(readValue)
25
26     # Main
27     if __name__ == '__main__':
28         # load the fsm
29         l = loader()
30         l.load(exampleFsm, "myFirstFsm")
31
32     # start execution
33     l.start()
    
```

Listing 1: Example of a FSM implementation.

The FSM is implemented by defining a class which derives from `fsmBase`. In the constructor the user can connect to any amount of PVs, addressing them with their name and then specify the first state to be executed. After that, the example

shows the definition of two states, called *idle* and *mirroring*. These are implemented as methods of the class, with the `_eval` suffix in their name. Initially the FSM evaluates the idle state, until the enable PV rises from 0 to 1, which causes the FSM to execute a transition to the mirroring state. In this state the enable PV is continuously checked, so that when an external user revert it back to 0 the FSM goes back to the idle state. Until then, the mirroring state listens to change events to the counter PV and copies the new value to the mirror one. This is done with the `changing()` method to avoid repeating continuously the put operation with the same value, which could slow down the Channel Access, and instead execute a put only once when the counter value changes.

At the end of the example, the loader usage is demonstrated. In this simple case a single FSM is loaded, with just its name as parameter, and the execution is started with the `start()` method. This is by default a blocking call and the execution can be halted using a keyboard interrupt.

## CONCLUSIONS AND FUTURE IMPROVEMENTS

Pysmllib is now a stable project and aims to provide a robust solution to the EPICS community to develop modern Finite State Machines. The focus on simplicity and the choice of the Python language make it a good choice for both new and advanced users, who may take advantage of the vast amount of Python scientific libraries.

While the user interface can be considered stable, future updates will focus on improving the internal components to improve the quality and expandability of the code. For example, the current logger facility should be deprecated in favor of the Python logging module to gain all of its functionalities. A more object-oriented approach to events could help to introduce more easily different kind of external events, and thus different kinds of inputs. Currently only the Channel Access inputs are supported, but an expansion to the PV Access could be helpful to users of this newer EPICS protocol. The library could also be generalized to work as a generic Finite State Machine engine, where the user is able to define its custom inputs and connect them to any kind of external system. For this to work, a rigorous I/O interface should be defined and documented.

Other improvements could be evaluated following user suggestions, based on real-world use cases. Contributions and fixes are welcome.

# NOMINAL DEVICE SUPPORT (NDSv3) AS A SOFTWARE FRAMEWORK FOR MEASUREMENT SYSTEMS IN DIAGNOSTICS\*

R. Lange<sup>†</sup>, ITER Organization, St. Paul lez Durance, France

M. Astrain, V. Costa, D. Rivilla, M. Ruiz, Grupo de Investigación en Instrumentación y Acústica Aplicada, Universidad Politécnica de Madrid, Madrid, Spain

J. Moreno, D. Sanz, GMV Aerospace and Defence, Tres Cantos, Spain

## Abstract

Software integration of diverse data acquisition and timing hardware devices in diagnostics applications is very challenging. While the implementation should manage multiple hardware devices from different manufacturers providing different applications program interfaces (APIs), scientists would rather focus on the high-level configuration, using their specific environments such as Experimental Physics and Industrial Control System (EPICS), Tango, the ITER Real-Time Framework or the MARTe2 middleware.

The Nominal Device Support (NDSv3) C++ framework, conceived by Cosylab and under development at ITER for use in its diagnostic applications, uses a layered approach, abstracting specific hardware device APIs as well as the interface to control systems and real-time applications.

ITER CODAC and its partners have developed NDS device drivers using both PCI express extension for instrumentation (PXIe) and Micro Telecommunications Computing Architecture (MTCA) platforms for multifunction data acquisition (DAQ) devices, timing cards and field-programmable gate array (FPGA) based solutions. In addition, the concept of an NDS-System encapsulates a complex structure of multiple NDS device drivers, combining functions of the different low-level devices and collecting all system-specific logic, separating it from generic device driver code.

## INTRODUCTION

The Instrumentation and Control Systems (I&C) used in big science facilities (BSF) are based on the use of multi-tier software applications. For example, advanced DAQ and timing systems include complex hardware elements that need software elements to configure all their functionalities. In the last years, the use of field-programmable gate arrays (FPGAs), System on a Chip circuits (SoC) and new development tools have demonstrated that software is a key part of implementing these systems [1]. The key points of using software in advanced I&C systems are adaptability, reusability and maintainability over the entire BSF project lifetime.

The Nominal Device Support (NDS) software framework has been implemented to meet these three goals. Initially developed by Cosylab [2], it was recently improved and extended by the ITER Organization, working with Universidad Politécnica de Madrid and GMV Aerospace and Defence. NDS is a driver development software framework for diagnostics measurement systems [3], focusing on data acquisition and timing devices. NDS device drivers are instantiated and configured to build complex systems, designed to solve specific applications. The applied methodology simplifies code reusability and testability, achieving high levels of software quality. Doxygen documentation, automated tests and static code analysis are used in all NDS modules. Specifically, the NDS framework provides a simplified solution for device driver development in I&C systems that use the Experimental Physics and Industrial Control System (EPICS) [4-6].

## NDS SOFTWARE LAYERS

Figure 1 shows the basic structure of a device driver in the NDSv3 framework. The application, called “control system”, uses the generic NDS control system interface to communicate with NDS device drivers and extensions. The NDS device drivers use the base and helper classes from the NDS-core library to access the hardware through the operating system’s low level drivers.

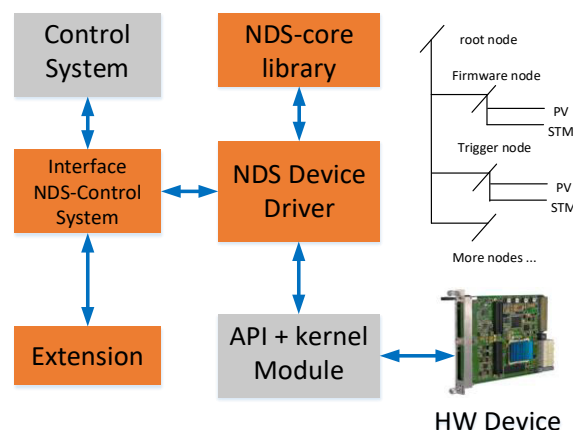

Figure 1: NDSv3 framework elements and basic layers.

## NDS-Core

The NDS-core layer (NDS-core library) provides a collection of C++ classes and helpers that standardise and simplify the implementation of the software device driver (NDS device driver) for a specific hardware device or communication interface.

\* This work was supported in part by the Spanish Ministry of Science, Innovation, and Universities Projects under Grant ENE2015-64914-C3-3-R and Grant PID2019-108377RB-C33, in part by the Spanish Ministry of Science, Innovation, and Universities Mobility under Grant PRX19/00449, and in part by the Comunidad de Madrid under Grant PEJD-2018-PRE/TIC-8571 and Grant PEJ-2019-AI/TIC-14507.

<sup>†</sup> ralph.lange@iter.org

A device driver implemented with NDS-core can be used by different kinds of applications called “control systems”. Examples for such applications are EPICS and the Real-Time Framework developed by ITER [7].

The basic objects of an NDS driver are *nodes* and *process variables (PVs)*. As with previous versions of NDS (see NDSv2 [2]), every variable has a unique name. The structure of this name represents the variable’s place in the facility, system, or subsystem. In NDSv3 this concept is maintained, but through abstraction much of the complexity is hidden from the end user. NDS PVs are named data or structures of data relevant to the experiment. To organise them, they are appended to a named node. Subsequently, nodes can be appended to other nodes, creating a tree-like structure that represents the device.

For example, a device might have Analog Input and Analog Output functionalities; these would be appended to a root node or port node to generate the following names: device(node)-ai(node)-ch0(node)-data(PV); device(node)-ao(node)-ch0(node)-data(PV).

Note that two different hardware devices manufactured by different companies implementing the same or similar functionalities can have an NDS device driver with a big part of the code in common. The most crucial point is that they have the same NDS PVs: if these match in name and functionality; software management and device interchangeability are simplified. This is one of the key concepts in the design of NDS based systems at ITER.

NDS-core provides several node and PV type classes to cover most functionality required in a device:

- *Base*: The base node is just a name holder.
- *Port*: A special node that connects with the NDS control system interface layer (see below). The names of PVs are generated from the ports they are appended to.
- *State Machine*: A node with a particular set of functions implementing finite state machine behaviour. The state machine node has a generic set of PVs that control the transitions or propagate states to other state machines below to form hierarchical state machines.

The NDS-core library allows the creation of different NDS PV types. NDS PVs can store a variable or trigger a specific function call, named *delegate*. The read/write operation of an NDS PV allows to read/write the data or trigger the delegate function. The assigned direction, i.e., the definition as an “input” or “output”, is determined from the control system’s point of view. The NDS PV types (classes) are:

- *Variable In*: This PV contains a value obtained from the hardware device to be sent to the control system. There are two different methods to deliver the data: The control system executes a read operation, accessing the scalar or array value, or the device driver executes a push operation, creating an interruption to the control system.
- *Delegate In*: This PV does not have an attribute, but calls a method when executing a read operation (defined in NDS as a *delegate method*). Typically, this

method operates on the hardware through the specific system device driver to read a value.

- *Variable Out* and *Delegate Out*: These PVs contain values received from the control system to be used by the device driver or support the trigger of a function that performs a write operation into the system device driver.

The NDS drivers built in this way are able to communicate using the NDS control system interface layer. This layer has to be implemented once for each control system that needs to use NDS and can be used with all NDS devices drivers.

To control the instantiation of a device and ensure uniqueness of PV naming, the NDS-core layer manages the creation and destruction of device driver instances using a factory (following a singleton pattern implementation). Through the factory, it is possible to get the information about registered drivers and instances. In addition, it gives access to the driver’s nodes (hierarchical), the NDS PVs and the state machines.

An important functionality of the NDS-core is the subscription and replication of PVs. When two NDS PVs are connected with a subscription (only possible from an NDS PV In to an NDS PV Out), pushing a value in the NDS PV In generates an update in the NDS PV Out. Similarly, two NDS PV In can be connected by a replication, where pushing a value in one NDS PV In replicates its value to the other. Note that both mechanisms, subscription and replication, are unidirectional. They allow sharing of information between drivers and nodes without the intervention of the control system, which is crucial for nodes related to archiving and real-time communication.

The NDS-core software module consists of:

- The source code implemented in C++ 11.
- Test code implemented with the help of Google-Test [8]. This test code includes a basic implementation of an NDS “control system” (see below) for test and debugging purposes.
- Doxygen [9] support files.

The NDS-core layer does not depend on other software modules (particularly from the EPICS project) and uses the C++ Standard Library. NDS-core can be built on Linux and Windows operating systems.

## Control System Interface

The control system interface of the NDSv3 framework implements the interface to communicate with the application that runs the NDS device. Currently, the NDSv3 framework contains two interfaces: one exclusively for running tests of the implemented device drivers (the test control system mentioned) and one to interface with the EPICS control system. The NDS-EPICS control system interface module connects EPICS process database records to NDS PVs. NDS-EPICS is based on the use of the asynDriver module [10, 11], which implements the EPICS Device Support for different records using standardised interfaces. Using NDS-EPICS, the user only needs to define the record templates and the substitutions files. (Examples

contained in the software unit.) Creating the interface to a hardware device in EPICS is straightforward if the NDS device driver provides such EPICS templates.

A third implementation of the control system interface, for the TANGO control system toolkit [12], exists in the original NDSv3 development by Cosylab, but has not been used or tested in the context of the ITER developments.

The NDS-EPICS software module consists of:

- The source code of the NDS-EPICS interface.
- An application generating an EPICS Input Output Controller (IOC).
- Test code, implemented using Python with the help of the pyEpics library. These tests verify all implemented asynDriver interfaces.
- Doxygen [9] support files.

## DEVICE DRIVERS

The NDS device drivers are plugin libraries. Changing or adding a device drivers does not require to change or recompile the core modules of NDS.

### Adding a Device Driver

The development of an NDS device driver using the NDS-core library requires the following steps:

- Analysis of the functional blocks available in the hardware device. This often means a mapping of the Application Program Interface (API) functions provided by the manufacturer in charge of managing the different hardware parts.
- Definition of the hierarchical driver organisation using a tree-like structure of nodes. These nodes can be new classes created by the user or complex nodes from the NDS-core library, e.g., DAQ, Waveform Generation (WFG), Digital Input Output (DIO), Trigger and Clock, Routing, Timestamp or Future Time Event.
- Definition of the operations to be executed in the state machine transitions available in each node. NDS-core defines the states UNKNOWN, INITIALIZING, OFF, ON, RUNNING and FAULT.
- Implementation of the driver constructor. This code includes the initialisation of the resources needed and the creation of the driver hierarchy. In addition, creating the nodes (defined by the user or from the NDS-core library) requires implementing the methods associated with the state machine transitions and the getters/setters of the NDS PVs of type delegate in and out.
- Completion of the methods that call the API of the low level driver for the specific hardware.
- Implementation of the test code, using the test control system and the GoogleTest library.
- Source code documentation using Doxygen.
- Generation of the packages for driver distribution.

The steps to add the interface with EPICS using the NDS-EPICS module are:

- Creation of a software unit including an EPICS application and an EPICS IOC. This application needs to be

compiled/linked against the NDSv3 libraries (nds-core, nds-epics) and the asynDriver module.

- Development of the specific EPICS database templates using the examples included in the NDS-EPICS module. Creation of the EPICS substitutions file.
- Configuration of the IOC using the st.cmd file, instantiating the driver and loading the databases.
- Verification of the IOC through an Operator Interface (OPI) or Channel Access operations.
- The NDS-EPICS layer offers the possibility to easily extend the driver implementation with functionalities specific to the EPICS Control System (e.g. execution of init or exit hooks)..

### Existing Device Drivers

Table 1 shows a set of device drivers for the PXIe and MTCA platforms that have been developed at different facilities. Functionally, they can be split into four different groups:

- Timing cards (using the PTP standard IEEE1588)
- Multi-function DAQ cards
- High sampling rate DAQ cards
- FPGA-based DAQ cards (including a customisable platform).

Of the two solutions in the last group, one is using the FlexRIO device from National Instruments (NI) that can be configured using LabVIEW/FPGA, and the other is based on a device from Advanced Industrial Electronic Systems (AIES), using Hardware Description Language (HDL) with XILINX Vivado.

Table 1: NDS Device Drivers

Devices	PXIe	MTCA
Timing IEEE1588	NI PXI6683H	PTM1588
DAQ	NI X-Series NI PXIe636x	Teledyn ADQ14 MFMC-FMC168 STRUCK SIS300
DAQ-FPGA	FlexRIO (LV FPGA)	MFMC

All device drivers packages contain the driver source code (see Figure 2), Doxygen-based generated documentation, test code developed with GoogleTest, a fully configured EPICS IOC application and Python code testing the EPICS IOC and OPI panels to use the driver using Control System Studio [13].

Figure 2: Elements in an NDS Driver software package.

Normally, such NDS device driver modules do not contain information about any specific use or application. They are generic drivers, meant to be integrated into bigger systems that implement specific use cases and include the specific knowledge. This is achieved by combining different driver modules using the extensions introduced in the next section.

## EXTENSIONS

Expanding the basic NDS concepts, the ITER Organization and its partners have contributed to the NDS open-source project by improving the existing and providing additional extensions.

### NDS Complex Nodes

The main functionalities required to create diagnostics and control instruments were identified and converted into pre-defined functional NDS nodes, called NDS complex nodes. With the intention to homogenise the driver development, the NDS-core library contains nodes supporting common functionalities: DAQ, WFG, DIO, Timing, Triggering, Clock and Routing. In these nodes, the PVs already have defined names, identifying their specific functionality. Therefore, an NDS device driver is in charge of implementing the configuration, status management and data acquisition with the help of software tiers provided by the manufacturer (kernel module and user space API) and the NDS-core library. Additionally, the complex nodes provide an API to simplify calls to update PV values and timestamps. Thus, while the set of PVs provided by the complex nodes is fixed, the final driver implementation can add and manage more PVs for additional functionality.

### NDS Plugins

The implementation of a specific application requires the use of multiple device drivers as well as other communication interfaces. In the case of the ITER experiment, there are two such interfaces: the synchronous data bus network (SDN) is oriented to data interchange using a network with a controlled latency and the data archiving network (DAN) is used to stream high throughput data to the archiving engines.

Figure 3 shows the basic architecture for the NDS interfaces to both DAN and SDN.

Figure 3: Plugins in an NDS-based application. The blue arrows show the NDS subscriptions.

In order to simplify the use of both interfaces for the developer, the NDS framework defines the concept of an NDS plugin. An NDS plugin is an NDS device driver that requires configuration by the user with the specific parameters of the user's application. This configuration is done through a file that contains all the configuration details in extended mark-up language (XML).

For the SDN plugin, the XML file contains the identification of the SDN topic with its data organisation as well as the mechanism of when to publish the topic. The topic can contain scalar or array fields (of different data types) and structures of these. Each field in the topic is connected to an NDS PV (using the subscription method). The topic is published either when a field changes or periodically with a publishing period defined in the XML file.

For the DAN plugin, the XML configuration similarly contains the details of the NDS PVs (from device drivers) that provide the values (scalar or arrays) that need to be archived.

Besides these two plugins, there is an additional one that implements the access to the EPICS pvAccess protocol. This solution provides a method for NDS based drivers to access industrial or legacy equipment that is interfaced using EPICS IOCs with standard drivers or other applications like middle layer services that provide a pvAccess interface. All EPICS PVs published by these IOCs or software applications can be accessed by NDS applications for reading, writing, and monitoring. This plugin is named NDS-PVXS because it uses the library developed by the PVXS Project [14].

### NDS Systems

Developing a diagnostic or an instrument in a big science facility requires integrating multiple hardware devices using different software device drivers. The application developer needs to orchestrate all these hardware elements to implement a correct sequence of operations, i.e., trigger configuration, data acquisition, time stamping, archiving, etc.

In the NDS framework, we have defined the concept of an NDS system, which is a special NDS device driver that manages hierarchically other NDS device drivers (that have already been implemented and tested). This is a key concept, because the developer does not need to program or change anything in the existing NDS device drivers but only configures them for their application. Using this approach, the developer is merely a user of the NDS device drivers and NDS plugins, responsible for configuring and coordinating their use. This noticeably reduces the development time and simplifies the integration of the final solution.

An NDS system is implemented for a specific use case solving the specific requirements. It is not a generic application, and it can be designed to only expose the specific NDS PVs needed, reducing the number of PVs that need to be managed by the control system.

Figure 4 shows the block diagram of an NDS system. A set of C++ classes for the different device drivers implement the subscriptions and replications of NDS PVs to

manage an NDS device driver from the NDS system level. The shown structure is the diagram of the system that has been developed as a working example for the NDS system extension.

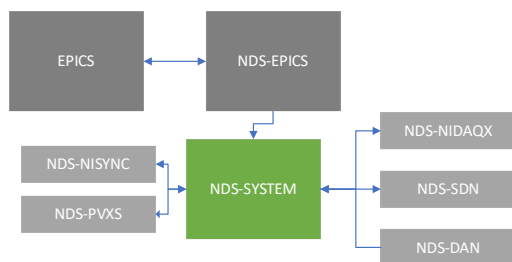

Figure 4: NDS device drivers and NDS plugins in an NDS system.

## ADVANCED FPGA-BASED SYSTEMS

The use of advanced FPGA-based DAQ devices, which implement functionalities that can be customised, requires software tools that simplify development and integration. For such applications, the existing NDS framework provides two different solutions.

The first one is based on National Instruments FlexRIO technology, which includes an FPGA that can be configured using the LabVIEW/FPGA tool. In addition, the IRIO Project [15] provides a library that simplifies the integration of these devices. On top of that library, NDS implements an NDS device driver named NDS-IRIO. To implement a custom algorithm in the FPGA using this set of tools, the developer would follow the IRIO design methodology, which automatically connects the FPGA code to the application and generates PVs with the names of the LabVIEW variables, requiring no modifications of the driver code for different use cases.

The second approach is based on the use of the new FPGA, SoC and Adaptive Compute Acceleration Platform (ACAP) with design methodologies that use High Level Synthesis and the OpenCL standard. The NDS-IRIO-OpenCL module implements a software layer that simplifies the integration of such systems [16].

## SOFTWARE QUALITY

The software modules implemented in the NDS framework have been developed using the Software Quality model implemented at ITER CODAC. The model is based on the ISO/IEC 15288 standard and there are documents for the different elements: the Software Requirements Specification (SRS), the Software Architecture and Design Description (SADD), the Software Test Plan (STP), the Software Test Report (STR) and the Software User Manual (SUM).

The most meaningful data are the results of the static code analysis and the test coverage of the different modules, obtained with the lcof software utility and a SonarQube [17] installation. The average test coverage value across the different modules is around 70% and has been increased with every new release. Static analysis shows no

issues; the cumulated number of reported code smell problems is less than 1%.

## CONCLUSIONS

The NDSv3 framework provides a complete set of software modules and documentation to develop complex diagnostics solutions involving timing, data acquisition and other advanced communication interfaces. The NDS implementation model is based on the use of specific device drivers and configurable plugins. The driver developer and the diagnostician can work separately, increasing efficiency and reliability by separating the software layers that contain device specific and application specific knowledge.

The ITER NDS complex nodes standardise most of the PV names, easing the usage of different hardware devices, which should share most PVs. As an added benefit, porting the device driver from one manufacturer API to another should re-use more than 80% of the code.

The new generation of NDS drivers makes use of the different plugins interchangeably and is able to connect to multiple control systems and other software applications. The extensively tested drivers are reaching a very respectable percentage of verification following ITER guidelines, paving the way to a successful deployment in the facility.

## PROJECT CONTRIBUTORS

NDSv3 was conceived and originally implemented by Cosylab.

The institutions involved in the recent developments are the ITER Organization, Universidad Politécnica de Madrid (grupo de Investigación en Instrumentación y Acústica Aplicada), GMV Aerospace and Defence, the European Spallation Source and UKAEA-JET/MAST.

The NDS source code for the initial version of NDSv3 is available at GitHub [18, 19]. The extensions implemented by ITER, the device drivers, the plugins and other contributions are available at the ITER Git server [20].

# DESIGN PATTERNS FOR THE SKA CONTROL SYSTEM

S. Vrcic, SKA Observatory, Manchester, UK

## Abstract

Square Kilometre Array Observatory (SKAO) comprises two radio-telescopes: the SKA Low Frequency Telescope, located in the Murchison Region, Western Australia, with the observing range 50 – 350 MHz; the SKA Mid Frequency Telescope, located in the Karoo Region, South Africa, with the observing range 350 MHz – 15 GHz. The SKA Global Headquarters is in the Jodrell Bank Observatory, near Manchester, UK. The SKA Low and SKA Mid Telescopes use different receptors (log-periodic antennas vs offset-Gregorian dishes), otherwise the telescopes share the same design concept, the design of many components, in particular software, is common to both Telescopes. Work on construction, which officially started on the 1. July 2021, was preceded by the extensive design effort which culminated in successful completion of the Critical Design Review (CDR). This paper describes the design patterns defined so far for the implementation of the Telescope Control System (and applies for both Telescopes).

## INTRODUCTION

The Square Kilometre Array Observatory (SKAO) is an International Organisation that comprises two radio-telescopes and spans three continents:

- The Global Headquarters (HQ) is located at the Jodrell Bank Observatory near Manchester, UK.
- The SKA Low Telescope, located in Murchison Region in Western Australia operates in the frequency range 50 – 350 MHz.
- The SKA Mid Telescope, located in the Karoo region in South Africa, operates in the frequency range 350 MHz to 15 GHz. The SKA Mid observing range is divided in 6 bands; each receiver can collect and process data for one band at a time; instantaneous bandwidth varies from band to band.

The SKAO was instigated by an idea to build a radio-telescope with a collecting area of 1 km<sup>2</sup>. The science goals are described on the SKAO website [1].

Instead of building a single gigantic dish, radio-astronomers use a technique called interferometry. A Radio-Interferometer superimposes electromagnetic waves collected by multiple receivers to amplify the signal of interest and eliminate signals generated by the ground-based sources and by other man-made equipment (including the telescope itself). The signals generated by sources not of interest are generally referred to as radio-interference (RFI). The SKA Telescopes are interferometers.

The SKA Low Telescope comprises 131,072 log periodic antennas, organised in 512 stations. The stations are placed so that the Telescope consist of the densely populated core and three spiral arms with receding density. Signal collected by the antennas is digitized, the beams are formed using

input from the antennas the belong to the same station, the beams formed by different stations are aligned in time, and correlated (input from each pair of stations is complex cross-multiplied) to extract information of interest and eliminate RFI. Integration in time and/or frequency may be performed to reduce the amount of output data. Up to this point, data processing is performed in real-time. The output of correlation is then captured, data sets formed and stored for further processing.

The SKA Mid Telescope comprises 197 offset-Gregorian dishes, each with the diameter of 15 meters. To cover the required frequency range, each dish is equipped with several receivers, but only one can be placed at the focus at any given time (consequently, before starting a new experiment a receiver may need to be replaced). The signal captured by the single pixel feed is digitized and processed in the same manner as in the Low Telescope.

After many years of preparation, the construction of the SKA Telescopes officially started on 1. July 2021 (artist impression of the SKA Telescopes shown in Fig. 1).

During the pre-construction phase design were developed and reviewed for each part of the Telescopes, including the Control System. The general principles for the design of the SKA Telescope Control System were established relatively early in the design process. Following the Critical Design Review (CDR), while preparing for transition to construction, work on the detailed design and development of the Control System software started, although with the limited resources. The lessons learned over that period are being applied as we update documentation, improve the development environment, and refine the design, including the design patterns.

This paper provides an overview of the design approach and patterns used in the SKA Control System, with the goal to collect input from the colleagues working on similar projects.

Figure 1: Artist impression of the SKA Telescopes.

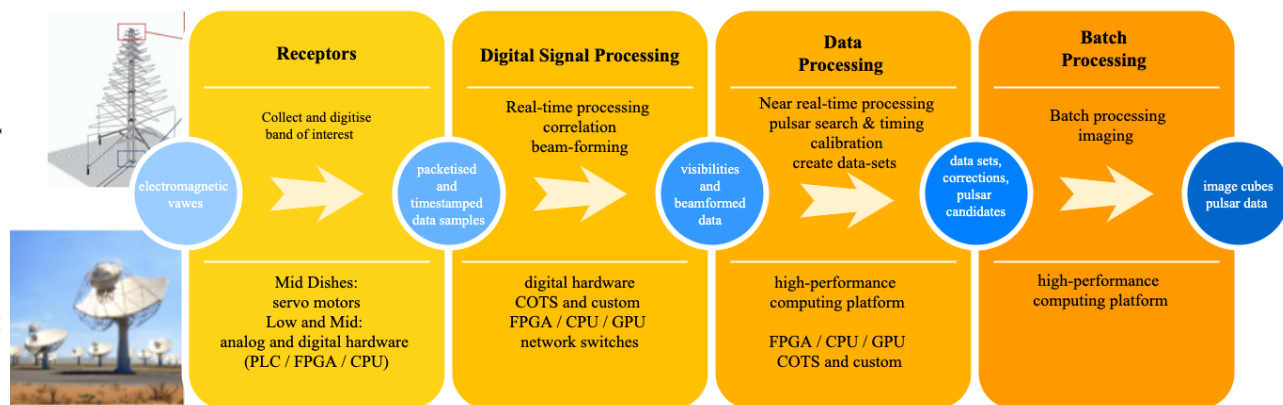

Figure 2: SKA Telescope functional overview and the technologies used.

## SKA TELESCOPE CONTROL SYSTEM REQUIREMENTS

Figure 2 provides a high-level overview of the functionality required and technologies used to implement the SKA telescopes. With exception of the antennae, similar technology is used in both telescopes. Analog hardware is used in receivers; once the collected signal is digitized, digital hardware and computers are used for signal processing and to packetize, transmit, receive, and store astronomical data as it is passed from one sub-system to the other. The SKA Telescopes use computing hardware equipped with Field Programmable Gate Arrays (FPGAs), Graphical Processing Units (GPUs) and Central Processing Units (CPUs). The log-periodic antennae in the SKA Low Telescope do not have moving parts. The dishes in the SKA Mid Telescope are equipped with servo motors that move the dish to point the dish focus towards the desired source and rotate the indexer (the tray where receivers are placed) to place one of the receivers in the focus.

The requirements for the Telescope Control System can be classified as: requirements related to monitoring and control of the equipment and requirements related to monitoring and control of the experiments (in the context of SKA referred to as observations).

### Equipment Monitoring and Control

Requirements related to monitoring and control of the equipment and software are standard requirements for the similar systems used in industry and scientific facilities. The following list is a brief overview of the required functionality:

- Monitoring (report status, periodically and on request, report state and mode changes, errors, and faults).
- Archiving (periodically report and store the status of all the components and systems of interest).
- Provide interfaces that allow operations to change configurable parameters and trigger state/mode changes. Both Human Machine Interfaces (HMI) and Machine to Machine Interfaces (MMI) are required.
- Support for hardware / software / firmware updates.
- Support for debugging, testing and maintenance.

The above listed requirements apply for all the levels of the monitor and control hierarchy: the telescope, each sub-system, and individual components.

The components and subsystems differ in complexity, as does the number of attributes, configurable parameters and commands exposed by different subsystems and components. For each component and subsystem, it must be determined what is the information of interest and how it should be represented; this will be an on-going activity during the detail design, development, integration, and commissioning.

Graphical User Interfaces (GUIs) that display overall status of each telescope, status of the major subsystems and interfaces and the list of active alarms will be provided. In addition, more detailed 'engineering' views will be provided to be used during the development, integration, testing and commissioning; and will continue to be used in operations by the maintenance staff. The plan is to arrange the views of the telescope hierarchically so that a click on a faulty component opens a more detailed view of the component.

Figure 2 shows the telescope functions and equipment directly involved in capturing and processing astronomical data. Figure 2 does not show functionality and equipment provided by infrastructure, such as: facilities, roads, lending strips, power, water, networking, IT equipment, and masers and other equipment that provides very precise time required for telescope operations. Most of the infrastructure comes with own COTS monitor and control systems, and User Interfaces (operator and maintainer consoles). Also not shown are Data Archives: Observing Data Archive, Scientific Data Archive, and Engineering Data Archive. The Telescope Control System will communicate with the COTS systems to collect information of interest (overall status, significant events and alarms), but will not duplicate all information. Also not shown are Data Archives: Observing Data Archive, Scientific Data Archive, and Engineering Data Archive.

### Observation Monitoring and Control

**Observing Modes** Both SKA telescopes support multiple observing modes: imaging, pulsar search, pulsar timing, and VLBI beam-forming, and several sub-modes for each observing mode. In addition, to support exploration of the transients, both telescopes are able to capture and, on re-

quest, offload a limited amount of captured raw data for each receptor. The Telescope Control System API (Application Programming Interface) shall allow users to configure a telescope for the desired observing mode and take advantage of the telescope versatility; in other words, the Control System shall not restrict users to a limited number of pre-defined configuration sets.

**Concurrency and Commensality** The SKA Telescopes provide processing resources for concurrent processing in all 4 observing modes; thus, allowing search for pulsars and precise timing of the known pulsars to be executed concurrently with surveys and imaging observations. The Mid Telescope, due to a huge instantaneous bandwidth (5 GHz), provides a limited concurrency for Band 5 observations.

**Subarrays** Not all science observations require all the receptors, some require only the receptors in the core while others are mostly interested in long baselines and therefore use only a small number of receptors in the core. To provide for efficient use of observing time, both telescopes are required to allow operations to subdivide the array (receptors and processing resources) and operate each subarray as an independent telescope, in terms of the observing mode, and the start and stop time of the observations. The requirement to support subarraying provides for more efficient use of resources but increases complexity of the Control System (and other subsystems).

### Observation Monitor and Control – Key Functions

The following is a brief overview of the Telescope Control System functions related to observation monitor and control:

- Assign resources (receivers and processing resources) to a subarray.
- Configure subarray for the observing modes. A number of parameters can be specified for each observing mode; a complete sub-array configuration is passed in the form of ASCII (American Standard Code for Information Interchange) encoded JSON (JavaScript Object Notation) script.
- Point the Mid Telescope dishes, track sources.
- Provide regular updates for delay and phase tracking corrections (to be applied during signal processing).
- During the observation, pass the updates received from the Science Data Processor (SDP) to the components used by the subarray, these include parameters for pointing and steering beams (station beams in the Low Telescope; beams for pulsar search, pulsar timing and VLBI in both telescopes), antennae weights to be applied in beamforming, RFI extinction related parameters and more.
- Start and stop tracking and data processing.
- Store data products (data sets).
- Release resources from a subarray.
- Derive and report overall status of the sub-arrays.
- Keep track of resource status and allocation, report status changes periodically and as requested.

## Non-Functional Requirements (NFRs)

The key non-functional requirements for the Telescope Control System are:

- **Resiliency** – ability to function in presence of errors and faults, and to recover from errors and faults. Resiliency is extremely important for the Control System, which should be able to report status and accept commands even when much of the telescope equipment is only partly functional, non-responsive or failed. Control System must be able to continue functioning when some of the components are unresponsive or provide unexpected response, and to resume normal operations when previously non-responsive or failed components recover.
- **Reliability** – Control System must be reliable, it should be the last component to fail. In all circumstances, the Control System should be able to reliably monitor and report status of other components, execute requests and commands and raise alarms when needed.
- **Performance** – Control System shall execute requests and detect and report status changes, errors, and alarms in timely manner. (The exact meaning of ‘timely manner’ is quantified in the actual requirements).

The key Control System related design decisions are to a great extent influenced by the concerns related to resiliency, reliability, and performance. Development of the SKA Telescope Control System is still in the early stages, we still have to prove that the design choices result in implementation that meets the requirements.

## SKA TELESCOPE CONTROL SYSTEM DESIGN

This paper summarizes key design decisions and provides an overview of the design patterns for the implementation of the SKA Control System.

### Distributed Control Logic

Each SKA Telescope consists of several major subsystems. Receptors (dishes in the SKA Mid Telescope, antennas/stations in the SKA Low Telescope), Central Signal Processor (CSP) and Science Data Processor (SDP) capture and process astronomical data. Other sub-systems provide infrastructure, communication networks, very precise timing, and preparation and execution of observations and telescope monitor and control.

Given the number of receptors and the signal and data processing capacity required, each sub-system consists of hundreds of hardware and software components. To handle complexity and size of the system, the sub-systems are further decomposed in smaller sub-systems and products.

Logic required for monitor and control is embedded in each sub-system and hierarchically organized. Each ‘level’ performs aggregation and reports overall status of the sub-system or component. Configuration and commands are passed from top to bottom, at each ‘level’ the higher-level parameters are translated into detailed configuration of the

subordinate components. This approach reduces complexity of individual software components and enables scalability and modifiability – important quality attributes as the SKA Observatory is expected to be used for at least 50 years; during that time refresh of the digital hardware and computing platforms is expected, as well as expansion of the array and addition of new observing and/or processing modes.

### Physical vs Functional View

In an interferometer, the functional view does not always directly map to the physical view. The requirement to operate each sub-array as an independent telescope further complicates ‘mapping’ of the functionality to physical equipment. SKA Control System provides two views:

- Physical (equipment and components).
- Functional (subarrays, resources, and capabilities).

### SKA Base Classes

A set of the SKA Base Classes has been developed to be used as the base for development of the monitor and control software. All components and sub-systems implement the same set of state and mode indicators, and commands to trigger state transitions. Each sub-system is required to implement a Master Controller which performs aggregation of the status and coordinates execution of commands. The Master Controller:

- Monitors status of all components and based on the collected information derives overall status of the sub-system.
- Implements a set of commands that can be used to trigger state transitions, update software (and firmware), set logging level and more.

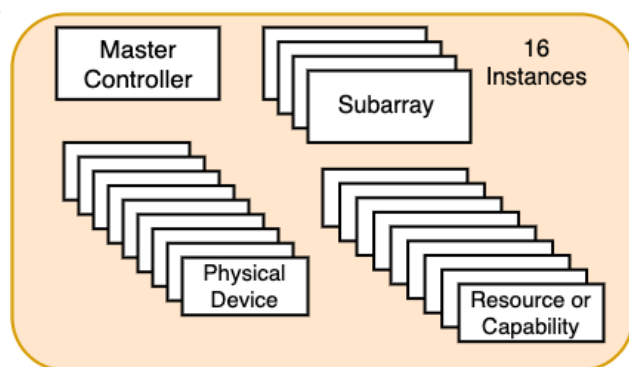

Figure 3: Design Pattern for implementation of monitor and control for sub-systems that process astronomical data.

Figure 3 shows the design pattern for monitor and control of sub-systems on the signal chain. Each sub-system implements:

- Master Controller which reports overall status of equipment and components, implements commands to trigger state transitions, upgrades, and other housekeeping tasks.
- Monitor and control for all physical devices.

- Multiple instances of Subarray (presently 16), which provides monitor and control functionality related to configuration and execution of observations.
- Monitor and control for resources and capabilities, i.e. entities that implement individual functions (in most cases implemented as FPGA bit streams and software pipelines).

### TANGO Controls Framework

Early in the design phase a decision was made to use TANGO Controls [2] as the base for implementation of the SKA Telescope Control System. TANGO Controls is an open-source toolkit that can be used for controlling any kind of software and hardware.

From the design point of view the key concepts are:

- TANGO Device – a software component (instantiation of a TANGO Device Class). Each TANGO Device models a device, software component, or sub-system.
- Tango Device Server – provides an execution environment for one or more TANGO Devices.
- TANGO Data Base – all TANGO Devices register with the TANGO DB which can be used to obtain the addresses of registered devices, and then access devices directly.

TANGO uses CORBA (Common Object Request Broker Architecture) [3] for request-reply communication and ZeroMQ [4] for publish-subscribe.

TANGO supports development in C++, Java and Python. SKA Control System is developed in Python.

### Decoupling TANGO API from the System Logic

As already mentioned, the SKA Control System is hierarchically organized and provides the same API at all levels of monitor and control hierarchy. This implies ‘deep adoption of TANGO’, i.e. TANGO API is provided for all sub-systems and components.

Unwanted consequences of this approach are:

- The framework (TANGO) becomes entangled into every aspect of the control system logic; the Control System becomes overly dependent on TANGO.
- Confusion regarding the significance of the status indicators, i.e. how to distinguish the TANGO Device (software model) from the device (sub-system or software construct) being modeled.

The SKA solution for those issues is to decouple the TANGO API (layer) from the ‘system logic’, so that the TANGO Device provides only the API, while the logic required for monitoring, status aggregation, error and fault detection, execution of commands, etc. is handled by a non-TANGO class, the so-called Device Manager.

### Loose Coupling of Components

In the case of the SKA Telescopes, due to large number of components:

- The FMECA (Failure Modes, Effects and Criticality Analysis) shows that, once the full system is deployed, at any given time some of the components will be out

of service or undergoing maintenance. This means that Control System must be able to correctly function in presence of errors and failures. The Control System must be able to handle situations where one or more components become unresponsive, and to resume normal operations once the components become available. Also the Control System should not expect individual components to complete state transitions in a particular order, each component may transition to ON, STANDBY or OFF individually, or may become unresponsive.

- Execution of commands at a telescope or sub-system level will take significant time, in some cases tens of seconds. This is particularly true for transitions that increase or decrease power consumption (ON/STANDBY/OFF), where delay is intentionally introduced to control inrush power. Reconfiguration of a subarray observing modes also may require significant time, as the commands propagate through the hierarchy of components, and the FPGAs get reprogrammed.

Although different in nature, the above-described aspects of the telescope behaviour may be addressed using the same technique, or more precisely by using techniques that promote loose coupling of components.

The SKA Control System uses the following techniques:

- Asynchronous communications. The commands that require I/O, must to be forwarded to subordinate components or sub-systems and/or require communication over the network, or access to hardware are implemented as non-blocking, meaning that the originator of the command is not blocked waiting for the command to be executed. The server (TANGO Device) immediately acknowledges receipt of the command and returns command to the caller; during the command execution, the device on request can report the progress, once the command is completed the originator is notified via an event (status change).
- Input queue for commands – When received, a command is added to the end of the input queue; the worker thread executes commands one-by-one. The input queue is implemented to handle exceptional situations, when the system is under stress due to unexpected

events; the system will be tuned so that, under normal circumstances, the queue is empty 90% of time. Not all devices have to implement the input queue.

- The subarray observing mode configuration is passed in a form of ASCII encoded JSON script, which contains the complete configuration for a single unit of observing. Use of data-centric self-contained messages and simple common types in data model support loose coupling.

## SUMMARY

The following is the summary of the key design decisions and patterns chosen for implementation of the SKA Telescope Control System:

- Hierarchical organization.
- Distributed control of process logic.
- Decouple physical and functional view.
- Set of SKA Base Classes.
- Standard set of state/mode indicators, and commands that trigger state/mode transitions.
- TANGO Controls framework.
- TANGO API provided at all levels of hierarchy.
- Decouple TANGO API from “system logic”.
- Use JSON to pass configuration messages.
- Use asynchronous communications.

Development of the SKA Telescopes is still in early stages, and the team still has to prove that the design choices made so far are adequate for the challenging requirements.

## ACKNOWLEDGEMENTS

Design for the SKA Telescope Control System is result of many years of work of many SKA team members, this paper a brief overview of the status.

# CONTROL SYSTEM FOR 6 MeV LINEAR ACCELERATOR AT LINAC PROJECT PINSTECH

N. U. Saqib<sup>†</sup>, M. Ajmal, A. Majid\*, D. A. Nawaz<sup>‡</sup>, F. Sher<sup>§</sup>, A. Tanvir  
LINAC Project, PINSTECH, Islamabad, Pakistan

## Abstract

At LINAC Project PINSTECH, 6 MeV electron linear accelerator prototypes are being developed for medical as well as industrial purposes. Control system of the linear accelerators is a distributed control system mainly comprised of EPICS and PLCs. Graphical User Interface (GUI) are developed using Phoebus Control System Studio (CSS) and Siemens WinCC Advanced software. This paper focuses on design, development and implementation of accelerator control system for various subsystems such as RF, vacuum, cooling as well as safety subsystems. The current status of the control system and services is presented.

## INTRODUCTION

Particle accelerators are complex machines that have been playing a major role in scientific innovations and discoveries. A particle accelerator is a device that uses electromagnetic waves, in the microwave range, to accelerate charged particles (electrons) to produce high energy charged particle or X-ray beams. In case of electron linear accelerators, electrons are generated from electron source such as electron gun (e-Gun) and are accelerated in a series of accelerating cavities by Radio Frequency (RF) waves, which are fed into the accelerating cavities by an RF source such as a klystron or a magnetron.

LINAC Project at PINSTECH aims at developing indigenous RF linear accelerators for medical and industrial applications. Along with ongoing progressive research and development, prototypes of medical linear accelerator (*Medical Linac*) for radiotherapy application and industrial linear accelerator (*Industrial Linac*) for Non-Destructive Testing (NDT) application are under development. Both of these accelerators are 6 MeV standing wave electron linear accelerators that produce high energy X-rays by striking high energy electron beam onto a tungsten target.

There are several subsystems that are required for operating a linear accelerator: an e-Gun system to produce and extract electrons, an RF system to accelerate the electrons produced by e-Gun, a good vacuum system to avoid arcing or breakdowns, a cooling system to maintain the temperatures of various devices at a desired point for stable operation. As particle accelerators grow more complex, so do the demands placed on their control systems. The complexity of the control system hardware and software reflects the complexity of the machine. Accelerator Controls and Electronics (ACE) Group of LINAC Project is responsible for controls, electronics and IT infrastructure for Medical and

Industrial Linac prototypes. Figure 1 shows block diagram of the linear accelerator that contains main subsystems and their interfacing. All these systems need to be controlled and monitored by a sophisticated control system, which enables safe and smooth remote operation of the Linac from control room. Next subsections provide a brief description of Medical and Industrial Linac prototypes.

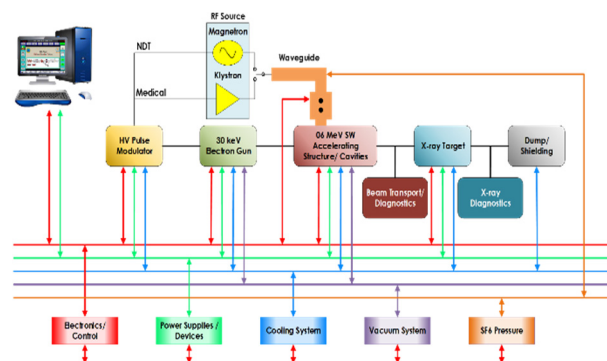

Figure 1: Block Diagram of Linac.

## Medical Linac

A medical linear accelerator customizes high energy x-rays or electrons to conform to a tumor's shape and destroy cancer cells while sparing normal tissues. Cancer is a leading cause of death worldwide and its types such as breast, lung, liver, prostate, head and neck carcinoma are most commonly diagnosed in Pakistan. Increasing number of cancer patients has made demand of cancer treatment machines. Therefore, it was need of the time to build an indigenous medical linear accelerator to cope with soaring number of cancer patients in available financial resources. For this purpose, a Klystron based 6 MeV Medical Linac prototype is being developed at LINAC Project PINSTECH. Accelerating cavity was designed indigenously, fabricated and brazed locally. Initially, there was one vacuum port and vacuum didn't sustain to a good pressure, recently a second vacuum port is installed and RF conditioning is under process.

## Industrial Linac

Out of several applications of industrial linear accelerators, one is radiography in for Non-Destructive Testing purposes, which provides a method for examination of internal structure and integrity of given specimen/material. Keeping this in view, an indigenous magnetron based 6 MeV Industrial NDT Linac prototype is in final stages at LINAC Project PINSTECH. Accelerating cavity was designed indigenously, fabricated and brazed for this purpose. Most of the parameters of both the linear accelerators are similar as shown in Table 1.

## CONTROL SYSTEM DESIGN

Control system acts as brain of a linear accelerator. It allows smooth and safe operation of the Linac by providing remote control/monitoring of accelerator hardware as well as interlocked environment for safety and protection. Control system at our facility is EPICS and PLC based four layer architecture [1,2]: Graphical User Interface (GUI) layer consisting of Phoebe Control System Studio (CSS), Middleware layer consisting of EPICS, Front-end layer consisting of PLCs, instruments and controllers, and Accelerator Hardware layer consisting various physical phenomenon that need to be controlled and monitored by the control system. Next subsections describe various components of the control system of our facility [3].

### Input/Output Controllers (IOC)

IOCs in our EPICS [4] based control system are soft IOCs deployed on CentOS 7 Linux Virtual Machine. IOCs communicate with various commercial-off-the-shelf instruments and controllers via interfaces like Ethernet, Serial (RS-232/422/485) and GPIB. They send commands and acquire signals from instruments and controllers. The IOCs deployed in our control system are organized in a hierarchical manner. First of all, in folders according to the subsystem they represent (RF, vacuum, cooling) and then according to the device they control (signal generator, delay generator, klystron modulator). For example, an IOC that controls signal generator which provides pilot signal to Klystron pre-amplifier is placed at `HOME/epics/ioc/RF/signalGenerator`. EPICS support modules provide enhanced functionalities for IOC applications. Support modules currently installed and configure in our control system include Asyn, Stream Device, Modbus, Calc, s7nodave and Sequencer modules. Separate virtual machines are used for IOC development and IOC deployment. At system reboot, all IOCs are started from a bash script containing path to their startup script files.

### Programmable Logic Controllers (PLC)

Siemens Simatic S7-300 and S7-1200 programmable logic controllers are installed, configured and programmed to interface field devices. Input/Output (I/O) modules include analog input, analog output, digital input, and digital output modules. Communication modules for Serial RS-232/422/485 interface are also installed for remote control & monitoring of commercial-off-the-shelf equipment. Interfacing between EPICS and Siemens PLCs is achieved via EPICS s7nodave support module that allows interfacing of Siemens Simatic S7 controllers with EPICS. PLCs

act as front-end controllers in our system to interface with the accelerator hardware.

### Operator Interfaces (OPI)

Operator interfaces (OPI) developed in Phoebe Control System Studio [5] are used to operate the linear accelerators from control room. Previously, OPIs were developed in Eclipse based Control System Studio, but later on, upgraded to Phoebe based Control System Studio. This transition provided more reliability and better features required by the control system. Several OPIs are designed according to the functionality they provide (Control, Monitoring, Trends). Also, specific equipment details OPIs are developed for various equipment such as Klystron Modulator, Oscilloscope etc. Example Phoebe OPIs are shown in Fig. 2.

For Industrial Linac, Human Machine Interface (HMI) screens are developed in Siemens WinCC Advanced and shown in Fig. 3.

Figure 2: Phoebe OPIs.

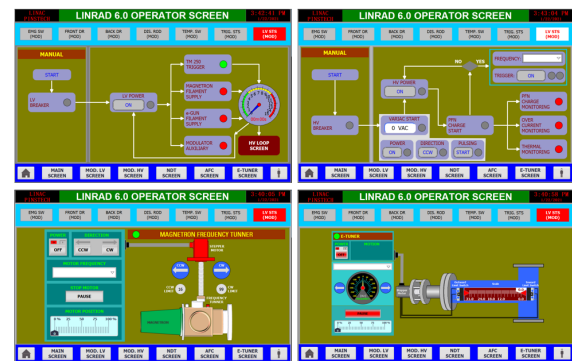

Figure 3: WinCC Advanced HMIs.

### Services

An archiver system and an alarm system are necessary services of a control system. These services inform operators about events happening during linear accelerator operation and their history, as well as provide data analysis functionalities to scientists and engineers.

**Archiver system** saves process variables history in a database which is a necessary task for a control system. It provides lot of benefits such as detection of a system fault, detection and analysis of undesired behavior of the system and also provides data to scientists and engineers for research purposes. Best Ever Archiver Toolkit Yet

(BEAUTY) is used for data archiving in our system. It contains archive engine command-line tool, which is provided with configuration and settings from XML files. Archive engine then utilizes Channel Access protocol to access process variables contained in EPICS IOCs into MySQL relational database. Phoebus CSS Data Browser is used to display history trends for the operating personnel. Figure 4 shows architecture of the archiver system.

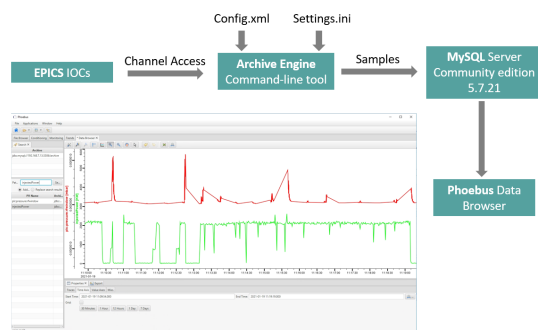

Figure 4: Archiver System Architecture.

**Alarm system** is a great tool for the operators to be notified about events happening during the operation of accelerator. Alarm system consists of Best Ever Alarm System Toolkit (BEAST) which contains alarm server. Configuration and settings are provided from XML files. Previously, alarm system consisted of RDB & JMS but after update to Apache Kafka, we have updated the alarm system accordingly. Alarm Panel, Alarm Tree and Annunciator provide a great alarm system. Figure 5 shows the alarm system architecture.

Figure 5: Alarm System Architecture.

## Computing Infrastructure & Network

Network deployed at LINAC Project is an Ethernet based Local Area Network (LAN). The overall LAN is divided into two segments: Technical Network and Office Network. Both networks are isolated and contain independent IT infrastructure. Control system consisting of measurement and control devices including commercial-off-the-shelf equipment and related devices are connected to the Technical network while Office network consists of users related devices including scientists' and engineers' PCs, printers, scanners, test equipment etc. Dell EMC PowerEdge servers are configured and installed to provide reliable services for both the networks.

**Technical Network** contains all components related to control system consisting of servers, desktop computers and commercial-off-the-shelf equipment. This provide isolation for achieving security and reliability. Figure 6 shows

various application/services provided by Dell EMC PowerEdge R630 virtualized server deployed in the Technical Network.

Figure 6: Technical Network Virtualization.

## ACCELERATOR SUBSYSTEMS

This section describes various subsystems of linear accelerator and how their components are interfaced with the control system. Subsystems of Medical and Industrial Linacs that significantly differ from each other with respect to control system point of view are described separately in each subsystem's section.

### RF System

**Medical Linac** RF system consists of Klystron as RF source, Scandinova Klystron Modulator as HV source for the Klystron, Stanford Research System Signal Generator as RF pilot signal provider to Klystron preamplifier, BNC Digital Delay Generator as trigger of the modulator, Rohde & Schwarz Oscilloscope as RF Power measurement device. All of these devices are interfaced with EPICS IOCs using Ethernet interfaces. Klystron modulator communicates via Modbus TCP protocol, Delay Generator via Telnet protocol and other instruments via Vxi-11 protocol. Figure 7 shows RF system interfacing with the control system. RF conditioning process is automated using EPICS Sequencer module to minimize human interaction requirement and make the process error prone and reliable.

Figure 7: RF System of Medical Linac.

**Industrial Linac** RF system consists of S-band Magnetron as RF source, indigenously developed 48 kV/110 A HV Pulse Modulator as HV source for the Magnetron. Modulator control system consists of Siemens Simatic S7-1200 PLC CPU along with analog and digital input/output modules. EPICS communicates with S7-300 via s7nodave module and provides data to Control System Studio via

Channel Access Protocol. Figure 8 shows interfacing of RF system and Control system.

Figure 8: RF System of Industrial Linac.

## Electron Gun System

Electron Gun system consists of indigenously developed high voltage pulse modulator to provide HV power to electron gun. Lambda ZUP Power Supply are installed to provide Low Voltage (LV) power to the electron gun filament.

**Medical Linac** EPICS IOC interfaces ZUP Power Supply via RS-422 and ramp up/ramp down of filament voltage, and conditioning of the filament is automated using EPICS Sequencer module.

**Industrial Linac** interfaces this supply via RS-422 PLC communication module and ramp up/ramp down of filament voltage, and conditioning of the filament is automated with PLC Ladder Logic programming. Figure 9 shows interfacing of e-Gun system and Control system.

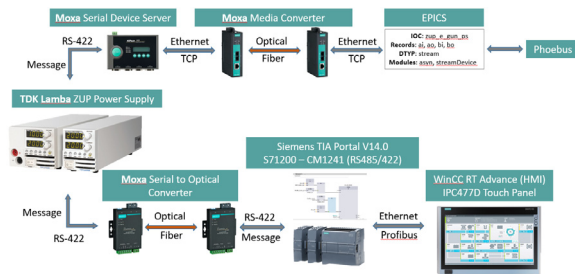

Figure 9: e-Gun System.

## Vacuum System

Vacuum is monitored using IMG-300 gauge card of Agilent Technologies XGS-600 vacuum gauge controller. The controller is interfaced with EPICS via RS-232 interface and also with Siemens S7-300 PLC via analog input module. Figure 10 shows interfacing of Vacuum system and Control system.

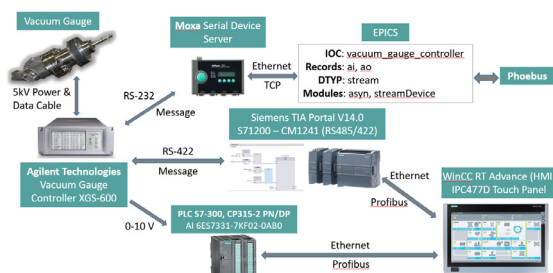

Figure 10: Vacuum System.

## Cooling System

Chiller provides cooling to the Linac hardware. K-type thermocouples are used to monitor temperatures at various points along the accelerator. Phoenix temperature transducers are interfaced with S7-300 PLC via analog input module. EPICS communicates with S7-300 via s7nodave module and provides data to Control System Studio via Channel Access Protocol. Figure 11 shows interfacing of Cooling system and Control system.

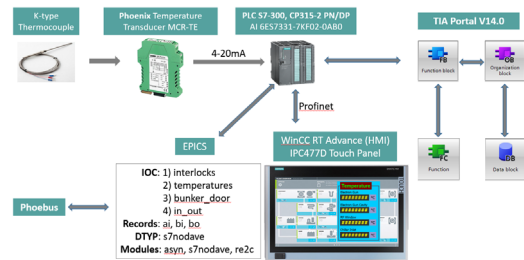

Figure 11: Cooling System.

## EXPERIMENTAL SETUP

Accelerator Hall (Main Lab) situated at LINAC Project PINSTECH hosts both Medical Linac experimental setup and Industrial Linac prototype. These linacs are operated from Control Room that is adjacent to Accelerator Hall. Control Room contains six LED screens. We have also configured and installed CCTV system for surveillance. One LED screen is used for CCTV cameras installed at different locations and five screens are used for different operator interfaces. Figure 12 shows the experimental setup of Medical Linac, Fig. 13 shows the NDT Linac prototype and Fig. 14 shows the Control Room.

Figure 12: Medical LINAC Experimental Setup.

Figure 13: NDT LINAC Prototype.

Figure 14: Control Room.

## CONCLUSION

Accelerator control system provides smooth, safe and reliable operation of the linear accelerators at the facility. Control system is continuously upgraded according to requirements from operating personnel and other groups of the Project. Accelerator control system community recommended practices are being followed to develop a state-of-the-art control system which can be comparable with control systems of other facilities.

## ACKNOWLEDGEMENTS

The authors thank all groups of the LINAC Project for their support. Also, we thank JACoW and ICALEPCS for providing literature that guides us towards right direction.

Shanghai Advanced Research Institute, Chinese Academy of Sciences  
Shanghai 201204, P. R. China

## Abstract

Shanghai High repetition rate XFEL aNd Extreme light facility (SHINE) is under construction. The 8 GeV superconducting Linac consists of seventy-five 1.3 GHz and two 3.9 GHz cryomodules. A cryomodule assembling and test workshop is established. Multiple facilities have been built for cryomodule and superconducting cavity test, including two vertical test facilities, two horizontal test facility, one multiple test facility and one liquid helium visualization facility. The local control systems are all based on Yokogawa PLC, which monitor and control the process variables such as temperature, pressure, liquid level and power of the heater. PID and other algorithms are used to keep liquid level and power balance. EPICS is adopted to integrate these facilities along with vacuum devices, solid state amplifiers, LLRF and RF measurement system, etc. The details of the control system design, development and commissioning will be reported in this paper.

## OVERVIEW

Owing to the wide range of applications of X-rays in the research fields of physics, chemistry and biology, facilities with the ability to generate X-rays were developed continuously in the last century. The free electron laser (FEL) is a novel light source, producing high-brightness X-ray pulses. To achieve high-intensity and ultra-fast short wavelength radiation, several X-ray FEL facilities have been completed or under construction around the world [1].

The first hard X-ray FEL light source in China, the so-called Shanghai High repetition rate XFEL aNd Extreme light facility (SHINE), is under construction. It will utilize a photocathode electron gun combined with the superconducting Linac to produce 8 GeV FEL quality electron beams with 1.003086MHz repetition rate.

## CRYOMODULE

Cryomodule (Fig. 1) is the key components of the superconducting linear accelerator, which composes of superconducting cavities, superconducting magnet components, beam position detectors, cryogenic cooling system, vacuum system, and mechanical support system. SHINE requires 75 1.3GHz superconducting cryomodules, which are connected in series to form the accelerator L1, L2, L3, and L4. In addition, two third-harmonic cavities with a frequency of 3.9GHz superconducting modules will be used to linearize the longitudinal emittance of the electron beam [2].

\* Work supported by Shanghai Municipal Science and Technology Major Project(Grant No. 2017SHZDZX02)

† chenguanghua@zjlab.org.cn

Figure 1: Cryomodule.

## CRYOMODULE TEST FACILITY

A superconducting cryomodule workshop is built for SHINE project. The infrastructure (shown in Fig. 2) includes ultra-clean processing and assembly, precision mechanical assembly and testing, cryogenic component multi-functional test facility system, superconducting cavity vertical and horizontal test facility system. They are used for superconducting cryomodule assembly and functional testing.

Figure 2: Layout of test facility.

The cryogenic component multi-functional test facility is used to test the working life of the tuner at cryogenic, the vacuum leakage rate and electrical performance at cryogenic of cold BPM, the working stability of superconducting magnet and current lead at cryogenic, the thermal load of each temperature zone, and the vacuum leakage rate of the coupler at cryogenic.

The superconducting cavity vertical test facility is used to test the performance of the superconducting cavity vertically to check whether the cavity has reached the design goal, so that it can meet the needs of engineering. The superconducting cavity horizontal test facility is used to test the performance of the cryomodule, check whether the cryomodule meets the design goal, and make it meet the needs of engineering. it includes cryomodule section and Feed Cap & End Cap.

## CONTROL SYSTEM

The control system is responsible for the device control, data acquisition, functional safety, high level database or application, as well as network and computing platform. It will provide operators, engineers and physicists with a comprehensive and easy-to-use tool to control the components of cryomodule test facility.

The control system will be mainly based on EPICS to reach the balance between the high performance and costs of maintenance. EPICS is a set of open source software tools, libraries and applications developed collaboratively and used worldwide to create distributed soft real-time control systems for scientific instruments such as particle accelerators, telescopes and other large scientific experiments [3].

As shown in Fig. 3, the control system can be divided into there layers to ensure the performance and scalability, which are operator interface layer, input/output controller layer and device local control layer.

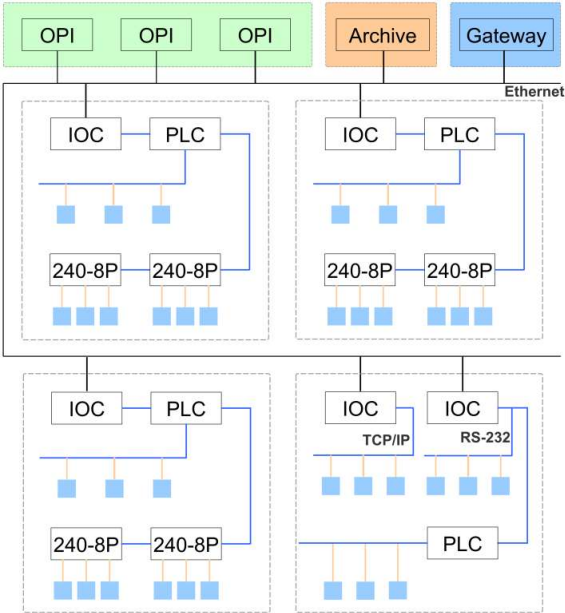

Figure 3: Architecture of the control system.

The local control layer is responsible for the monitor and control of temperature, pressure, cryogenic valve, liquid level, heater power supply, vacuum and so on. The signal of horizontal test facility is shown as Table 1. The multi-functional test facility and vertical test facility are similar.

Table 1: The Signal of Horizontal Test Facility

Signal	Qty	Type	
Temperature	120	Input	CX-1030-CU-HT
Pressure	2	Input	Analog
Liquid Level	3	Input	Analog
Cryogenic valve	4	Input	Analog
Cryogenic valve	4	Output	Analog, PID
Function safety	14	Input/Output	Digital
Heater Power Supply	16	Input/Output	Analog, Digital
Vacuum Gauge	3	Input	Serial port
Ion Pump	3	Input	Serial port
Magnet Power Supply	3	Input	Ethernet

TEMPERATURE MONITORING

Temperature monitoring(Fig. 4) is one of the key technologies for the test facility. LakeShore Cernox CX-1030-CU-HT is considered to be used as the temperature sensor(Fig. 5). Because the resistance of the cryogenic probe is not in the range of the PLC temperature monitoring module, temperature meter is used. The Cernox temperature probe is connected with temperature meter 240-8P by four wires to reduce error and reduce interference during transmission. 240-8P has 8 channels to connect temperature probe. The data from temperature meter is transmitted to PLC temperature module in sequence via profibus protocol. As shown in Fig. 6, F3LB01-0N is utilized as the model of PLC temperature module.

Figure 4: Temperature monitoring

Figure 5: Temperature sensor.

Figure 6: Structure of F3LB01-0N.

PRESSURE MONITORING

Pressure Transmitters(shown in Fig. 7) has 3 types applied to pressure monitoring. KELLER PAA-41X (0-100mbar, 4-20mA), KELLER PAA-33X (0-1600mbar, 4-20mA), and KELLER PAA-33X (0-3000mbar, 4-20mA). PLC module is Yokogawa F3AD08-4R (analog input module, 8 channels, 4-20mA), the internal circuit diagram of F3AD08-4R is displayed in Fig. 8.

Pressure Transmitters measures 2K helium circuit pressure(high pressure), 2K helium circuit pressure(low pressure), along with cryogenic pipeline pressure. 16-bit analog-to-digital module is selected, and the acquisition accuracy meets the requirement.

Figure 7: Pressure transmitter.

Figure 8: Internal circuit diagram of F3AD08-4R.

## MONITORING AND CONTROL OF CRYOGENIC VALVE

The model of cryogenic valve selects Toko Valex T-8800, while the model of digital electropneumatic valve positioner(Fig. 9) picks SAMSON 3730-2. PLC modules are Yokogawa F3AD08-4R (analog input module, 8 channels, 4-20mA) and Yokogawa F3DA04-5R (analog output module, 4 channels, 4-20mA). The internal circuit diagram of F3DA04-6R is displayed in Fig. 10.

Cryogenic valve contains cooling valve and bypass valve. Its function is to control the flow of helium gas. When needed, open the valve to allow helium to enter the pipeline to cool the cryomodule.

Figure 9: Digital electropneumatic valve positioner.

Figure 10: Internal circuit diagram of F3DA04-6R.

## LIQUID LEVEL MONITORING AND STABILITY CONTROL

Liquid level monitoring and stability control(Fig. 11) is another key technology for the test facility. Level gauge has AMI 2K level probe. Liquid level gauge obtains AMI 1700-2K (0-10V analog output) as its model. The PID algorithm is used to realize the closed-loop control of the 2K liquid helium level. There are two control methods: manual control and PID control. The manual control is to set cryogenic valve opening on the interface while the PID control is that the PID program automatically sets the opening of the cryogenic valve. PLC module is Yokogawa F3CU04-1S (PID module, 0-10V analog input, 4-20mA analog output).

The final goal is to stabilize the height of the liquid level at a certain value. The liquid level gauge is partly in liquid helium and partly in air. The level gauge is connected with the liquid level acquisition instrument by four wires to reduce error. AMI 1700 is the liquid level acquisition instrument, it displays liquid level height, and it supports 4-20mA signal and 0-10V signal. AMI 1700 converts the height of the liquid level to voltage, and exports the voltage signal to the PID module F3CU04-1S. F3CU04-1S has its own algorithm, the parameters include setting value and output value. F3CU04-1S receives 0-10V voltage signal, which corresponds to the valve opening. It controls the valve dynamically according to the linear conversion relationship.

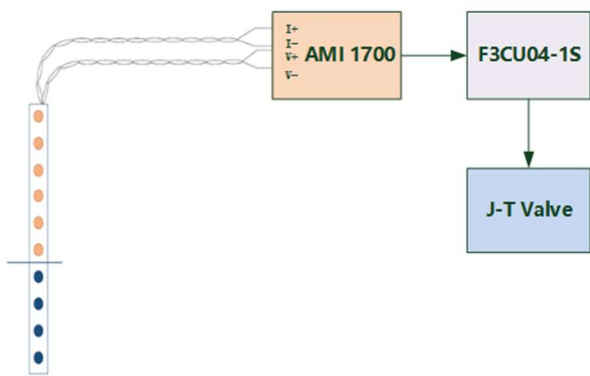

Figure 111: Liquid level monitoring and stability control.

As the algorithm diagram is shown in Fig. 12,  $e$  is the difference of setting value and target value. The target value is obtained from the liquid level sensor.  $u$  is the output of PID control, which conforms to the algorithm formula with 3 diagnostic parameters ( $k_p, T_I, T_D$ ) in Fig. 13. These 3 parameters should be determined in the commissioning site.

Figure 12: Algorithm diagram.

$$u(t) = K_p \left[ e(t) + \frac{1}{T_I} \int_{s=0}^t e(s) ds + T_D \frac{d(e(t))}{dt} \right]$$

Figure 13: Algorithm formula.

## MONITORING AND CONTROL OF HEATER POWER SUPPLY

Omega KH-112/10 50W is utilized as the model of the heater, which is used for cryomodule heating up and cryomodule compensation of total thermal load power. Heater power supply model (shown in Fig. 14) is TDK Z60-3.5-C, the heater power supply has two modes (constant voltage and constant current), and constant current mode is used in this project. PLC includes Yokogawa F3XD16-3F DC digital input module, F3YC08-0C relay digital output module, F3AD08-5R 0-10V analog input module, and F3DA08-5R 0-10V analog output module. It realizes switching on/off power supply remotely, power failure status readback, and power operation mode readback (constant voltage, constant current). It achieves power supply output current value readback, power supply output voltage value readback, and power supply output power value readback. It fulfills current output setting. Constant control of the total thermal load power of the cryomodule has two methods: manual control and automatic control. The manual control is to set the current setting value on the interface while the automatic control automatically sets the current setting value, which is realized with Python + cothread. Cavity dynamic load + heater compensation output power = total power (constant).

TUBR04

356

Figure 14: Heater power supply model.

## FUNCTION SAFETY CONTROL

The function safety logic is established between the system and the device. When a fault occurs, it can reliably and quickly protect the important components, send an alarm signal, and report the fault information to the control system. For input signals, the system can realize alarm latch, reset, and bypass processing from the software. Latch refers to saving the signal alarm state. Reset refers to releasing the alarm latch. Bypass means that the software temporarily releases the function safety response to the input signal. Yokogawa F3XD16-3F DC digital input module and F3YC08-0C relay digital output module are adopted for the PLC modules. The Interface of function safety control is shown in Fig. 15.

Figure 15: Interface of function safety control.

## IOC AND OPI

MOXA DA-682B running Linux/CentOS is chosen as IOC to communicate with local I/O devices with serial port, using Modbus/TCP protocol. We make use of PyDM (Python Display Manager) to build the graphic user interface. It is a new framework for building control system GUI based on PyQt, allowing us to make a rich desktop app including all types of buttons (push, toggle), images and a lot more. It is also convenient to add new functions to existing widgets and add new widgets. A user interface of vertical Dewar is shown in Fig. 16.

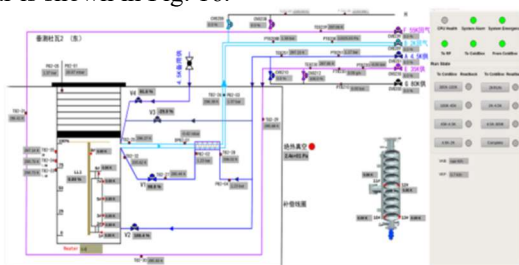

Figure 16: Control interface of vertical test platform.

Hundreds of EPICS PVs are archived by Archiver Appliance which is deployed on dual-server cluster as hot backup. Each server can provide data query service for all PV channels. Besides, with its excellent data retrieval performance, the archive client can be launched from a web page and used to browse and plot data as shown in Fig. 17.

Figure 17: Temperature of archiver appliance.

The control system of cryomodule test facilities has been operating stably for several months. The local control system makes use of Yokogawa PLCs and the corresponding algorithms, such as PID to keep liquid level and power balance. It is mainly used to monitor and control the parameters of temperature, pressure, liquid level, power of the heater and so on. The high level control system is based on EPICS to integrate all the devices in various systems, networked together to allow communication between them.

# THE MIRROR SYSTEMS BENCHES KINEMATICS DEVELOPMENT FOR SIRIUS/LNLS\*

G. N. Kontogiorgos<sup>†</sup>, A. Y. Horita, L. M. Santos, M. A. L. Moraes, L. F. Segalla,  
Brazilian Synchrotron Light Laboratory (LNLS), Campinas, Brazil

## Abstract

At Sirius, many of the optical elements such as mirror systems, monochromators, sample holders and detectors are attached to the ground with high stiffnesses to reduce disturbances at the beam during experiments [1]. Granite benches were developed [2] to couple the optical device to the floor and allow automatic movements, via commanded setpoints on EPICS [3] that runs an embedded kinematics, during base installation, alignment, commissioning and operation of the beamline. They are composed by stages and each application has its own geometry, a set number of Degrees-of-Freedom (DoF) and motors, all controlled by Omron Delta Tau Power Brick LV. In particular, the mirror system was the precursor motion control system for other benches [4 - 6]. Since the mechanical design aims on stiffness, the axes of mirror are not controlled directly, the actuators are along the granite bench. A geometric model was created to simplify the mirror operation, which turn the actuators motion transparent to the user and allow him to directly control the mirror axes.

## INTRODUCTION

The latest Sirius mirror bench mechanical design version will be installed in Mogno and Ipê beamlines. They are composed by three stacked granites pieces (Fig. 1), the first one is supported by three levellers on the floor, the second is above the first and it has a ramp to form a wedge with the third granite.

Figure 1: Granite assembly before installation and commissioning.

The mirror positioning depends on the relative motion between those components. Air-bearings were disposed both to guide and lift the granites between interfaces. The pressure, flow and activation of the air-bearings are commanded by a pneumatic panel.

## KINEMATICS

### Kinematic Model

As mentioned, the hole granite stack is supported by three levellers (The leveller is the component A of Fig. 2). They do not have feedback sensor, the position is measured by three Heidenhain gauges (Component B of Fig. 2) which touch the granites, so the measurement is done at the bench itself, not on the actuator. Although the controller can read the real position of the granite, this mechanical design allows the granite to slide over gauge and the leveller. This result presents incoherence between real position and the controller readback position. Furthermore, the geometry is much more complicated when considering friction and sliding on mechanics. To contour those problems, approximations were done on the geometry (As will be shown now) and an iterative actuation was developed (As will be shown later).

Figure 2: Leveller actuator (A) and feedback encoder (B).

The levellers could be interpreted as a parallel robot called tripod. The tripod was modelled using two reference frames [7], one rigidly coupled to the top platform ( $S_1$ ), which is the moving one, and the other frame is at rest on the laboratory ( $S_0$ ). Three vectors  $\vec{r}_i(S_1)$   $i = 1, 2, 3$ , connect the  $S_1$  origin to the three vertical Heidenhain sensors points that touch the platform. This is the first approximation of this model. Figure 3 illustrates both reference

frames, the vectors for each sensor and their projection on the sensors axes represented at laboratory reference frame.

Figure 3: Referential transformation for tripod, part of mirror system kinematics.

The relationship between both reference frames is described by two rotations ( $R_x, R_z$ ) and one translation about  $\hat{y}_0$  axis ( $q_3$ ), which are the allowed DoF for a tripod robot. Using the homogeneous transformation matrices  $T$ , it was possible to find the representation of the vectors rigidly coupled to  $S_1$  on  $S_0$  frame, the  $\vec{r}_i(S_0)$   $i = 1, 2, 3$ , which is the frame where the encoders are.

$$\begin{cases} \vec{r}_1(S_0) = T(R_x, R_z, q_3) \vec{r}_1(S_1) \\ \vec{r}_2(S_0) = T(R_x, R_z, q_3) \vec{r}_2(S_1) \\ \vec{r}_3(S_0) = T(R_x, R_z, q_3) \vec{r}_3(S_1) \end{cases} \quad (1)$$

The sensors movement are limited into  $\hat{y}_0$  direction and the projection of the vectors represented on  $S_0$  frame system onto  $\hat{y}_0$  direction gives us the sensors positions  $e_i$ ,  $i = 1, 2, 3$ .

$$\begin{cases} e_1(R_x, R_z, q_3) = |\vec{e}_1| = \hat{y}_0 \cdot \vec{r}_1(S_0) \\ e_2(R_x, R_z, q_3) = |\vec{e}_2| = \hat{y}_0 \cdot \vec{r}_2(S_0) \\ e_3(R_x, R_z, q_3) = |\vec{e}_3| = \hat{y}_0 \cdot \vec{r}_3(S_0) \end{cases} \quad (2)$$

Those relationships are usually called the inverse kinematics because they express the “actuator” position in function of the desired DoF’s (on robotics these desired positions usually are the tool positions).

To couple the tripod to the granite actuators a transformation from parallel robot into serial robot was performed. The forward kinematics of the tripod is now necessary since each DoF represented in terms of the encoders could be transformed into an actuator of a serial robot. This set of equations are non-linear and finding the forward kinematics analytically is not possible. There are two ways of solving it: approximation by Taylor expansion and numerical methods. Since the angles are small and it would reduce the complexity of solution, the small angle approximation was chosen and the inversion of the linear system became possible.

The first air interface, shown on Fig. 4 item D, between the first and second granite has three actuators: one on the  $\hat{x}_0$  direction (item C) and the others on the  $\hat{z}_0$  direction (item B, the other cannot be seen from a single view because it is on the other side of the granite).

Figure 4: Granites' disposition of actuators and interfaces of granite bench.

Both  $\hat{z}_0$  direction actuators can perform rotation ( $R_y$ ) towards an axis parallel to  $\hat{y}_0$  and translations ( $q_3$ ) on an axis that is parallel to  $\hat{z}_0$  if the motion is done in a coordinated way. The problem of transforming actuators into serial joints arises again since the  $z$  actuators forms a parallel robot. Some geometrical analysis led us to the following expressions:

$$\begin{cases} q_3 = \frac{z_{upper}d_{upper} + z_{lower}d_{lower}}{d_{upper} + d_{lower}} \\ R_y = \arctan \frac{\theta_{wedge} z_{lower} - z_{upper}}{|\theta_{wedge}| d_{upper} + d_{lower}} \end{cases} \quad (3)$$

Where  $z_i$  is the actuator position,  $d_i$  is the distance from the desired  $R_y$  pivot axis parallel to  $\hat{y}_0$  axis to the  $\hat{z}_0$  actuator and  $\theta_{wedge}$  is the wedge angle (both  $i = upper, lower$ ). This last parameter is only required to set the equations orientation, since the beamlines designers set the bench orientation according to their needs.

The last actuator (on granite bench because the internal mechanism has the piezo actuator) is the Fig. 4 item A, the wedge actuator, control the movement to lift the third granite through the ramp. Some caution must be taken here about the movement of the wedge, since it is used to lift the mirror parallel to  $\hat{y}_0$  axis in the case that all rotations are zero. Although the pure movement may present undesired parasite motion, the hole inverse kinematics working together (this will be discussed further).

With all actuators properly modelled, a kinematics scheme could be synthesized in a serial robot model, Fig. 5.

Figure 5: Mirror system kinematic scheme.

The scheme  $\vec{r}_{nominal}$  is the fixed machine offset from the first joint to the control point  $S_8$ , usually set on the center of the mirror. This point is interesting because you are always commanding the positions to the mirror near the specified beamline mirror center. The  $\vec{r}_{offset}$  is the user offset and was created to correct alignment positions or to set new positions to the mirror center as user want. The  $q_i, i = 1 \dots 4$  are the variable translations performed by the actuators and the  $d_i, i = 1 \dots 4$  are the fixed offsets between the joints. The levelers transformations results onto joints on  $S_1, S_2, S_3$ , the  $\hat{x}_0$  direction actuator (Item C, Fig. 4) is the  $S_4$  actuator, the composed movement in Eq. (3) with B actuators are performed by  $S_5$  and  $S_6$  joints and the last one, the  $S_7$  joint is rotated by  $\theta_{wedge}$  angle to model the wedge. The forward kinematics is totally modelled with this scheme and the rotations  $R_x, R_y, R_z$  and translations  $U_x, U_y, U_z$  could be found in function of the encoders.

### Kinematics by Steps

There is no mechanism on levellers-granite interface that locks the parasite motion and the entire system can drift along undesired axes during some commanded movement. A hypothesis from mechanical design group is that a segmented movement instead of usual closed loop control would be a better approach to avoid this problem.

The proposal is setting the actuators in open loop while three encoders guarantee that each motor reach their specific position during the process.

The user would be able to define a threshold, which controls how close to the exact final position the levellers should get. At each iteration of the algorithm the position of the levellers is compared to the desired position, by reading the virtual motors. While their position is not inside the threshold band a new step is calculated based on the distance from the final position, then the motors are commanded to move several counts equivalent to the step. Once they reach this new position, the reference is compared again and the process continues. Figure 6 shows the state machine representation of the algorithm.

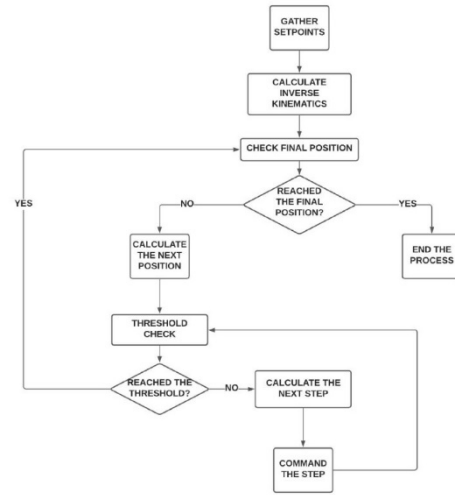

Figure 6: State machine representation of the kinematics by steps algorithm.

### Numeric Solution for Inverse

The core of mirror kinematics is the inverse kinematics calculation since it gives the setpoints for actuators control loop. The user inputs for inverse kinematics are the DoF  $\vec{u} = (R_x, R_y, R_z, U_x, U_y, U_z)$  of the granite bench at the control point  $S_8$ , related to  $S_a$ , the laboratory reference frame. The forward kinematics is a non-linear set of equations and finding its solution analytically is impossible. Then, the Newton method [8] was chosen for finding iteratively the encoders readings corresponding to some user input. The forward kinematics can be written as:

$$\vec{u} = \vec{f}(\vec{e}). \quad (4)$$

Where  $\vec{e}$  is the actuators or encoders positions vector and note that  $\vec{u}$  is the output vector on forward kinematics but it is the input on inverse as we are going to see. Let us define an error function  $\vec{G}$ , which is going to be minimized

$$\vec{G}(\vec{e}, \vec{u}) \triangleq \vec{f}(\vec{e}) - \vec{u}. \quad (5)$$

The method iteration can be defined as

$$\vec{e}_{k+1} = \vec{e}_k + J^{-1}(\vec{e}_k) \vec{G}(\vec{e}_k, \vec{u}). \quad (6)$$

Where  $J$  is the Jacobian matrix of  $\vec{f}$  and  $k$  is the iterator index. The iteration loop stops by the norm of  $\vec{e}_{k+1}$  condition, which must be less than one count.

## TESTS AND VALIDATIONS

The mirror kinematics validation was done by an external set of instruments. Six Heidenhain gauges were positioned in such a way to get the last granite position (Fig. 7).

Figure 7: Setup for the kinematic validation.

Each granite surface which is touched by the gauges is modelled as a plane generated by three known points from the metrology data. Those points are fixed on the granite reference frame (e.g. this frame could be chosen) and a coordinate transformation with respect to  $\vec{u}^{meas} = (R_x^{meas}, R_y^{meas}, R_z^{meas}, U_x^{meas}, U_y^{meas}, U_z^{meas})$  allows the representation of those points on the laboratory reference frame. The Heidenhain gauges measurement are represented by one of three coordinates of the plane equation while the other coordinates are the gauges' location on the plane, which has been obtained from metrology measurements.

The model described above gives the gauges positions in function of the coordinates  $\vec{u}^{meas}$ . The validation of kinematics can be done by the Newton-Raphson method, since  $\vec{u}^{meas}$  can be found in function of gauges data. Each DoF was subject to a programmed movement on PowerPMAC using the developed kinematics and each gauge position was gathered with another PowerPMAC controller.

Some data were corrupted during the gather and not all analysis could be done in this paper, which is going to be done in future works. The useful data could be compiled in Table 1 and Fig. 8 illustrates the control data and post processed data from the measurement devices.

Table 1: Formatting of References

Parameter	Rx	Rz
Accuracy	3.44e-1	6.16e-1
Rx drift	3.44e-1	2.04e1
Ry drift	3.57e-2	5.71e-3
Rz drift	2.87e-1	1.79e1
Tx drift	2.94e3	1.01e1
Ty drift	1.95e1	1.70e2
Tz drift	8.64e1	1.52e2

Figure 8: Measurement of a rotation towards x-axis done by mirror controller system and by validation method.

The accuracy is the difference of setpoint and the mean value of the measured data at the end of motion. The drifts are the difference from the position immediately before and the position after that this step motion is undone, which should be ideally zero.

## CONCLUSION

The kinematics play an important role during beamline operation since it improves the user experience on its devices. Commissioning, alignment and operation are much easier when the user controls the mirror axes directly and no hand calculation is needed to find the positions of the actuators to perform a pure movement on the mirror.

Some tests were performed recently to characterize the motion of the system being operated by kinematics interface. A validation methodology was developed and now it can be improved and applied on the next beamline bases since some data was corrupted during tests before installation. Although there were problems, the present analysis offered several information for further project improvements.

# MOTION CONTROL IMPROVEMENTS FOR THE KIRKPATRICK-BAEZ MIRROR SYSTEM FOR SIRIUS/LNLS EMA BEAMLINE\*

G. N. Kontogiorgos<sup>†</sup>, C. S. B. N. Roque, M. A. L. Moraes, Brazilian Synchrotron Light Laboratory (LNLS), Campinas, Brazil

## Abstract

The Kirkpatrick-Baez (KB) mirror system is composed of a vertical focusing mirror (VFM) and a horizontal focusing mirror. Both concave mirrors focus the X-ray beam by reflecting it at small grazing angles. The relocation of this system from UVS XDS beamline to Sirius EMA beamline facilitated a full revision of the motion control system, whose controller was migrated to Omron Delta Tau Power Brick LV. The beam focus is controlled by bending the mirrors through camshaft mechanisms coupled to low current Faulhaber motors. Although the amplifier is designed for higher currents, controller settings allowed the use of lower currents. Another improvement made is the ability to drive both bender motors in gantry mode and still control the lag between them. Each bender has a capacitive sensor to monitor the position of the center of the mirror, which is read by the analog input of the controller and made available by EPICS [1]. The VFM is supported by a tripod and a new kinematics was developed to reference the center of the mirror as the point of control. This paper presents the implementation of the new motion control KB system and its results at Sirius EMA beamline.

## INTRODUCTION

The KB mirror system from XDS beamline at the previous accelerator UVS has been reconditioned for its operation at EMA beamline at Sirius. A full review of mechanisms and optics was done at the system since it was in operation for years at XDS. Some parts were adapted with new concepts brought from other Sirius devices, such as DCM and mirror systems [2,3]. The new parts give the system more repeatability since the backlash is reduced by the substitution of bushing-axis mechanism to parallel leaf spring translator. The mechanical enhancement favoured upgrades on the mirror bending control system.

A closed loop was developed using Power Brick controller for the mirror bending system. Since this controller has more features than the one used previously, the entire system, including its rough positioning by its supporting bench, has been redesigned. A kinematics inspired on mirror systems [4] was developed for a better user experience during commissioning, alignment, and operation because no hand calculation would be necessary to position the mirrors by commanding the actuators one by one.

The present paper is going to present further studies of driving low current stepper motors inspired on [5], the peripheral sensors that offer monitoring during operation and the details of kinematics implementation.

## SYSTEM ARCHITECTURE

The KB system is composed of eleven motors with encoders, two piezos for fine pitch and two capacitive sensors. These are divided into two subsystems: VFM and HFM. Each subsystem is composed of a mirror with two motors responsible for driving the bending mechanism, with a capacitive sensor at the center of the mirror, and a base.

The HFM base is composed of one motor for each translation ( $U_x$  and  $U_y$ ) and one for rotation around the X axis. The VFM base is more complex, composed of a tripod responsible for the required rotations ( $R_x$  and  $R_y$ ) and translation on the Y axis.

All motors and encoders are controlled using a Power Brick LV. The capacitive sensors signals are read using the analog input in the same controller after being conditioned through the standard PI device. The piezos are controlled individually using PI servo controllers.

For the final users, all necessary commands are implemented in a graphic user interface (GUI) using process variables (PVs) made available by EPICS.

## MIRROR BENDER

### *Driving Low Current Motors with High Current Amplifier*

The Power Brick LV controller was adopted at Sirius for its ability to cover a range of motion control solutions. This controller is integrated with a 5 / 15 A amplifier [6]. The mirror bender motors used in the KB System are 250 mA and although the manufacturer does supply controllers with low current drivers, we opted to adapt the 5 / 15 A amplifier due to cost and time constraints. It has a bending system with two stepper motors AM2224 series model 0250 [7] coupled to a camshaft that pushes the mirror to bend and sets its focus.

Rising the inductance was the first setup to match the motor and controller specifications. To delay the current rising time, different values of inductors were placed in series with a low current test motor and the amplifier circuit could properly control the current on the motor coils.

Adding new components to the motor phases would change the motor properties, increase system cost, and decrease robustness. A detailed analysis led to the conclusion of limiting 48 V amplifier output PWM duty cycle. Since the current rise on the PWM on time and fall on the PWM off time [8], limiting the on-time voltage we chop the maximum reached current.

Figure 1: Proof of concept of current limiting by PWM scale factor.

Figure 1 shows the experimental setup for the validation of the duty cycle limiter concept. The phase A of ARSAPE AM1524 stepper motor A was submitted to a current bias of 100 mA from Power Brick. The current probe B was measuring the current passing on phase A coil and two voltage probes C and D were disposed to measure the voltage across the coil.

Starting from 95% of the full value of PwmSf, the percentual of the scale factor was reduced to zero and current measurements were performed at each scale factor value. The mean value of each measurement was calculated and plotted into the Fig. 2.

Figure 2: Percentual of full value of PwmSf versus Mean value of current at phase A submitted to a constant bias from the controller.

The test proved the current limitation, although the controller was trying to keep the current at 100 mA, it was not possible since PwmSf was limiting its output. This solution was chosen by its simple design. To ensure that the motor will not be damaged, phases fuses were displaced on final implementation.

### Gantry Mode

To synchronize the bender motors movements, we created both the forward Eq. (1) and inverse (which is trivial from forward since the equation system is linear) native kinematic scripts implementing the following equations:

$$\begin{cases} X = 0.5(m_5 + m_6) \\ Y = 0.5(m_5 - m_6) \end{cases} \quad (1)$$

Where  $Y$  is the desynchronization angle and  $m_i$  are the motor positions. The  $X$  value is the bending parameter and can be interpreted as the bisector between the motor axes. Values set to the  $X$  parameter should move both motors in a synchronized manner, keeping the  $Y$  lag angle constant between them.

### Capacitive Sensor Analog Input

There is a capacitive sensor behind each mirror to monitor the distance of the center of the mirror to infer the bending radius. An optical characterization of the mirror system was done using a Fizeau interferometer, which aims to find the relation between the mirror bending radius and the position read from the capacitive sensor.

This setup allows us to close the loop between bending motors and the capacitive sensor. Since the capacitive sensor does a direct measurement of the bending radius (in opposite to the bending motors encoders, which are coupled to the motor axis and perform an indirect measurement of the mirror bending radius) the control system would be more accurate on its setpoints. Closing this outer loop was not done yet due to the beamline deadlines but this is the next step on improving KB's positioning system.

### VFM KINEMATICS

The VFM is supported by a tripod, a parallel robot with three degrees of freedom: Rx, Rz and Y, in Sirius reference frame. There is a linear stage coupled to the tripod that allows movements along the X axis. Those movements are required for the sake of simplicity on positioning the mirror on the correct place. The kinematics feature circumvents the need for iterative operation, improving time and user experience on the positioning of the mirror. Figure 3 shows the graphic user interface used with kinematics.

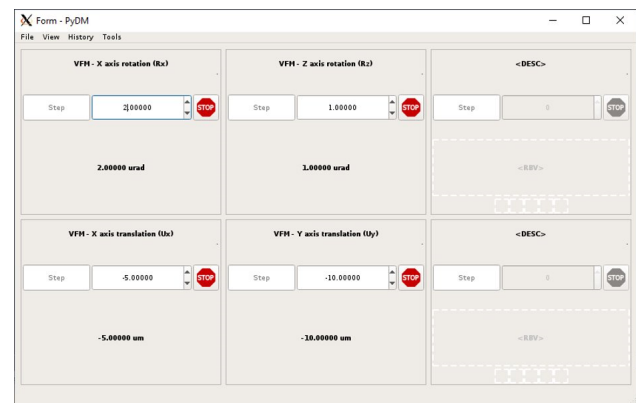

Figure 3: Test user interface for KB operation.

The stage above the tripod must be modelled together to obtain a single set of equations that describes the relationship between user positions and motor positions. This was done by transforming the parallel tripod robot into a serial robot with three joints, each one responsible for the three degree-of-freedom. Applying Taylor expansion on the tripod inverse kinematics (the angles are very small) turns the system easily inversible with a solver from the Python

SymPy library solver [9]. The operation resulted on the forward approximated equations and those positions could be translated to the robot joints. The full model was obtained by adding the linear stage into this serial version of tripod. Figure 4 shows the joint scheme derived from the system showed in Fig. 5.

Figure 4: Kinematics joint scheme for geometric modelling.

Figure 5: Tripod draw from system specification [10].

The KB solution uses the forward kinematics, which could be found by applying the basic transformation matrices on the robot joint scheme. The inverse kinematics is fundamental to command the motors with a setpoint input on Rx, Rz, Y and X axes and was found from the forward kinematics equations. The Power Brick embedded algorithm uses the Newton method [11] to solve the forward kinematics for the motors using as input the four user axes.

## CONCLUSION

The EMA beamline KB system has been conditioned, it was successfully migrated to the new standard controller used at Sirius, the Omron Delta Tau Power Brick LV.

The studies and methodologies used on this work made possible and reliable to control low current motors with high current amplifier.

It was also possible to receive the capacitive sensors analog signals in the controller. This allows the simplification of the architecture and facilitates future improvements in closing the outer loop with this extra feedback.

The new kinematics used for the base of VFM improved usability and its equations were fixed, considering the reference frame transformation instead of simple geometric relations, as used before, which infer more accuracy to the motion.

To enhance the bending system and incorporate more accuracy on its movements, further work is going to set up a closed loop control using the capacitive sensor as feedback. This approach would measure the real bending radius instead of indirect measurements from the motors encoders.

At the time of this publication, the system has been commissioned and it is fully functional with the new improvements implemented.

## Abstract

CARNAÚBA (Coherent X-ray Nanoprobe) and CATERETÊ (Coherent and Time-Resolved Scattering) are the longest beamlines in Sirius – the 4th generation light source at the Brazilian Synchrotron Light Laboratory (LNLS). They comprise Four-Bounce Crystal Monochromators (4CM) for energy selection with strict stability and performance requirements. The motion control architecture implemented for this class of instruments was based on Omron Delta Tau Power Brick LV, controller with PWM amplifier. The 4CM was in-house designed and consists of two channel-cut silicon crystals whose angular position is given by two direct-drive actuators. A linear actuator mounted between the crystals moves a diagnostic device and a mask used to obstruct spurious diffractions and reflections. The system is assembled in an ultra-high vacuum (UHV) chamber onto a motorized granite bench that permits the alignment and the operation with pink-beam. This work details the motion control approach for axes coordination and depicts how the implemented methods led to the achievement of the desired stability, considering the impact of current control, in addition to benchmarking with manufacturer solution.

## INTRODUCTION

The Four-Bounce Crystal Monochromators (4CM) was in-house designed to compose the set of optical systems in the longest beamlines in Sirius [1]: CARNAÚBA [2] (Coherent X-ray Nanoprobe) and CATERETÊ [3] (Coherent and Time-Resolved Scattering).

The energy is selected by two channel-cut silicon crystals whose angular position is given by two direct-drive actuators. A mask, mounted between the crystals, is used to obstruct spurious diffractions, having as actuator a linear stage.

The system is assembled in an ultra-high vacuum (UHV) chamber onto a motorized granite bench that permits the alignment and the operation with pink-beam.

The adopted motion controller for this system was the Omron Delta Tau Power Brick LV (PBLV) and his PWM amplifier. This works discuss the methods that led to achieve the requirements of stability and coordination, considering current control influence, and compares with manufacturer control solution, Aerotech Ensemble Epaq MR (Epaq).

## SYSTEM ARCHITECTURE

### Granite Bench

The granite bench is designed to both ensure high stiffness and allow the movement for alignment [4] of the monochromator and operation with pink beam, moving the UHV chamber to a position that the beam passes between the crystals.

Air-bearings in the bottom and top granite interface permits a frictionless motion in the translation in the X direction and rotation in the Y direction.

Furthermore, three levelers that supports the bottom granite compounds the translation in Y direction and rotations in X and Z directions.

The actuators of the granite bench are 2-phase stepper motors. The feedback of the position are made with a Heidenhain's quadrature incremental length-gauge for each leveler and a pair Renishaw's BiSS-C absolute linear encoder.

Figure 1 illustrates the 4CM granite bench and his UHV chamber installed in CARNAÚBA beamline.

Figure 1: 4CM granite bench and UHV chamber.

\* leandro.martins@lnls.br

## Motion Controller

The motion controller used in this system is the PBLV. The PWM amplifier is able to provide currents of 5 A continuous and 15 A of peak and has maximum switching frequency of 30 kHz. It is able to decode differential quadrature and BiSS-C encoders, necessary in this project, besides others types of protocols [5].

It was considered the use of the Epaq, but for limitations encountered in the available features, the PBLV was chosen. As the standard motion controller for medium and high complexity applications in Sirius's beamlines, PBLV makes coordinating and triggering with other systems more compatible. In compensation, it was challenging to maintain the same Epaq performance, due to his linear amplifiers.

## Crystals

The incoming pink beam is diffracted four times by two Si-111 channel-cut crystals, disposed in the configuration  $++-$ . In this configuration, the crystals rotates in opposite directions, as seen in Fig. 2. In order to guarantee that the beam doesn't suffer any offset, is essential the channel-cut crystals have equal gap between his optical surfaces and the parallelism at each channel-cut.

From the Bragg's law, described in Eq. (1), we have the relation of the angle of diffraction (crystal angle  $\theta$ ) and wavelength ( $\lambda$ ) of the output beam, being the first diffraction order and given the distance of crystallographic planes  $d = 3.135\,416\,1\text{ \AA}$  for Si-111.

Equation (2), that describes the photon energy ( $E$ ) from: Planck's constant ( $h$ ), speed of light ( $c$ ) and wavelength ( $\lambda$ ).

Substituting Eq. (1) in Eq. (2), we get the energy ( $E$ ) in function of diffraction angle ( $\theta$ ), as described in Eq. (3).

$$\lambda = 2d \sin(\theta) \quad (1)$$

$$E = \frac{hc}{\lambda} \quad (2)$$

$$E = f(\theta) = \frac{hc}{2d \sin(\theta)} \quad (3)$$

Each crystal are positioned by a direct-drive rotary stage, Aerotech APR200DR-155 (APR), indicated in Fig. 2 item d. It consists in permanent magnet synchronous motor (PMSM), Hall sensors and Renishaw's interpolated quadrature encoder system, with two readheads  $180^\circ$  spaced, each on with an angular resolution of  $26.6\text{ nrad}$  [6].

## Mask

A mask is used to prevent reflections and spurious diffractions contaminates the output beam. It must be positioned based on the beam offset caused by the first pair of diffractions, which is function of the angle of the first channel-cut angle ( $\theta_1$ ) and the gap between the optics surfaces, described in the Eq. (4) and illustrated in Fig. 2.

$$\text{Offset} = 2 \cdot \text{gap} \cdot \cos(\theta_1) \quad (4)$$

Figure 2: Representation of the crystals and mask. Indicating: the beam offset; the crystals gap; the adopted directions as positive for upstream crystal ( $\theta_1$ ), downstream crystal ( $\theta_2$ ) and mask; and the Sirius' coordinate system ( $x_{mask}$ )

A screw-driven linear stage, Aerotech MPS50SL-025 (MPS) moves the mask between both crystal, indicated in Fig. 3 item c. In the configuration present at this application encloses a DC brush servomotor with 14:1 gearbox, a screw with 1 mm/rev of pitch, a rotary encoder with 512 lines/rev; resulting a resolution  $34.8\text{ nm}$  at the load [7]. As the encoder is situated at motor's axis, one of the precautions taken during metrology procedures was to ensure that there is no considerable backlash. MPS also carries a diagnostic device, being a photodiode in CATERETÊ and a gold plated part in CARNAÚBA, that generates electrons by photoelectric effect.

Figure 3: UHV components 3D model, namely: indicates upstream crystal; (b) indicates downstream crystal; (c) indicates the mask; (d) indicates the APR stages.

## GRANITE BENCH KINEMATICS

The UHV chamber position is set by the relative motion of the stacked granite blocks performed by both motorized air-bearings and levelers mechanisms. The coordinated motion of all actuators enhances the user experience since the embedded kinematics [8] moves the control point in relation to the laboratory reference frame and no hand calculations of actuators position is needed.

The 4CM bench has a customized control point feature, playing an important role during alignment since the user

has three options for setting the reference frame<sup>1</sup>: rotation axis of the upstream or downstream crystal, and the midpoint between them.

## DC BRUSH CONTROL

Having the DC brush a low rated current (0.16 A), was used the PBLV function PWM scale-factor, limiting the duty cycle [9] in 40 %, in order to avoid damage to the motor. A phase fuse was also included for redundancy.

The position control of the MPS stage have relatively more relaxed restrictions, due the usual small displacements and the size of the mask comparing to the beam size.

## PMSM CONTROL

### Phase Commutation

The phase commutation of the PMSM of the APR stage is made using the PBLV's algorithm, using the direct-quadrature-zero transform, common in field-oriented control (FOC).

As stage encoders are incremental, it is necessary to use Hall sensors for proper phase switching until the position is referenced by the home procedure; after this, having previously been characterized the rotor angle at position reference, the encoder is used as phase position feedback for higher resolution in commutation.

### Current Control

Each phase of the APS stage have as electrical nominal specifications of resistance of 4.4  $\Omega$  and inductance of 1.7 mH. Low values of inductance motors are commonly susceptible to induced noise due current ripple caused by PWM drivers, like the one used in the PBLV.

In order to mitigate this kind of problem, a switching frequency of 20 kHz it was used. Even so, that did not prevent undesirable oscillations in the position reading.

Tests were made adding series inducers in each phase, but no significant improvement was observed, not even any correlation with the resultant inductance value.

The best results were achieved using the voltage-mode and adjusting the gains of the PBLV current-loop<sup>2</sup> to behave as a "pass-through" [10]. As trade-off, there is no proper torque control, what is not critical for this system.

### Servo Control

The position and velocity control is made using the PBLV's standard servo-loop, which permits adjust digital filters, proportional-integrative-derivative (PID) and feed-forward gains.

Since the current-loop is not being closed for the APR stage, acting as a gain, the servo-loop was configured to be executed at the phase interruption, eliminating a full phase-cycle delay, what makes the servo-loop be executed at the

same frequency of the phase algorithm, 20 kHz, improving even more the stability of the system.

On other hand, this configuration makes that encoder conversion tables are not processed, because they runs at the servo interruption, so the position and velocity feedback is processed at the same manner of the phase position [11]. The result of this is the loss of capacity of make average between the signals from both encoders present at the stage, a technique used to minimize errors from encoder interpolation and scale imperfections [12].

The stability of each APR stage was evaluating the position error, at a 20 kHz rate, for angles between 0° and 18° and the resulting cumulative amplitude spectrum (CAS) is presented in the Fig. 4. The values to each angle, integrating from 1 Hz to 2500 Hz, is as presented in the Table 1. Figure 4 make it clear that there are some well-defined frequencies that impact the stability of the system.

Table 1: Position Error CAS (1 Hz-2500 Hz)

Angle	Upstream Position Error	Downstream Position Error
0°	24.6 nrad	39.2 nrad
3°	24.6 nrad	33.3 nrad
6°	25.1 nrad	34.6 nrad
9°	20.2 nrad	34.6 nrad
12°	22.2 nrad	34.8 nrad
15°	21.6 nrad	39.1 nrad
18°	19.0 nrad	33.9 nrad

As a disclaimer, this test does not cover the whole stage position range, due to mechanical problems.

## CRYSTALS COORDINATION

One of the most important requirements, besides the position stability, is the coordination between the crystals, in other words, how accurate is energy selected by the two channel-cut crystals. The tolerance is defined based in the crystal energy resolution and diffraction angle. Using the worst-case, the coordination error should be maintained below 1  $\mu$ rad.

### Epaq Coordination Modes

During the analysis of coordination using the Epaq controller, it was noticed that the suggested operation mode for this kind of operation, denominated electronic gearing, results in errors far beyond the acceptable limit for this application. This error occurs also in the difference of setpoints, indicating that there is a lag between the commands for both stages. The tests are at constant velocity of 1 °/s and results in coordination errors of approximately 210  $\mu$ rad.

Another studied method was the gantry mode, in which satisfactory results were obtained around 1  $\mu$ rad. However, this kind of operation sets one of the stages as the follower, disabling any input command from the user, that is necessary during the monochromator calibration. To toggle this mode,

<sup>1</sup> The control point could be set anywhere changing the kinematics parameters. Those predefined points were chosen by the beamlines' staff

<sup>2</sup> Integrative gain have no effect for voltage-mode

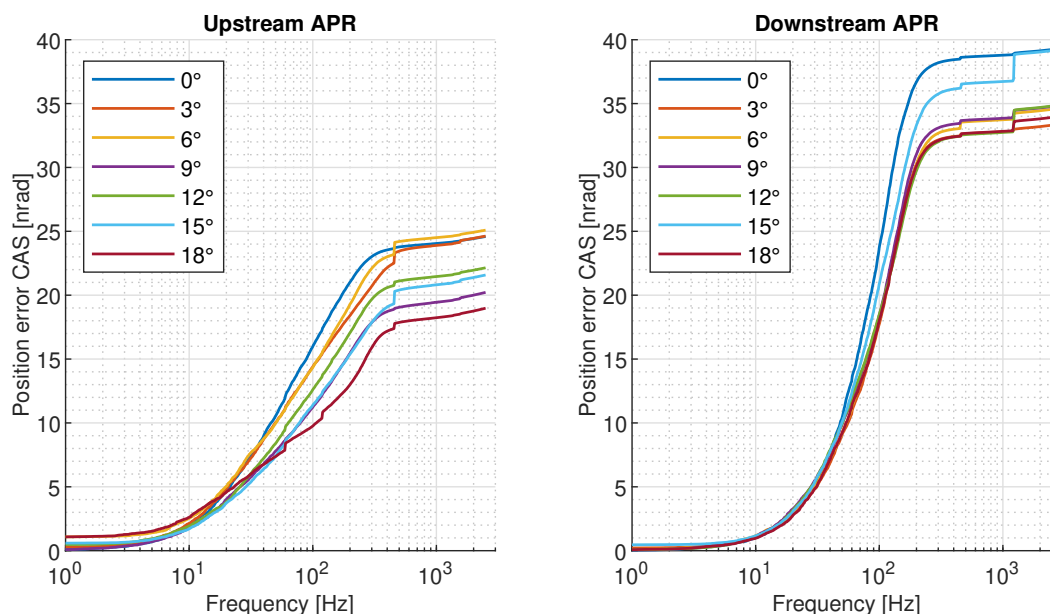

Figure 4: Cumulative amplitude spectrum in position error at each angle.

it is necessary to reset completely the Epaq, making loose the position reference. Also, with gantry mode enabled, the limits of the follower stage are not respected, being unwanted for system integrity.

Figure 5 compares this two modes, together with the coordination error when commanding both stage at the same command line, to the same position, namely uncoupled.

Figure 5: Ensemble Epaq MR coordination modes.

### PBLV Coordination

In was used the native kinematics scripts for the transform energy (user input) in angle (in encoder counts units), also implements the coordinated movement between the crystals, being available an offset in the angle of each crystal for the monochromator energy calibration purposes.

Evaluating the coordination error at the same velocity of the tests with Epaq, 1 °/s, we can observe that, neglecting

pike of 20  $\mu\text{rad}$  occurred in acceleration period, the error is well behaved, remaining below 1  $\mu\text{rad}$ , as seen in Fig. 6.

Possibly adding proper feedforward gains attenuate the error during the acceleration. Furthermore, it possible to use the PBLV feature of gantry cross-couple, causing the error of one of the stages to be taken into account in the servo-loop of the other.

Figure 6: Power Brick LV coordination error.

## CONCLUSION

The results of implementation of control for 4CM had satisfactory results, but there still scope for improvements- e.g. adjustment of feedforward and gantry cross-couple gains, coordination with undulator and investigation of noise sources.

This work also put to the test the capabilities of the PBLV controller, which is of great value for new complex projects to be developed for Sirius.

## Abstract

The High-Dynamic Double-Crystal Monochromator (HD-DCM) has been developed since 2015 at Sirius/LNLS with an innovative high-bandwidth mechatronic architecture to reach the unprecedented target of 10 nrad RMS (1 Hz - 2.5 kHz) in crystals parallelism also during energy fly-scans. After the initial work in Speedgoat's xPC rapid prototyping platform, for beamline operation the instrument controller was deployed to NI's CompactRIO (cRIO), as a rugged platform combining FPGA and real-time capabilities. Customized libraries needed to be developed in LabVIEW and a heavily FPGA-based control architecture was required to finally reach a 20 kHz control loop rate. This work summarizes the final control architecture of the HD-DCM, highlighting the main hardware and software challenges; describes its integration with the EPICS control system and user interfaces; and discusses its integration with an undulator source.

## INTRODUCTION

With performance numbers in the range of single nm and tens of nrad, the High-Dynamic Double-Crystal Monochromator (HD-DCM) is a high-end control-based beamline instrument for energy selection with fixed-exit monochromatic beam [1]. It has been developed at the Brazilian Synchrotron Light Laboratory (LNLS/CNPEM) for the 4th-generation Sirius light source [2] to be the first vertical-bounce DCM to reach, even in motion, 10 nrad RMS inter-crystal parallelism over the broad frequency range from 1 Hz to 2.5 kHz, representing improvements by factors between 3 and 100.

Due to its singular architecture, different aspects of the HD-DCM have already been detailed to the community: conceptual design, mechatronic principles and thermal management [3–5]; results of in-air validation of the core, together with system identification and control techniques in the prototyping hardware [6, 7]; offline performance of the full in-vacuum cryocooled system, including scans solutions [8]; dynamic modelling work, updated control design and FPGA implementation in the final NI's CompactRIO (cRIO) [9–11]; and calibration and commissioning procedures, together with the first experimental results with beam [12]. Here, updated schemes of the control system, as a result of operational maturity with two units at the MANACÁ and EMA undulator beamlines, and the emerging control-related strategies and bottlenecks concerning a holistic beamline operation are discussed.

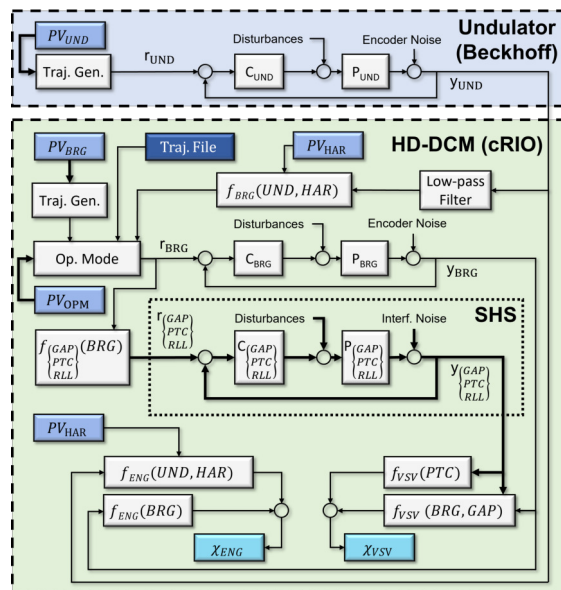

Figure 1: Simplified control diagram for the current HD-DCM integration at Sirius undulator beamlines.

## APPLICATION OUTLINE

The application, as currently implemented at the EMA and MANACÁ beamlines, can be briefly introduced via the simplified control diagram in Fig. 1. Planar undulators by Kyma have been provided for the early operation phase, before the definitive Delta undulators that have been developed in-house for Sirius become available. Then, due to the perspective of short-time replacement, only basic features have been specified. Indeed, running on Beckhoff controllers, the systems can be operated by the users only via a limited set (PV\_UND) of high level *process variables* (PVs) in the EPICS control system [13]. Complementary, the quadrature signal of the phase encoders have been derived to be used as the leading digital signals to the HD-DCMs, if desired.

The HD-DCMs can be defined by four main closed control loops running in NI's CompactRIO (cRIO) hardware. Firstly, BRG, with a bandwidth of 20 Hz, is responsible for controlling the angle of incidence of the beam on the so-called *first crystal*, for energy selection according to Bragg's law of diffraction. Then, GAP, PTC and RLL, with bandwidths between 150 and 250 Hz, are part of the so-called *crystal cage* (CCG), responsible for positioning the so-called *second crystal* with respect to the first one, so that fixed-exit monochromatic outgoing beam can be maintained at

different Bragg angles. The GAP controls the distance between the crystals, while PTC and RLL (for pitch and roll angles) control the inter-crystal parallelism. Due to a careful mechatronic architecture, in practice the originally *multiple-input-multiple-output* (MIMO) system can be statically decoupled, so that the loops may be addressed independently and simpler *single-input-single-output* (SISO) controller design techniques, such as loop-shaping, can be used (see [6, 10]).

The plants and controllers are represented as  $P_i$  and  $C_i$ , respectively, where  $i$  refers to UND, BRG, GAP, PTC and RLL. Each loop follows a reference  $r_i$  and provides a measurement  $y_i$ , being subject to actuator and plant disturbances, as well as measurement noise from sensors (encoders and laser interferometers). The most strict requirements for the HD-DCM are related to the errors ( $e_i = r_i - y_i$ ) for: BRG, which ideally should be limited to the sub- $\mu$ rad range to preserve the energy selection; and, more critically, PTC, specified as 10 nrad RMS (1 Hz-2.5 kHz) to preserve the beam position over long lever-arms at the beamlines (see [3]).

The reference signals for the CCG loops are defined as nominal or calibrated (linear or non-linear) functions  $f_i$  of the Bragg angle, being more suitably derived from  $r_{BRG}$ , rather than from  $y_{BRG}$ , to prevent disturbances and noise contamination which would deteriorate the CCG performances. The reference  $r_{BRG}$  itself, in turn, may result from three possibilities, namely: a trajectory calculated internally in the cRIO just before motion, a real-time conversion from a leading signal, or a trajectory previously stored in a file in the cRIO, thus defining three operational modes (PV<sub>OPM</sub>).

The first is the *stand-alone* mode, in which the HD-DCM can be operated at a high level via EPICS PVs. With user-defined parameters, an internal block in cRIO generates a 3rd-order trajectory and  $r_{BRG}$  is updated accordingly to a target value. This is a basic mode for *stand-still* or *step-by-step scanning* experiments, either at bending magnet or undulator beamlines. In the latter case, as at EMA and MANACÁ, the undulator phase must be independently adjusted by the user, so that the appropriate tuning between its emission spectrum and the HD-DCM energy is assured for ideal flux and beam shape/size. Although not optimum in terms of timing, this can often be handled via standard step-scanning beamline pieces of software. Moreover, this would also be a straightforward option for the so-called *fly-scanning* continuous motion operation in bending magnet beamlines. Indeed, by reducing the previous state-of-the-art pitch parallelism levels at stand-still from about 50 to 10 nrad RMS, the HD-DCM can already provides more accurate beam delivery for a number of experiments, such as crystallography and imaging. Yet, it is by keeping these unprecedented high-performance numbers in fly-scans that scientific opportunities are created in spectroscopy, with typical experiment times reduced by up to one or two orders of magnitude for much higher throughput, and new strategies.

Next, in the *follower* mode,  $r_{BRG}$  is updated in real time as a nominal or calibrated function of a leading input signal, which can be either an external real-time trajectory gener-

ator or a direct instrument signal, such as the phase from an undulator source at an undulator beamline, which is the case for EMA and MANACÁ. Indeed,  $r_{BRG}$  can be completely determined by the undulator phase value, a desired harmonic number (PV<sub>HAR</sub>) from the emission spectrum, and energy-conversion functions  $f_{BRG}$ . Then, by controlling the undulator alone, the user would ideally obtain a well-tuned fixed-exit monochromatic beam over the whole energy range, allowing the fly-scan potential to be explored as well.

Lastly, expanding flexibility in fly-scans and integration options, the HD-DCM can be potentially used in a *triggered* mode, in which arbitrary trajectories can be directly consumed from a file after a software or hardware trigger. At bending magnet beamlines, this would release boundaries related to the embedded 3rd-order trajectory generator in the HD-DCM, while preventing complementary real-time external trajectory generators for customized profiles. At undulator beamlines, in turn, not only may it also open opportunities with respect to possibly limited profiles in undulator controllers — which is the case with the Kyma commissioning undulators —, but, more importantly, it creates additional integration options, other than the control-loop-based ones that define the follower mode. The price to be paid is that more advanced following and synchronization functionalities must be provided by the undulator system as well, which has been considered for the Delta undulators.

Finally, complementary performance indicators can be computed in real time to indicate compliance. Firstly, the virtual source vertical shift  $\chi_{VSV}$ , as a function  $f_{VSV}$  of the Bragg angle, the gap value and the pitch angle, is a useful figure, either in bending magnet or undulator beamlines<sup>1</sup>. Then, in undulator beamlines, such as EMA and MANACÁ, the mismatch  $\chi_{ENG}$  in energy tuning between the source and the HD-DCM, as a function  $f_{ENG}$  of the Bragg angle, and the harmonic number and the phase, can be seen as a crucial parameter, particularly during fly-scans.

To conclude, as demonstrated in the *Results and Discussions*, it turns out that getting the measurement signal  $y_{UND}$  from the undulator currently brings significant practical limitations to the experiments, which, so far, have been non-ideally mitigated with an undesired aggressive low-pass filter for the encoder signal. All of this shines light on the increasing complexity and interdependence among the several instruments in new-generation beamlines. In particular, the results presented here will serve as guidelines for a more adequate architecture with the forthcoming Delta undulators and/or for upgrades in Kyma's. The main issues and alternatives are discussed in the following sections, after a brief review of the HD-DCM control hardware and software.

## CONTROL ARCHITECTURE

During the prototyping phase, the HD-DCM mechatronic concept was validated in a rapid control prototyping tool in

<sup>1</sup> An indicator for the lateral shift of the virtual source  $\chi_{VSH}$  could be computed as well, but, it has a more complex dependence on the Bragg and roll angles and, fortunately, is not a critically sensitive parameter.

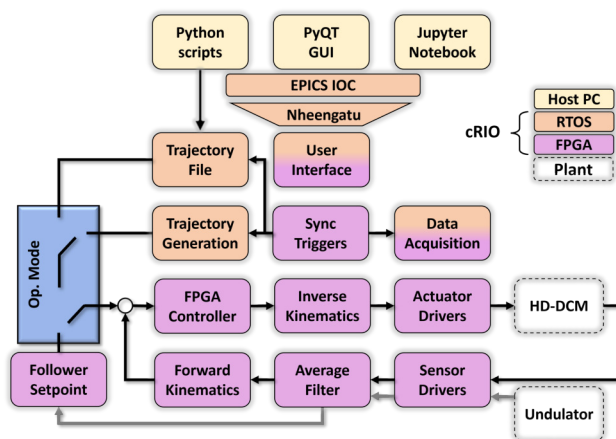

Figure 2: HD-DCM control architecture.

a real-time target machine from Speedgoat [7] – in which, besides preliminary operation, essential functionalities, such as plant identification and controller design via loop-shaping, were also developed [6]. To summarize the architecture, the FPGA layer was responsible for input and output drivers, while complex calculations were handled by its powerful processor at the real-time operating system (RTOS). However, in spite of being very flexible for rapid prototyping, this platform is not intended for reliable continuous operation, as demanded in a beamline environment. Therefore, NI cRIO was chosen as the standard controller for Sirius beamlines due to its industrial applications certifications and wide range of hardware modules, among other reasons.

The first architecture proposed for the control platform migration to cRIO was, naturally, the same one used in the Speedgoat xPC, but benchmark tests [11] revealed that the cRIO processor could not calculate the control loops sufficiently fast to meet the mechatronic requirements – namely, the high order controllers should run in a 20 kHz deterministic loop. Hence, an alternative approach with the whole control loop placed in the FPGA defined the final control architecture, which, as illustrated in Fig. 2, can be divided in three layers: FPGA, RTOS and Host Computer

Due to the results of the benchmark tests (see [11]), all the critical deterministic tasks are implemented in the FPGA layer. The *sensor drivers* are composed of decoders for BiSS-C absolute encoders, and incremental encoders and interferometers. Then, since the quadrature incremental signals demand high acquisition rates – specially when nanometric resolution is combined with relatively high velocity specifications –, the high frequency sensing noise is attenuated by decimation (or downsampling) from 10 MHz to 20 kHz in the *average filter*. Next, the *forward kinematics* converts individual sensor measurements into control coordinates, completing the feedback signal processing.

The reference signal depends on the selected operating mode. In the *stand-alone* mode, trajectories are first generated in the RTOS and internally executed by the *synchronization triggers* in the FPGA. Then, in the *follower* mode, the current integration architecture (see Fig. 1) is such that

the *follower setpoint* calculates the BRG reference as polynomial functions of the averaged undulator encoder. Finally, in the *triggered* mode, trajectory files, previously generated via *Python scripts* and loaded in the cRIO memory (RTOS), are executed according to internal or external triggers that are managed by the *synchronization triggers* in the FPGA.

Once the reference and feedback signals are processed, the FPGA *controller* block can be executed. This implementation is particularly challenging because of the high-order controllers, broad numerical ranges, and high-resolution demands, especially in calculations. Hence, a new controller deployment workflow was created for standardization and reliability purposes, as described in next section. To complete the feedback control loop, the *inverse kinematics* distributes the forces and torques from control coordinates to actuator actions, which are passed by the *actuator drivers* to 3-phase brushless, stepper and voice-coil motors<sup>2</sup>. Complementary, two additional features implemented via FPGA FIFOs (first in, first out) are: a bidirectional *user interface* and a triggered *data acquisition* lossless logger for files.

Next, since all time-critical features are already addressed at the FPGA, no deterministic task relies on the RTOS layer, which is, then, used to manage four main tasks, namely: 1) the RTOS side of the *user interface*; 2) the *EPICS IOC* server implemented via *Nheengatu* [14] (further discussed in the following sections); 3) the generation or loading of *trajectories*; and 4) the RTOS side of the *data acquisition* file logger. Finally, working as an EPICS client, the Host Computer layer is responsible for providing user-friendly graphical interfaces (GUIs) and more sophisticated operational routines via Python scripts or Jupyter Notebooks, as discussed in more detail in the following sections.

## Matlab-LabVIEW Integration Toolbox

The most challenging step for executing complex calculations in an FPGA is the trade-off between multiple hardware resources and timing constraints, like FPGA slices, memory blocks, lookup tables, Digital Signal Processors and timing violations, while taking care of the integrity of the results and proper numeric representations. That is the case in the HD-DCM controller, in which five SISO controllers<sup>3</sup>, with up to 16 states each, process data at high loop rates and deliver forces and torques for a nanometric-precision motion control system.

Therefore, aiming at achieving a standardized procedure, a new workflow was defined, as depicted in Fig. 3. The first six steps are performed in Matlab and Speedgoat environments, whereas the last two using LabVIEW and cRIO: 1) *Plant identification*: stimulus and response analyses for system identification using *multisine* techniques. 2) *Loop-shaping controller design*: phase-margin and gain-margin analyses, with high low-frequency gain for disturbance attenuation and low high-frequency gain for noise rejection.

<sup>2</sup> The stepper motor is used in the long-stroke stage for the GAP, not discussed here for conciseness. For more details, see [3, 8].

<sup>3</sup> Again, the complementary long-stroke control loop was left out of Fig. 1 for the sake of clarity, but it, indeed, consumes resources in the hardware.

Figure 3: HD-DCM FPGA controller design and deployment workflow.

3) *Robustness analysis*: analyses of plots of open-loop Bode, Nyquist, sensitivity and characteristic loci for robustness and SISO validations. 4) *Conversion to FPGA data types*: reduction of high order controllers into lower order ( $\leq 4$ ) transfer functions to preserve the transfer function integrity, with the required numeric representation reduction from double-precision floating point to single-precision floating point. 5) *FPGA controller validation*: testing of all transfer functions after data type conversion, to check if the increased quantization errors cause undesired changes in the dynamic system behaviour (Bode plot) (see [11]). 6) *Export from Matlab to LabVIEW*: file generation for exporting the transfer functions coefficients with no data loss. 7) *Deployment to FPGA*: updating of the multiple transfer function coefficients as constants into FPGA bitstream, as part of the strategy for saving hardware resources. 8) *Machine tests*: closed-loop controller validation using the real hardware, and performance analyses for compliance with specifications.

## EPICS and Python

With the appropriate hardware, and low- and mid-level architectures validated in cRIO, an essential feature for the high-level user operation was having the HD-DCM control system compatible with EPICS, such that the day-to-day beamline work can be based on user-friendly graphical interfaces, or robust and efficient scripts.

With the standardization of the cRIO at Sirius beamlines, the Nheengatu solution has been internally developed by the Beamline Software Group (SOL) to integrate EPICS with cRIO (see [14]). In the HD-DCM, it is used for publishing cRIO variables as PVs in an EPICS IOC server running in the RTOS, as shown in Fig. 2. This occurs via two different communication interfaces, namely: inter-process communication for RTOS PVs; and NI's FPGA Interface C API for direct access to FPGA PVs. Most PVs are accessed through RTOS, except for the time-critical ones, like software triggers used for motion or data acquisition.

As a side note, it is worth mentioning that, although the architecture for time-critical PVs avoid delays related to real-time software processing, memory sharing between RTOS and FPGA, and also FPGA processing, it is important to keep in mind that the standard update rate in the EPICS server is only 10 Hz. So, hardware triggers are also essential for fast integration and synchronization at the beamline, having been implemented for low latency synchronization (update rates up to 9 MHz) for compatibility with the TATU FPGA-based solution that was also recently developed by the SOL group for Sirius beamlines [15] (see also [12]).

Next, the framework used to build the EPICS GUI is called PyDM (Python Display Manager) [16], which is based on PyQt and includes a variety of widgets (plugins) for QtDesigner for building GUIs that communicate with EPICS PVs. Besides these widgets, customized Python routines were also added to the GUI project for more specific behaviors. The main advantage of using PyDM is the possibility of rapidly assembling control system GUIs connected to EPICS PVs, and adding code when necessary in a natural, *pythonic* way. Also, PyDM has been widely used at Sirius for beamline operation GUIs, thus, knowledge, objects and routines could be reused for the HD-DCM GUI.

Then, to automate, standardize and speed up procedures and operations with the HD-DCM, several sets of Python scripts and Jupyter Notebooks have been developed. The structure is flexible, such that many tasks can be scripted independently, simply addressing EPICS PVs for different purposes. Yet, a more controlled Python library has also been created to handle generic tasks and sub-tasks, as well as essential routines and procedures. Among the most important library procedures are: homing, for machine start-up, which previously required trained human operation via GUI, but now can be executed robustly by any user via a script in only 3 minutes; and calibration routines with the X-ray beam, such as tuning with respect to the undulator and fixed-exit refinement (see [12]).

## RESULTS AND DISCUSSIONS

For higher positioning accuracy and scanning throughput, the HD-DCM mechatronic architecture is based on what has been developed over the last decades for lithography machines in the semiconductors industry [17]. Now, to investigate the integration of the HD-DCM at the beamlines, examples in that field can also be explored as general references. Indeed, in [18], the leader-follower configuration for the reticle with respect to the wafer stage is conceptually equivalent for the HD-DCM with respect to the undulator in Fig. 1. However, fundamental differences can also be listed, including: type of motion; setpoint levels; and repeatability of tasks, motivating continued research.

One basic issue in adapting the strategy in [18] – i.e. with the measurement signal as input to the follower stage – to the HD-DCM is that there the wafer stage is also an ultra-low-noise nanometer-level system, whereas the undulator is an instrument that performs at the micrometer-level. Indeed, Kyma's encoder has a resolution of 0.5  $\mu\text{m}$ , such that  $y_{\text{UND}}$  in Fig. 1 contains already a variation of a few microns peak-to-peak from quantization noise alone. When this is coupled to the HD-DCM,  $r_{\text{BRG}}$  becomes a signal with broad-

Figure 4: HD-DCM inter-crystal pitch (PTC) control error in stand-still condition at the EMA beamline at Sirius.

band noise reaching several  $\mu\text{rad}$  even at stand-still, critically deteriorating the HD-DCM closed-loop performance.

An example is given in Fig. 4, with measurements made at 6 keV at the EMA beamline, comparing the PTC control error in stand-alone and (low-pass filtered) follower modes. It can be seen that even with a Butterworth corner frequency as low as 2 Hz the RMS value is increased by about 20%, marginally respecting the desired spec of 10 nrad RMS. In this sense, some improvement can be expected by increasing the resolution of the encoder, thus reducing the noise background. Yet, this action alone would hardly completely solve the problem, because  $y_{\text{UND}}$  also captures the dynamics of the closed-loop undulator system, which may not have a sufficiently high performance due to its limited bandwidth and mechanical architecture.

Consequently, following  $y_{\text{UND}}$  during motion for fly-scans makes the problem even worse, as the disturbances in the undulator are increased. Another practical issue is that the low-pass filter adds delay to the reaction of the HD-DCM, detuning the emission spectrum and the Bragg angle, which may reduce the beam flux and/or distort its shape. A sensitivity analysis for tolerable margins for  $\chi_{\text{ENG}}$  (not shown here due to space limitation) has been carried out via X-ray simulation tools by the Optics group, resulting in margins as low as  $\pm 4 \mu\text{m}$  for 10% increase in the beam full width at half maximum (FWHM). Within this budget, metrology accuracy, motion control errors, and delay effects must be considered. Hence, with typical motion errors measured within  $\pm 2 \mu\text{m}$  peak-to-peak (at least for velocities up to a few hundred  $\mu\text{m/s}$ ) and the operation filter currently set 2 Hz, undulator velocities would be limited between 25 and 500  $\mu\text{m/s}$  (depending on the undulator phase and harmonic) (if other errors are neglected). This translates to maximum scan speeds between 40 and 100 eV/s, which are at least 10 to 50 times slower than what can be expected under improved conditions, or in bending magnet beamlines.

This delay offset can be partly compensated via calibration, but practical limits are quickly found for more aggressive setpoints. Therefore, the ideal scenario probably involves directly extracting  $r_{\text{UND}}$  as the leading signal from the undulator controller, or making the undulator control system

Figure 5: Virtual source vertical shift indicator  $\chi_{\text{VSV}}$  in fly-scans of 1 keV at the EMA beamline at Sirius.

also capable of operating as a follower. Another alternative consists in linking the two systems solely via synchronized triggers, requiring that compatible trajectories be loaded in the different systems and executed accordingly. All these options are under investigation, but none of them are directly available with the current undulator solution. Still, in all cases, suitable velocity, acceleration and jerk parameters should be carefully identified to preserve performance.

An example of the fly-scanning capabilities is given in Fig. 5. The virtual source indicator  $\chi_{\text{VSV}}$  is shown in follower mode for scans of 1 keV around 9 keV at the third harmonic of the Kyma undulator at the EMA beamline. Results for simulated smooth reference-based signals at different velocities and real encoder-based signals filtered at 2 and 5 Hz at the lower velocity are compared with 10% of the vertical beam size FWHM. The time axis has been normalized for readability, with the actual scans taking between 4 and 12 seconds. In the reference set, the peak-to-peak error increases by a factor 3 as larger speeds are associated with larger disturbances, yet, the standard deviation remains within to 10% of the beam size. In the encoder set, however, rougher setpoints and noise make the standard deviation exceed the margin even for the 2 Hz filter, which becomes worse with 5 Hz.

## CONCLUSION

The efforts in designing and implementing the High-Dynamic DCM, as a high-end mechatronic machine at Sirius beamlines, have been rewarded with unmatched stand-still performance and scanning capabilities. The control framework relies on a complex multi-system architecture, which has been gradually optimized, from the FPGA drivers to the user experience and automatic calibration routines in Python/EPICS. Now, global integration bottlenecks start to be revealed, stimulating a more holistic approach towards beamline operation.

## ACKNOWLEDGEMENTS

The authors would like to gratefully acknowledge the funding by the Brazilian Ministry of Science, Technology and Innovation, and the contributions of the LNLS and the MI-Partners teams to this project. The HD-DCM is also a

PhD project carried out with the CST group at TUE, with Marteen Steinbuch, Hans Vermeulen and Gert Witvoet.

# OPC-UA DATA ACQUISITION FOR THE C2MON FRAMEWORK

E. Stockinger\*, B. Copy<sup>†</sup>, M. Bräger, B. Farnham, M. Ludwig, B. Schofield,  
CERN Beams Department, 1211 Geneva, Switzerland

## Abstract

The CERN Control and Monitoring Framework (C2MON) [1] is a monitoring platform developed at CERN and since 2016 made available under an LGPL3 open source license. It stands at the heart of the CERN Technical Infrastructure Monitoring (TIM) that supervises the correct functioning of CERN's technical and safety infrastructure. This diverse technological infrastructure requires a variety of industrial communication protocols. OPC UA [2], an open and platform-independent architecture, can be leveraged as an integration protocol for a large number of existing data sources, and represents a welcome alternative to proprietary protocols. With the increasing relevance of the open communication standard OPC UA in the world of industrial control, adding OPC UA data acquisition capabilities to C2MON provides an opportunity to accommodate modern and industry-standard compatible use cases.

This paper describes the design and development process of the C2MON OPC UA data acquisition module, the requirements it fulfills, as well as the opportunities for innovation it yields in the context of industrial controls at CERN.

## INTRODUCTION

C2MON must consolidate information from a wide range of sources and so support a diverse set of devices and communication technologies through independent data acquisition modules. OPC UA is considered a key technology to managing heterogeneous machine interoperability and therefore fundamental to developments in advanced industrial environments [3]. As an open protocol, it addresses the common problem of insufficient interoperability by allowing equipment from different vendors to communicate with a host through the same interface [4]. Along with its high data modeling capabilities, OPC UA is a compelling candidate for adapting C2MON to modern use cases.

More generally, trends in industry urge Supervisory Control and Data Acquisition (SCADA) systems towards greater scalability and compatibility with Cloud Computing. While the C2MON server layer has already been adapted to natively support configurability injection and process monitoring [5], the OPC UA data acquisition (DAQ) module presented here pioneers these concepts on the data acquisition layer.

## MONITORING OF THE DAQ PROCESS

The continuous monitoring of software plays a key role in ensuring smooth operation. Effective monitoring solutions enable a timely detection and treatment of issues related to

quality-of-service and provide insight into system resource management [6]. The states or qualities to be monitored can be inherently complex and multidimensional, and so elude a direct measurement through single metrics. Kaner et al. [7] suggest the use of multidimensional metrics as a more meaningful representation of a complex quality.

C2MON provides extensive functionality for monitoring the elements within the supervised facilities. The connection between these elements and the processes on the C2MON data acquisition layer is also supervised through C2MON as a fundamental function. However, the DAQs are independent Java processes. Their internal states are not monitored through C2MON, but contain information relevant to ensure the availability, security and usability of the data acquisition infrastructure.

The metrics identified to be of relevance are diverse in nature. For example, the health of the machine and the operating system running the DAQ process can among others be tied to CPU, memory or disk usage, and the network load. Other metrics deal with the JVM and cover garbage collection threads and log messages. These are generic metrics which are provided by several external tools and client libraries. Other metrics are tied to the DAQ and the area of data acquisition. For example, these metrics could expose meta-information regarding OPC UA-specific concepts such as OPC UA subscriptions and their respective filter types.

Within the OPC UA DAQ process, metrics representing such internal states are exposed as observable endpoints through the Spring Actuator [8] project and Micrometer [9]. The metrics can be scraped out-of-the-box through the monitoring toolkit Prometheus [10] and be represented by a multi-dimensional data model. They can then be gathered and aggregated into a form enabling a global analysis by administrators and operators.

The choices of technological solutions were largely taken due to the prevalence of Spring within the C2MON infrastructure, and to be in line with the guiding principles of C2MON which prefer the use of proven technologies and of open-source resources where possible to facilitate reusability in other projects [1].

## CONFIGURABILITY

There are two distinct aspects to configurability within the OPC UA DAQ. On the one hand, there is the need to configure the data to be monitored through C2MON. This use case is integral to the C2MON platform and impacts all tiers of the software architecture. This configuration data is stateful and managed on the application-level across the different DAQ modules and client applications. On the other hand, C2MON acts in heterogeneous environments with diverse hardware requirements. Operators and administrators

\* elisabeth.stockinger@live.at

<sup>†</sup> brice.copy@cern.ch

benefit from a system catering to the high configurability of the OPC UA protocol.

Therefore the OPC UA DAQ module introduces a set of additional configuration options through the Java implementation of the Spring framework. Externalized Spring configurations can be specified in a variety of ways [11], profile specific application property files being the de-facto standard in the C2MON environment. This allows for the specification of different configuration profiles for example in between production and test environments, as well as an easy integration into container orchestration systems such as Docker [12] or Kubernetes [13].

The composition and configuration of required DAQ processes and the servers to be monitored is only known at runtime within the C2MON configuration strategy, and is susceptible to change. Therefore, handling configuration through Spring requires the dynamic creation and management of dedicated configuration scopes. The default Spring configuration scopes [14] do not support configuration options on the level of single connections to OPC UA servers out of the box. Therefore a custom Spring scope was defined to govern the life cycle of all software elements involved in the supervision of individual servers.

The OPC UA DAQ offers configuration options dealing among others with redundancy and connection settings, security, and modification strategies for information defined on the OPC UA servers.

In addition to monitoring, integration of Spring Actuators allows the remote management of applications through JMX and HTTP. Operators can for example change specific configuration settings on running processes, write data directly to OPC UA nodes or execute OPC UA nodes of the method type.

## SECURITY

C2MON as a data communication network faces the risk of cyber-attacks and malware threatening confidentiality, integrity or availability of processes. One of OPC UA's distinguishing features among other low-level networking protocols is its extensive security model [15] which has been verified among others in [16] and [17].

OPC UA can be employed at different levels of the automation pyramid where the security requirements may differ. The uses of OPC UA as a communication interface can span from the isolated shop floor network to access via the internet as shown in Fig. 1. The different use cases are supported by OPC UA's layered approach to security, allowing a trade-off with other quality indicators such as performance or flexibility, depending on the needs of the environment.

OPC UA relies extensively on X.509 certificates [18] for security across these layers, addressing among others application authentication, user authentication and authorization, confidentiality, and integrity.

These certificates support a variety of trust models. Even within a single organization, several trust models can be in place, for example direct trust models where an administra-

tor manages certificates on a case-by-case basis, hierarchical models, or fully-meshed Webs-of-Trust. Given that C2MON is a generic framework which must be adaptable to a variety of environments and use cases, the OPC UA DAQ module should support generic trust models and be configurable in its security modes. There are two major aspects to this solution: the client certificate must be configurable to comply with server requirements, and the server certificate must be processed and validated accordingly.

To satisfy generic use cases, the OPC UA DAQ module can be configured in one of three ways:

- the client certificate may be loaded from local storage,
- a self-signed certificate can be created on the fly, and
- connection can be established without a certificate.

Certificate validation is achieved through a PKI directory, a common approach in security management. This allows administrators to define their own solutions for certificate verification, be it through on-line or off-line methods.

While OPC UA offers rich potential in the area of user authentication and authorization, which would be valuable to exploit for any monitoring application context, this functionality is not currently supported within C2MON.

## REDUNDANCY

Redundancy refers to the integration of several exchangeable instances in an environment. If one redundant component experiences faults, it can be replaced by another. Redundant setups can significantly increase component reliability and robustness and therefore are vital to critical systems.

OPC UA Part 4 [20] defines an extensive and versatile redundancy model encompassing redundant servers, clients, and networks, all of which can co-exist with one another. Server redundancy can be either *transparent* in which case fail-over cases between servers are handled exclusively on the server-side, or *non-transparent*, requiring the client to take action during a fail-over process. The server additionally has a *fail-over mode* which specifies the capabilities and behavior of the redundant setup, each mode imposing different requirements on the client. However, all redundancy modes defined within OPC UA can fall back to a lesser mode, where “Cold Redundancy” is the smallest common denominator.

Complex industrial environments often include servers which communicate through OPC UA but employ different and potentially proprietary models of redundancy. There are several such vendor-specific redundancy models within the context of TIM, demonstrating the need for standardization within industry.

While redundancy is increasingly relevant to ensure high availability, user demand for OPC UA redundancy is currently limited within the TIM environment. Most relevant to the artifact presented here is the use case of server redundancy, where the C2MON DAQ, acting as the OPC UA client, is presented with multiple sources of the same data.

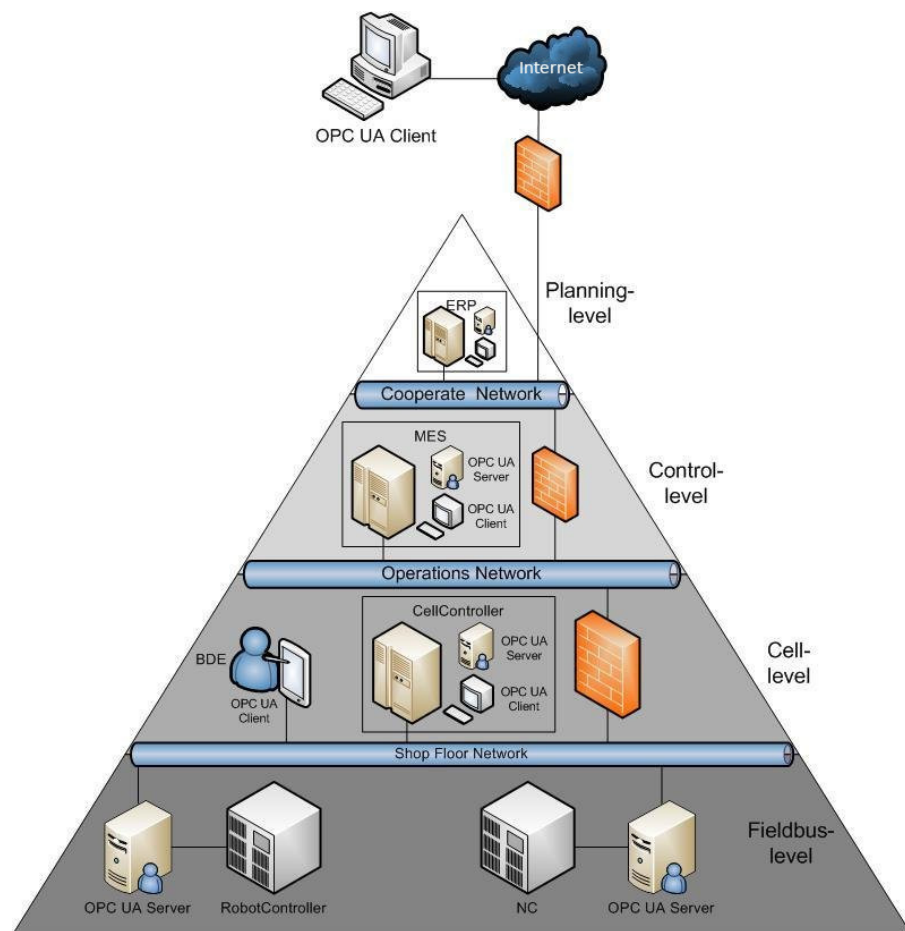

Figure 1: OPC UA as a communication interface in the automation pyramid, as depicted in [19].

For reasons of portability and testability, the design choice was made to only support redundancy in cold failover mode until there is user demand for other modes.

## POTENTIAL AND PROSPECTS

The integration of OPC UA as a powerful open standard into C2MON has implications beyond a greater range of supported devices. There are several potential areas of future research and application within the context of CERN.

### Configuration Management

C2MON configuration is passed inbetween the application layers at runtime via asynchronous messaging. This allows the dynamic addition and removal of entities to supervise. However, the configuration itself is static: configuration elements are mapped to specific DAQ processes, and there is only one configuration for each process. The static nature of the configuration of acquisition items is a potential obstacle in deploying C2MON within IoT projects: the conversion is Java-based, resource-intensive, and relies on proprietary services.

As an alternative to being passed between the architectural layers at runtime, it is possible to externalize the configuration. This approach enables a number of design patterns

including service discovery, distributed configuration management, or load balancing. Similarly, configuration could be adapted to fit the capabilities and requirements of a DAQ when started within a dynamic environment. In the case of the OPC UA DAQ, instances could be configured to dynamically restrict subscriptions to data points producing very frequent updates on OPC UA servers which do not natively support deadbands. Similarly, data points with a low priority could be omitted if a server were to run low on memory during operation.

Spring supports the externalization of configuration natively. The Spring Cloud Config project [21] provides a dedicated platform for externalized configuration in a distributed system, which would integrate with a dynamic configuration handling within C2MON.

In order to benefit from Spring's support for externalized configuration within software components, these components must be managed by the Spring's inversion of control (IoC) [22], a mechanism abstracting the creation and management of component dependencies. The use cases described here are not currently supported by the C2MON framework core nor required within the TIM environment, but are only offered by the OPC UA DAQ module. The C2MON DAQ core initialization strategy historically relies on Java class

reflection, and predates the wide adoption of IoC design patterns in the C2MON technology stack. By externalizing the management of software components to Spring, we allow our OPC UA DAQ module to benefit from the rich options for configuration handling offered by the Spring ecosystem. This new approach to process configuration will hopefully be generalized to the C2MON DAQ core and benefit all other DAQ modules in the near future.

### *OPC UA as an Integration Platform within CERN*

Equipment within a plant shop floor commonly offers several forms of communication, using proprietary communication protocols side-by-side with OPC UA or other open protocols. Redundant server setups may be supported natively only in configurations using proprietary communication protocols. Similarly, vendors may offer redundant server setups for OPC UA servers which rely on custom or proprietary architectural abstractions rather than the extensive redundancy model defined within the OPC UA standard. This non-standardized treatment negatively impacts system interoperability and integration.

Yielding to the prevalence of non-standard redundancy models, the OPC UA DAQ was designed to be extensible towards external models while supporting the OPC UA model of redundancy. The scope of extensions to vendor-proprietary models was restricted to initial connection, failover, and monitoring of connection status to ease the effort of switching from vendor-proprietary protocols to OPC UA without loss of functionality.

Likewise, only minor changes are necessary within the CERN environment to support OPC UA compliant certificates for increased security. CERN offers an established and well-accepted infrastructure regarding certificate authorities and certificate management, which is however not equipped to handle the creation of OPC UA-compliant certificates. Developers and administrators must therefore either forgo an integration of the CERN root certificate, or they must develop and maintain a custom add-on application polling the official revocation list and certificate authority, and handling certificate renewal.

The only factor preventing compatibility in the CERN certificate management services is the integration of certain extensions required by OPC UA. This issue would be easy to solve, thereby positively impacting the standardization of certificate creation and management across the organization.

OPC UA also offers functionality for user authentication and authorization. The exploitation of this functionality would open up new possibilities for auditing and access control. However, this would require C2MON to manage user authentication and authorization through a standardized interface across all DAQs and client applications. Such an interface is not available at present, among other reasons due to the stark differences in capabilities of supported protocols. The implementation of user authentication, authorization and of auditing are relatively open in the OPC UA specification, and out-of-the-box solutions offered by vendors are not cohesive. While this impedes the provision of standard

auditing and access control functionality in heterogeneous environments, the integration of such an infrastructure is a worthwhile venture for future investigation.

Finally, OPC UA can reduce the complexity of an existing infrastructure whilst adding functionality. This is the case in some areas of alarm handling in the CERN infrastructure. Some systems supervised through the CERN C2MON instance declare alarms internally and publish them through JMS rather than publishing the data points themselves. Several intermediate steps are required to supervise these alarms in C2MON:

- The alarms must be transformed from into a JMS message that is compatible to C2MON.
- These JMS message are passed through a message broker to a process-specific DAQ.
- The filtered alarms are transformed into the C2MON “DataTag” format and passed to C2MON through the JMS queue.
- The alarms arrive at the C2MON cluster either in the state “on” or “off” and are further processed accordingly.

The devices exposing alarms in this fashion within the TIM environment offer communication through an OPC UA server. These data points can therefore be published directly to the new OPC UA DAQ module rather than as alarms to a separate and process-specific DAQ process.

This would allow the omission of the process-specific DAQ as well as the message format transformation, and so streamline the supervision pipeline in C2MON.

Alarms could in this fashion be defined and managed dynamically based on these data points using the rich configuration and validation functionality offered by C2MON client services [23, 24], avoiding consistency issues and increasing efficiency.

The current and proposed processes for handling alarms are contrasted in Fig. 2.

### *OPC UA as a Simulation Interface*

The high complexity of services and processes acting within a SCADA system requires a holistic evaluation in a close-to-production setting to assure security and safety [25–28]. Ludwig *et al.* have found the sufficient validation of control systems for power supply at CERN not to be feasible using laboratory approaches [29]. They propose a simulation-based validation strategy for introducing new hardware into the environment using a custom simulation engine for power supply crates.

[29] describes a setup of redirecting traffic within OPC UA servers to target their so-called “VENUS” simulation engine instead of the physical crates, whilst keeping all other aspects of the SCADA systems in a production state. This allows for the validation of different hardware compositions within the production environment.

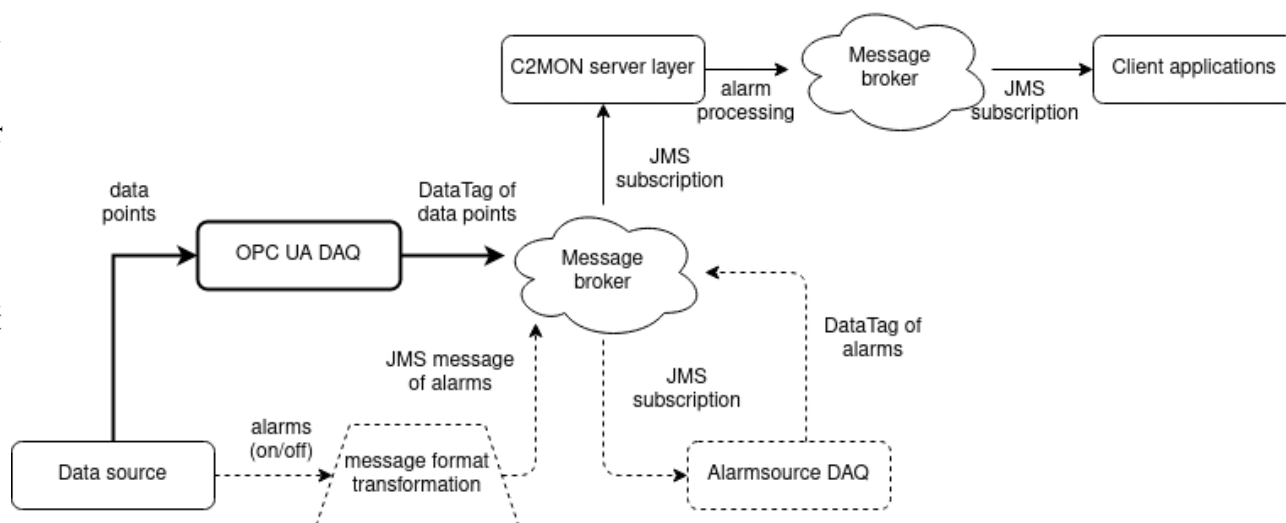

Figure 2: The pipeline of supervising alarms from systems currently publishing alarms as data points. Dotted elements indicate architectural blocks which could be omitted by exposing data points directly through OPC UA. Bold elements depict the alternative path through the OPC UA DAQ.

Rather than change the simulated hardware composition, it is also possible to trigger load and conditions exceeding those nominally observed in production. In this fashion, the SCADA layer can be examined for its tolerance to corner cases and exceptional circumstances. The OPC UA DAQ can so be used as an interface for validating the behavior of the SCADA system in adverse circumstances.

## CONCLUSIONS

Along with extensive OPC UA integration, C2MON combines the powerful open-source Java management platform with OPC UA's rich data model and ubiquity in industry. The C2MON OPC UA DAQ module leverages OPC UA's potential as an integration platform on the plant level. Its support for Java process monitoring and its extensibility towards vendor-custom redundancy models makes it ideally suited to the ever-evolving demands of large-scale infrastructure monitoring. Finally, OPC UA can benefit a range of use cases within modern industry such as testing new hardware compositions within a simulated environment as well as testing the SCADA layer under simulated peak loads.

## Abstract

The SPIRAL2 cryogenic system has been designed to cool down and maintain stable operation conditions of the 26 LINAC superconducting resonating cavities at a temperature of 4.5 K or lower. The control system of the cryogenic system of the LINAC is based on an architecture of 20 PLCs. Through an independent network, it drives the instrumentation, the cryogenic equipment, the 26 brushless motors of the frequency tuning system, interfaces the Epics Control System, and communicates process information to the Low Level Radio Frequency, vacuum, and magnet systems. Its functions are to ensure the safety of the cryogenic system, to efficiently control the cooldown of the 19 cryomodules, to enslave the frequency tuning system for the RF operation, and to monitor and analyze the data from the process. A model based Linear Quadratic regulation controls simultaneously both phase separators the liquid helium level and pressure. This control system also makes it possible to perform a number of virtual verification tests via a simulator and a dedicated PLC used to develop advanced model based control, such as a real time heat load estimator based on a Luenberger Filter.

## INTRODUCTION

### Cryogenic System

Spiral2 accelerator delivers high intensity beams of various ions for research in nuclear fields. It is mainly composed of a LINAC (LINEar Accelerator) composed of 26 accelerating cavities installed in 19 cryomodules, made of bulk niobium and immersed in a liquid helium bath.

The cryogenic system, as shown in Fig. 1, is split in two levels: at the ground level stands the cryoplant with its refrigerator and helium collecting system, and in the underground accelerator tunnel, the 19 valves boxes form the cryogenic lines and feed the cryomodules with liquid helium [1].

### Type-A and Type-B Cryomodules

The type-A and type-B cryomodules respectively contains one and two accelerating cavities. The helium bath is controlled through three valves shown in Fig. 2. The valve CV001 is used to fill the cryomodule by the bottom during the cooldown whereas CV002 and CV005 ensure respectively level and pressure regulation in the bath, which are measured by the LT200 and PT001 sensors. CV010 serves the shield outlet temperature regulation around 60 K.

Figure 1: View of the Spiral2 cryogenic system.

Figure 2: Type-A cryomodule and its associated valves and sensors.

## ARCHITECTURE OF THE CONTROL SYSTEM

Liquid helium production and routing, as well as the automated safeties and the controls of the helium liquid bath, are ensured by a PLC-based control system. Data are issued from those PLCs to the Spiral2 Epics system for storage.

The core of the Linac cryogenics control system illustrated in Fig. 3 is made up of a fleet of 20 Siemens PLCs, one for each cryomodule and another one serving as a hub to ensure communication between the cryomodules and the outside systems, three WinCC Pro supervisions, 1 workshop terminal, 26 brushless motors driving the Frequency Tuning Systems (FTS) of the RF cavities. In addition, there

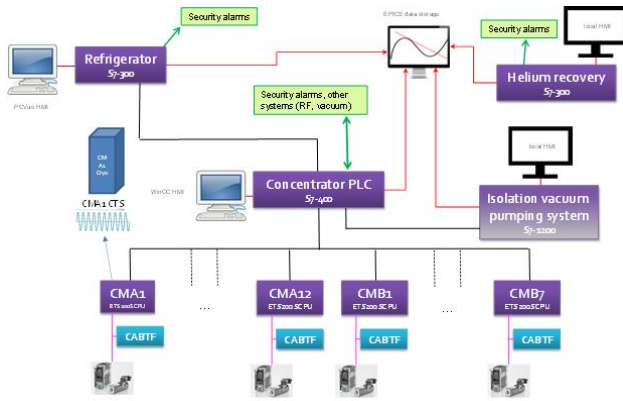

Figure 3: Control system architecture.

are nearly 70 instrumentation boxes for the control of temperatures, pressures and helium levels, vacuum pressures, heating supplies. Orders, sensors feedback and others data are exchanged via the private cryogenic network, which is completely autonomous with independent supervision. During power cuts, batteries make it possible to secure the cryogenic automated system (PLC, supervision and network) and to keep control at all times.

The cryoplant works with its own control system: Siemens PLC and PCVue user interface. Other dedicated Siemens PLCs and their local user interface are used for gas recovery management, for the isolation vacuum pumping system of the Linac, and for the vacuum system of the hot sections and RF cavities

## MAIN FUNCTIONS

The functions of the concentrator PLC and 19 cryomodules PLC are shown in Fig. 4. The PLCs provide controls independently for each cryomodule by opening or closing the valves and reading process measurements: pressure and level controls, cooldown and warmup regulation. Additionally, the FTS is managed by the same PLC. The orders are made manually by cryogenics operators from the HMI.

### Sequential Function Chart

The cryogenics control of the cryomodules is mainly based on sequential steps shown in Fig. 5, each defining a working mode.

- X1: Hot mode, cryomodule is at ambient room temperature.
- X2: checking of the FTS state.
- X20 and X21: waiting cooldown order.
- X22 and X23: the shield and cavity are cooled separately at 60K and 4K. Input valves are opened to immerge the cavity.
- X4: normal mode, the cavity is immersed in the liquid helium bath at 4K. Only this mode allows the activation of the RF fields in the cavity.
- X5: Safety mode: Following a major fault of the cryomodule, helium input is closed and the output valves are completely opened.

- X6: Stand by, the cavity is regulated at a higher temperature to reduce the helium consumption.

### Human Machine Interfaces

Three redundant WinCC Pro supervisions are running on virtual machine. Those HMI are located in a cryogenics

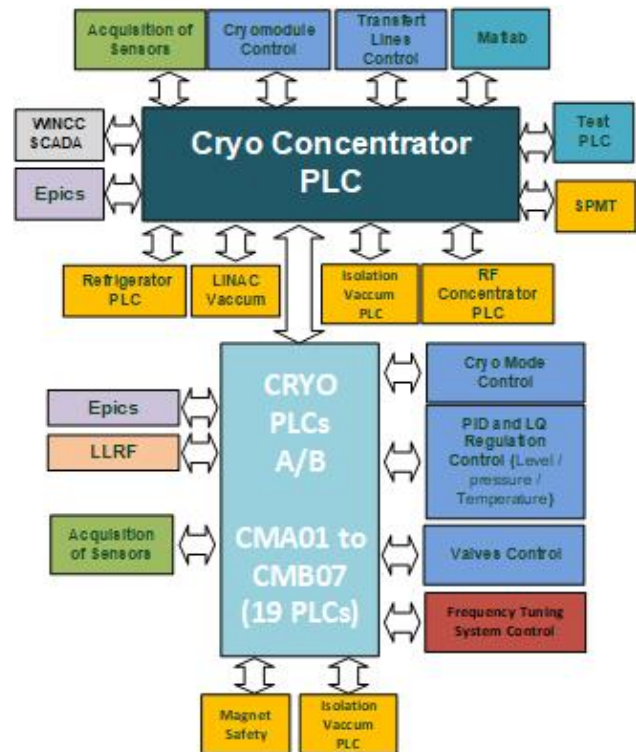

Figure 4: PLCs functions.

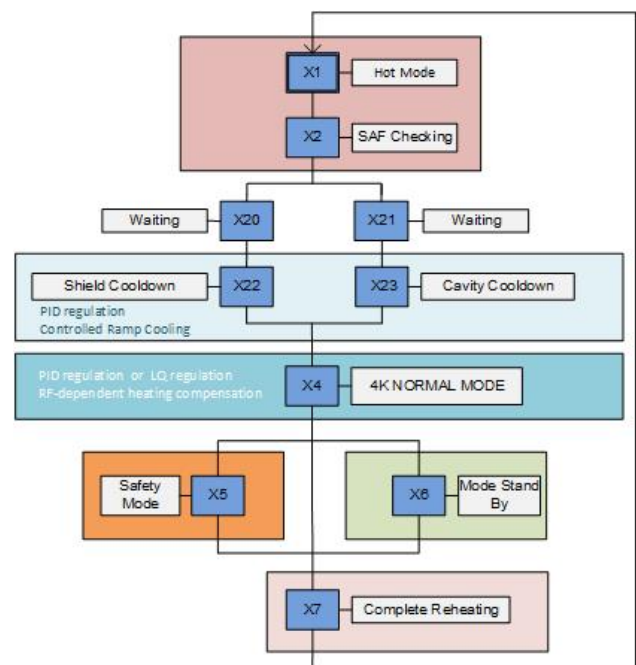

Figure 5: SFC of the cryogenics modes.

dedicated control room, and are also reachable from distance. They include all the necessary data to drive the cryogenic system, and display the associated commands of the connection box, from transfer lines to cryomodules (see Fig. 6). It is made up of around 200 pages and 6000 variables. The alarms are archived.

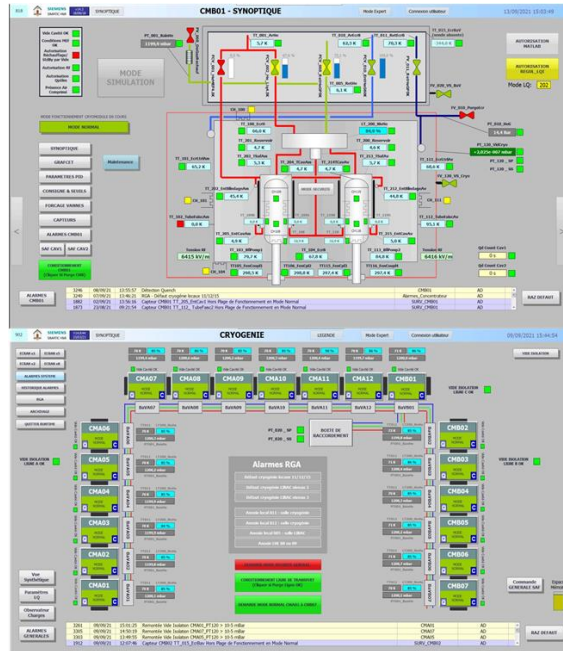

Figure 6: Cryogenics system supervision.

## Frequency Tuning System

As the resonance frequency of the superconducting cavity is dependent to its volume, a mechanical device is used to adapt it in real time according to the RF regulation requirements. In the case of type-B cryomodule, the volume is modified through the insertion of a diver inside of the cavity, and in the case of the Type-A, a plier controlled by a screw enable the distortion of the 4 K cold cavity itself. On each cavity, those devices are managed through a single axis motion by the cryomodule PLC, following the phase shift instruction issued by the LLRF. As the deformations of the cavity are only possible at 4 K, hot and cold operating areas are defined (see Fig. 7) according to the cryogenic mode, to prevent any mechanical deterioration as well as any premature wear of the motorization system. In the tuning area, FTS can be positioned around a theoretical tuned position F0, around which it is moved to regulate the RF field.

## Simulation

A simulation mode, with a dedicated window on the HMI supervision, was implemented to overwrite commands and sensors feedback on demand. This mode proved itself useful in the commissioning of the cryogenic system, to check every working mode and every safety conditions. This simulator is still used, mainly for the operations of the yearly maintenance phases.

## Liquid Helium Bath Control

RF regulation is strongly dependent of the liquid helium bath pressure range ( $1200 \pm 2$  mbar), and obviously to the immersed state of the cavity. In its earlier version, this requirement is managed by the cryomodule PLC with two PID controllers: the liquid helium bath pressure is regulated through the opening percentage of the output valve (CV005), and its level through the opening percentage of the input valve (CV002). Those controllers working in parallel are managed from a dedicated HMI window (see Fig. 8) where the cryogenics operators can tune the PID parameters and adjust the setpoint.

Moreover, during the cooldown steps, another PID controller regulate the cavity temperature by opening the CV001 valve. The cooling of the Linac is completely controlled with the application of an automatically sliding temperature set point. As shown in Fig. 9, the descent is slowed down from 300K to 150 K and then accelerated from 150K to 4 K in order to limit the time in the critical temperature range 150–50 K.

## Dynamic Heat Load Compensation

All control parameters are only valid inside a certain range of conditions, expressed in term of heat load. The cavity RF fields being different for the variety of ions accelerated in Spiral2, the cryogenic bath load will also vary. To avoid permanent optimization of the control parameters, it has been decided to work always at the maximum heat load working point, which is defined as the heat load when the cavity is at its nominal RF field, 6.5 MV/m gradient. Hence, when RF is off, electric heaters are used to mimic the RF load inside

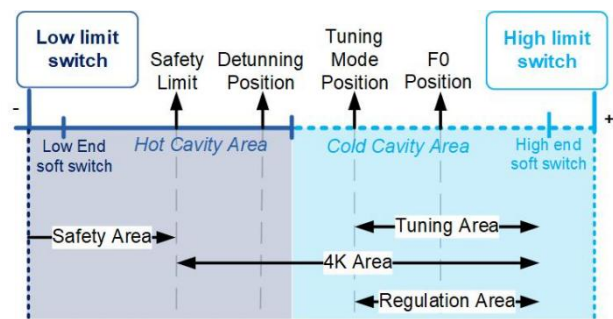

Figure 7: Type-A cavity FTS operating areas.

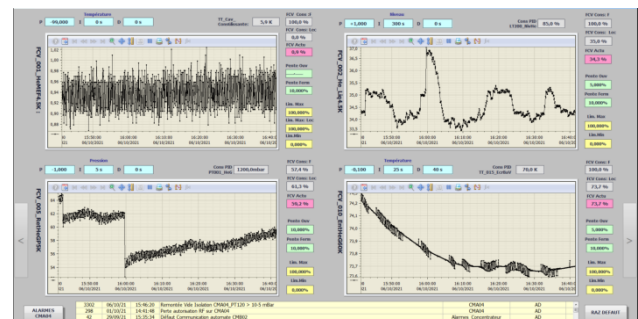

Figure 8: PID parameters supervision.

Figure 9: Cooldown of a type-A cryomodule.

the helium baths. Moreover, to keep the liquid helium distribution balanced, the heat load working point is evened up for all the type-A (12.275 W) and type-B (27.47 W) cryomodules. A feedback of the RF field level allow the cryomodule PLC to deliver the correct electrical power to the heater in order to reach those heat load setpoints.

## MODEL BASED TOOLS

### Cryogenics Modelling

The type-A and type-B cryomodules were modeled using the Simcryogenics [2, 3] library on MATLAB/SIMSCAPE environment. In order to be simple enough to be usable with a PLC, the cryomodule model is linearized to provide the state space equation, linking the opening of the valves and the liquid helium bath state.

$$\begin{aligned}\dot{x} &= Ax + Bu \\ y &= Cx + Du \\ x &= [\rho \ e]^T \\ u &= [CV002 \ CV005]^T \\ y &= [LT200 \ PT001]^T\end{aligned}$$

With  $\rho$  the density of the liquid helium bath,  $e$  the internal energy, CV002 and CV005 the opening of the input and output valves, LT200 and PT001 the helium liquid level and pressure measurements. The state space matrix are computed via a MATLAB graphic interface and transferred from MATLAB to the cryomodules PLCs.

### Linear-Quadratic Controller

The linearized model, paired with a disturbance estimator (see Fig. 10), is used to provide a Linear Quadratic (LQ) controller of the liquid helium level and pressure [3].

The feedback gain  $K$  and the estimator gain  $L$  are computed with MATLAB tools, through the minimization of the quadratic criterion  $J$ .

$$J = \int x' Q x + u' R u$$

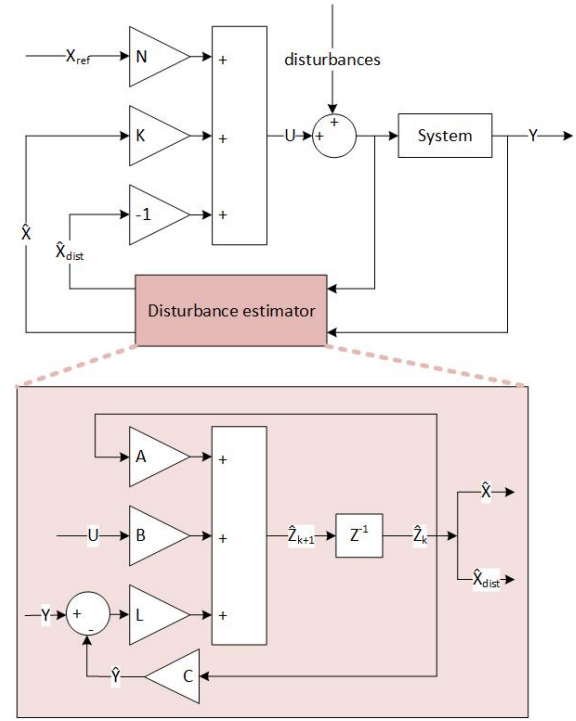

Figure 10: Block diagrams of the LQ controller.

$$\begin{aligned}Z &= [X \ Y_{dist}]^T \\ Z_{k+1} &= AZ_k + BU_k + L(Y_k - \hat{Y}_k) \\ Y_k &= CZ_k\end{aligned}$$

The weighting of the variations of the sensors and actuators, as well as the weighting of estimations and errors, are adjustable with a dedicated HMI. The gains are then transferred to the cryomodule PLC with the state space matrix.

This regulation, as it uses knowledge of internal coupling between the liquid helium heat load regarding to the input and output helium flow, shows significantly better performance regarding the pressure stability, especially in the normal 4 K cryogenic mode, than the two separate PID controllers that were firstly used. However, as it is based on a linearization of the modeling around one single working point, its performance is strongly dependent to the distance of the ongoing heat load to this theoretical point. On the contrary the PID regulations can still be robust enough to be used in degrade situation or in the cooldown steps, so it is always possible to manually switch to these controllers.

### Heat Load Estimator

The measurement dynamic heat losses, e.g. the variations of the heat load, is an indicator of the cavity state, which could itself be an indicator of the RF losses, or of the beam losses. As it is impossible to have a dynamic measurement of those losses while the accelerator is in nominal operating mode, a state observer was designed [4] (see Fig. 11) and implemented in a dedicated PLC to work in real-time,

without risks of slowing down the cryomodules PLCs. This estimator PLC communicate with a selected panel of cryomodules PLCs to read the measurement of the CV002 and CV005 valves opening, and liquid helium bath pressure and level.

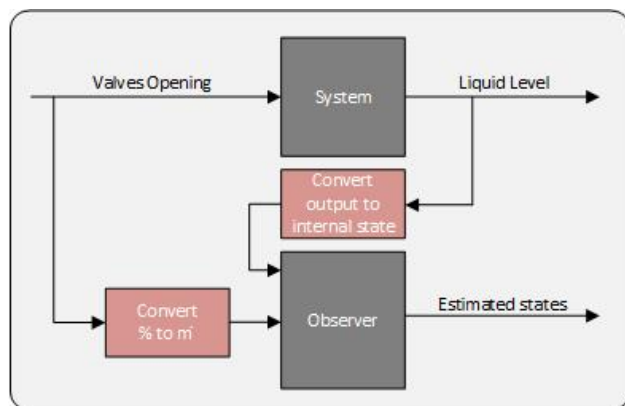

Figure 11: Block diagram of the estimator.

The linearized state space equation is augmented to include the heat load in the state vector. The estimator use a conversion of the input and output valves opening into mass flow, and any estimation error is attributed to a variation of the heat load.

First tests showed that this estimator is able to deliver a slow but correct enough estimation of the heat load, as illustrated by the Estimator 1 in Fig. 12. However it is too dependent on the output valves opening value, which are disturbed by thermo-acoustics oscillations. Others strategies of estimation are being studied to mitigate the weight of those disturbances. For instance the estimator 2 in the Fig. 12 also aims at computing the error of the output mass flow, in addition to the attribution of the error of estimation to the heat load. The result is slower, but, as it is less dependent on the CV005 working point variations, its performance concerning the offset error is improved.

Future improvements on the cryogenic system are expected to mitigate the thermo-acoustic phenomena, and thus

to stabilize the CV005 and allow the estimator to provide faster and/or more reliable heat load estimations.

Figure 12: Estimated Heat Load.

In the long term planning, the goal is to design a software sensor able to provide dynamic heat load data from every cryomodule, working with several Kalman and/or Luenberger estimators with different response time. Those data could be useful for the beam tuning and other analysis about the cryogenic system performance.

## Abstract

Commissariat à l’Energie Atomique et aux Energies Alternatives (CEA) is in charge of the tuning regulation systems for the SARAF-Linac project. These tuning systems will be used with Low Level Radio-Frequency (LLRF) to regulate three rebuncher cavities and HWR cavities of the four cryomodules. These systems were already tested on the Rebuncher and Equipped Cavity Test Stands (ECTS) to test respectively the warm and cold tunings. This paper describes hardware and software architectures. Both tuning systems are based on Siemens Programmable Logic Controller (PLC) and EPICS-PLC communication. Ambient temperature technology is based on SIEMENS motor controller solution whereas the cold one combines Phytron and PhyMOTION solutions.

## INTRODUCTION

### Context

SARAF particle accelerator is composed of elements to accelerate, control and tune a beam. To work properly, radio-frequency signals are generated by the Low Level Radio-Frequency (LLRF) system.

These signals are used in many parts of the accelerator to correct the beam. We will focus this document about two of these systems that are using motors to reach this goal: rebunchers and cavities.

First motorized tuning system is located in the Medium Energy Beam Transfer (MEBT) line. It is part of rebunchers. Second motorized tuning system is located inside cryomodules, next to each cavity, Fig. 1.

Figure 1: SARAF motors location.

### Constraints

Both motorized tuning systems are working in vacuum and radiation environments due to particle accelerator requirements. A third environment parameter has to be taken into account and will distinguish two motorization systems: Temperature.

In fact, motors are localized in MEBT, and so rebunchers, will be at ambient temperature therefore cavity motors will be in a cryogenic environment. We will see in next chapters that this difference will heavily impact hardware choice.

## Goals

Motors have to be defined by taking account of working environment but also process requirements. In our case, motor goals are similar but ways to obtain them are different.

In fact, motors have to move or apply constraints to an element to obtain required frequency of 176 MHz. Motor movements are done according to frequency feedback measured by the LLRF. Using this feedback provides us a way to regulate movements or constraints to obtain required frequency. Rebuncher motors will linearly translate a beam inside element to get correct frequency and cavity motors will apply mechanical constraints to cavity in order to obtain required frequency.

## REBUNCHERS

### Presentation

Rebunchers are dynamic tuning devices located on the MEBT section of the SARAF particle accelerator [1], Fig. 2.

Figure 2: MEBT rebunchers.

There are three similar rebunchers, all located in the MEBT. They are composed of vacuum devices like pumps, gauges and valves but also radio-frequency parts and an outside motorization connected to an internal endless screw that moves radio-frequency passive elements near the beam and so gives the possibility to modify feedback frequency.

Movement range of these elements is about thirty millimeters and requires a high precision position system and without high-speed response dynamic from the system.

### Hardware

According to previously mentioned requirements we will now provide details about hardware used and specifications.

**Actuator** Rebuncher tuning system requires a position accuracy and speed is not relevant so we choose to use a brushless motor that gives good results for this kind of use.

Moreover, due to vacuum high torque requirements, motors don't have an internal physical brake but are using constant-current to immobilize the motor's axis. In fact, motor stator

\* tom.joannem@cea.fr

† david.darde@cea.fr

coils are together powered with a constant power and so generate magnetic field that blocks the motor's rotor.

In addition radiations environment near particles beam impose to remove electronics from devices and so to use remote control systems. So motors are without embedded electronic and controllers will be located in remote cabinets outside radiation area, in a maintenance corridor.

Eventually SARAF control system is based on Siemens PLC and so motors are to be compliant to it. To conclude and to respond to the need we choose synchronous motors from Siemens that gives stepper functionality. This Siemens range of hardware is called as Siemens synchronous motors 1FK7, Fig. 3.

Figure 3: Siemens brushless motor.

**Position Sensor** Because of radiation environment optical coders can't be use. In fact, incremental and absolute standard position encoders are using optical, and so electronic elements, not compatible with this specific environment.

A position sensor technology compliant with radiation exists: resolvers. These devices don't have embedded electronic and use coils to send impulse electrical signals to a remote acquisition system. The system will receive pulses in the same way than incremental optical coders and will be able to provide a reliable motor angle position.

Resolvers could be embedded with motors, on the rotor axis on remotely connected on a mechanical axis, Fig. 4. In

Figure 4: Siemens resolver.

our case we choose to locate the position sensor on the motor axis to have the best precision possible so it is embedded in the motor and provided as an option.

**Conditioning Device** Resolver signals are specific and requires a conditioning device to convert feedback signals to a usable position, Fig. 5.

In fact, resolvers sensors provide three signals: A for first coil pulse, B for second coil pulse and Z or N for a reference signal. Conditioning device have to count pulse according with motor speed acquisition rate to provide position to motor controller.

Figure 5: Resolver conditioning card.

In order to be compliant with resolver and Siemens PLC we used Sinamics sensor module.

**Controller** Siemens motor controller are composed of two elements: control unit to connect with PLC and power stage according to motor speed rotation and torque connected to motor itself, Fig. 6.

Figure 6: S110 motor controller.

Because we use resolver sensor only one control unit can manage feedbacks from resolver conditioning devices: Siemens S110.

Communication between motor controller and position sensor conditioning device is done with Siemens communication protocol S7. By this way, motor controller can manage motor position and correct it if necessary.

Additionally to this functionality, motor controller is connected to PLC Central Processing Unit (CPU) to receive position commands and to send feedbacks. This communication is done with another Siemens communication protocol based on a Ethernet physical layer: Profinet.

Eventually security motor movement limit switches are connected to controller front end in order to manage motor movement outside normal movement range.

**PLC CPU** Siemens PLC CPU used on our experiments is the 1516 and provide use the possibility to communicate with motor controller thanks to Profinet and with IOC host via TCP-IP, Fig. 7. CPU is composed of two communication cards and give the possibility to use one card per communication protocol.

Figure 7: Siemens PLC CPU 1516.

In case of power shutdown, position of the motor is memorize in the non-volatile memory of the PLC CPU and so avoid a calibration procedure because of motor position lost.

**IOC Host** To communicate with EPICS PLC CPU have to be connected to an Input Output Controller (IOC). Communication is managed with TCP-IP and Modbus Protocols. IOC is host on a Industrial PC (IPC).

**Global Control Architecture** According to previously detailed devices we can now define the global control architecture for rebuncher motorization system.

## Software

**Frequency Measurement** Frequency feedback used for motor position regulation is provided by the LLRF and have to be send to PLC CPU and then to motor controller.

To do it the LLRF writes the frequency value to his own IOC, then it communicates it to PLC CPU IOC that receives it and modifies position command to motor controller according to frequency dynamic.

**Regulation Process** Frequency regulation process is done using frequency limits. In fact, user defines positive and negative frequency limits, when these limits are reach a motor movement is done to reach frequency target of 176 MHz. Motor movement is divided in five phase: acceleration to high speed, high speed, deceleration from high to low speed, low speed and stop. Two speed profiles have be defined to optimize regulation response time. Low speed is active when measured frequency is lower than 10% of target frequency minus frequency limit. While frequency is within limits motors do not move.

This way to regulate lets the possibility to the operator to manage how precise the regulation should be and also prevents too much motors movement to avoid frequency perturbations created by fast motor movements.

**Graphic User Interface** EPICS control view provides frequency measurement, motor position, movement limit switches status and more.

From this view automatic frequency regulation parameters could be set, manual motor movement could be done and also motor calibration for maintenance.

## CAVITY TUNING UNITS

### Presentation

Cavity Tuning Units (CTU) are dynamic tuning devices located on each cavity of each cryomodule of the SARAF particle accelerator. They will be a total of twenty-seven similar systems.

Cryomodule control system manages vacuum, cryogenic, current lead and tuning systems.

Tuning systems are composed of an inside cryogenic environment motorization connected to an internal endless screw that apply a mechanical constraint on related cavity. Modify mechanical characteristic of cavity gives the possibility to modify feedback frequency.

### Actuator

Cryogenic environment requires a compatible motor and it remote control. Should be added to cryogenic environment, vacuum and high radiation. To answer to these requirements we use for our experiments hardware based on space applications feedbacks.

We use Phytron stepper motors dedicated for extreme conditions, Fig. 8.

Figure 8: Phytron CSS motors.

We will detailed in next chapters how control architecture of this motor has evolved with our experiments.

### Control Architecture Based on Siemens 300 PLC Generation

First control architecture was done with previous generation of Siemens PLC cards. Indeed, Phytron provides a control card named “1-STEP-Drive” that fits with Siemens ET200S remote input-output cards, Fig. 9.

This control architecture was with last generation Siemens 1516 CPU and previous generation ET200S cards. In this configuration motor did not include embedded resolver.

### Control Architecture Based on Siemens 1500 PLC Generation

Second control architecture was done with last generation of Siemens PLC cards. Indeed, Phytron provides a control

Figure 9: ET200S and Phytron controller.

card named “TM StepDrive 1x24..48V/5A” that fits with Siemens ET200SP remote input-output cards, Fig. 10.

Figure 10: ET200SP control architecture.

This control architecture was with last generation Siemens 1516 CPU and last generation ET200SP cards. In this configuration motor did not include embedded resolver.

### Control Architecture Based on Siemens 1500 PLC Generation with Position Feedback

This architecture is similar to previous control architecture with additional hardware. In fact motor includes embedded resolver and a fast acquisition digital input card was added on the CPU rack, Fig. 11. We could get resolver position and confirm that motor move according to positions commands.

Figure 11: Fast acquisition card.

In previous configurations we controlled motor with an open-loop control architecture but with the resolver implantation we could detect any issue thanks to a close loop. Pre-

viously the only way to detect that motor did not move even when command was send was to verify feedback frequency. It should change according to mechanical constraints on cavity, if not motor is considered as blocked.

This architecture was tested on the Equipped Cavity Test Stand (ECTS) after a motor block event due to an issue on the cavity constraints endless screw.

### Control Architecture Based on PhyMOTION Control

Control architecture of Phytron motors for SARAF cryomodules is no longer based on dedicated Siemens compatible control cards but with a Phytron modular control system, Fig. 12.

Figure 12: PhyMotion controller.

The PhyMOTION is composed of power card, communication card, like for Profinet, and control cards. We managed SARAF cryomodules PLC-based control architecture to be similar for each cryomodule. In fact one PLC CPU manage every cryomodule features for one cryomodule and we apply the same philosophy for the PhyMOTION.

Cryomodules are composed from six to seven cavities each one connected to a Phytron motor. Each cryomodule have is own PhyMOTION controller composed of motor control card, one per motor. These cards can manage motors power but also position feedback from resolver.

SARAF project strategy was not to use resolver to get a close loop regulation system but to use frequency measurement

## FUTURE APPLICATIONS

### Control Architecture Based on PhyMOTION Control with Position Feedback

Thanks to SARAF project feedback about PhyMOTION integration we will be able to deploy a close loop control with cryogenic motors in our next experiments.

Motor with embedded resolver will give us the possibility to improve reliability without depending of an external measurement source.

## CONCLUSION

Technology for motor command and position feedback into radiation, vacuum and even cryogenic environment improves and provide user friendly hardware and software solutions that can be connected with industrial standards.

Embedded resolver gives the possibility to have a local close loop control and improve diagnostics for non-accessible devices.

## ACKNOWLEDGEMENTS

We would like to thanks every people that help us and contribute to motors integration study, deployment and test in both CEA department DIS and DACM.

# OpenCMW - A MODULAR OPEN COMMON MIDDLE-WARE LIBRARY FOR EQUIPMENT- AND BEAM-BASED CONTROL SYSTEMS AT FAIR

Ralph J. Steinhagen, H. Bräuning, D. Day, A. Krimm, T. Milosic,  
D. Ondreka, A. Schwinn, GSI Helmholtzzentrum, Darmstadt, Germany

## Abstract

OpenCMW is an open-source modular event-driven micro- and middle-ware library for equipment- and beam-based monitoring as well as feedback control systems for the FAIR Accelerator Facility.

Based on modern C++20 and Java concepts, it provides common communication protocols, interfaces to data visualisation and processing tools that aid engineers and physicists at FAIR in writing functional high-level monitoring and (semi-)automated feedback applications.

The focus is put on minimising the required boiler-plate code, programming expertise, common error sources, and significantly lowering the entry-threshold that is required with the framework. OpenCMW takes care of most of the communication, data-serialisation, data-aggregation, settings management, Role-Based-Access-Control (RBAC), and other tedious but necessary control system integrations while still being open to expert-level modifications, extensions or improvements.

## ARCHITECTURE

OpenCMW is a light-weight modular middle-ware twin-library that combines ØMQ, REST and micro-service design patterns illustrated in Fig. 1. The Majordomo Protocol Broker (MDP) provides reliable (a)synchronous request-reply as well as publish-subscribe (and related radio-dish) communication patterns between external clients and workers, implementing the business logic that may reside either internally or externally to the MDP process. Its core relies primarily on the high-performance and low-latency ØMQ-based transport layer but can, for example, be optionally

extended by HTTP to also support REST or HTML-based communication patterns, and optionally secure worker access via RBAC [1–16].

OpenCMW strongly embraces lean-code principles and hence aims at minimising boiler-plate code and to aid light-weight development of network-based, semi- to fully automated real-time feedback applications. It thus provides template implementations for common tasks such as to

- aggregate, synchronise, and to sanitise data received from multiple devices,
- allow to inject custom domain-specific user-code to numerically post-process the received data, and
- derive control signals and forward these to other services using common communication libraries.

This business logic is implemented by workers that cover:

- optional class-based domain-object definitions for the input parameter and return value, and
- two event-handler interfaces that are registered either with the MDP or Event Store, and that implement the call-back functions further described below.

Notably, developers do not need to rely on IDL-type or other proprietary definitions that, based on our experience, may become hard to synchronise and maintain in later development iterations. The interfaces are defined by standard POCO or POJO domain-objects that OpenCMW analyses using `constexpr` compile-time (C++) or run-time (Java) reflection, further described below.

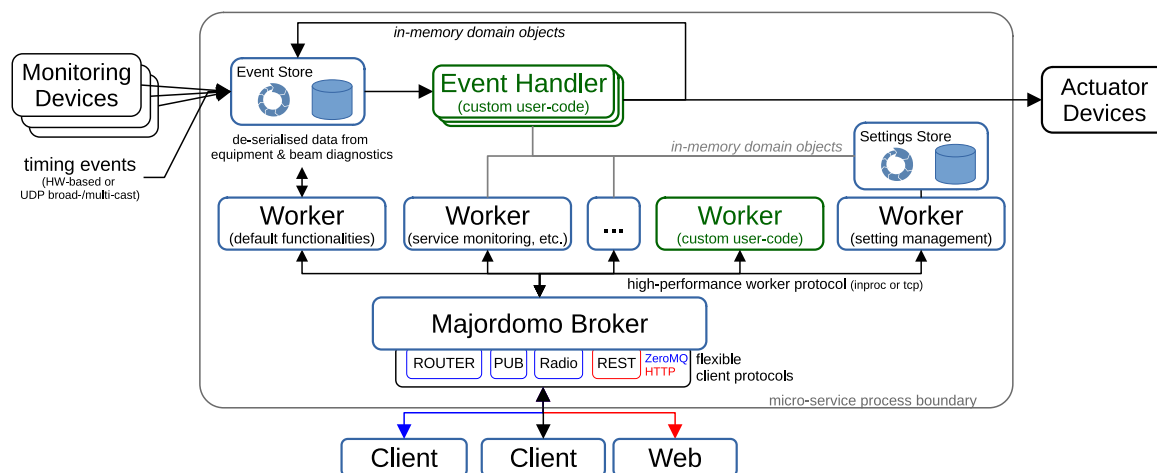

Figure 1: OpenCMW micro-service system architecture combining the Majordomo and event-sourcing design pattern.

## DEVICE MODELLING

FAIR provides a wide variety of particle beams with different properties and extraction parameters that are transported to multiple experiments or storage rings either time-multiplexed or even simultaneously. Accelerator operation is thus organised into semi-repetitive ‘patterns’ and nested substructures (aka. ‘timing contexts’ or ‘<ctx>’) that are triggered by timing events in order to orchestrate the required rapid real-time succession of individual actions, data acquisition, or device reference settings changes.

OpenCMW is flexible with its domain-object modelling and supports arbitrary setting-types from single scalar fields up to complex nested tree-like data-structures. However, based on operational experience at GSI, CERN and other accelerator facilities, and to be compatible with the existing implementations, most equipment is modelled using a reduced flat ‘device/property’ scheme only [21]. This scheme models settings essentially through ASCII-based endpoints, that include filters and loosely follows the more commonly-known RFC 1808 URI definition [22]:

```
<device>/<property>?ctx=<ctx>;  
<filter_i=val_j>; ... ;<filter_n=val_m>
```

with the ordering of the optional context selector and filters after the initial ‘<device>/<property>’ being arbitrary and separated by a semi-colon (;) or ampersand (&).

## DATA AGGREGATION

Most monitoring and feedbacks are rarely SISO but more commonly MIMO systems. OpenCMW thus provides facilities that aid in the aggregation and synchronisation of input data that may arrive through different transport channels, protocols, and from a large number of equipment- or beam-based systems. To process this data efficiently, as well as to simplify and reduce potential error sources for developers, two aggregation strategies are provided:

- continuous sample-by-sample or chunked data not aligned to a <ctx>: these are typically processed by a GNU-Radio-based flow-graph, commonly used in the domain of software-defined-radios (SDRs [17]), as illustrated in Fig. 2;

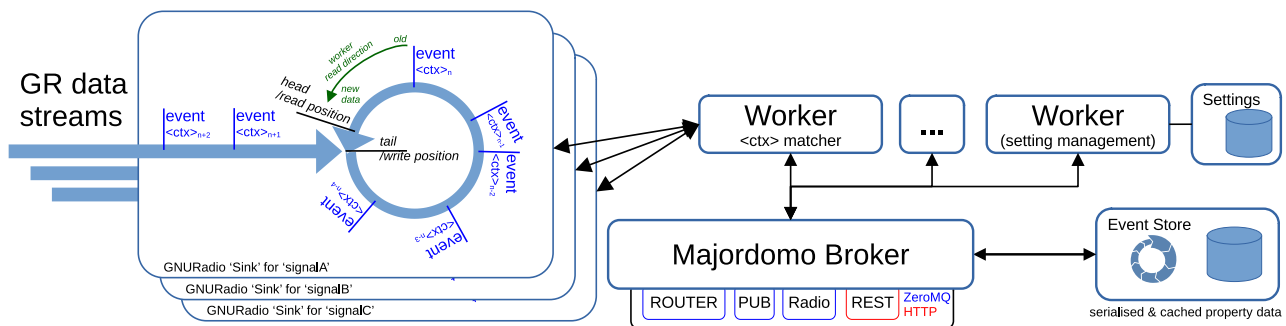

Figure 2: Schematic GNU-Radio-based (GR) processing of continuous data as used by the FAIR Digitizers [17–20]. The data processed by the flow-graph is stored in non-blocking circular buffers (sinks) similar to tagged b-trees that allow to efficiently chunk the data according to the required timing <ctx> scope.

- chunked data that is already (partially) aligned to a timing <ctx>: these are typically processed using the event-sourcing pattern that combines the data across multiple input sources or larger superordinate <ctx> or to perform signal post-processing routines on a chunk-by-chunk basis as illustrated in Fig. 3.

The event-sourcing relies on different types of workers:

- ‘adapter’: tasked with receiving and de-serialising the specific (possibly foreign) wire-format, and storing the resulting domain-object alongside its meta-information into the event store’s event stream;
- ‘<ctx>-matcher’: collecting multiple source domain-objects into one combined new ‘aggregate’ which is usually triggered by timing events or arrival of a new <ctx>. The new aggregate is stored inside the same (or optionally another) event store event/stream, either once all required data arrived or once a configurable time-out w.r.t. the aggregation start is reached;
- post-processing workers: performing the actual post-processing and control actions based on user-supplied worker handler-callback code;

The handler-callbacks are triggered whenever a new aggregate is written to the event store, receive the actual and past issuing events, data to facilitate FIR- and IIR-type filtering, and may notify the MDP to publish the intermediate results.

## DESIGN CONSIDERATIONS

There have been many expensive software failures, accidents, and inefficiencies in the past, most famously the Ariane flight 501 and Mars Climate Orbiter that failed due to avoidable type- and physical-unit conversion errors [23, 24]. Our accelerator domain is not immune to these type of failures, and struggles in addition with organically grown code-bases that often – as a consequence of Conway’s law<sup>1</sup>, time- and resource constraints – cannot be adequately pruned, refactored or optimised. OpenCMW thus aims at lean, modern, and long-term sustainable architecture that avoids the above mistakes by design.

<sup>1</sup> “[Developers will] produce a design whose structure is a copy of the organization’s communication structure”, [25]

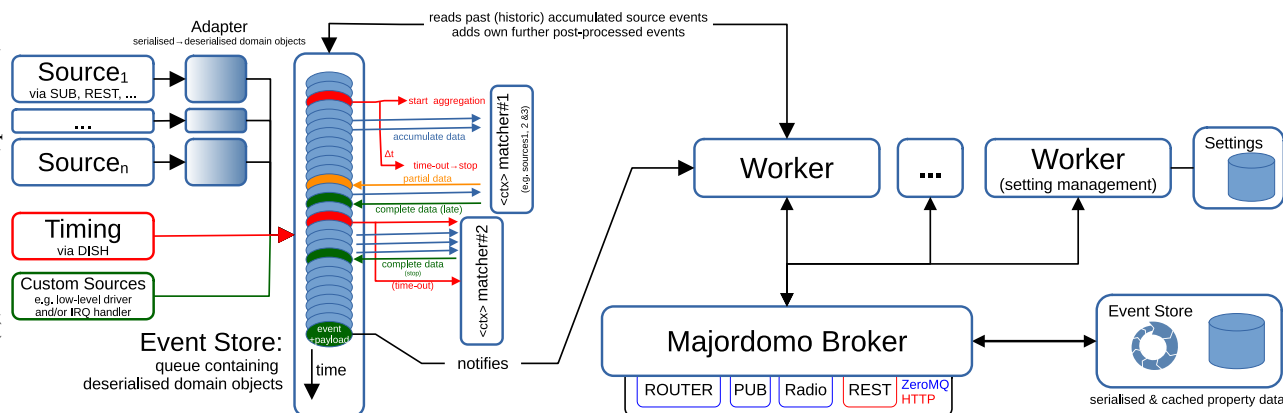

Figure 3: Schematic <ctx> multiplexed-based data aggregation based on the event-sourcing design pattern [11].

The transport layer and data serialisation are basic core functionalities of OpenCMW or any middle-ware for transmitting, storing and later retrieving information by (often quite) different subsystems. With a multitude to choose from, a non-negligible subset of frameworks claim to be the fastest, most efficient, easiest-to-use, etc. A fair comparison of their performance is rather complex, highly non-trivial, and thus subjective because the underlying assumptions of 'what counts as important' is quite different between specific domains.

Instead, we want to document the rationale as to why we decided to implement a new middle-ware, its considerations, constraints, technical core choices, and goals that went into OpenCMW's design in the hope that it might be interesting, perhaps be adopted, inspire new ideas, or any other form of improvement. OpenCMW's core paradigms, loosely ordered according to their importance, are:

1. undogmatic lean and agile software design principles.
2. performance: end-to-end real-time latency minimisation between the service's data object being ready, serialised, and sent, until it is received, fully de-serialised, and ready for further processing by the client<sup>2</sup>.
3. loose coupling between server- and corresponding client-side-definitions to provide soft sustainable upgrade paths.
4. strict separation of concern between the communication transport layer, serialiser protocol, and user supplied custom-code: OpenCMW provides extendable interfaces to transparently exchange or add new transport and serialisation protocols simplifying the custom user-code that does not need to be aware of the actual protocols that the client may request. This enables more modular implementation, easier maintenance, and efficient code-sharing of code blocks between different projects.
5. static compile-time reflection<sup>3</sup>[26, 27]: derive interfaces directly from C++ or Java domain-objects:

<sup>2</sup> Network-IO bandwidth limit driven trade-offs between size and en-/decoding speed are not of primary concern for our use-case

<sup>3</sup> N.B. Java is presently limited to run-time reflection.

- less error-prone and more efficient compared to other IDL-based solutions that need to rely on external code-generation tools.
- greatly reduces the cognitive complexity, see List. 1 and the appendix for code examples.
- improves productivity of new, occasional, or less-experienced developers who need to be only "vaguely" familiar with C++ or Java.
- supports UTF8, all primitive/fundamental data types, nested objects, common data containers.
- efficient (first-class) support of large collections of numeric (floating-point) data.

6. strong type- and physical-units safety [28–30].

7. OpenAPI [31]: self-documented data-structures with optional constexpr data field annotations to communicate the service's data-exchange-API intent to the client (e.g. physical unit, access constraints, human-understandable description, etc.). This meta-information can be used to re-generate the domain-objects on the client-side.

8. Modern C++20 [32] and Java 11 standards:

- more concise with respect to expressing developer's intent and constraints.
- easier, safer, and more intuitive syntax for new or occasional developers.
- better performance, due to larger proliferation of compile-time constexpr and consteval expressions and library functionalities.

9. minimise external library dependencies: especially rely on those already or targeted to become official part of the C++ ISO standard [26, 28, 32].

10. minimise code-base and code-bloat while providing hard-to-implement core-functionalities: small code fits more likely into CPUs's cache and thus results in faster execution. Also from a maintenance perspective, more code requires more time to read and understand, and is harder to modify, test, or fix.

```

1  struct CppDomainObjectExample {
2      Annotated<float, thermodynamic_temperature<kelvin>, "device specific temperature">    temperature    = 23.2F;
3      Annotated<float, electric_current<ampere>, "this is the current from ...">           current      = 42.F;
4      Annotated<float, energy<electronvolt>, "SIS18 energy at injection before being captured"> injectionEnergy = 8.44e6F;
5      std::string                                notAnnotated    = "Hello World!";
6      // [...]
7  };
8  // refl-cpp-based: targeted and becomes obsolete with the next C++ standard
9  ENABLE_REFLECTION_FOR(CppDomainObjectExample, temperature, current, injectionEnergy, notAnnotated)

1 public class JavaDomainObjectExample {
2     @MetaInfo(description = "device specific temperature", unit = "K")
3     public float    temperature    = 23.2f;
4     @MetaInfo(description = "this is the current from ...", unit = "A")
5     public float    current      = 42.f;
6     @MetaInfo(description = "SIS18 energy at injection before being captured", unit = "eV")
7     public float    injectionEnergy = 8.44e6f;
8     public String    notAnnotated    = "Hello World!";
9     // [...]
10 }

```

Listing 1: C++ POCO and equivalent Java POJO domain-object reflection example.

11. unit-test and CI/CD driven development to minimise errors and detect potential (also quantitative performance) regressions.
12. free- and open-source LGPLv3-licensed code-base.

It is important to us that this code can be re-used, built- and improved-upon by anybody and thus we hope that the above paradigms lower the entry-level and improve the likelihood of OpenCMW to be adopted also by external users that wish to understand, upgrade, or bug-fix 'what is under the hood' or what is of specific interest to them.

## PERFORMANCE

In real-time control and notably for feedback systems, performance depends not only on correct results but also when it is applied to the accelerator or presented to the operators. The required maximum latency that is to be minimised, corresponding group-delay and phase-lag depends on the specific application. OpenCMW's primary use-case are high-level software-based monitoring and (semi-)automated feedback applications at FAIR with bandwidths of up to 25 Hz and latencies well below 10 ms. The framework itself should contribute only with a small proportion to these latencies.

Since the OpenCMW architecture by design strongly decouples, and since there are a wide range of possible combinations, we independently benchmarked the transport-layer only using small dummy-payloads and serialisation without the transport layer.

### Majordomo Broker

The performance results for our Java-based Majordomo implementation for both MDP in-process (InProc) and external worker (TCP, via *localhost*) is shown in Table 1. The performance is largely determined by the specific ØMQ implementation (*JeroMQ*) in the above case [33], polling loop optimisation, and by itself contributes very little to the overall latency. This is deemed sufficient for our few Java-based applications with lower latency requirements. The C++-based Majordomo implementation, based on *libzmq* and loosely on the MDP reference implementation [34, 35],

Table 1: OpenCMW-Java Majordomo Performance (Test-System: AMD Ryzen 9 5900X)

ØMQ Transport Type	msgs/s
REQ/REP synchronous via TCP	12594
REQ/REP synchronous via InProc	27247
REQ/REP asynchronous via TCP	285714
REQ/REP asynchronous via InProc	400000
SUBSCRIBE via SUB-Socket	1538461
SUBSCRIBE via DEALER-socket	666666

aims at latencies below 1 ms to be compatible with FAIR's SDR applications [17–20]. This is presently being optimised and will be released soon.

### Serialiser

OpenCMW aims to provide interfaces for service-client communication where: a) high-performance is important – usually relying on binary-type (de-)serialisation wire-formats – and b) where ease of access, notably, REST and Web-based compatibility is important, often relying on string-based wire-formats such as JSON, YAML, XML, etc. Figure 4 shows the round-trip performance results for OpenCMW and various other common implementations for both C++ and Java [1, 2, 36–42].

While some implementations provided only map-style interfaces, each serialiser has been extended and optimised to (de-)serialise the same equivalent domain-object back-to-back to have more comparable results with the compile-time reflection-based approach. A large spread within but also between binary- and string-based wire-format encoding libraries is visible. The 'CmwLight' serialiser is OpenCMW's functional open-source re-implementation of the existing proprietary CMW-Data protocol that is presently used internally at GSI[21]. The benchmark is available at [43]. Pull-Requests to improve the OpenCMW and other serialisers are welcome. Tentative results indicate that many of the serialiser supporting binary wire-formats seem to be optimised for simple data structures that are typically much smaller than 1k Bytes rather than large numeric ar-

Figure 4: Round-trip performance for converting the input- to output-domain-object via the given wire-format for numeric (left) and `std::string`-data (right) dominated domain-objects (N.B. log-scale, smaller is better).

rays that were either slow to encode and/or required custom serialiser extensions. *Jsoniter* showed the best results for parsing JSON in Java [39]. We thus decided to use it as the parsing back-end for the *OpenCMW-JSON* deserialiser also to avoid common mistakes and error-handling when processing incomplete or erroneous JSON streams that the deserialiser must be able to handle. Since these error types are non-issues for the serialiser side, we adapted a custom JSON serialiser implementation to the compile-time reflection approach which proved to be more performant. This is also the reason for the visible performance differences between *OpenCMW-JSON* and *jsoniter* in Fig. 4. At the time of the test, the C++ *simdjson* library was not yet evaluated but appears promising and will thus be included in future benchmarks [44].

## DOMAIN API EVOLUTION

An important consideration for every distributed system is how to be able to update the API defining domain-objects without having to simultaneously update every other component of the system. To allow for a reliable update strategy OpenCMW uses the transferred metadata to validate the data during deserialisation.

The MDP broker (or any other caller of the serialiser) can control if metadata should be serialised, the type of checks that should be performed on deserialisation, and how errors should be treated. The behaviour of the error handling can be controlled with domain-object annotations.

To optimise the performance impact for high update rates, OpenCMW assumes domain objects stay identical during one connection and only performs checks on the first update. The MDP client calls the verbose deserialiser on the first update and the fast deserialiser on subsequent updates. If there are differences in the first update it can:

- ignore compatible changes like new optional fields or missing optional fields. The client code can still check for the presence of optional fields through the return value of the serialiser.
- request a fallback property if available and warn the user of the legacy API.
- throw an exception.

Worker implementations should keep future extensions in mind when defining their domain objects, but not at the cost of a clean design. When changes are necessary, new (non-mandatory) fields can be added in a backward compatible way if they don't change the meaning of the other data. If non-compatible changes like changing data types are performed, a fallback property providing the old domain object should be offered in the 'two on production' pattern[45, 46]. It is encouraged to also make use of the 'aggressive obsolescence' and 'experimental preview' patterns, to keep the burden of API maintenance manageable. There is no explicit versioning of the domain objects, mismatches in domain objects are determined by the deserialiser.

## CONCLUSION

OpenCMW is a new open-source modular event-driven micro-service and middle-ware library for equipment- and beam-based monitoring as well as feedback control systems for the FAIR Accelerator Facility.

Based on modern C++20 and Java concepts, together with the benefits and chances of an agile open-source development, we believe that the above lean software development principles are key ingredients and will help experienced as well as entry-level engineers and physicists to write, share, and improve functional and long-term maintainable code for high-level monitoring and (semi-)automated feedback applications both at FAIR, other laboratories as well as used by other interested developers elsewhere. For detailed information, code examples, or to participate in this project, please visit and interact with the authors via [1–3].

## ACKNOWLEDGEMENTS

The implementation heavily relies upon and re-uses time-tried and well-established concepts from ØMQ (notably the Majordomo communication pattern [8]), LMAX's lock-free ring-buffer disruptor [11], GNU-Radio real-time signal processing framework [17], Javalin for the RESTful interface [47], as well as previous implementations and experiences gained at GSI, FAIR and CERN [21, 48–57].

# INTEGRATION OF OPC UA AT ELBE

K. Zenker\*, R. Steinbrück, M. Kuntzsch,

Institute of Radiation Physics, Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany

## Abstract

The Electron Linac for beams with high Brilliance and low Emittance (ELBE) at Helmholtz-Zentrum Dresden-Rossendorf (HZDR) is operated using the SCADA system WinCC by Siemens. The majority of ELBE systems is connected to WinCC via industrial Ethernet and proprietary S7 communication. The integration of new subsystems based on MicroTCA.4 hardware, which do not provide S7 communication interfaces, into the existing infrastructure is based on OPC UA using the open source C++ software toolkit ChimeraTK.

This paper discusses OPC UA related contributions to ChimeraTK, that cover an OPC UA backend implementation, development of logging, data acquisition and history modules and improvements of the control system adapter for OPC UA in ChimeraTK. Furthermore, a user data interface based on OPC UA for ELBE is introduced and one ELBE real-life example is described, that makes use of all the afore-mentioned features.

## INTRODUCTION

The Electron Linac for beams with high Brilliance and low Emittance (ELBE) at Helmholtz-Zentrum Dresden-Rossendorf (HZDR) is in operation since 2001. It is operated using the SCADA system WinCC by Siemens. The majority of ELBE systems is connected to WinCC [1] via industrial Ethernet and proprietary S7 communication. However, in recent years new subsystems had to be integrated into the existing infrastructure, which do not provide S7 communication interfaces. The Open Platform Communication (OPC) interoperability standard for the secure and reliable exchange of data in industrial automation environments is developed and maintained by the OPC foundation [2]. Its Extension called OPC Unified Architecture (OPC UA) [3] is an open standard for information modeling and machine-to-machine communication, that features e.g. build-in security/authentication and is the foundation of the so-called 4th industrial revolution in industry. It is platform independent and different open source implementations exists that provide support for various development environments like e.g. Python, C/C++, Java and Labview. Because of those features OPC UA has been chosen at ELBE to establish a link between the new subsystems and S7 devices.

As shown in [4] two types of communication were established in the past:

- OPC UA communication between an application and MicroTCA.4 [5] based hardware, i.e. FPGA via direct memory access (DMA) over PICE

- OPC UA communication between an application and Siemens S7-300/400 PLCs

The former communication is established based on the ChimeraTK framework introduced in the following section. The latter communication is based on commercially available OPC UA gateways introduced after. In the following sections OPC UA related components of ChimeraTK and an OPC UA based ELBE machine data interface are presented. Thereafter, the use of the new features is demonstrated by means of an ELBE subsystem as a real-life example.

## OPC UA IN CHIMERATK

ChimeraTK [6, 7] is a C++ based open source toolkit for modular control application developments. ChimeraTK provides dedicated libraries for access to devices/data (DeviceAccess library [8]), the application itself (ApplicationCore [9]) and a control system server (ControlSystemAdapter [10]). Both, the Device Access Library and the Control System Adapter library, can be used to implement additional so called device backends and control system adapter implementations. The general structure is shown in Fig. 1. Highlighted in green are parts of ChimeraTK that were contributed as part of the OPC UA developments at ELBE.

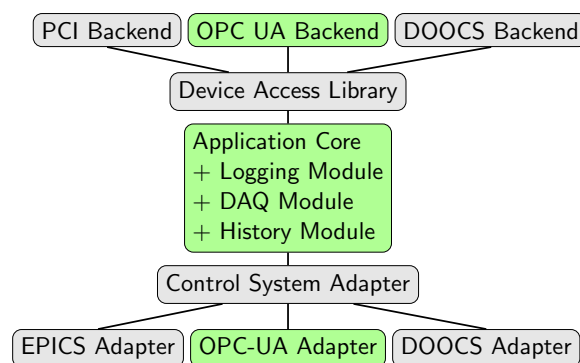

Figure 1: Overview of ChimeraTK. Only selected control system adapters and backends are shown. Contributions discussed in this paper are shown in green.

In general, so far the OPC UA communication in ChimeraTK is implemented using client/server communication, based on TCP/IP. This means no real-time communication can be realized using this approach. Real-time communication would only be possible using the Publish/Subscribe mechanism of OPC UA in combination with Time-Sensitive Networking (TSN) and hardware that supports TSN.

\* k.zenker@hzdr.de

## Control System Adapter

The control system adapter that allows building OPC UA servers [11] was originally developed in cooperation with the Technical University of Dresden and DESY[12]. This work is presented in [3]. Now it is further developed together with the Fraunhofer Institute of Optronics, System Technologies and Image Exploitation IOSB [13], who are also involved in the development of the OPC UA stack open62541 [14], which is used to implement the OPC UA control system adapter in ChimeraTK. Its main task is to expose all process variables and attached meta data like the variable description and engineering unit defined in the ChimeraTK application via an OPC UA server with corresponding nodes. The nodes are only updated with values of the corresponding ChimeraTK application variable upon request. If no client is connected to the OPC UA server updates of the process variables in the ChimeraTK application are not reflected on the OPC UA server side.

A major improvement compared to the version discussed in [3] is the extended mapping feature of the OPC UA control system adapter. In the past it was only possible to add additional static process variables to the variable tree via a mapping file. Now it is possible to extend the variable tree defined in the ChimeraTK application in an arbitrary manner, by copying or linking variables and complete folders including subfolders to different places in the variable tree. In addition, variable names and the meta data can be edited. If the variable name is changed the variable is copied in the variable tree, meaning a new OPC UA node is created. Else if not explicitly stated different in the mapping file the new location is simply linked to the source variable. This is done by adding a reference to the source OPC UA node keeping the number of nodes of the OPC UA server constant. Such a mapping feature is useful in case client applications expect a certain variable structure. For example, when the ChimeraTK application and its variable tree is changed, client applications are still operational if the previous variable tree is created via the mapping. This allows to decouple client developments from server developments.

Another major change is that numeric node identifiers of process variables, which were initially used for all variables of the ChimeraTK application, were replaced by string node identifiers. The string node identifier is created from the variable name and path as created in the ChimeraTK application. This solves the problem that node identifiers changed, when changing the variable tree of the ChimeraTK application. It happened, because node identifiers were assigned dynamically at server start by scanning the applications variable tree. Using a string node identifier guarantees a static node identifier as long as the variable name is not changed in the application.

Furthermore, changes in ChimeraTK, like the introduction of a data validity flag, were reflected in the OPC UA control system adapter by adding corresponding meta data to variables. Only recent changes in ChimeraTK, i.e. the

introductions of the new data types *Bool* and *Void*, are not reflected yet.

Finally, the version of the open62541 stack was upgraded from version 0.2 to version 1.2. This new version includes full encryption support. An encryption endpoint for the OPC UA server will be added in the near future, thus two endpoints will be available following the security policies *None* and *Basic256Sha256* as defined in [15]. The *Basic256Sha256* endpoint will support only encrypted and signed messages and thus ensure a high security level.

## Application Core

Different control systems supported by ChimeraTK include different control system specific features, e.g. for data archiving, that are not part of ChimeraTK. In case of OPC UA such features could be implemented in the OPC UA control system adapter utilizing the full functionality of OPC UA and e.g. its historizing mechanism. However, it was decided to add features that are needed at ELBE directly to the ApplicationCore library of ChimeraTK. Therefore, they can be used by all control system adapters of ChimeraTK applications.

First, a logging module was added. It covers four different severity levels and three different target streams – a message variable in the control system, a logging file and standard output to the console – that can be combined. The logging level, target stream and the number of messages included in the message variable can be configured at run time.

Second, a module for data acquisition (DAQ) and archiving was developed [16]. It includes two different backends – a ROOT [17] based and HDF5 [18] based backend. The backend type can be defined in the server configuration that is loaded at server start. The HDF5 backend does not yet cover compression and stores any ChimeraTK data type to a float data type in the HDF5 file. In case of the ROOT backend loss-less compression based on the ZStd algorithm [19] is supported and ChimeraTK data types are mapped to native ROOT data types, which improves the data compression rate.

In addition to this module for data archiving a software package with dedicated tools was developed [20]. The main component of this packages is a Graphical User Interface (GUI), that allows DAQ data inspections. It is a python GUI based on the widget toolkit Qt [21] and on the scientific graphics and GUI library pyqtgraph [22]. It can construct time lines out of the DAQ data and allows to visualize specific data periods. Also, it is possible to jump to events that fulfill a specific threshold criteria, e.g. that a certain temperature is above a certain threshold level. A table allows to inspect a statistical summary (mean and standard deviation) for time line data.

Finally, a history module was added, that allows to create a RAM based history for selected process variables. The history is available as a pair of two process variables each holding a data array. One variables holds the variable values and a second variable holds corresponding time stamps. Data of the history module is used in Human Machine In-

interfaces (HMI), that show actual data trends for ChimeraTK applications. It complements the data available by the DAQ module described above with data that is not yet written by the DAQ module.

### Device Access

The device access library allows access to devices that are not necessarily part of the machine, that is running the ChimeraTK application. E.g. as shown in Fig. 1, there is a PCIe backend that allows to access FPGA data via PCIe communication. At ELBE typically the FPGA is part of a MicroTCA.4 platform and it is added by the MicroTCA Carrier Hub (MCH) to the computers PCIe root complex.

In addition to such a classical device access often a communication between different applications is needed. Such a cross application communication can also cover communication between different control systems, e.g. if a ChimeraTK application using the OPC UA Control System Adapter communicates with a DOOCS [23] server via the DOOCS backend shown in Fig. 1. In case of OPC UA, this requires an OPC UA backend [24], which was developed at ELBE. In fact the backend is an OPC UA client and features synchronous and asynchronous data access. The latter is based on subscriptions in combination with items to be monitored that are attached to the subscription. Two methods to select process variables from the ChimeraTK application, i.e. the OPC UA server, to be monitored are available:

1. Map file based process variable selection.
2. Automatic process variable selection.

If using the map file, one needs to specify the OPC UA node identifier, the corresponding OPC UA name space and a name that is used to map the variable to ChimeraTK. The automatic mapping only works if one connects to an OPC UA server that is based on the ChimeraTK OPC UA control system adapter. It maps all process variables available on the server one to one to the ChimeraTK application. In some cases this might be not sufficient to create a process variable tree as needed by the application. In that case, one can use an additional mapping layer provided by ChimeraTK [7], that allows to restructure the variable tree of devices. In addition to the server address and port, the sampling interval can be specified in the backend configuration. It defines the update rate of monitored process variables independent of the update rate of the source process variable of the OPC UA server. The publishing interval is set equal to the sampling interval, which means each sampled value is sent without buffering directly to the backend by the OPC UA server.

## OPC UA GATEWAY INFRASTRUCTURE

As discussed in [4] at ELBE commercially available OPC UA gateways [25] (UA Link) by IBHsoftec are used as a data bridge between Siemens S7-300/400 PLCs and OPC UA based applications. Initially only used for the LLRF system introduced in the following section, the gateway infrastructure was developed further to provide an OPC UA

based ELBE machine data interface in general. A hierarchy of different gateways as shown in Fig. 2 was set up at ELBE.

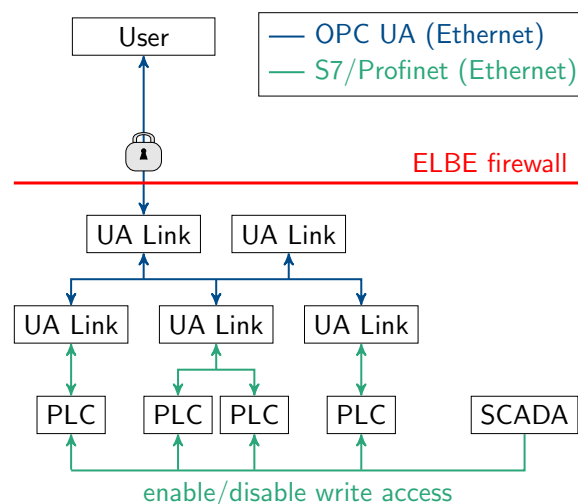

Figure 2: UA Link hierarchy used at ELBE.

In the lowest hierarchy level, UA Link devices are connected to individual PLCs. Already at this level data of different PLCs is aggregated at ELBE. At ELBE typically about 20000 PLC process variables per UA Link are made available via OPC UA. In the hierarchy level above two aggregating UA Links are connected to all the UA Links in the hierarchy level below. They serve as access points to the OPC UA user interface and include an identical process variable tree, that is a subset of the process variables available in the hierarchy level below. If needed UA Links at this level can also be replaced by workstations running a software [26] that directly uses the configuration of the UA Links.

One of the aggregating UA Link acts as the access point for external users via an encryption based secured connection. For this UA Link machine data is accessible read-only. The second UA Link in this hierarchy level is used for ELBE internal applications. Read and write access is granted to this UA link. However, all PLC registers published via the OPC UA user interface are duplicated on the PLC, which allows to disable write access on the PLC level. Thus, only the duplicates are accessed by the UA Link and operators can control external write access via OPC UA for dedicated process variables or at all from the SCADA system. The duplication also allows data type adjustment and scaling. Restructuring and renaming of process variables is done in the upper UA Link hierarchy level.

In addition to PLC data published via the UA Link, special process variables dedicated to the users can be added to the variable tree on the UA Link. Users can have read and write access to those variables. One example for such variable is a count rate measured by the users and exposed via OPC UA to the SCADA system. Like that such information is available to operators for machine setting optimization.

User authentication for external users is done via user certificates following the X.509 standard in combination with a Certification Authority (CA). A Public-Key-Infrastructure

(PKI) including a ROOT CA and dedicated user group CAs was set up at ELBE. Thus, only the CAs certificates and the corresponding revocation lists need to be placed on the UA Link, which simplifies the configuration. User certificates are handed out by the ELBE group and are signed with the corresponding user group CA certificate.

## EXAMPLE: THE LLRF SUBSYSTEM AT ELBE

The digital low level radio frequency (LLRF) system of ELBE was the first sub system building on the OPC UA control system adapter discussed here. It is used to control the amplitude and phase of cavities used for particle acceleration and bunching at ELBE [27]. Operators interact with the LLRF system via the SCADA system WinCC. It runs OPC UA clients that are connected to the ChimeraTK LLRF applications (LLRF server). Currently at ELBE seven LLRF servers are running. A simplified overview of the system including only a single LLRF server is shown in Fig. 3.

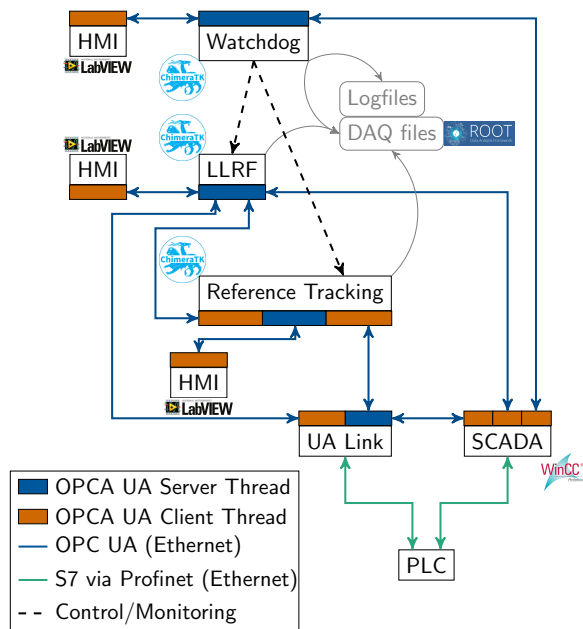

Figure 3: Overview of the control system infrastructure related to the LLRF system at ELBE. Here only one out of seven LLRF applications is shown.

The LLRF servers are controlled and monitored by a second ChimeraTK application called Watchdog server[28], which also monitors the computer where the applications are running. WinCC runs also an OPC UA client that is connected to the Watchdog server, which allows to forward the LLRF Server status to WinCC and also to restart LLRF servers via WinCC. Logging output of all applications controlled by the watchdog are available via OPC UA and it is written in addition to log files stored on disc via the logging module discussed above.

A simple feedback algorithm [27] correcting long term drifts of amplitude and phase introduced by temperature

variations is implemented in a separate ChimeraTK application called Reference Tracking server (see also [27]). This server needs data from the LLRF servers as well as machine data, which is read from ELBE PLCs via the UA Link by the OPC UA backend. Calculated corrections are written back to the LLRF server via the OPC UA backend. The Reference Tracking server calculates corrections for all LLRF servers meaning it creates seven OPC UA client threads for the LLRF servers and one OPC UA client thread to the UA Link.

All ChimeraTK applications include the DAQ module introduced before and produce ROOT data files that are written to disc as indicated in Fig. 3. In addition to the WinCC interface to the ChimeraTK servers, application specific expert HMI GUIs have been set up at ELBE. They are implemented using LabVIEW, which features an OPC UA client. Details about LabVIEW client applications are presented in [4].

## CONCLUSION

The SCADA system of ELBE is the S7 communication based software WinCC. New subsystems that are integrated to ELBE, like the LLRF system that is based on the MicroTCA.4 platform, do not support S7 communication. In this paper we have shown how such systems are integrated using OPC UA. The integration is based on the C++ toolkit ChimeraTK. The already existing OPC UA control system adapter was extended by additional mapping features that allow to decouple the HMI and application development. Also it was updated to the latest version of the open62541 OPC UA stack it is based on. That allows to make full usage of the encryption provided by OPC UA. In addition ChimeraTK was extended by an OPC UA backend, common modules for logging, data acquisition and online data history, to fulfill the needs at ELBE. Those developments are not only relevant if using the OPC UA control system adapter of ChimeraTK. All other supported control systems benefit, either by the common modules or by the OPC UA backend that allows to integrate data from any OPC UA server to any ChimeraTK application.

The OPC UA based machine data interface presented in this paper, allows external users secure access to ELBE data, which was not available before.

In future, we plan to support more features of OPC UA in the OPC UA control system adapter, like support for OPC UA events or registration to local or global discovery servers according to the OPC UA standard.

## ACKNOWLEDGEMENTS

The authors would like to thank our IOSB collaborators and the ChimeraTK team, especially Martin Killenberg and Martin Hierholzer, for their continuous support and feedback.

# INTERFACING EPICS AND LabVIEW USING OPC UA FOR SLOW CONTROL SYSTEMS

Jalal Mostafa, Armen Beglarian, Suren A. Chilingaryan, Andreas Kopmann  
 Karlsruhe Institute of Technology, Eggenstein-Leopoldshafen, Germany

## Abstract

The ability of EPICS-based control systems to adapt to heterogeneous architectures made EPICS the defacto control system for scientific experiments. Several approaches have been made to adapt EPICS to LabVIEW-based cRIO hardware, but these approaches, including NI EPICS Server I/O Server: (1) require a lot of effort to maintain and run, especially if the controllers and the process variables are numerous; (2) only provide a limited set of metadata; or (3) provide a limited set of EPICS features and capabilities. In this paper, we survey different solutions to interface EPICS with LabVIEW-based hardware then propose EPICS OPCUA device support as an out of the box interface between LabVIEW-based hardware and EPICS to preserve most of EPICS features and provide reasonable performance for slow control systems.

## INTRODUCTION

The KARlsruhe TRItium Neutrino (KATRIN) experiment is a large-scale scientific experiment to determine neutrino mass using Tritium beta decay [1]. Large-scale scientific experiments like KATRIN employ diverse hardware from different vendors to support the control system infrastructure, e.g., NI cRIO, Siemens S7, custom hardware chips, etc. For instance, KATRIN employs around 10,000 process variables that are distributed in bunches of 100 to 300 process variables on different NI cRIO, NI cFieldPoint, and Siemens S7 devices. The heterogeneity of such systems imposes a new challenge of providing a unified layer of control and interoperability between these heterogeneous systems and other services like alerts, data archiving, and analysis. The Experimental Physics and Industrial Control System (EPICS) solves this problem using an intermediate C++ software layer.

EPICS is a set of tools and libraries to develop distributed server-client control systems for large-scale scientific experiments e.g. particle accelerators. It can solve the challenge of heterogeneity by acting as an abstract software layer for all devices through implementing a C++ abstraction interface called Device Support. Operator's setpoints and sensor measurements are then channeled through EPICS server or Input/ Output Controller (IOC) using one of EPICS network protocols: Channel Access (CA) and its successor Process Variable Access (PVA). Figure 1 shows a simplified illustration of the EPICS server architecture of the EPICS server. An EPICS server keeps all process variables in in-memory structures called Database. When a client asks for a process variable, the EPICS server access these structures using a module called Database Access. The EPICS server can read

data from the hardware using the device support layer where the data is mapped to the corresponding process variable through database access and then published on the network using CA or PVA. Operator's setpoints work similarly, but in the opposite direction: an EPICS client (the operator) sets a process variable on an EPICS server using CA or PVA, which is implemented on the hardware using Device Support.

This architecture imposes new challenges on the interoperability between EPICS and NI LabVIEW-based cRIOs. The LabVIEW programming environment offers very tight integration with EPICS. Several approaches have been made to provide an integration for LabVIEW with EPICS, but they usually require an effort to maintain and run, provide a limited set of metadata, or provide a limited set of EPICS features and capabilities. In this paper, we propose an EPICS-LabVIEW integration based on Open Platform Communications Unified Architecture (OPC UA) protocol.

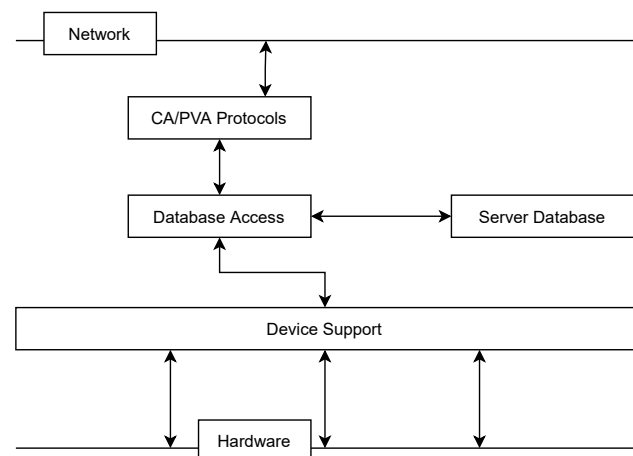

Figure 1: EPICS Server Simplified Internal Architecture.

## RELATED WORKS

Several works have been done before to interface LabVIEW with EPICS: most notable is *EPICS Server I/O Server* [2]. *EPICS Server I/O Server* is a complete implementation of EPICS CA protocol for LabVIEW from NI. It allows the developer to create LabVIEW Shared Variables to publish EPICS process variables on the network, a complicated process that involves many clicks to accomplish a simple task, especially when the process variables are numerous. The metadata that EPICS Server I/O Server provides is limited to alarms only leaving behind important metadata like description and engineering units.

Another LabVIEW/EPICS interface that depends on Shared Variables is *NetShrVar* [3]. *NetShrVar* uses the proprietary NI-PSP protocol to bind a process variable in an EPICS C++ server to a LabVIEW shared variables using a set of complex configurations written in XML.

*lvPortDriver* [4] allows users to develop EPICS device support in LabVIEW code and to start an EPICS C++ server through the same LabVIEW program. This is possible through an *asynDriver* [5] C++ layer and a LabVIEW VI library. Although *lvPortDriver* inherits platform independence from EPICS but compilation and deployment are still needed for each specific NI target CPU architecture.

[6–8] employs shared memory between LabVIEW program and EPICS C++ server to interface EPICS with LabVIEW. Other than being in need to compile for each NI target architecture, these solutions are platform-specific and they are hard to port from one operating system to another.

*IRIO* [9], *Nheengatu* [10] allow developers to run EPICS on cRIO and other NI devices based on a middleware library that allows direct access to NI hardware, but it depends on the target architecture.

## EPICS-LABVIEW INTERFACE USING OPC UA

Figure 2: EPICS/OPC UA Architecture.

OPC UA provides seamless integration with EPICS. It is an open service-oriented protocol that can run on any hardware and operating system and thus provides a good fit for interoperability between EPICS and LabVIEW-based hardware.

Figure 2 shows how EPICS can interface with LabVIEW. The LabVIEW developer writes standard OPC UA code on the target device. An standard EPICS server can communicate to the OPC UA server running on the LabVIEW target using a device support module for OPC UA [11].

The OPC UA Device Support for EPICS provides the easy representation of hierarchical data structures, access control, and data monitoring. All standard data types for both input and output are supported. It adds an extra record type *opcuaItem* which allows representing OPC UA objects in EPICS by destructuring the OPC UA object to standard data types records.

The OPC UA server/client architecture abstracts the communication of EPICS with the cRIO and thus allows deploying a one-time compilation EPICS server on any commodity server or virtual machines or containers to add modularity, isolation, and scalability to the architecture.

## PERFORMANCE EVALUATION

To evaluate this architecture for slow control systems like KATRIN, we launch an OPC UA server on NI cRIO 9047 and then run an EPICS server running on a workstation with Intel Xeon CPU E5-1630 v3 @ 3.70 GHz and 1 Gbps Ethernet connection, and linked to the cRIO through the EPICS OPC UA Device Support module. The OPC UA objects in our experiments are represented using a flat data architecture: each process variable is represented by an OPC UA variable inside a distinct OPC UA object. We operate experiments by simulating sensors (read from cRIO to EPICS) and setpoints (write to cRIO through EPICS). Table 1 shows the experimental setup of 300 process variables based on the requirements of the KATRIN control system.

Table 1: Update Rate and Expected No of Elements for Each of the 300 Values

Update Rate	Exp. No of Values in 1 Hr.
10 Hz	36000
2 Hz	7200

### Sensor Mode

We launch two experiments for the sensor mode evaluation where, in both experiments, the OPC UA server on the cRIO is generating incremental values for each of the 300 process variables for a duration of an hour: (1) 2 Hz experiment, one value for each of the process variables every 500 ms; and (2) 10 Hz experiment, one value every 100 ms. The EPICS server is monitoring all the 300 variables in both experiments over one OPC UA subscription, then we use *PyEPICS*[12] to read the values from the EPICS variables through CA monitoring. The EPICS OPC UA Device Support is configured to use the timestamp from the OPC UA protocol.

In an hour interval, we noticed that the expected number of values for each record is attained. No loss of data in both 10 Hz and 2 Hz experiments.

### Setpoints Mode

We simulate setting values to actuators through EPICS and that are controlled by the OPC UA server. We then launch an EPICS client developed in C with real-time priority threads (one thread per process variable), as illustrated in Fig. 3. We want to check two metrics in this mode: lost values rate and response time (time delay between setting the value in EPICS and implementing the setpoint in the OPC UA server). This is possible through having two records for each EPICS process variable in the EPICS database: (1) the *ao* output record to output the variable to the OPC UA server using EPICS timestamp, and (2) the *ai* readback record to read the process variable values back using an OPC UA subscription and OPC UA timestamp. We then monitor both records; the loss rate is then computed by comparing values from both monitors (output and readback).

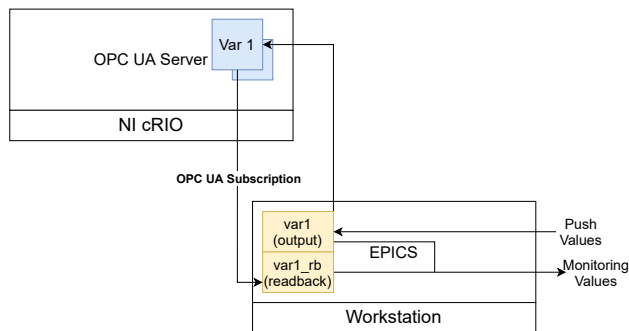

Figure 3: Setpoints Mode Experimentation.

Figure 4: Comparison of Data Loss between the Output Record and the Readback Record in 10 Hz Experiment for the 300 Process Variables.

While the loss at 2 Hz is zero in the output and the readback records, the loss rate at 10 Hz is zero for the output record but around 0.6% for the readback in an hour experiment interval which means EPICS has processed the setpoints very well, but the OPC UA server did not implement them. Figure 4 shows the loss rate of the output record using the output monitor and that of the readback record using the readback monitor.

## CONCLUSION

Using OPC UA protocol can be a good connection interface to integrate EPICS C++ code and NI LabVIEW-based hardware without a strong impact on performance for slow control systems. Comparing both 2 Hz and 10 Hz experi-

ments, we notice the performance is limited by the OPC UA server which depends on the performance of the cRIO or the system hosting it. Therefore, we plan to use this architecture for the KATRIN experiment where the maximum update rate is 2 Hz and can guarantee no data loss.

## Abstract

When integrating devices into a control system, the device applications usually contain a large fraction of error handling code. Many of these errors are run time errors which occur when communicating with the hardware, and usually have similar handling strategies. Therefore we extended ChimeraTK, a software toolkit for the development of control applications in various control system frameworks, such that the repetition of error handling code in each application can be avoided. ChimeraTK now also features automatic error reporting, recovery from device errors, and proper device initialisation after malfunctioning and at application start.

## GOALS AND REQUIREMENTS

If the business logic of a control application is intertwined with code for device opening and communication error handling, it becomes hard to read. Hence, this should be avoided. In an ideal case, the application programmer does not have to write any device handling code, and a framework takes care of all the necessary actions, reports faults to the control system and handles the device recovery. For this to work with many different kinds of devices, a sufficient level of abstraction is necessary.

- The framework has to provide a common API for all devices.
- The framework has to guarantee that the user code can always read and write all its variables, and therefore needs to separate read/write operations in the user code from the actual hardware access.

These are the two key places where the framework has to have an appropriate interface. The second point is a consequence of the fact that the framework is taking care of connecting to a device, initialising the device, reporting the connection status to the control system and propagating information about faulty connections.

## THE ChimeraTK FRAMEWORK

ChimeraTK, the *Control system and Hardware Interface with Mapped and Extensible Register-based device Abstraction Tool Kit*, is a framework for writing control applica-

tions. [1] An overview is shown in Fig. 1. ChimeraTK consists of three main components:

- The DeviceAccess library provides a common interface to different device types by introducing a backend plugin mechanism.
- The ControlSystemAdapter allows to integrate into various control system middlewares as a native application. [2]
- The ApplicationCore library connects many application modules, which make up the business logic, with the devices and the control system.

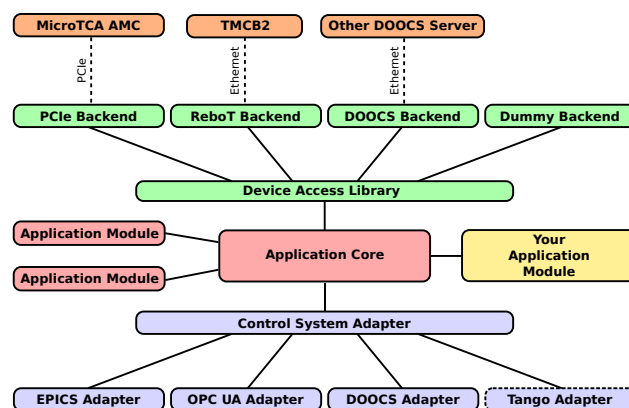

Figure 1: Overview of the ChimeraTK framework. All components connected with solid lines are part of the same executable.

All these components are part of the same executable. The C++-code written by the application programmer consists of application modules for ApplicationCore. ApplicationCore is interfacing to DeviceAccess and the ControlSystemAdapter internally. The user never directly interacts with these libraries on the C++ level. Which devices to use and the parameters for the control system integration are loaded from configuration files at application start.

## The DeviceAccess Library

The DeviceAccess library is the interface to various devices. The device usually is a hardware component which is being integrated into the control system, but it can also

\* martin.killenberg@desy.de

be another control system application. DeviceAccess comes with an extensible backend interface. Support for PCIe-express communication and a suite of dummies for unit testing are built into the base library. Backends for DOOCS [3, 4], OPC UA [5, 6] and Modbus [7, 8] are available as runtime-loadable plugins. A backend for EPICS [9] is currently under construction. [10] The plugin mechanism allows to easily add support for further devices and protocols.

An important abstraction step in DeviceAccess is the introduction of so called register accessors. These are objects representing a device register in the application. It contains a buffer with the data content, and read() and write() functions to synchronise the buffer and the device. Each of those registers is identified by a name. For numerically addressed protocols like PCIe-express or Modbus, a register name mapping is built into the library.

### The ApplicationCore Library

The main idea of ApplicationCore is to build the application from small, self contained application modules (see Fig. 2). Each module has a set of input and output vari-

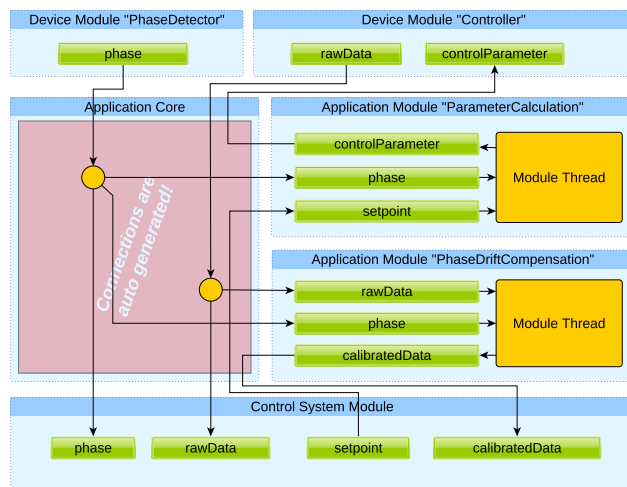

Figure 2: Applications written with ApplicationCore consist of self-contained application modules. Each module has its own thread and interfaces to the rest of the application via input and output variables. The connections of those variables to the device modules and the control system module are automatically generated by ApplicationCore.

ables and its own processing thread. All inputs and outputs are identified by a name, which associates it with a process variable that is part of the variable household of the application. ApplicationCore automatically connects the inputs and outputs of all components (application modules, device modules and the control system module) which access the same process variable. The code inside a module does not care where the data is coming from and where it is going to. Each module is completely self contained.

Under the hood the variables of the different modules are connected via lock-free queues, which makes ApplicationCore a multi-threading library with very effi-

cient, modern inter-thread communication. However, this is completely transparent to the user as there are no locks involved.

In ApplicationCore there are two kinds of inputs: Push-type inputs and poll-type inputs. Read operations of poll-type inputs return immediately and the variable contains the latest value. Read operations of push-type inputs block if no data is written. Once data is available, the reading thread is woken up. Typically each application module has at least one push-type input which the module thread is waiting for. Like this, the modules automatically synchronise with each other, without the need for locks or sleeps.

### The ControlSystemAdapter Library

While the DeviceAccess library is a client interface to the devices, the ControlSystemAdapter turns the application into a server which introduces the published process variables to the control system. It consists of the ControlSystemAdapter base library and a concrete implementation for a control system middleware. ApplicationCore is using the interface of the base library and is completely independent of the actual adapter implementation. The adapter implementation is linked as separate library.

For a proper integration into the control system of a facility, each adapter implementation comes with a mapping layer which allows to change the names of variables to match the facility's naming scheme or create special data types only available for the particular middleware protocol.

Currently ControlSystemAdapter implementations are available for DOOCS [11], EPICS 3 [12, 13] and OPC UA [14].

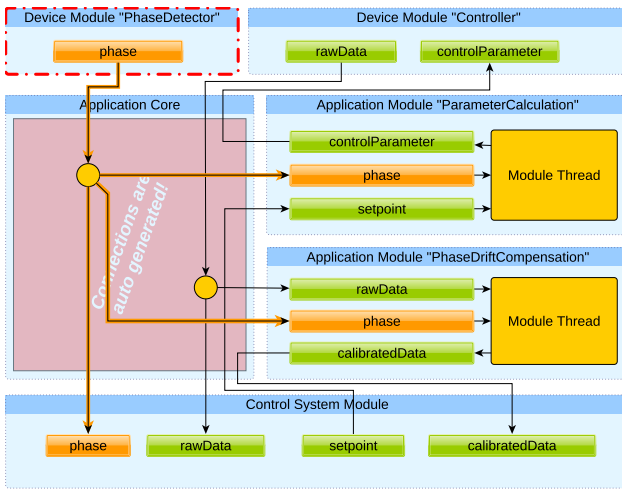

## EXCEPTION HANDLING AND DEVICE INITIALISATION

### Handling Faults

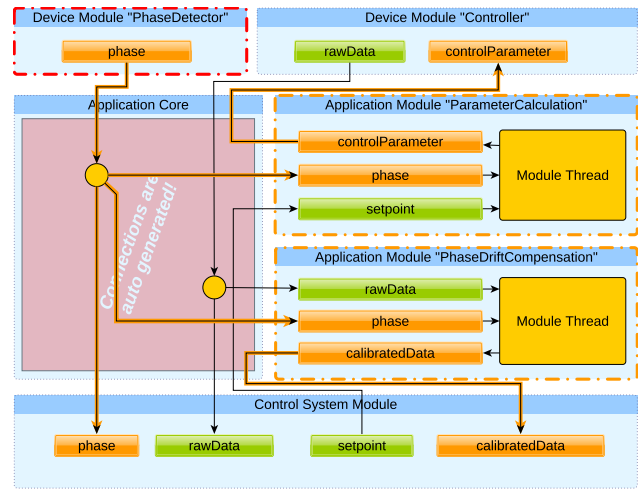

Once a problem, usually a communication error, has been detected in DeviceAccess, this is internally reported to the backend. The backend informs all register accessors about the fault. From this point on, all read() operations to poll type accessors and all write() operations will throw a runtime\_error exception when being called. All push-type accessors will send exactly one runtime\_error exception through the queue (instead of data), and then no further data is sent until the next value has been received after device recovery (see discussion in the ApplicationCore section).

Each device backend implementation is responsible for re-establishing the connection when its open() function is called again. Usually this means trying to re-connect via whatever protocol is used to communicate with the device. Like this, no special, device-dependent code is needed on the higher levels.

In ApplicationCore, the exceptions from the accessors are caught and handled. As the main point of the exception handling scheme is to keep the user code free from device handling code, the user code in the application modules must

(a) The device module “PhaseDetector” has seen a runtime error. All of its outputs are flagged with data validity faulty (orange).

(b) All application modules which have at least one input flagged as faulty automatically switch the data validity of all their outputs to faulty.

Figure 3: Propagation of the data validity flag in ApplicationCore.

not see these exception. The exception is reported to the device module, which in the background is trying to recover by periodically calling open() on the backend. At the same time the device status reported to the control system changes to *not functional*.

Without further actions, the application modules with the user code would not be aware that the device has a problem and that data is not updating any more. For instance if there are poll-type inputs for calibration parameters, which are read in addition to the push-type main data, the application module would keep processing data without noticing that the calibration parameter might be outdated. That’s why a mechanism has been introduced to automatically propagate a data validity flag in ApplicationCore.

Whenever an exception is caught in a process variable, the last good data value is re-sent with the data validity set to faulty (Fig. 3a). For push-type data this means, that the receiving module will be triggered exactly once. For poll-type data, the same value is read over and over again, but being flagged as faulty.

Application modules are small, self contained code blocks where all outputs logically depend on all inputs. This allows for an automatic propagation of the data validity flag: As soon as one input is flagged as faulty, all outputs of the module are also flagged as faulty. Like this, the flag is propagated for all data that is calculated from faulty inputs (Fig. 3b). Notice that in Fig. 3b the rawData from the “Controller” device is not marked as faulty, although one of the inputs of the device (controlParameter) is invalid. For device modules (and also the control system module) there is no automatic data validity propagation because they are not small, self contained units where all outputs logically depend on all inputs.

This mechanism covers the two possible scenarios: Modules which use the faulty data as their main data, which

means they read them as push-type input to synchronise their execution to it, are processing the data exactly once to propagate the data validity flag. Modules which use the faulty data as poll inputs keep running, but flag their data as invalid. A typical use case is the phase parameter in Fig. 3. The phase is a typically slowly drifting parameter which is used to calibrate the rawData. It is a safe assumption that the calibration is still approximately correct, and the facility can keep running with it, even if there is a short communication problem with the phase detector. The calculated calibratedData is flagged as faulty to indicate that there is a problem. If the problem persists, the calibration will become less and less reliable. The decision whether operation can continue with faulty inputs obviously is a case by case decision. Although usually the code in application modules does not care about the data validity because it is propagated automatically, the flag for each input is available, such that critical decisions that depend on data being valid can be done.

## Device Recovery

When a device can be re-opened successfully, the application and the device have to synchronise their states. The device might have re-booted, in which case many devices need to be initialised (reset-flags cleared, clocks set, dynamic ranges of ADCs and DACs adjusted etc.). For this to be automated, ApplicationCore provides the possibility to register a callback function. It is provided by the user code and executed immediately after the communication to the device is established. The parameters written in the initialisation phase often are implementation details of the firmware which should not be connected to the control system module. In this function the user code has direct access to the device and all of its registers, without adding process variables to the variable household of the application (in contrast to the

input and output variables of application modules, which are all visible in the control system due to the automatic connection code).

After the device initialisation function has been called, all output variables from the application to the device are written. This assures that the device and the application both have the same parameters everywhere. The device module remembers the last written value of each variable, so it can be restored in the device even if an output is not re-written by the application. This is especially important for parameters which are directly connected from the control system module to the device module. Obviously a user does not want to re-enter all parameters again in a panel after a device has come back online.

In a third step, all push-type data is fetched from the device and written to the application once. This data does not carry the data validity flag `faulty` any more, so the flag is cleared automatically in each module once all of its inputs are back to data validity OK.

Finally, after the device is initialised and all data to and from the device has been transferred once, the device status flag, which is reported to the control system, is set to OK as well. The application is back to normal operation.

### Application Start

At application start, all devices start as *not functional*, and the device recovery procedure is launched. In the section about automatic fault handling it was described that an application module keeps running, even if a poll-type input is flagged with data validity `faulty`. This is working under the assumption that the last good value can be used to continue operation, even if the value is not being updated any more. At the first start of the application, when no communication to the device is established yet, this mechanism is not working because there is no previous good value.

To solve this issue, the concept of an *initial value* has been introduced in ApplicationCore. All application modules require that this first, valid value has been received by all inputs before operation is started. This is assured by ApplicationCore, which only starts the user-written main loop once all initial values are present. Each application module starts by performing its calculation with these initial values, and writing its outputs before doing the first (blocking) read on any input. Subsequent modules now also get their initial values, and the application takes up operation in the correct order. The control system adapter is getting the initial values from the persistency layer of the control system middleware, and is sending them once at application start.

If a device is not available at application start, this means that parts of the application will not start running. This does not pose a problem, it rather is a feature. Only those modules which cannot calculate valid data anyway are waiting, and once these data are available, the sequence of propagating them is automatically started. Even if all the application modules would be waiting for initial values, this does not mean that the application is non-responsive. The commu-

nication on the control system side is always working, and the status which device is faulty is shown there. There is nothing more the application can do in this situation, except for waiting for the device to become available.

The start sequence for opening a device is the same as for the recovery case: Once the communication is working, the initialisation callback function is executed, then all process variables from the application are written to the device, and finally the initial values are read for all push-type variables and propagated.

Although it should be avoided, it sometimes is inevitable to have circular dependencies between application modules, which would mean that modules are mutually waiting for the initial value from the other module before they can send their outputs. This circle needs to be resolved manually. One of the modules has to send a safe start value on its output before receiving the initial values. This cannot be done automatically because only a programmer who knows the application logic can decide where to break the circle and which “safe” initial value to send. As unintended circular dependencies prevent a proper application start and are difficult to debug, ApplicationCore comes with a built-in circular dependency detection. If an application module does not receive an initial value until a timeout, it will print which variables are affected to simplify the debugging process.

## CONCLUSION

The ChimeraTK framework for the development of control system applications features the ApplicationCore library for the development of modular applications, which interacts seamlessly with the DeviceAccess library for hardware access and the ControlSystemAdapter for the integration into different control system environments. ChimeraTK has lately been extended with automatic device initialisation and exception handling. Special emphasis has been put in a clean initialisation and recovery procedure.

ApplicationCore based device applications are used to operate the low level radio frequency systems at several accelerators using different control system software (EuropeanXFEL [15] and FLASH [16] at DESY, Hamburg, using DOOCS; ELBE [17] at HZDR, Dresden, using OPC UA [18]; TARLA [19] in Ankara using EPICS3 and several others). The improved device handling and automatic re-initialisation has reduced the time and manual steps which are required bring the system back online after a major fault or maintenance period. This results in reduced downtimes and a higher availability and reliability of the whole facility.

The ChimeraTK suite is open source software which is published under the GNU General Public License or the GNU Lesser General Public License (depending on the software component). It is available under [20].

## Abstract

The Indian-based Neutrino Observatory collaboration has proposed to build a 50 KT magnetized Iron Calorimeter (ICAL) detector to study atmospheric neutrinos. The paper describes the design of back-end event builder for Mini-ICAL, which is a first prototype version of ICAL and consists of 20 Resistive Plate Chamber (RPC) detectors. The RPCs push the event and monitoring data using a multi-tier network technology to the event builder which carries out event building, event track display, data quality monitoring and data archival functions. The software has been designed for high performance and scalability [chronous data acquisition and lockless concurrent data structures. Data storage mechanisms like ROOT, Berkeley DB, Binary and Protocol Buffers were studied for performance and suitability. Server data push module designed using publish-subscribe pattern allowed transport & remote client implementation technology agnostic. Event Builder has been deployed at mini-ICAL with a throughput of 3MBps. Since the software modules have been designed for scalability, they can be easily adapted for the next prototype E-ICAL with 320 RPCs to have sustained data rate of 200MBps.

## INTRODUCTION

The Indian-based Neutrino Observatory (INO) collaboration has proposed to build a 50 KT magnetized Iron Calorimeter (ICAL) detector to study atmospheric neutrinos and to make precision measurements of the neutrino oscillation parameters. The detector will look for muon neutrino induced charged current interactions using magnetized iron as the target mass and around 28,800 Resistive Plate Chambers (RPCs) as sensitive detector elements [1]. The mini-Iron Calorimeter (mini-ICAL) detector, a prototype of the ICAL detector is being set up at the Inter Institutional Centre for High Energy Physics' (IICHEP) transit campus at Madurai. The mini-ICAL detector has 20 glass Resistive Plate Chamber (RPC), which act as sensors and are stacked in between 11 iron plates of 4 metre x 4 metre size. The iron plates are magnetised by passing electricity through copper coils wound around. This is expected to serve the purpose of understanding the engineering issues in constructing the main ICAL, and at the same time provide important inputs on the ICAL's operating parameters and physics measurement capabilities. E-ICAL with 320 RPCs is planned to be setup in Madurai, India. Max throughput expected for E-ICAL is around 200MBps with 10% hit rate and 10k trigger rate.

## SYSTEM OVERVIEW

The system consists of several sub-systems: RPC DAQs, Backend Data Acquisition System (BDAQ), Trigger System, Calibration System (CAU), Magnet System, Gas System, and LV/HV System as shown in Fig. 1. Description of each system is beyond the scope of the paper [2].

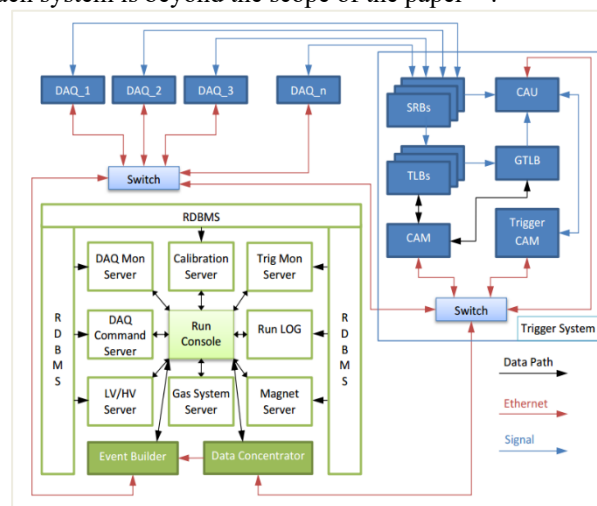

Figure 1: System overview.

Neutrino interacts with the iron plates along its line of travel, triggering events in several RPCs along its path. Orthogonal strip channels (X&Y) on RPCs pick up the charged particles, which are produced from the interaction of neutrino with iron plates. RPC-DAQ modules are connected in hybrid network topology to backend system. Trigger System detects events of interest and notifies RPC-DAQs to transmit event data event data which consists of strips hit and timing information over TCP socket to the designated Data Concentrator (DC) node. Data Concentrator nodes collect event data packets from all the triggered RPC-DAQs and assigns the timestamp and Event Number to the data packet. The updated RPC-DAQ data packets from the data concentrators are pushed to event builder

## Backend Data Acquisition System (BDAQ)

The BDAQ system as shown in Fig 2. comprises of several subsystems that are intended to acquire event data and monitor data from the RPC-DAQs. The system also provides event building, event display, data quality monitoring, data archival mechanisms and run manager. BDAQ is a distributed system consisting of several subsystems; Data Concentrator, Event Builder (EB), Run Manager, Data

Quality Monitoring, Data Visualization, Long term data archival. The scope of the paper is limited to the development of Event Builder module.

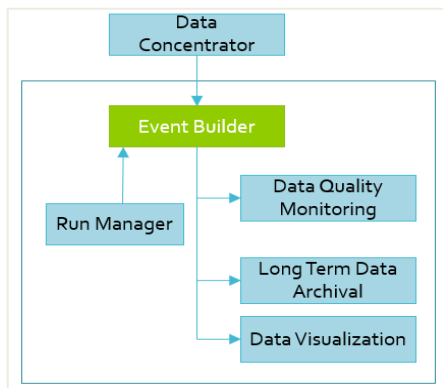

Figure 2: Backend Data Acquisition system.

## EVENT BUILDER

Each muon interaction triggers several RPC events; Event builder node is responsible for collating the individual RPC event data packets based on the event number and storing the built-event collection in the required data format. The main functional requirements of Event Builder software include:

- Event data acquisition from Data Concentrator;
- Monitoring of data from RPC DAQs;
- Event Collation from the RPC event data;
- Local data archival in the selected data format;
- Pushing the collated event data to remote consoles;
- Online muon track visualization.

## Software Architecture

The software has been developed following layered architecture as illustrated in Fig. 3. Communication layer implements Asynchronous TCP/IP module for receiving variable length RPC data from Data Concentrator, Data push module for forwarding the complete built event to the other remote nodes. The event building layer consists of Data Serializer that parses the data bytes to create valid message object which is binned into a concurrent data structure based on the event number. A high-performance lockless data structure has been used for event collation.

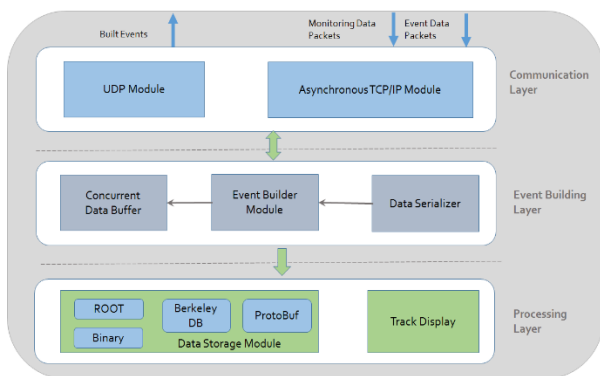

Figure 3: Software Architecture.

The collated event is published to Server push module and processing layer. Processing layer handles the storing the event in the required data format and displaying the track information. Data storage module implements different storage schemes; ROOT, binary, Berkeley DB, ProtoBuf and XML.

## Core Modules of EventBuilder

**Data acquisition module** Data acquisition provides high performance, catering to the system data throughput requirements. The module is optimized to eliminate any possible memory allocation overheads.

**Event building** Event building algorithm is crucial part of the software. Event building module collates the complete event from out of order RPC data. The module design implements the necessary concurrency control mechanism to handle multi-threaded data acquisition.

**Backend data store** The collated event is processed by back end store, archiving the data locally. Data storage module write throughput should satisfy required system throughput, otherwise it would create back pressure in acquisition pipeline.

**Server push module** Server data push module publishes the data to the interested subscriber nodes like data quality monitor consoles and data visualization consoles.

## Data Acquisition Module

In general, there are several IO models followed for developing network application, which are broadly divided into thread based and event based models.

**Threaded Server** Creating a thread per connection with blocking IO calls is the simplest solution for server application. This multi-threaded approach provides concurrent processing of requests. This approach is not scalable due to limited CPU/Memory resources

**Synchronous non-blocking IO** consists of a single threaded event loop waiting for the readiness of the multiple subscribed socket handles, and triggered socket events will be synchronously dispatched to the corresponding event handler. It is based on synchronous event demultiplexing mechanism. Although this approach can handle more number of sockets than thread-per-connection, but still this is not scalable.

**Asynchronous IO** is based on asynchronous event demultiplexing. The operations are initiated asynchronously by the application and they run to completion within the I/O subsystem of the OS. Once the asynchronous operation is initiated, the thread that started the operation becomes available. The completed events are inserted into completion event queue and Asynchronous event de-multiplexer removes the completed events and returns to the caller by invoking the corresponding completion handler. Concurrent Asynchronous Event Demultiplexer can improve the performance by making use of thread pool for demultiplex and dispatch completion handlers concurrently [3] [4][5].

The data acquisition module has been developed using multi-threaded *async* IO and is a state full TCP server that keeps track of all the clients connected to it. To reduce memory allocation/deallocation overhead, the server has a

pool of *SocketAsyncEventArgs*, which reuses the same object for every receive. Buffer Manager handles allocation with dynamic resizing keeping a pool data buffers. The complete message received is propagated to the next module in the pipeline through event trigger mechanism. The module has been implemented using F#. *Async* workflow in F# helped to improve code readability avoiding traditional call back approach. The use of functional features like Active Patterns and Pattern Matching improved expressiveness.

### Event Building Module

Event building is a multi-producer single consumer problem, where many RPC message events are being pushed simultaneously. The main responsibilities of the module include;

- Out of order individual RPC events need to be collated to form the complete event.
- Having a provision for accommodating the delayed events if any.
- Collated events propagation to the event processor module should be serialized based on the event number

Figure 4: LMAX Disruptor based ring buffer.

Event building module has been developed following LMAX disruptor algorithm [6] as shown in Fig. 4. Disruptor algorithm is based on a bounded ring buffer that allows multiple producer threads without using locking. Each item in ring buffer can hold a list of RPC events, so the ring buffer is a collection of collections. Putting the messages into the buffer is a 2-phase process. First the producer needs to claim a slot in the ring buffer. The sequence/slot number to claim is calculated from the event number, which gives access to a slot in the buffer and the event data is inserted into RPC collection based on RPC ID. All the events with the same event number are collected in the same event slot. The events occupy corresponding entry within a RPC collection based on RPCID. Hence, it does not require locking.

The event slot will be open for event collection until the buffer has no available slot or a timeout occurs. This gives provision for accommodating any delayed events. This event collation process continues for remaining events. A

new event claims an occupied slot by publishing the event occupying the slot and updating the cursor variable. Cursor variable tracks the next slot number available for event processing. The event processor handler will be notified which copies the published event data. The algorithm ensures the collated events are propagated to the event processor in order based on the event number. The size of buffer and timeout is calculated based on event trigger rate

### Backend Datastore Module

The following are the desirable features of backend data store

- Efficient data access, particularly data write speeds need to match with the max system throughput, as it would create back pressure in the system pipeline
- Cater to large sets of data to suit physics runs which continue for several hours
- Lightweight and embeddable to prevent inter process communication overhead
- Efficient object to event byte stream encoding to save disk space
- Columnar data access/vertical storage techniques that enables retrieving only the selected fields from event record without loading the complete event object
- Forward and backward message format version compatibility as the schema is likely to change over the time, but the archived old format data should still be readable
- Provide extensive querying and data analysis features

**Data storage schemes** The following data storage schemes were studied and implemented in the software.

- Binary Serialization: Event object is serialized to data byte stream including meta data describing the class. This is the simplest solution [7][8].
- XML: XML Serialization converts object public fields and properties to readable xml stream, which creates a verbose xml file [9].
- BerkeleyDB: This is a light weight embeddable data management library. The memory footprint is just 300KB, but can manage the databases up to 256TB in size. It is a NoSQL database based on key-value pairs. It runs in the address space of the application, hence no communication overhead and all the data access methods are defined through function-call interface [10]
- Google Protocol Buffers(ProtoBuf): It produces faster and smaller byte stream as schema is defined external to the data. It is based on base128 varint encoding. It can support data versioning [11]
- ROOT: CERN developed ROOT framework [12] has been used for event data archiving in mini-ICAL system. It is an Object-Oriented framework for large scale data handling applications. It provides efficient data storage and access system designed to support huge structured data sets. The main reason for choosing ROOT as a backend is its edge in analysis and visualization features.

## Server Data Push Module

There are other remote consoles that require the built events for track visualization and data quality monitoring. The server proactively pushes the data to the interested nodes without clients polling for the data. This supports implementation of remote consoles in a technology agnostic manner; browser based, web applications, desktop application or mobile application depending on the usage. This is met with the following design approach as illustrated in Fig. 5.

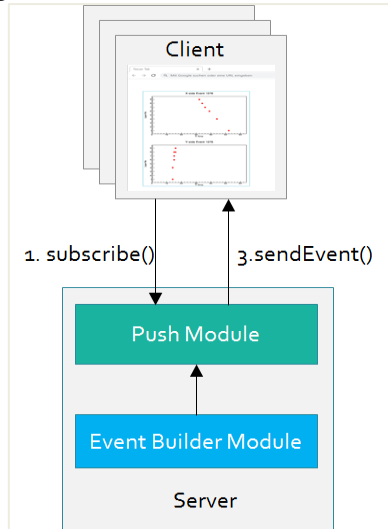

Figure 5: Server data push module.

The remote consoles get subscribed to the back-end server publisher module for various types of events and the server manages the clients into groups based on the subscription type. When the data is ready, the push module will publish it to all the subscribed nodes.

Instead of developing the transport mechanisms for HTTP/TCP from scratch, open source server push technology SignalR [13] is considered. SignalR creates persistent connection between client and server and pushes the server content to clients instantly. It is an abstraction over http and TCP protocols. It supports the following transport techniques for handling real-time communication; http transports websockets [14], SSE, Long polling. Out of which, websockets provide bidirectional persistent communication. if websockets is not available, SignalR falls back to next transport method, based on the capabilities of the server and client

## PERFORMANCE

Event builder with all the integrated modules (acquisition, data serialization, event building, event store modules) has been tested for performance with various data storage types. The test setup consists of multiple DC simulator clients sending data to EB server on 1 Gbps Ethernet link. It was observed binary data and BerkeleyDB write throughput was considerably better than ROOT as shown in Fig. 6. With the designed ROOT TTree structure, the write speed observed was around 8MBps due to the write overheads (file meta data). With mini-ICAL, the maximum

throughput requirement is around 3MBps. However, due to efficient columnar data access and data visualization, ROOT has been used for data archiving.

Storage Type	Throughput
Binary Data	~90MBps
ROOT	~8MBps
BerkeleyDB	~90MBps

Figure 6: Performance.

## TESTING & INSTALLATION

The software was functionally tested with Data concentrator simulator & Front End Electronics (FE) simulator at BARC lab with all the modules integrated to verify the throughput and data validity. The software was installed at IICHEP, Madurai for mini-ICAL. It has been recording data since 2017.

## CONCLUSION

The modules have been developed with scalability as design concern. Asynchronous IO based data acquisition module is scalable with the increasing the number of connections. Disruptor algorithm based event buffer provides lock-less data structure for event building. The optimized data structure can be scaled to work for E-ICAL by tuning the buffer parameters.

Non-blocking multi-threaded networking and event building module has been tested up-to 90MBps on 1Giga bit Ethernet network. The required network throughput (200MBps for E-ICAL) can be achieved by upgrading the hardware resources (like 10 Giga bit network and SSD drives). For improving the data write speeds, multi-threaded file writing, multi-level data writing and high performance NoSQL databases like BerkeleyDB will be explored.

## ACKNOWLEDGEMENTS

Authors would like to thank the colleagues from TIFR, Mumbai for their suggestions and guidance.

# CONTROL SYSTEM OF A PORTABLE PUMPING STATION FOR ULTRA-HIGH VACUUM

M.Trevi<sup>†</sup>, L.Rumiz, E.Mazzucco, D.Vittor, Elettra Sincrotrone Trieste, Trieste, Italy

## Abstract

Particle accelerators operate in Ultra High Vacuum conditions, which have to be restored after a maintenance activity requiring venting the vacuum chamber. A compact, independent and portable pumping station has been developed at Elettra to pump the vacuum chamber and to restore the correct local pressure. The system automatically achieves a good vacuum level and can detect and manage vacuum leaks. It has been designed and manufactured in-house, including the mechanical, electrical and control parts. By means of a touch screen an operator can start all the manual and automatic operations, and monitor the relevant variables and alarms. The system archives the operating data and displays trends, alarms and logged events; these data are downloadable on a removable USB stick. Controlled devices include two turbomolecular pumps, one primary pump, vacuum gauges and one residual gas analyser. The control system has been implemented with a Beckhoff PLC (Programmable Logic Controller) with RS-485 and Profibus interfaces. This paper focuses in particular on the events management and object-oriented approach adopted to achieve a good modularity and scalability of the system.

## INTRODUCTION

Sometimes sectors of the accelerator vacuum chamber need maintenance or updates requiring venting, but when they have been carried out it is necessary to create ultra-level vacuum conditions to go back to normal operations.

At Elettra, ultra-level vacuum is usually created locally using a pumping station with on electromechanical logics on board (relays, mechanical timers, etc.). The main disadvantage is that it is not programmable and in case of failure it can stop without any information about the reason (for example a mains interruption due to a thunderstorm). Another disadvantage is that, due to its dimensions, the system is not easily moveable inside the accelerator tunnel. These issues led us to design an automatic and autonomous system managing entire parts of the system: alarm management, operator interface, archiving of variables and events like commands, value changed, etc. An important requirement was the compactness of the entire system that has been achieved by suitable choices of mechanical, electrical and automation components. Moreover another feature that we wanted to reach was the possibility to record log and trend.

PLC, I/O boards and wirings are contained in a 3-unit rack (~180 mm height). The controller based on a Beckhoff CX5120 PLC is compact with very good heat dissipation. The Beckhoff development environment feature an IDE and OOP (Object Oriented Programming) capabil-

ities. An Exor panel has been chosen as HMI.

For the development of the software we have taken inspiration from a template on the Beckhoff site based on OOP [1]. We chose to create OOP syntax in order to be independent on that of the manufacturer. In this way it should be possible to move the software to other controllers. We have assumed that these controllers implement structured text and that a function block can be divided in actions.

The OOP paradigm is mainly based on three principles:

- *Encapsulation*: the internal state of an object can be modified by a public method.
- *Inheritance*: a child class can derive and redefine methods from a super class. The inheritance defines a hierarchy between classes; the mechanism is static and defined at compilation time.
- *Polymorphism*: it is a dynamic mechanism used at run time. If a class has a method  $m()$  and one subclass (child) redefines  $m()$ , the polymorphism allows executing an  $m()$  version according to which kind of subclass object is calling it.

In the PLCs software classes are implemented by Function Blocks (FB), as defined in the IEC 61131-3 standard [2]. The instance of a FB is equivalent to the object of a class. The standard mentions typical keywords of OOP like *methods*, *extends*, *implements*, etc. We have not used these elements in order to comply as much as possible with other kinds of controllers that do not implement these keywords. *Methods* are replaced by dividing the FB code in several independent parts called *actions*. *Extends* are replaced by writing FB I/O interfaces in order to implement the same concepts.

Another important aspect of the design was alarms and commands management. An alarm can be configured in order to allow the following actions: auto-reset, acknowledge and recording. A command can be recorded by means of the PLC logging system or by the *audit trail*, which is a logging mechanism provided by the HMI. In this log the HMI writes setpoint changes, commands sent to the PLC and it tracks who did what. This feature is widely used in industrial systems [3]; adopting it is particularly easy to save and move log files outside the system for data analysis.

All the system configurations can be easily changed many times during the design and commissioning of the software using a form which we have designed in C# VS2015. The result of this form is written in an XML code to be imported in the file system of the HMI project.

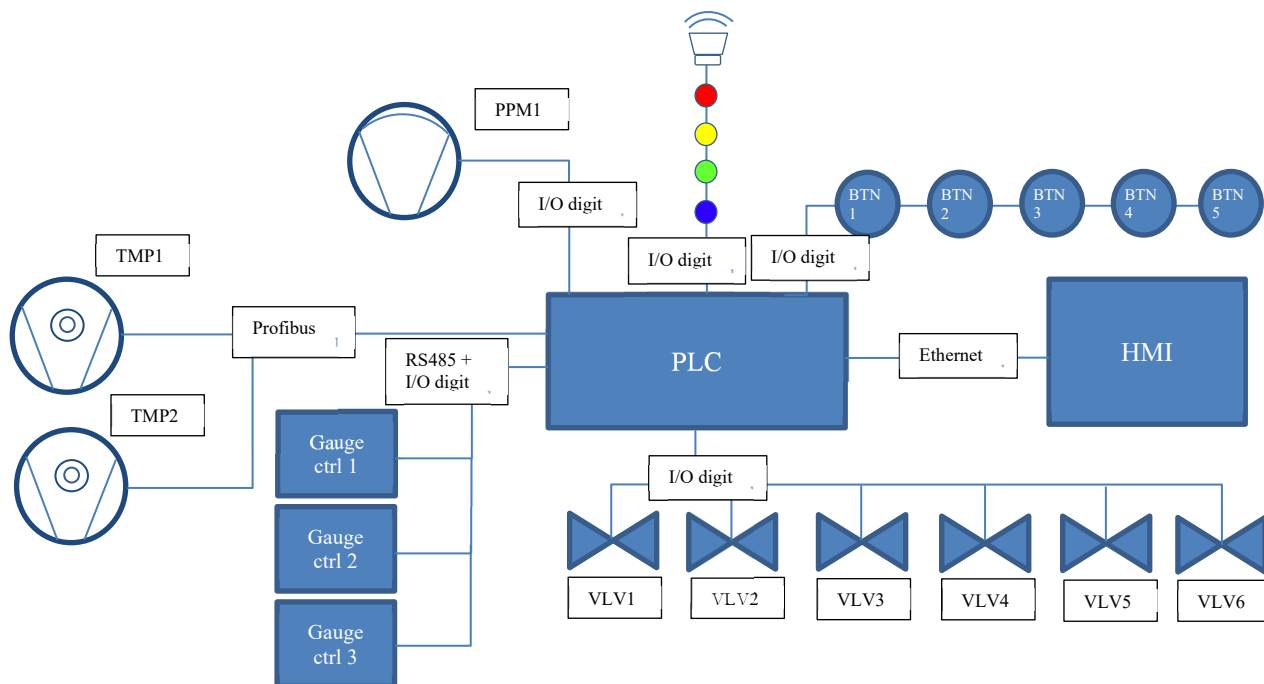

Figure 1: Architecture.

## BRIEF DESCRIPTION OF PROCESS

When a vacuum chamber is installed in the accelerator it has to be brought to ultra-high vacuum conditions ( $\sim 10^{-9}$  mbar). This process is divided into three steps, corresponding to three different vacuum levels and three different kinds of vacuum pumps to be used:

- *Primary pump* (Primary Pump Motor - PPM): starts creating flow vacuum;
- *Turbomolecular pump* (Turbomolecular Pump Motor - TPM): can create high vacuum, in the range  $10^{-6}$ - $10^{-8}$  mbar;
- *Ionic pump* (SIP): allows reaching the target of  $\sim 10^{-9}$  mbar.

The system described in this paper uses the first two kinds of pumps. We have implemented following two features:

- *Leak test*: the test to search for leaks in the vacuum chambers. It is performed by means of a leak detector connected to the vacuum chamber and using helium as a tracer gas; the helium gas has a very small monatomic molecule that can easily penetrate even the smallest holes that the external atmosphere put in contact with the internal vacuum;
- *Residual Gas Analyser* (RGA): instrument that analyses the residual gases inside the vacuum chamber once it has been pumped to a given level. It provides information on the presence of any vacuum leak or contaminants, and on the quality of the vacuum chamber cleaning. Moreover, during some laboratory or industrial processes, it can identify and follow the trend of the partial pressures of the gases introduced into the system (pure gases or mixtures).

The system can be switched in manual and automatic mode. In manual through the HMI it is mainly possible to command valves and pumps and to set the device configurations. The system will normally be used in automatic mode: this means that when an operator pushes the automatic start button, the PLC automatically sends commands to valves and pumps in order to reach the target pressure.

## ARCHITECTURE

Figure 1 shows complete architecture of system. Hardware and software details following.

### Hardware

The PLC communicates via Profibus with the turbopump controllers (TMP) and via RS485 with the controllers of the vacuum gauges. The HMI screen is interfaced via Ethernet and the other devices (primary pump, valves, buttons and traffic light) are connected via digital I/Os. In addition, the gauge controllers provide threshold contacts to warn the PLC of any anomaly on the pressure with faster response time.

The traffic light has the following components and meanings:

- *Buzzer*: activated when at least one alarm has to be acknowledged;
- *Red light*: activated when there is at least one alarm;
- *Yellow light*: activated when there is at least one warning;
- *Green light*: if continuous it means that the machine is in automatic mode, if blinking it means that the cycle has started;
- *Blue light* - means that the machine is operating in manual mode.

## PLC Software

The main idea has been to divide each task in a number of smaller subtasks. This principle is widely adopted for example for FBs and commands that a device has to execute.

The pumping system is divided into zones which have a logical and process meaning. As shown in Figure 2 the system is divided in 5 zones: *A*, *B*, *C*, *D* and *E*. A zone is defined as the part of the pumping system that can be sectioned by valves. Only the main PLC program can interact with the zone I/O interfaces, which can include other devices interface of FBs like sensors and pumps. In this way this implementation allows to comply with encapsulation.

The main code of this kind of FBs is empty because they are divided in actions. Every action has a task which can:

- be executed by an external command; in this case we call it a *method* or
- expose FB object states to the program or
- interact between internal actions.

The action that implements a command has three features compliant with the method principle:

- call derived FB (class);
- can add code after calling derived class if necessary;
- does not call the derived class in case of rewriting action (override).

These features allow the implementation of *inheritance* and *methods override*.

Figure 2: P&Id Process and Instrumentation Diagram.

## OBJECT MODELING

The UML-Class Diagram has been used to model the machine devices.

### UML (Unified Modelling Language)

UML [4, 5] is a general-purpose, modelling language in the field of software engineering, which is intended to provide a standard way to visualize the design of a system.

A class diagram is a type of static structure diagram that describes the structure of a system by showing:

- classes;
- attributes;
- operations (or methods);
- relationships between objects.

In the Figure 3 we can see that the boxes (FB/class) are connected by different kinds of arrows and lines:

- dashed line with arrow means that there is an association like a dependency between classes; the depend-

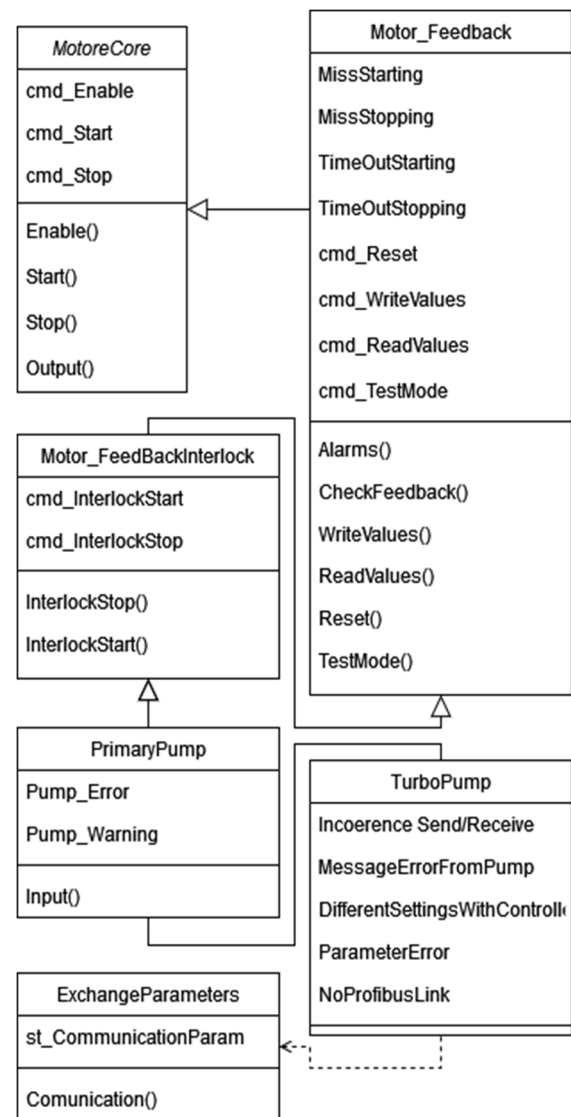

Figure 3: UML - From MotorCore To Pump.

ent class object might use an object of another class in the code of an action/method;

- solid line with arrow means that there is a generalization between FB/class, so there is an inheritance.

The boxes are divided into three parts: on the top we have the name of FB/class, in the middle we have the attributes managed by FB/class, at the bottom we have the actions/methods.

### Devices Modelling Example

In order to respect the OOP paradigm, the design of machine device FBs starts from a generic FB (superclass) which is then adapted according to the requirements.

Figure 4 describes the machine model where we can observe the OOP paradigm application in a logical class.

Figure 3 shows the pumps description and the derivation from a generic FB (superclass) of two derived classes: primary and turbomolecular pump FB. They are derived from *Motor\_FeedBackInterlock*, which means that primary and turbomolecular pumps have interlock features to start and stop, but also *Motor\_FeedBack* and *MotorCore* features.

We would like to underline that a simple push button can be modelled by an OOP paradigm. In our case we have a button with a LED frame and therefore we start from a button that has the electric input (*ButtonCore*) and we derive the *ButtonLight* that has a feedback too.

Figure 4 shows how the machine has been modelled: the machine is divided in zones. A zone can be enabled by a command as well as a device. Every zone has at least one *Pirani* sensor and so *Zone\_Pirani* has been derived from *Zone\_Core*. From this point there are other three derived FB/classes in order to respect their composition. As explained in the UML chapter different kinds of lines and arrows show different relationships between classes.

Note that, for example, *Zone\_Pirani\_TP* is derived by *Zone\_Pirani* but depends on *Turbopump* class that is modelled in Figure 3.

We can also see this modelling from a P&Id (Process and Instrumentation Diagram) schematic as in Figure 2.

Figure 4: UML Machine Model.

In this way we can check matching between a mechanic based scheme and a UML scheme.

### FB I/O INTERFACE

Every FB interface that describes something to be displayed on HMI has been designed in order to have the same interface both for a logical or physical type. In addition, it was decided to have a minimum common set of commands and states to be managed in the same way at HMI level.

Having the same interface is useful to organize information to and from a FB. We have divided them in:

Inputs:

- Physical input, connected to PLC boards;
- General input: Boolean, numbers and strings;
- General input: Boolean, numbers and strings used in test mode;

Output:

- Physical output, connected to PLC boards;
- Logical status: represents the status of objects described by FB;

In/Out:

- Alarm;
- Command: corresponds to executing an action/method;
- Data: every kind of number that represents for example thresholds, timers, parameters, configuration, etc.

In/Out variables have been necessary to allow FB/classes to change variables value both inside and outside the code. Note that an Input variable has a part dedicated to TestMode which means that this variable is used when a simulation is running and the object is in TestMode. Simulation is very useful before the commissioning to test automatic cycles, behaviour in case of alarms, etc. Another point to take into consideration in this kind of interface organization is that in the code you can manage devices or logical parts in the same way: they have enable commands, read/write value actions, alarms

and warning statuses.

Regarding the second choice, in order to have a minimum common set of states and commands, let's consider for example that we want to reuse the management of an object visualization and therefore, according to the status of an object, display the following states common with different colours:

- *Alarm* in red;
- *Warning* in yellow;
- *Run* in green;
- *Testmode* in blinking blue;
- *Disabled* in light grey;
- *No link* in blinking yellow.-

ALARM AND COMMAND SETTINGS

Another important design choice was how to manage the setting of alarms and commands. In fact, every alarm and command is represented by a 16-bit word to define the configuration. One of the mandatory requirements of the project was the possibility to log and record alarms and actions. Also, anomalous events must be recorded, for example a short black out.

The idea is to have a central logging function in the PLC that is called each time an event happens; examples are a button pushed by an operator or a device that changes state to alarm. An alarm can require an acknowledgement by an operator or be reset automatically. Moreover, an alarm or a command can be logged/recorded. A state associated to each alarm defines if it is active and if an acknowledgement is required. For these reasons the 16-bit word representing an alarm or a command is divided into two parts: 12 bit for the configuration, 4 bit for the state. In this way each alarm and command is represented by a number from 0 to 65535.

While logging is managed by the PLC for example with a circular buffer, the recording action is more complex. To do that we have used the audit trail feature of the HMI, while another feature of the HMI has been employed to acknowledge alarms. For this purpose, a graphical interface using a form written in C# VS2015 has been developed. The form analyses the dictionary created by the HMI. The dictionary is a XML list where tags are described by name and address information. There is a table where it is possible to put the tag name to be found and its setting number. There are some buttons to create tag and alarm files in XML format. According to this number the code configures alarms and tags with the appropriate XML setting based on the specific IDE language. Figure 5 and Figure 6 show an example of setting values contained in a Windows form and the effects on the XML code; the code 52224 is used to configure an alarm to be resettable and acknowledgeable.

```
<requireAck>true</requireAck>
<blinkTxt>false</blinkTxt>
<requireReset>true</requireReset>
<actions>
<macroAction actionFunction="setBit" parameters="XTOP7M/GVL/g_st_Alarms/st_Zone_C/st_TP/ui_MissStarting;
</actions>
<useractions>
```

Figure 5: XML extract.

Figure 6: Part of Windows Form.

FUTURE IMPROVEMENTS

There are a number of features that have not been implemented yet because this system is a prototype, but will be taken into account in future implementations.

For example, it would be useful to provide a TCP/IP interface to receive commands and send data via *Tango* for remote panels. Furthermore, there would be the possibility of a *VNC* connection by a remote host with a server on the HMI.

Other features that we want to implement are automatic interlock messages: for example, if we want to open manually a valve that cannot be opened or if the start button is pressed and the cycle does not start, a message should appear to show the reason to the operator. In this way it would be possible to create a troubleshooting system to help the operator to make the right operation to fix the problem and start the system faster.

Moreover, we would like to consider converting the present PLC program in order to use Beckhoff OOP keywords and eventually evaluate improvements in terms of complexity and performance in the two solutions.

Finally, it would be useful to design a superclass for generic serial communications to allow deriving from it the Profibus and RS485 classes.

# EPICS BASED HIGH-LEVEL CONTROL SYSTEM FOR ESS-ERIC EMITTANCE MEASUREMENT UNIT DEVICE

M. Giacchini, M. Montis, INFN-LNL, Legnaro, Italy  
C. Derrez, J.P.S. Martins, R. Tarkeshian, ESS-ERIC, Lund, Sweden

## Abstract

The European Spallation Source (ESS) [1] will be a neutron source using proton beam Linac of expected 5MW beam power [2]. The beam commissioning of low energy beam transport (LEBT) started on 2018 and currently expected to reach to the end of Medium Energy Beam Transport (MEBT). Several diagnostics are installed to characterize the proton beam and optimize the beam matching in radio frequency quadrupole (RFQ) section and rest of accelerator. Among all diagnostics, Allison scanner and Slit-Grid type emittance measurement units (EMUs) will aid by characterizing the beam in transverse plane (both horizontal  $x$  and vertical  $y$ ) in LEBT and MEBT, respectively. Here in this paper the Slit-Grid EMU is explained and the software layer developed in EPICS [3] and realized to orchestrate the entire apparatus and control the different sub-systems will be described.

## INTRODUCTION

The emittance measurement unit (EMU) aims to measure the transverse emittance by sampling the transverse phase space. At European Spallation Source (ESS) the Allison Scanner and Slit-Grid EMUs will be used to characterize the proton beam transversely in keV and MeV energy ranges, respectively. The Slit-Grid units, designed and delivered by ESS Bilbao [4], are installed in both transverse directions in MEBT, in order to characterize the beam after RFQ, see Figure 1. According to the baseline parameters, the MEBT will operate with peak current of 62.5 mA, energy of 3.63 MeV and RMS size of 2 mm. The Slit-Grid will be used to optimize matching of the beam to the other sections of the accelerator.

Considering the control system aspect, a single EMU device is composed of different sub-systems (acquisition, motion, etc.) which are harmonized and managed by EPICS, the distributed control system framework adopted as standard for the ESS Project. This article reports the upgraded on low-level and high-level control system.

## EMITTANCE MEASUREMENT

The transverse emittance is an invariant quantity describing the distribution of the particle beam in transverse phase space (horizontal  $x$  and vertical  $y$ ).

The RMS emittance formula commonly used is the following:

$$\varepsilon_{RMS} = \sqrt{\langle x^2 \rangle \langle x'^2 \rangle - \langle x \cdot x' \rangle^2} \quad (1)$$

where  $\langle x^2 \rangle$  is the variance of the particle's position,  $\langle x'^2 \rangle$  is the variance of the angle the particle makes with the direction of travel in the accelerator and  $\langle x \cdot x' \rangle$  represents an angle-position correlation of particles in the beam.

Figure 1: Scheme showing the Emittance measurement using Slit-Grid EMU. Source: Cheymol, R. Miyamoto, "Preliminary Design of the ESS Slit and Grid System"

## INSTRUMENT DESCRIPTION

A Slit-Grid EMU is composed of a slit and a grid unit, mounted on separate moving actuators to scan the beam entirely. The slit samples small slices from the beam at almost equal position following drift space, the angular distribution of the particles is transformed into a position distribution and sampled using a profile monitor, in our case a secondary emission grid. By scanning the slit across the beam, the whole phase-space is reconstructed, see Figure 2.

Figure 2: Phase-space sampling using a slit-grid system. Source: B. Cheymol et al., "Design of a New Emittance Meter for Linac4"

Particular aspects and design solution adopted are the following [5]:

- For the EMU slit, it was shown that graphite is the chosen material to withstand irradiation. As consequence two graphite plates that form the slit are mounted in the slit head
- The EMU slit is designed in order to scan all the beam aperture. Since the beam envelop is  $\phi 40$  mm,

- the blades width has to be  $>40$  mm, for a total height  $>80$  mm. therefore the design for the graphite plates is plates of 40 mm x 54 mm x 3 mm;
- For the slit, the reference values are an aperture of 100  $\mu\text{m}$  and a slit thickness of 200  $\mu\text{m}$
  - The distance between the Slit and the Grid is 400 mm.
  - The grid has 24 tungsten wires, 35  $\mu\text{m}$  diameter and the pitch of the grid is 500  $\mu\text{m}$ .
  - The resolution of the actuators is at least 25  $\mu\text{m}$ .
- The hardware described is shown in Figure 3.

Figure 3: Slit and Grid devices composing the EMU apparatus.

## HARDWARE AND SOFTWARE ASSUMPTIONS

The EMU system has been designed in order to satisfy the ESS-ERIC requirements in terms of hardware and software standardization. In particular the system is following these criteria.

### Hardware

According to the diagnostic apparatus, it is possible to observe two different functional systems: motion and data acquisition [6].

The EMU motion system is actuated with stepper motors, controlled by a motion controller; slits (horizontal and vertical) and grids (horizontal and vertical) will be stepped across the beam with separate stepper motors (for a total of 4 axes). Two pair of limit switches are installed on each EMU actuator, one for the motion control system, and the other one for the Beam Interlock System.

The EMU data acquisition is devoted to acquire signals from the grid sub-system and provide the information to the high-level software layer designed to elaborate and provide the emittance measurement. The hardware related to the acquisition is composed by an analog front-end for signal conditioning and a digitizer board; in addition to the acquisition chain, a bias voltage supplying line is applied to the grid and an Event Receiver Timing board is required to synchronize the acquisitions with the accelerator global timing.

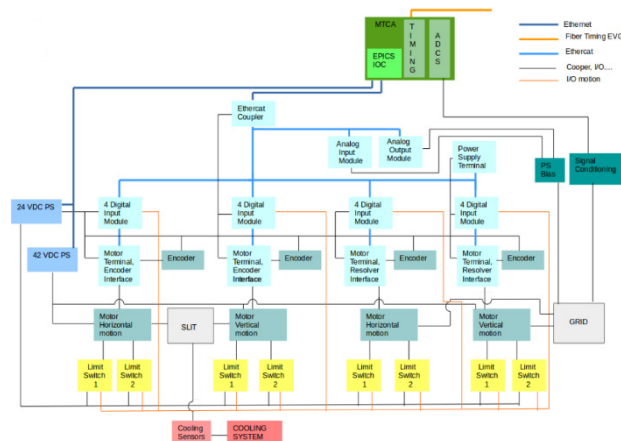

Figure 4: EMU hardware scheme. (Source: I. Mazkarian, "EMU Development Document" [6])

According to the ESS-ERIC guidelines, these two systems are based on Beckhoff® EtherCAT modules [7] for the motion and  $\mu\text{TCA}$ ® standard for data acquisition [8]. The main schema related to the hardware is shown in Figure 4.

### Software

The ESS-ERIC project has adopted the EPICS framework as standard to develop, implement and control the entire facility.

The structure of the control system framework has passed some evolutions in the past years in order to create and provide a solid architecture easy to use and maintain. This aspect is absolutely important in a project where stakeholders' contributions and the final maintenance in charge of ESS-ERIC internal staff are crucial points.

In order to satisfy these requirements, the last solution provided by the project is the ESS EPICS Environment (E3): it is a design concept and a toolkit intended to facilitate development by abstracting away some of the low-level complexities intrinsic to large EPICS implementations (primarily dependency management), and to allow for more manageable quality control of released modules as well as Input/Output Controllers (IOCs). It allows to easily build EPICS modules directly from source and automatically resolves module dependencies, and allows for site specific modifications to EPICS modules without needing to directly modify the source tree [9].

The entire software implemented for the EMU system and described in this contribution is entirely based on the E3 framework.

## CONTROL SYSTEM ARCHITECTURE

The EMU device (hardware and software) was originally provided by ESS Bilbao. Under software aspects, the EMU application was not developed using the last E3 environment but with a previous version of the framework. As consequence, several incompatibilities were inherited in the application and a renewal was mandatory; at the same time, additional requirements came up and they had to be developed from scratch. For this reason, a complete software re-design has been done.

The main conditions and requirements considered at this stage were:

- The entire software application must adopt E3 framework. This includes both low-level layer (hardware driver interfaces) and high-level layer (pure software application);
- Slit and Grid axes must be synchronized with data acquisition;
- The algorithm defining the logic in the high-level layer must consider the following set of information as inputs for the emittance measurement:
  - Slit/Grid plane control
  - Slit start position
  - Slit end position
  - Possibility to provide step size or number of steps (per slit position)
  - Grid micro-steps
  - Possibility to operate in *yaw* mode (slit and grid move in sync with a prefixed offset)
  - Number of samples per acquisition
  - Acquisition rate
  - Number of pulses per position
- The algorithm must include the possibility to use pre-calculated slit/grid position instead of providing start and stop positions;
- The entire measurement campaign must be stored in NeXus [10] data format.

Because the software update involves both external contributor (in-kind partner) and internal ESS-ERIC staff, a big constraint in the development stage was related to the necessity to rewrite the entire system application (high-level and low-level software) in parallel by different groups in different places: while the INFN partner was in charge of realizing the high-level control software, ESS-ERIC was in charge of the low-level software migration to the new standard. With this work organization, tasks coordination and teams' communication are crucial to rapidly get progresses.

In order to execute the different upgrades in parallel, a modular approach for the software architecture was adopted: according to the scheme represented in Figure 5, the entire system is composed by 3 main modules:

- Data acquisition (low-level)
- Motion (low-level)
- Experiment supervision and Emittance calculation (high-level)

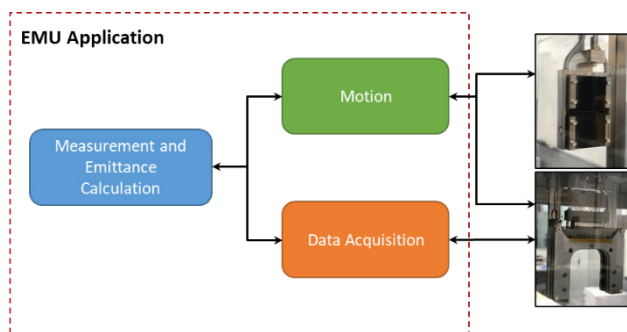

Figure 5: EMU software schema adopted during the application development: it is possible to observe the low-level applications (Data Acquisition and Motion) and the high-level orchestration.

While the driver software interfaces were under upgrade, dedicated simulation mockups were developed in order to provide a set of “black box” applications devoted to simulating the real hardware (Figure 6).

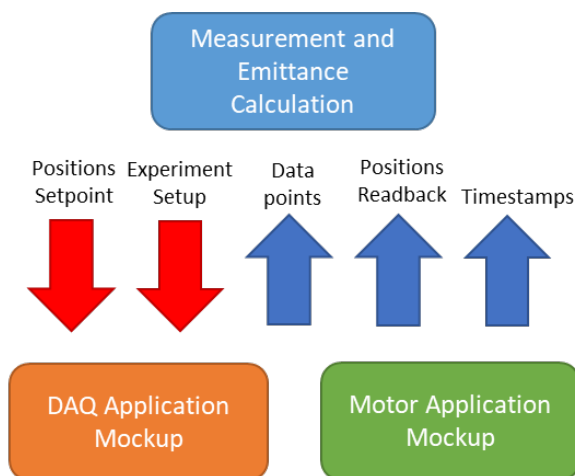

Figure 6: EMU low-level mock-ups used to simulate data acquisition and motion hardware.

## LOW-LEVEL SOFTWARE UPGRADE

The data acquisition software layer used in this project is the same that has been used for all the beam instrumentation systems in ESS and it's based in areaDetector drivers. The low-level driver is implemented as an NDAarrayPortDriver class, which provides the raw analog data as NDAarrays that are further processed by a series of areaDetector plugins. The result of the process chain is the average of the current in each wire of the grid, calculated over a region of interest.

For the motion control, the low-level software is implemented using ECMC [11] framework, the standard platform for the accelerator systems in ESS, built as the software support for the Beckhoff hardware system. ECMC provides the high-level access of the motion system using the EPICS motor record, alongside many other features like the “PLC objects”: pieces of code in ExprTK [12] language that are loaded inside the EtherCAT master kernel

module and can perform tasks like the automation of the axis homing procedure, protection routines, etc...

## HIGH-LEVEL ORCHESTRATION APPLICATION

The high-level orchestration layer is a pure software application and it defines the core part of the emittance measurement. In particular it is in charge of:

- Provide the interface between the system and the user;
- Coordinate data acquisition and motion systems;
- Calculate the beam emittance and all the relative parameters required by the user;
- Collect all the experimental data and store it via NeXus service.

One of the assumptions chosen for the application's design was to create a unique program which does not use any kind of external script or tool. The idea behind this assumption was to provide a standalone portable EPICS application. In order to follow this approach, the high-level orchestration program has been composed by the following parts:

- A set of state machine programs used to coordinate the low-level functional sub-systems;
- A set of EPICS Databases devoted to map the information exchanged between high-level and low-level and between application and final user;
- Additional custom C libraries used to implement particular functions required by the application and not available in the standard one.

The core of the main application is the set of state machines: using the common Sequencer EPICS module, different SNL programs were defined [13]. A main state machine is dedicated to control the system, taking in charge of capturing the measurement scan parameters, execute preliminary checks, coordinate and synchronize motion and data acquisition, elaborate the data coming from the field, execute emittance calculation and send the information of interest (measurement raw data and metadata) to the NeXus service. Secondary state machines have been created in order to operate minor functionalities, such as parameters calculation for measurement setup and optimization (conditions checks).

Because of the estimated size of the data of the measure campaign (number of acquisitions, samples acquired per wire, etc.), one critical point the SNL program had to manage was the allocated memory at application start-up, coming up with the definition of multi-dimensional arrays used to manipulate sets of signals coming from the field. In order to overcome this possible critical point, 2 different elements had been used in the SNL program:

- The signal coming from the DAQ system were preliminary manipulated via EPICS AreaDetector [14] and a set of its plugins: Processing plugin, ROI plugin and Stats plugin (Figure 7);

- Custom C functions devoted to define pointers, data structures and all the calculations required by the measurement campaign. These functions were grouped and managed as local library and inherited in the SNL program through the *Escape to C Code* mechanism.

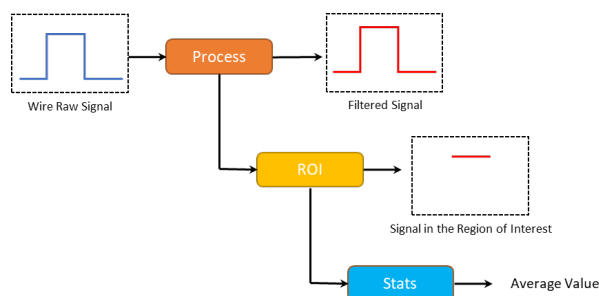

Figure 7: Wire signal processing with EPICS AreaDetector plugins.

In order to store the sensible information (raw data and experiment metadata) in the NeXus service, the ENeXAr tool [15] was used. This application a Python service developed internally at ESS-ERIC that can be used to archive PVs into NeXus files through simple CLI commands; this solution was extremely useful to easily integrate the service inside the orchestration state machine.

As previously mentioned, NeXus service is in charge of storing experimental raw data measurements and metadata using HDF5 file format [16] largely used in research environment. In addition to this storage system, the canonical EPICS Archiver service is used to store all the control variables of interest.

## TEST AND FURTHER DEVELOPMENT

Preliminary tests demonstrated that the application requires a minimum 16GB of RAM to be stable. This high request of memory is caused by the number of data structures initialized by the state machine during application start-up.

The first bunch of tests were dedicated to verify the correct management of the functional sub-system (data acquisition and motion) using the simulated environments. For this purpose, the Graphical User Interfaces shown in Figures 8-10 were developed.

Once these tests will satisfy all the projects requirements in terms of functionalities, a second bunch of tests will be performed connecting the EMU application with the real hardware and with the new low-level drivers. In parallel to this task, the main application will be revised with the intention of optimizing memory consumption.

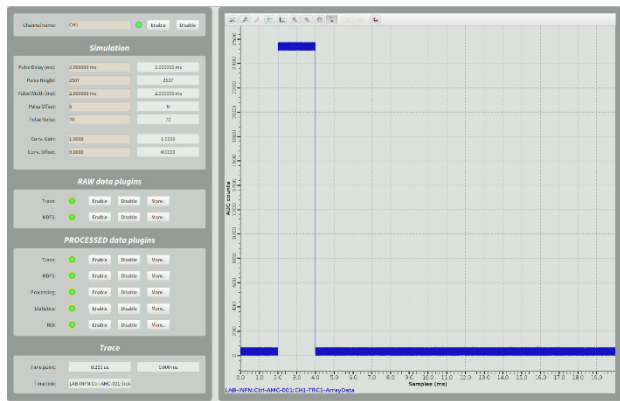

Figure 8: GUI developed for data acquisition system.

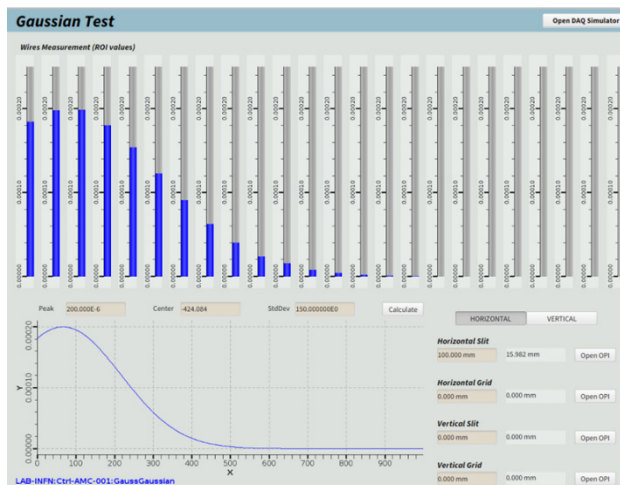

Figure 9: GUI developed for motion system.

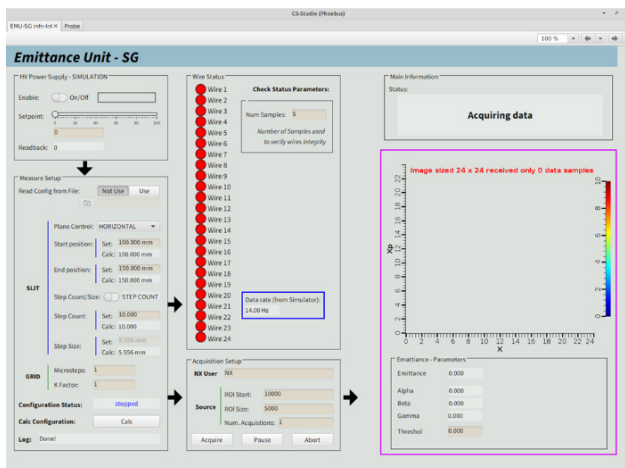

Figure 10: GUI developed for the EMU application.

## CONCLUSION

The Emittance Meter Unit is an important equipment for calculating the transverse emittance related to the beam in the MEBT section of the linac. Due to the requirement and indications coming from ESS-ERIC Guidelines in terms of hardware and software standards, the application developed has been a great challenge in the matter of technical

solutions adopted during the software upgrade: time optimization had a key role in the entire work.

The application has been tested with the simulated environment and the preliminary results are promising. Further tests with the real hardware are scheduled in the next period. In the meanwhile, code optimization in terms of memory usage will be done.

In addition, the long-term goal the team would achieve is using the results of this work is to establish a scanning instruments EPICS framework for the entire project, reusing it on the EMU systems in the LEBT and on the Wire Scanners instrumentation.

## ACKNOWLEDGMENTS

This work can't be possible without the contribution of the colleagues of ESS Bilbao, the Beam Diagnostic Team and the ICS at ESS.

# DESIGN AND DEVELOPMENT OF THE NEW DIAGNOSTICS CONTROL SYSTEM FOR THE SPES PROJECT AT INFN-LNL

G. Savarese\*, G. Arena, D. Bortolato, F. Gelain, D. Marcato, V. Martinelli, E. Munaron, M. Roetta  
INFN/LNL, Legnaro, PD, Italy

## Abstract

The need to get finer data to describe the beam is a relevant topic for all laboratories. For the SPES project at Laboratori Nazionali di Legnaro (LNL) a new diagnostic control system with more performing hardware, with respect to the one used in legacy accelerators based on Versabus Module Eurocard (VME) ADCs, has been developed. The new system uses a custom hardware to acquire signals in real time. These data and ancillary operations are managed by a control system based on the Experimental Physics and Industrial Control System (EPICS) standard and shown to users on a Control System Studio (CSS) graphical user interface. The new system improves the basic functionalities, current read-back over Beam Profilers (BP) and Faraday Cups (FC) and handlings control, with new features such as: multiple hardware gain levels selection, broken wires correction through polynomial interpolation and roto-translations taking into account alignment parameters. Another important feature, integrated with the usage of a python Finite State Machine (FSM), is the capability to control an emittance meter to quickly acquire data and calculate beam longitudinal phase space through the scubeex method.

## INTRODUCTION

The SPES project, acronym for Selective Production of Exotic Species, is the new leading project of the Legnaro National Laboratories (LNL) an Italian international center for the nuclear and astronuclear physics research. The objective of the SPES project is to study exotic beams made up of ions much more neutron-rich than those we can find in nature. It will exploit the legacy accelerator ALPI (Linear Accelerator for Ions) and will be employed as another ions source in parallel to the existing ones. [1] Since the beam will be post-accelerated in the ALPI accelerator, the beam line is made up of instruments aiming to optimize the beam transport, to reduce the energy spread, to clean the beam from undesired isobaric masses, to boost the beam charge and to pulse the beam. In a transport beam line the fundamental elements to monitor the beam shape, position and intensity are the diagnostics. They are essential to understand how to modify system parameters to obtain the desired beam [2].

The SPES project was the trampoline for the LNL to upgrade the hardware used to acquire and elaborate data and to adopt the Experimental Physics and Industrial Control System (EPICS) standard [3], that is a set of software tools developed to operate particle accelerators allowing information access and exchange between different subsystems. In fact a general upgrade of the legacy diagnostic control system

was needed since the computer technologies improvement and the increasingly challenging accelerator data acquisition requested the design of a new modular and maintainable software and a hardware offering better performances.

This paper shows the most significant details and advantages of the new hardware configuration and the EPICS Input Output Controller (IOC) developed to communicate with the hardware components and the other subsystems already developed at the LNL.

## THE LEGACY CONTROL SYSTEM

The legacy diagnostic control system is currently mounted in the ALPI and PIAVE (Positive Ions Accelerator for VErY low velocity ions) facilities and its target is to control and display details related to Faraday Cups (FC) and Beam Profilers (BP). Our FCs are copper cups used to collect and measure all the beam current; a metal shield, charged with high negative voltage, avoids that secondary electrons exit the cup. Our BPs are made up of two perpendicular grids (vertical and horizontal) with 40 parallel tungsten wires. Other diagnostic instruments are the collimators (or slits), used to narrow the beam, and the Emittance Meters (EM), which measures the longitudinal phase space and the energy spread.

Figure 1: Diagnostic box with the legacy pre-amplifier grids.

Figure 2: VME Rack.

Figure 3: Legacy diagnostic GUI.

\* giovanni.savarese@lnl.infn.it

The electronics, for grids signals, is made up of an analog board, as shown in Fig. 1, mounted close to the detector to reduce the signal path. It has a current to voltage converter for each wire of the grid and a multiplexer system generates an output buffer to send to a Versabus Module Eurocard (VME) ADC board. The current amplification, performed by the converters, is controlled by two transistor-transistor logic (TTL) signals connected to two analog switches; the saturation levels are respectively 10 nA and 100 nA and the lower detectable current is 1 nA [4].

The VME ADC board, Fig. 2, is located outside the bunker to ease maintenance and reduce the exposure of electronic instrumentation to radiations. This board provides 12 bits resolution and supports a conversion rate of 100 KHz. Current signals coming from the FC are directly amplified and digitized. BP signals come as two buffers of 40 voltage signals and the board scans them thanks to a clock signal, composed by 40 TTL period pulses of 200  $\mu$ s each one, kept 1.6 ms apart. The clock signal and the selection gain signals pass through a digital buffer, suited to drive 50  $\Omega$  loads in a daisy-chaining arrangement through subsequent boxes.

At the beginning, the software layer was based on C programs developed on VxWorks Operating System (OS). Then it was replaced by a custom EPICS based control system, hosted by the VxWorks OS with a device driver realizing the interface between the field and the EPICS server host: the IOC receives the BPs and FCs digitized values and apply a software conversion to retrieve the current values [5].

The steppers motor controllers are VME cards built at the LNL, together with the associated power drivers: every single controller is able to manage up to 8 motors. The controller is VME based and is hosted, with the associated EPICS IOC, by a VxWorks OS.

A Control System Studio (CSS) Graphical User Interface (GUI), Fig. 3, has been developed to read the EPICS Process Variables (PVs). The main panel shows general information about diagnostic boxes, such as BPs and FCs status and commands. When selecting a specific diagnostic, users are redirected to a page showing the beam vertical and horizontal profile and the FC current. From the same page, it is possible to graphically adapt the signal full-scale, but not the hardware gain value, and to insert or extract the BP and the FC when presents.

## CONTROL SYSTEM UPGRADE

The new control system will be EPICS based and will run on a Linux virtual machine instead of on an embedded OS. It will exploit a more performing hardware and an improved software with new features. Since the control system upgrade will take some time, and in an initial period there will be a mixed regime with both the old and the new control system, the requirements are: both hardware and software must be backward compatible with the exiting ones and modular; to improve the acquisition precision and the position control; possibility to hide broken wires, which usually falsify the measurement, and reorder switched wires; create

an improved GUI similar to the legacy one; integration of different type of handling systems.

### Hardware

Knowing these requirements, we developed a custom multi input and output purposes controller and a pre-amplifier box [6].

Figure 4: Custom pre-amplifier box developed at LNL.

Figure 5: Custom controller developed at LNL.

In the new configuration, two 40 wires cables start from the same BP and reach the same pre-amplifier box, Fig. 4. They bring information about the vertical and horizontal profile each. The new pre-amplifier box is made up of two board, each with 40 Operational Amplifier (OA). Each OA converts the received current value into a voltage value in the range [-10, 10] V performing a signal amplification based on the selected gain. The selected gain is the same for all the OA in the box. There are 4 gain levels allowing to read current values from 1 pA up to 10  $\mu$ A. The converted signals, using the clock signal received from the controller, are then multiplexed over a single wire and forwarded to the controller. The new pre-amplifier box can be controlled by both the legacy VME board and the new controller.

To replace the legacy VME crates, we chose to use the controller in Fig. 5 which is a smarter and more cost-effective solution for those applications, not involved in high-reliability processes, where the control tasks are reduced to simple analog and digital I/O operations. The core element is the Field Programmable Gate Array (FPGA) allowing to perform real time tasks, fast peripherals control, data acquisition, digital data pre-processing and data buffering. The configurable digital and analog I/O channels and the external communication through gigabit Ethernet and Wi-Fi make the controller

a complete and improved data acquisition system for real time applications with respect to the legacy electronics. The I/O channels flexibility and the fact that the FPGA can be programmed to generate clock and gains signals, equal to the ones generated by the VME crates, makes the controller backward compatible allowing the communication with both the legacy analog boards and the new pre-amplifier boxes.

Thanks to its modularity, a single controller can manage up to 4 pre-amplifier boxes (equivalent to 4 BPs) and 4 FCs. BPs values arrive to the controller as two buffers of 40 voltage signals and an ADC digitizes them into two arrays of 16 bits values. The ideal conversion is expressed in Eq. (1). These arrays are stored in specific registers of the FPGA. On the other side, the controller uses a CAENels board to read FCs current values. The readable current range spans in the range  $[-FS, FS]$ , where FS stands for the hardware full-scale imposed by the selected gain which can be 1 mA or 1  $\mu$ A. The digitized value is saved as a 20 bits value in the FPGA register and Eq. (2) describes the ideal conversion.

$$X_{BP,i} = \frac{V_{BP,i} \cdot 2^{16}}{2 \cdot FS_{BP}} = V_{BP,i} \cdot G_{BP} = I_{BP,i} \cdot G_{PA,i} \cdot G_{BP} \quad (1)$$

$$X_{FC} = \frac{I_{FC} \cdot 2^{20}}{2 \cdot FS_{FC}} = I_{FC} \cdot G_{FC} \quad (2)$$

## EPICS IOC

For the software development we chose to use the EPICS framework and we implemented a new IOC from scratch. The IOC reads the data saved in the controller's FPGA, elaborates those data and communicates with external IOCs controlling different types of handling systems. To provide a common interface, during the transaction phase where both the control systems will coexist, a software abstraction layer inside the new IOC communicates with the PVs of the legacy diagnostic IOC and integrates them in the new control system.

**Current values retrieval** To communicate with the controller, the IOC makes use of IPBUS. IPBUS is an IP-based communication protocol and the transport protocol can be UDP (User Datagram Protocol) or TCP (Transmission Control Protocol) based. At LNL we developed an EPICS device support to implement the IPBUS protocol based on UDP. Through this module we can associate a generic PV to specific FPGA memory register. This way PVs can access acquired data or can change the acquisition mode changing the related control bits. Thanks to these control bits, users can select the gain to apply during the acquisition.

Once the IOC has loaded the raw values, knowing the hardware specifications and given a set of calibration values to compensate the ADC and OA errors, the logic retrieves the correct current value. For BPs, the controller acquires array of values, so the conversion and the calibration is specific for each value, moreover the error contribution comes from both the ADC and the OA. Another feature available when

dealing with arrays is the possibility to define a mask to redirect each value to the correct index of the output array.

$$I_{BP,i} = \left( \frac{X_{BP,i} \cdot S_{BP}}{G_{BP}} + O_{BP} \right) \cdot \frac{S_{PA,i}}{G_{PA,i}} + O_{PA,i}[A] \quad (3)$$

$$I_{FC} = \frac{X_{FC}}{G_{FC}} \cdot S_{FC} + O_{FC}[A] \quad (4)$$

On the other side, the abstraction layer, which does not communicate with the new hardware, gets the current values stored in the legacy PVs through the Channel Access (CA). The abstraction layer is used only for those diagnostics still controlled by the legacy control system.

**Broken wires** In BPs, a frequent problem is the presence of broken wires. Usually a broken wire is a disconnected wire, not measuring current, or a deformed wire touching one of the adjacent wires creating a short-circuit; in the latter case we have two adjacent broken wires showing saturated negative current and saturated positive current each. Given the array of the current values, user can select the index of the supposed broken wire and hide it. When there are broken wires a PV executes a C subroutine to restore the correct value.

Currently users can choose between two methods: the first sets broken wires current values equal to the mean value between the previous and the next valid wire; the second interpolates the array with a polynomial function of grade 7. With this grade, we saw a good approximation of the real values but other tests are still undergoing.

**Handling control** At the LNL we have different actuators controlled by specific IOCs: stepper motors, pneumatic motors and pneumatic pistons. Given the actuator type, the diagnostic IOC instantiates a set of standard PVs connected to the PVs of the IOC controlling that specific actuator. This way, users can move the correct instrument knowing nothing about the actuator details.

In addition to the interface with multiple IOCs, the handling logic converts the actuator position from its reference system (r.s.) to the beam line (or absolute) r.s. and vice-versa. This is achievable using a set of roto-translation matrices. More in details we assumed the detector instrument is mounted at the end of the actuator with a certain offset, along the X and Y axis, and a rotation angle along the XY plane. Similarly, the actuator is mounted over the flange with its set of offsets and angles. In the end, the flange is mounted with a specific distance from the center of the beam line and, depending on the box, it has a rotation angle. These three roto-translation matrices have the same shape described in Eq. (5) which represents a standard roto-translation along the z-axis. With these considerations, the correct parameters and the actuator position in its r.s., the logic returns the instrument accurate position represented in Eq. (6).

$$T = \begin{bmatrix} \cos(\theta) & -\sin(\theta) & O_x \\ \sin(\theta) & \cos(\theta) & O_y \\ 0 & 0 & 1 \end{bmatrix} \quad (5)$$

$$\begin{bmatrix} P_{xb} \\ P_{yb} \\ 1 \end{bmatrix} = T_{fb} \cdot T_{mf} \cdot T_{im} \cdot \begin{bmatrix} P_{xi} \\ P_{yi} \\ 1 \end{bmatrix} \quad (6)$$

On the other side, the abstraction layer, which does not know the alignment offsets, links the *insert* and *extract* commands to the legacy PVs not applying roto-translations. In those cases, the instruments position is nominal.

**Collimators control** Collimators (or slits) are a couple of metallic plates used to narrow the beam and the main parameters to control are the slot's center and aperture. In contrast to BPs and FCs, that can be only completely inserted or extracted they can reach different positions. There can be multiple types of collimators: two actuators, each with its plate, mounted over the same flange; two actuators, each with its plate, mounted over opposite flanges; a unique actuator, with both plates, controlling only the slot aperture size; a unique actuator, with both plates, controlling only the slot center position.

Considering that each slit has its own roto-translation logic, the control logic has an abstraction layer that, based on the collimators configuration, translates the set and read commands to show a common interface to the end user.

### Graphical User Interface

A new CSS GUI, emulating the existing one, with additional features has been developed. The main page shows a list of the available transport elements such as triplets, dipoles and more. Chosen a specific item, users are redirected to the correct page. Since it is useful to monitor the measured current while changing a transport element parameters, diagnostics and transport element pages occupy only half of the horizontal screen size. Figure 6 shows the most important pages: the page showing the BP and the FC details and the page with the collimators position control. Other available pages are: the handling alignment parameters page, the broken wires page and the beam dynamics parameters page (with the parameters used to find the best beam trajectory).

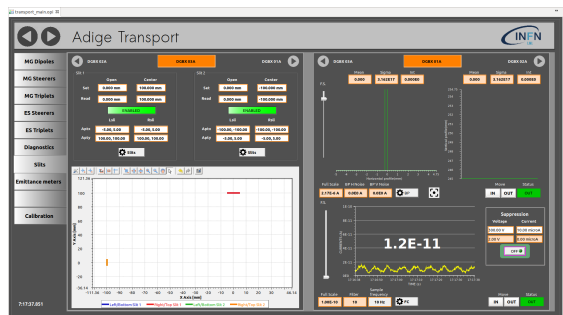

Figure 6: CSS based diagnostic GUI.

The BP section can show the vertical and the horizontal beam profile using two independent graphs or an intensity map; a slider allows to change the graphs full-scale and consequently the hardware gain. Each graph shows the correct position of each wire and the mean point of the current waveform. In addition the page shows the standard deviation and the total current measured by each profile. The FC section shows a graph with the current trend and a panel to set the suppression level. In both sections the page shows the actuator status and allows users to insert or extract the instrument. Another improvement is the presence of a set of parameters to graphically remove data noise and a set of buttons to open the actuator specific page.

The collimators page shows every slit system mounted in a specific diagnostic box. Two control modes exist: read and set the slot aperture and center; read and set the left and right slit position. Only collimators systems with two actuators have both the control modes, the others can control only the center or the aperture. At the page bottom there is an XY graphs showing the current position of each slit.

### EMITTANCE METER

The emittance meter is based on two identical slit-grid type instruments that scan the beam in two orthogonal planes [7]. This method offers very clear results since the beam divergence is scanned directly and simplifies the calculations involved during the data analysis. The slit-grid instrument, consists of a grid (the detector), orthogonal to the beam, formed by 77 parallel wires, uniformly spaced by 1 mm and a plate (the collimator), parallel to the grid and placed 300 mm before the grid, with a slot of 0.3 mm aligned with the grid center. This solution allows for angular measurement in the range  $\pm 60.0$  mrad. A chassis holds the collimator and the detector and moves them together.

The electronics used to control the emittance meter acquisition and motion is the same used for the diagnostics. The main difference is that each emittance meter grid signal requires two pre-amplifier box channels and two controller channels. To reconstruct the correct signal the IOC combines together the signals belonging to those channels and then applies the conversion logic previously described. The motion control follows the same rules defined for the previous instruments.

### Acquisition Procedure and Data Analysis

When the device is placed in the beam path, the slit selects the beam *slice* at that position and the grid reveals its divergence distribution. This way, the emittance measurement is performed by gradually inserting the slit across the beam path and measuring the divergence distribution on equally spaced rows, covering the whole beam area.

To perform this procedure the control system uses a python based Finite State Machine (FSM). It is a python script running in background using the *pysmlib* library [8]. This library helps creating event based FSMs, each running on a different thread, for EPICS control systems. The connection through

# CONTROL SYSTEM FOR 30 keV ELECTRON GUN TEST FACILITY

D. A. Nawaz<sup>†</sup>, M. Ajmal, A. Majid, N. U. Saqib\*, F. Sher  
LINAC Project, PINSTECH, Islamabad, Pakistan

## Abstract

At LINAC Project PINSTECH, an electron gun test facility for indigenously developed 30 keV electron guns is developed to control and monitor various beam parameters by performing electron beam tests and diagnostics. After successful testing, electron gun is then integrated into 6 MeV standing wave linear accelerator. This paper presents the control system design and development for the facility.

## INTRODUCTION

At LINAC Project PINSTECH, two RF standing wave linear accelerator prototypes are being developed. One is Medical linear accelerator (*Medical LINAC*) for use in medical applications such as cancer treatment, and the other is Industrial linear accelerator (*Industrial Linac*) for use in Non-Destructive Testing (NDT) applications. Electron source is one of the main components of an RF linear accelerator which provides charged particles to be accelerated by means of radio frequency [1]. Indigenously electron guns developed by Beam Transport and Diagnostics Group (BTDG) of LINAC Project are the electron sources for the linear accelerator prototypes at the project. Low energy 30 keV electron guns are designed and fabricated for integration into the 6 MeV linear accelerators. Characterization, testing and validation of electron gun parameters are important tasks that need to be properly done before integration into the accelerator [2]. For this purpose, Electron Source Operation and Characterization lab is developed at LINAC project PINSTECH that contains test facility. Next section describes overview of the experimental setup at the Lab.

## OVERVIEW

The Lab is divided into two main areas: Experimental High Voltage (HV) Area and Control Room Low Voltage (LV) Area. Both of these areas are described in following subsections.

### Experimental Area

*Experimental Area* consists of test bench and high voltage components. It consists of a low energy 30 keV electron gun along with beam diagnostic equipment integrated on a CF-63 based test bench. The designed electron gun is diode type based on thermionic emission which incorporates the modern dispenser cathode. The system is evacuated down to  $1e-8$  mbar with turbo molecular pump. Cold cathode ionization gauge IMG 300 is used for pressure measurement. A Faraday cup is integrated with transitional feed through to measure the beam current and a Ce doped

YAG screen is used to measure the beam profile. The cathode of the gun is powered up with low voltage DC power supply, and beam extraction voltage is applied through high voltage DC power supply. Experimental area is remotely monitored and controlled from *Control Room* by means of a PLC-based control system. The schematic picture of experiment is shown in Fig. 1. Due to presence of high voltages, and for elimination of EMI, *Experimental Area* is completely caged, grounded and isolated.

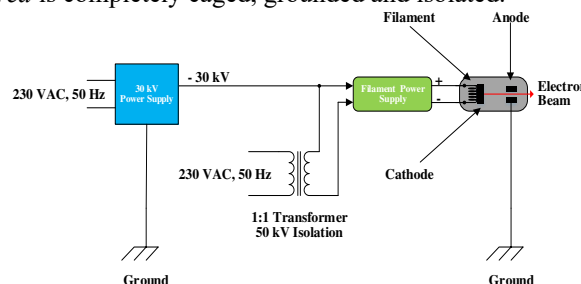

Figure 1: Schematic diagram of experiment.

### Control Room Area

Control Room Area consists of two main components: *Operator Computer* and *Control Panel*. Operator computer consists of branded Dell i7 CPU, 24-inch LED monitor, keyboard, mouse and printer. The control panel consists of a C-type rail containing Siemens Simatic S7-300 PLC CPU, input, output and communication modules. The I/O modules allow support for digital inputs, digital outputs, analog inputs, analog outputs and RS-232/422/485 communications. The control panel can be divided into two parts: front panel and back panel. PLC controller along with its power supply, I/O and communication modules, and IPC477D touch panel are installed at the front panel. Circuit Breakers are installed at the back panel which provide protection in case of any short circuit or fault current.

## CONTROL SYSTEM DESIGN

Control system acts as brain of the electron gun test facility. It enables operator to remotely monitor and control the complete system in a safe and interlocked environment to avoid any undesirable condition. In order to design the control system, hardware required was to have the following features: modular configuration for scalability, distributed configuration for separating high and low voltage area, Ethernet and serial interfaces for integration of commercial-off-the-shelf equipment, future availability for upgradation, knowledge and expertise for assistance. Keeping in view the above features, Siemens Simatic hardware and TIA-portal software packages were selected to design and develop the control system for electron gun test facility.

\* najm.control@gmail.com

## Logical Layout

The idea for development of the test bench control system is same as arrangement of experimental setup i.e. modular configuration divided into two areas: High Voltage (HV) and Low Voltage (LV). We need to monitor and control devices and interlocks inside the experimental area which is at high potential and also monitor and control electronic devices and interlocks from the control panel which is at the ground potential. LV area control module consists of main processing unit i.e. S7-300 CPU placed inside control panel situated in the Control Room Area, and HV area control module consists of slave unit i.e. ET-200M placed inside HV deck situated in the Experimental Area [3]. These two control system modules are connected via optical fiber to provide isolation. To program the PLCs, Ladder Logic programming language is mostly used. Logical layout of the control system is shown in Fig. 2.

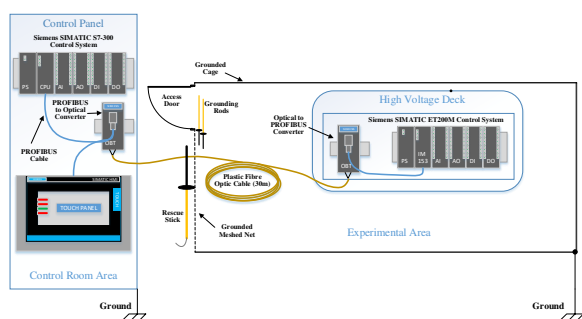

Figure 2: Logical layout of Control System.

## Network Layout

CPU, slave module and touch panel need to communicate with one another for data transfer. This communication is achieved by means of a PROFINET-PROFIBUS network. Figure 3 shows the network layout configuration in Siemens TIA-Portal. ET200M based slave module is networked using PROFIBUS interface with the main processing unit S7-300. As PROFIBUS is a copper medium, it can carry EMI. Hence, PROFIBUS is converted to optical network and vice versa using Optical Bus Terminals (OBT) at both ends. ET200M module delivers/collects information to/from the main processing unit. PLC S7-300 CPU, IPC477D based HMI station, and operator computer are networked using ETHERNET interface as shown in Fig. 3.

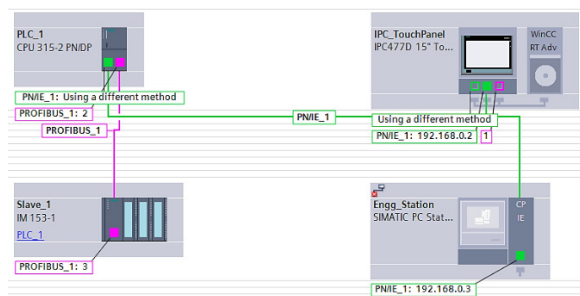

Figure 3: TIA-Portal Network layout.

## Equipment

Several signals have been monitored and controlled from different instruments, power supplies, vacuum gauge controllers and faraday cup stepper motor. The brief explanation is given below:

### Vacuum and Temperature

Vacuum of electron gun is measured from IMG-300 card of Agilent Technologies Vacuum Gauge Controller XGS 600. This card provide an analog signal corresponding to the vacuum and is acquired in the control system through an analog input module of S7-300. Desired/permissible vacuum window is programmed inside PLC for activating interlocks. Electron gun temperature is measured from K-type thermocouple through Phoenix transducer into the analog input module.

### Filament Power Supply

TDK Lambda power supply is used for providing voltage to the filament. It is controlled and monitored through digital and analog input/outputs.

### Pico ammeter

Keithley Pico ammeter is used to measure beam current. It contains serial interface (RS-485) for remote monitoring and control. RS-485 communication module is used to interface ammeter with PLC CPU.

### High Voltage Power Supply

High Voltage is provided from Glassman High Voltage Power Supply. It is controlled and monitored through digital and analog inputs/outputs.

### Solenoid Power Supply

Delta Elektronika Power Supply is the solenoid power supply for the electron gun experimental setup. It is controlled from PLC via RS-232 interface.

### Faraday Cup Motor

Faraday cup is moved back and forth with the help of stepper motor. Stepper motor driver receives pulse train, enable and director commands from PLC.

### Interlocks

Several interlocks are incorporated for machine and personnel safety and protection with the help of PLC.

## Human Machine Interface (HMI)

Two HMI stations are deployed in the test facility to remotely monitor and control the system. Both of these stations contain same HMI screens.

- PC based Human Machine Interface
- SIEMENS IPC477D Touch Panel based Human Machine Interface

Figure 4 shows layout diagram of the present deployed control system.

The existent PLC based control system is under process of upgradation to EPICS based control system. Operator interfaces currently developed in Siemens WinCC Advanced would be shifted to Phoebus Control System Studio and the existing Siemens PLCs will be interfaced with EPICS using s7nodave support module. Figure 5 shows layout of control system upgrade that will contain following additional hardware and software components:

Currently, Glassman high voltage DC power supply is used for extraction of electrons from the electron gun. This is a continuous DC mode power supply whereas the electron gun in RF linear accelerator is operated in pulsed mode. An indigenously developed 48 kV/110 A high voltage pulse modulator is developed for the facility. Control system for the modulator is already developed using S7-1200 PLC. It would be included in the system upgrade after interfacing with EPICS.

Magnets are installed along the beamline for beam steering and focusing. Delta Electronics power supplies are installed for these magnets. The power supplies contain serial interfaces (RS-232/422/485) for remote interfacing. EPICS Asyn and Stream Device modules would be used to remotely monitor and control these power supplies via EPICS IOC.

Experimental setup consists of Experimental Area and Control Room Area. Experimental Area is surrounded by Faraday cage which is grounded to eliminate EMI and provide protection from high voltages. Figure 6 shows the experimental area, Figure 7 shows the Faraday cage and Figure 8 shows the Control Room Area.

Figure 7: Faraday Cage.

Figure 8: Control Room Area.

## CONCLUSION

The automated electron gun test facility is efficiently providing infrastructure to test and characterize indigenously developed electron guns for integration into the RF linear accelerators. The planned upgrade of control system will further enhance the capabilities of the test stand for pulsed beam diagnostics and analysis.

## ACKNOWLEDGEMENTS

The authors thank Beam Transport and Diagnostics Group (BTDG) of LINAC Project for their support that made this work possible.

# AUTOMATIC RF AND ELECTRON GUN FILAMENT CONDITIONING SYSTEMS FOR 6 MeV LINAC

A. Majid<sup>†</sup>, D. A. Nawaz, N. U. Saqib\*, F. Sher  
LINAC Project, PINSTECH, Islamabad, Pakistan

## Abstract

RF conditioning of vacuum windows and RF cavities is a necessary task for eliminating poor vacuum caused by outgassing and contamination. Also, startup and shutdown process of linear accelerator requires gradual increase and decrease of electron gun filament voltage to avoid damage to the filament. This paper presents an EPICS based multi-loop automatic RF conditioning system and Electron Gun filament conditioning system for Klystron based 6 MeV Linear Accelerator.

## INTRODUCTION

Particle accelerators are a crucial instrument for scientific innovations and knowledge in all fields of research and engineering. As accelerators grow more complex, so do the demands placed on their control systems. The complexity of the control system hardware and software reflects the complexity of the machine. At the very same time, the machine must have simple access and operation, as well as a greater level of stability and adaptability.

Radio Frequency (RF) charged particle accelerators use accelerating RF cavities to accelerate electrons or ions to energies up to hundred mega electron volts. A particle source produces ions or electrons, which inject into the cavity with some minimum initial energy. A significant amount of RF power must be coupled into the accelerating cavity structure to transfer energy to the charged particles. High power klystron amplifiers are commonly employed as a RF power generation source for accelerators. In addition, waveguides and couplers are utilized to transmit RF power from the klystrons to the cavities. Injected RF power resonates with incoming particles, accelerating them to produce a higher energy, faster moving charged particle beam.

Several auxiliary systems, such as a water load and cooling system, vacuum maintenance system, control system and safety interlocks support the entire process. Maintaining a good quality vacuum in the LINAC cavity and connected components is critical for uninterrupted beam transport and smooth operation. When RF power is fed into the cavity during start-up and operation of the accelerator, the vacuum level degrades owing to poor manufacturing of the cavity's internal structures, RF breakdowns, outgassing, and arching. To cope with this issue, an auxiliary vacuum system is employed which consists of one or more series-connected pumps that continually generate a low-pressure zone inside the cavities. Radio frequency (RF) breakdown is a typical problem in accelerating structures and has been widely researched [1, 2, 3]. It is vital to avoid severe RF

breakdown since it can harm accelerating structures and microwave devices irreparably. Breakdowns and multipacting restrict the power that the cavity can absorb during the conditioning process [4]. This phenomenon limits the RF structure from working in high-power mode and from producing full-energy beams. The frequency of breakdown is highly linked with the vacuum state and RF power intensity. Outgassing and sparking impact vacuum performance and restrict the RF field level that can be consistently attained.

Therefore, for safe operation, RF power is gradually injected into the cavity, ramping up in multiple stages from the lowest to the highest level while constantly monitoring the LINAC characteristic parameters such as vacuum level, temperature profile, arching, and other system interlocks [5]. The process of gradually "warming up" the LINAC cavity is known as RF conditioning. The amount of time required for conditioning, varies on the nature of cavity and might range from a few days to months.

This paper presents the design and development of a system for automated RF conditioning of electron linear accelerator cavities at the LINAC project PINSTECH. RF power conditioning scheme, hardware setup, logic design and software development techniques have been thoroughly addressed. The suggested structure is implemented with the Experimental Physics and Industrial Control System (EPICS), which is a collection of software components and tools used by developers to create distributed control systems for particle accelerators, big experiments, and massive telescopes [6]. In the last section, test setup developed for automated conditioning of electron gun filament has been discussed.

## CONDITIONING STRATEGY

Numerous conditioning strategies have been employed at different accelerator facilities [7, 8, 9]. Linear accelerator prototypes (Medical and Industrial) at the LINAC project PINSTECH comprises of standing wave cavities structure, produces 06 MeV electron beam and runs at 2.5MW input RF power at resonance mode when the cavity is fully tuned. Electrons are injected by a 30keV electron gun and RF power is applied by a klystron that generates an oscillating RF signal of 50Hz frequency, 2.5 MW peak power and 5usec pulse width. The average power effectively delivered into the cavity is determined by three factors: peak amplitude, pulse width, and frequency.

$$P_{inj} = P_{peak} \cdot T_{on} \cdot f$$

Where  $P_{inj}$ ,  $P_{peak}$ ,  $T_{on}$ ,  $f$  represent injected power, peak power, pulse width and frequency, respectively. These three parameters can be changed to enhance or reduce injected power.

<sup>†</sup> aaminahmajid@gmail.com

\* najm.control@gmail.com

Figure 1: RF power conditioning strategy w.r.t vacuum dynamics of accelerator cavity.

At the beginning of the conditioning process, the lowest possible RF power is injected and its strength is increased gradually while constantly monitoring the vacuum quality. Magnitude and direction of power gradient  $\frac{\Delta P_{inj}}{\Delta t}$  is adjusted based on vacuum dynamics. Pressure level data is a solid indication of breakdowns and outgassing phenomenon occurring inside the cavity. The desired operating range of pressure for power ramp up is  $5 \times 10^{-8}$  mbar or below. If the pressure rises up to  $5.0 \times 10^{-7}$  mbar, a high-pressure warning signal is generated and the RF power ramp-up process is halted. Consequently, pressure tends to settle down and vacuum quality improves. However, if the vacuum quality deteriorates further and pressure level exceeds  $1 \times 10^{-6}$  mbar, a vacuum interlock is triggered and RF power is ramped down instead, with a relatively greater step size. Figure 1 illustrates the relationship between RF power gradient with pressure level of cavity.

Power ramp-up scheme consists of three nested loops that correspond to the RF pulse parameters  $P_{peak}$ ,  $T_{on}$  and  $f$ . These parameters act as main incrementing variables of respective loops. They are initialized at lower values and increased by a step size with each iteration of loop. Basic flow of the program is described in following steps:

1. Set Peak power, rep rate and pulse width of RF pulses to an initial value of 20kW, 0.7usec and 5Hz, respectively.

#### Innermost Loop (Increase RF Pulse peak power)

2. Increase RF pulse amplitude gradually while constantly monitoring the vacuum level. As power level rises, breakdowns begin to occur and vacuum level shows frequent surges. Depending on vacuum gradients and trends, adjust the step size and delay between two successive levels of RF power.
3. Condition to the maximum power that can be obtained without frequently activating the vacuum interlock.
4. After the pressure and breakdown rate have been reduced, increase the RF power to a higher level. Repeat this procedure until peak power reaches 800kW.

#### Middle Loop (Increase RF Pulse width)

5. Increase pulse width gradually up to 5 usec with step-size,  $\Delta T_{on} = 0.2 \text{ usec}$ . For each increased level of pulse width, repeat steps 2-4 until 1.6MW peak power has been achieved.

#### Outermost Loop (Increase RF Pulse rep rate)

6. Increase pulse rep rate gradually up to 50Hz with a step-size  $\Delta f = 5 \text{ Hz}$ . For each increased level of frequency, repeat steps 2-5 until RF pulse peak power has reached up to 2.5MW with 50Hz rep rate and 5usec pulse width.

## HARDWARE DESIGN AND INSTRUMENTATION

The suggested RF conditioning methodology employs a variety of cutting-edge devices and instruments from diverse vendors. The following are the primary components employed in the conditioning setup: vacuum gauge controller, programmable logic controller (PLC), Inverted magnetron gauges, signal generator, peak power meter, oscilloscope, arc detector, delay generator, high speed RF interlock switch, temperature sensors, relays, safety interlocks, klystron and water-cooling system. The overall block diagram of the RF conditioning system is shown in Fig. 2.

RF signal is produced by signal generator, and passed to the klystron through an RF interlock switch. This switch is triggered by a gating sequence generated by the delay generator. As a result, the incoming RF pulse is transmitted only for a specific duration of time, obtaining the desired pulse width. This pulsed RF power is amplified by klystron and transferred to the cavity through waveguides.

During the RF conditioning process of high-power vacuum components such as cavities, couplers, windows, etc., it is necessary to monitor the vacuum quality, arcing, and forward and reflected RF-power levels. To monitor forward and reflected power, two directional couplers are connected to the wave-guide. Signals from directional couplers are measured with a high-speed oscilloscope that is interfaced with control software EPICS through TCP/IP. A pumping station consisting of a rotary and turbo pump linked in series maintains the vacuum level inside the cavity. These pumps operate continuously in order to attain the specified set point. Pumping speed is estimated based on pressure level feedback from vacuum gauges. Two IMG gauges are used to measure the pressure within the cavity at two different locations. A vacuum gauge controller is used to read gauge data and deliver it to the PLC through its analogue output.

Siemens S7-300 PLC system has been employed, as a field controller, to collect pressure readings and monitor auxiliary systems such as water load, temperature control, and arc detection. The PLC controller communicates with Sensors/actuators and exchanges data with the primary control software built in EPICS. PLC is connected with arc detector, pressure switches, temperature sensors, and flow meter. In case of a malfunction or an abnormal circumstance, the PLC generates an interlock signal, which disables the RF switch.

## LOGIC DESIGN AND SOFTWARE DEVELOPMENT

Control system architecture is developed in the EPICS environment that also serves as an integration tool for all software components. EPICS StreamDevice support module is configured and installed to communicate with field instruments via TCP/IP or RS232/485 protocol. StreamDevice is a generic EPICS device support for devices with a "byte stream" based communication interface. For each device that needs to be interfaced with control software, a soft IOC (input-output controller) is developed in EPICS. These IOCs act as servers, collecting data from the attached instrument and broadcasting it to many clients through the channel access networking protocol.

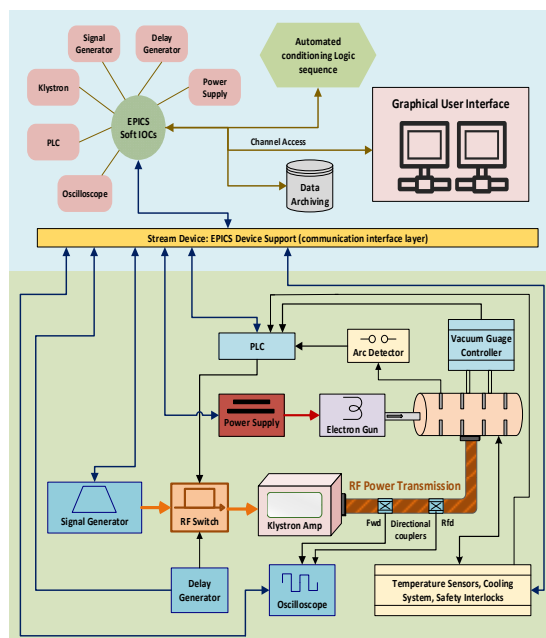

Figure 2: Hardware setup and instrumentation.

For conditioning tasks, soft IOCs have been developed and configured that interface with their respective equipment. Examples include klystron, signal generator, e-gun power supply, delay generator and PLC, allowing their complete remote access. Each IOC has a dedicated database that stores information in the form of records or process variables (PVs). PVs are configured and linked with the real-system field parameters. IOCs can communicate with other IOCs, as well as with databases and front-end applications. All process variables are accessible anywhere on the network via channel access protocol.

The EPICS sequencer module is used to program the algorithm for the automated conditioning system in state notation language (SNL). This application operates in the background and exchanges data with the relevant IOCS and databases. It reads the most recent values of process variables and makes decisions according to control logic. Front-end application often known as Graphical User Interface (GUI) is developed in Control System Studio-Phoenixbus. An interactive graphical user interface has been created, allowing the user to modify and monitor associated process variables and their trends. Operators can connect and communicate with any instrument from any remote location using the front-end application. To perform RF conditioning, operator can send start/stop requests and set values of related parameters such as initial power, final power, step size and time delay etc.

These values are sent to the sequencer program that evaluates the next decision and updates relevant PVs in the database. IOCs serve as a link between database and field instruments for updated information exchange. The sequencer program is written in the form of states, and its flow chart is depicted in Fig. 3. It has five states: **Start**, **Vacuum Monitor**, **Increment**, **Decrement** and **Fault**.

program begins with the 'Start' state, at the request of operator's start command, initializing all variables: Initial and final RF pulse frequency, rep rate, amplitude and the step sizes denoted by  $f_0$ ,  $f_{\text{max}}$ ,  $T_0$ ,  $T_{\text{on-max}}$ ,  $P_0$ ,  $P_{\text{max}}$ ,  $\Delta f$ ,  $\Delta T_{\text{on}}$  and  $\Delta P$ , respectively. If all the interlocks are cleared and system is in ready mode, program advances to the next state, *Vacuum Monitor*.

In the *Vacuum Monitor* state, program waits for a set period  $\Delta t$  (default: 2 min) and monitors pressure data with 1 Hz frequency, making the next decision based on the vacuum quality. This decision can be further divided into three segments: a) If pressure level remains in normal range for the entire two minutes, it advances to *Increment* state. b) If pressure increases to the warning level, program returns to the same *Vacuum monitor* state and waits for the pressure to settle down. c) If pressure continues to rise and crosses the alarm limit, program immediately switches to the *Decrement* state.

In the *Increment* state, program steps up the RF power level in three nested incrementing loops. It achieves this, by iteratively increasing pulse peak amplitude, pulse width or frequency based on the preceding level in the loop and step size. After stepping up RF power, it returns to *Vacuum Monitor* state.

In the *Decrement* state, program steps down the power by decreasing RF pulse amplitude. After reducing the RF power level, it pauses for a defined period before returning to the *Vacuum Monitor* state.

Meanwhile, if system interlock occurs, program enters

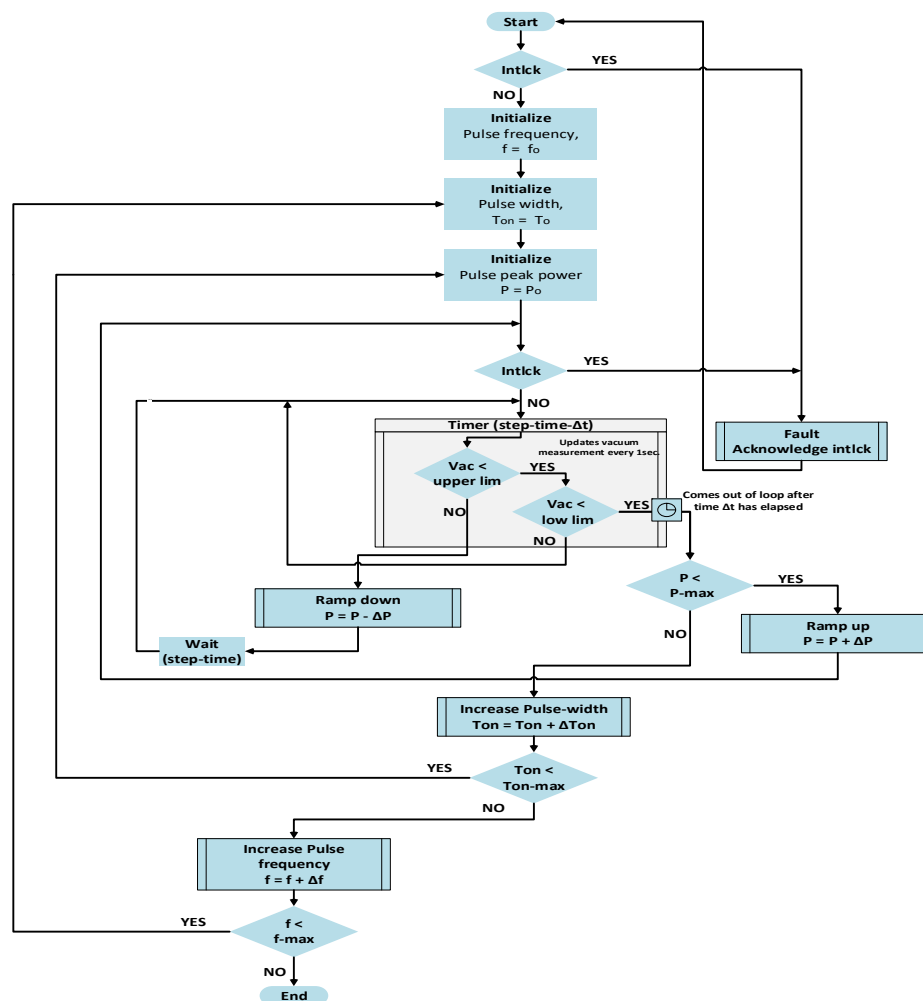

Figure 3: Flow chart of conditioning algorithm.

the *Fault* state and turns off RF power. Once the fault has been recovered and acknowledged, the conditioning process can be restarted only if the operator sends the start instruction. When the maximum required level of RF power is attained, the conditioning process is terminated, and the program transmits a complete signal to the database and GUI. The program can be paused at any time during operation through GUI. Furthermore, all associated parameters such as power gradient, step sizes, time delays, and limitations may be adjusted at any moment for a more flexible operation and conditioning procedure.

## ELECTRON GUN LOW VOLTAGE CONDITIONING

A high voltage DC electron gun generates the electron beam that is injected into LINAC. The gun filament is composed of tungsten and is housed in a chamber filled with barium oxide. A tungsten disc is positioned at the end of the chamber and is primarily responsible for electron emission. A low voltage and high current (12V, 2.5Amp) is supplied to the filament that heats the tungsten disc indirectly. As a result, when the disc attains a breakdown temperature of 1200°C, it begins releasing electrons with a few electron

volts of energy. These electrons are then excited by a 30 KV pulsed power supply and kicked into the accelerating cavities for further gain in energy and speed.

During the low voltage (LV) excitation of electron gun filament, a sudden rise in temperature might cause thermal breakdowns and damage the electrodes. Therefore, for the safe beam on operation, low voltage applied to the gun filament should be increased gradually from 0 to 10V to maintain a minimum temperature gradient. This is referred to as LV conditioning of electron gun filament. The conditioning process eliminates contaminants on the insulating ceramic and the electrode surface, avoids poisoning of electrodes and improves breakdown threshold. During LV conditioning a vacuum level of  $1 \times 10^{-8}$  mbar is maintained to transport electron beam smoothly and avoid electric discharges. Voltage ramp up strategy must be in accordance with the vacuum quality.

A test setup has been developed for automatic LV conditioning and ramp up of electron gun filament voltage. Gun filament is powered up by DC power supply, which is serially interfaced with EPICS soft IOC. A serial to optical converter has been used as an intermediate link to provide

isolation from power supply. All parameters of power supply: set voltage, actual voltage and actual current are linked with IOC. Their values are also accessible from database and GUI. A sequencer program is developed for automatically ramping up the power supply voltage with respect to the vacuum level. A single loop program increases, holds or decreases gun voltage according to pressure level of cavity. Vacuum warning and alarm limits are adjustable from the GUI. Program continuously monitors interlocks and pauses the ramp-up process in case of any alarm or fault. This is to prevent excessive discharges during the conditioning.

## RESULTS

Automatic RF conditioning system has been developed, installed and tested at LINAC Project, PINSTECH. Numerous experiments have been conducted using the developed software and performance is satisfactory. This setup facilitates users for safe and reliable conditioning of accelerator cavities with minimum human intervention.

Figure 4 depicts a specimen of data during one of the RF Power conditioning trials. It shows 150-minute span of the process where injected power and pressure measurements are represented by red and green curves, respectively. RF power was systematically increased by the control software. Discontinuities in graph (around: 11.30 and 12:00) reflect the RF power cut-down events due to vacuum spikes and system fault. In the beginning [11.00-11:30], RF power was increased with larger step, but for the remaining period power gradient was decreased due to small margin in pressure level and warning limit.

Figure 5 illustrates a snapshot from electron gun LV conditioning process that was being controlled by the developed software. Electron gun filament voltage and cavity pressure are plotted by red and blue colors, respectively. Their relative trend in graph can be divided into three categories: First segment [12:36-12:50] represents 'Increment' state where vacuum quality is good and filament voltage is increased smoothly with constant rate, Second segment [12:50-13:05] shows 'Hold' state where vacuum is in warning range, and program holds the filament voltage. Third and the last segment shows voltage 'Decrement' state, where pressure crosses alarm limit at 13:07 and voltage is decreased quickly.

Figure 6 displays Operator Interfaces (OPI) for RF conditioning and e-gun conditioning systems. GUIs are user-friendly and facilitate operator with the provision of adjusting variables (limits/step sizes), acknowledging alarms as well as initiating, monitoring or ceasing the conditioning process.

## CONCLUSION

An optimal scheme for RF power conditioning of standing wave linear accelerators is proposed and discussed. Aim of this work was to develop an automated system to perform recommended conditioning strategy in a reliable

Figure 4: RF Power conditioning Process.

Figure 5: e-Gun LV conditioning.

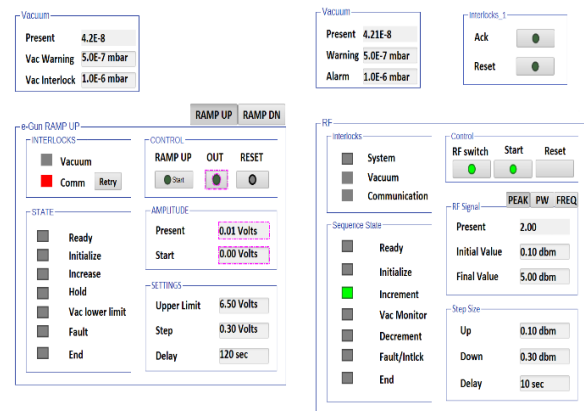

Figure 6: OPIs for RF & e-gun conditioning.

and efficient manner with minimum surveillance. The proposed system has been successfully implemented in EPICS platform and PLC has been used as main controller for interfacing of hardware electronics. Both software and hardware design strategies have been discussed. All components and instruments used for this project are easily available commercially. System's parameters are accessible and reconfigurable based on the requirement of end-user. A similar setup for LV conditioning of electron gun filament has also been developed. This system has been tested and installed at LINAC Project, PINSTECH. It has been effectively used during several experimental runs and its performance is well in-line with the desired requirements.

## Abstract

The preparation of the upgrade of the ATLAS electronics for the High Luminosity LHC is in full swing. The Tile Calorimeter is preparing the upgrade of its readout electronics and power distribution systems. One of such systems is the High Voltage (HV) regulation and distribution system. The new system is based on HVRemote boards mounted in crates located at the counting room. The HV will be delivered to the on-detector electronics using 100 m long cables. The crates will be equipped with a system-on-chip that will be responsible for the control and monitoring of the HV boards. The control of the HVRemote and its dedicated HVSupply boards is done by means of a serial peripheral interface bus. A SCADA component is under development to communicate with and supervise the crates and boards, and to integrate the HV system in the control system of the detector. The control system will be able to send notifications to the operators when the monitored values are out of range, archive the monitored data and if required, perform automated actions.

## INTRODUCTION

Located in the central region of the ATLAS detector [1], the Tile Calorimeter (TileCal) [2] is composed of iron plates interpolated with plastic scintillating tiles that work as active material. The light resulting from the interaction of the particles with the plastic tiles is guided by wavelength shifting optical fibers to the photomultiplier tubes (PMT). The signal generated by the PMT is then processed by the on-detector and off-detector data acquisition electronics. TileCal uses approximately  $10^4$  PMTs divided over the 256 modules that compose the four TileCal operational barrels (EBA, EBC, LBA and LBC). The operation of TileCal requires a high voltage system able to regulate and monitor the HV set to each individual PMT with a precision within 0.5 V rms. For the High Luminosity Large Hadron Collider (HL-LHC) a new high voltage system is under development [3, 4] for TileCal, along with other hardware upgrades [5, 6]. It will consist of HV source boards, regulation and monitoring boards housed in crates located in the off-detector area, with the HV being delivered to each PMT by 100 m long cables. With the regulation boards located off-detector, they are not required to be radiation hard and they have also the advantage of easier

access for repairs which can be executed during data-taking periods.

The Detector Control System (DCS) of TileCal is responsible for the supervision and control of the TileCal electronics and infrastructure, continuously monitoring temperatures, voltages and currents [7].

## HIGH VOLTAGE BOARDS

### HVSupply

The HVSupply board is responsible for providing the direct current (DC) HV and the three low DC voltage levels, (12 V, -12 V, 3.3 V) required by the HVRemote board to operate. The HV will be supplied by two commercial DC/DC converters (Hamamatsu C12446-12) with a combined maximum output current of 20 mA and adjustable voltages up to -1000 V. The supervision will include the monitoring of the supplied voltages and respective current consumption as well as the readings of on-board temperature probes and on-chip temperature. The digital control and monitoring is achieved by using a dedicated Serial Peripheral Interface (SPI) bus. An analog switch was also implemented in the board which will allow the HV DC/DC converters to be switched off when a hardware interlock signal is removed. The interlock signal can either be interrupted by the TileCal DCS or by the Detector Safety System (DSS).

### HVRemote

The HVRemote board is composed of 48 HV channels for regulating and monitoring the individual channels voltages in the range from -500 V to -950 V. Enabling or disabling the output of the HV channel is available by software in groups of 4 channels. However it is possible to disable the output of any of the HV channels by hardware (by means of a jumper) allowing, for example, to isolate it from a short circuit in the long cable or in the HVBus board (located on-detector). Temperature probes are available to monitor the board temperature and assess the cooling conditions. Each of the boards will have a unique serial number allowing the crate controller and the Supervisory Control and Data Acquisition (SCADA) control system to identify each individual HVRemote board. The communication between the on-board circuits and the crate control is done via a dedicated SPI bus. Figure 1 shows a simplified diagram of the HVRemote board control.

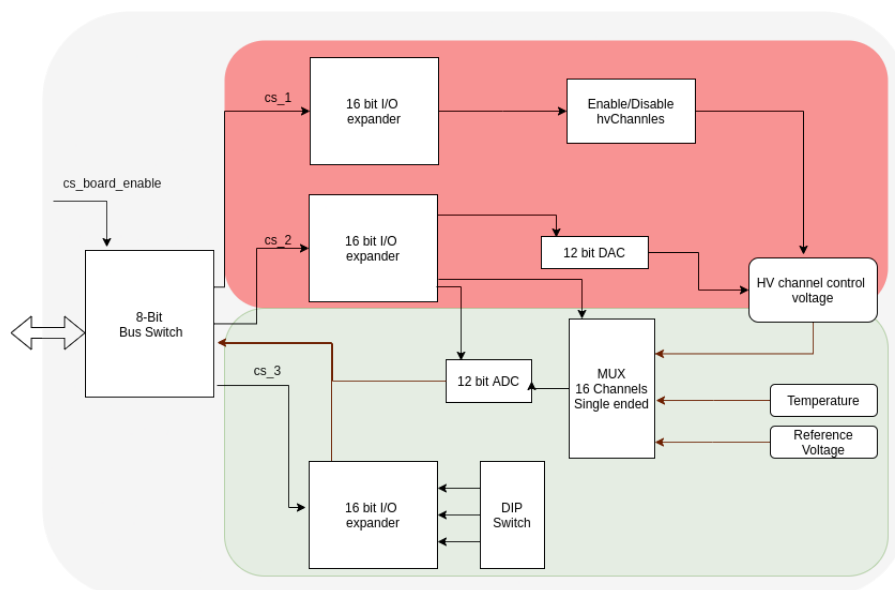

Figure 1: Simplified block diagram of the HVRemote control. The area of the diagram with the pink background represents the control of the HV and the one with the green background represents the monitoring path. The enabling of the Switch allows a specific board to receive the SPI commands from the controller.

## HV Bus Board

The HV-bus boards root the HV delivered by the 100 m long cable to the designated PMT. Each board is equipped for 12 PMTs and 3 (in EBA/EBC) and 4 (in LBA/LBC) boards are needed per TileCal module. The HVbus is the only element of the HV distribution and regulation system which is located on-detector but since it does not have active elements (only resistors) there is no specific radiation requirement.

## CRATE CONTROL

The control of the first HVRemote prototype was based in the Tibbo board and it was mounted directly on the HVRemote board [3]. Taking this approach, the final system would require the availability of more than 500 ethernet sockets and respective network cables, which would be a challenge due to space restrictions on the racks at the electronics rooms. At the end it would also be a complex system to maintain since a large number of Internet Protocol (IP) addresses would had to be kept and correctly mapped inside of DCS. To avoid dependencies on such constrains as well as to make the maintenance of the HV system easier and at the same time allowing the upgrade of the controller board if required, it was chosen to have a single controller installed on the crate. In this new design, the controller will be used to control both the HVRemote and the HVSupply, each with its dedicated SPI bus. Thus it was decided to use a System-on-chip (SoC) for the final crate control.

## Interface Board

The interface board, that will be connected in the crates back-plane will hold a ZYBO board [8] and two port expanders. The ZYBO board is equipped with a Zynq-7000

SoC featuring a dual-core ARM processor and a Field Programmable Gate Array (FPGA) logic from Xilinx. The board is equipped with an EEPROM programmed with an unique Media Access Control (MAC) address, a built-in RJ45 connector for ethernet, Pmod connectors, among other features. The General Purpose Input and Output (GPIO) and SPI signals were assigned using Vivado and can be accessed at the assigned Pmod ports/pins. The boot of system was created with the PetaLinux tool integrating the design developed with Vivado. Relative to the Linux distributions, we are currently testing with CentOS 7 and Ubuntu. The root filesystem (rootfs) and boot are executed from the local Secure Digital (SD) card. There are two port expanders located on the interface board that will be used to select one board at a time, the boards on each SPI bus (each bus will be operated independently from the other). For this matter, a set of GPIO signals will be used to enable the assigned bus port expander, instead of the standard SPI chip select.

## Software

The software running on the SoC (or in the Raspberry Pi used in the tests) operates as SPI controller [9]. The actual software for the board control has been written in Python and it has been used a Raspberry Pi 4 to develop it. Libraries implementing the required SPI instructions have been prepared to operate the control chips within each board. For example, setting I/O pins from the port expanders with a specific configuration. The communication between the DCS and the controller is (currently) a simple home-made protocol over TCP/IP allowing the commands or queries to be sent from the DCS to the controller and replies flow in the opposite direction, see Fig. 2. When the server is started it initiates the SPI bus and creates a socket which listens and

waits for commands or queries. At the restart of the server after a crash or un-programmed reboot of the SPI controller, the server does not initialize the boards, avoiding this way losing the previous configurations. From the DCS side, there are two types of requests; automatic queries (usually readings) which are updated regularly, and the commands which are initiated by the user and have priority over the automatic queries. Queries and commands handling are implemented in the software using a "to-do" list, where a process takes the command/query from the top of the list and sends it to the server to be handled. When the handling of the query or command is complete, the process takes the next item from the list and the process repeats itself. When the list is empty, the software updates the list with the group of automatic queries.

Figure 2: Architecture of the new HV system control tree.

## INTEGRATION WITH TILECAL DCS

The slow control system of TileCal is based on the SCADA *WinCC OA* [10] and uses a set of software packages that ease the coherent integration of the hardware and its respective control component into the DCS. TileCal DCS is a distributed system comprising (currently) six individual SCADA systems, occupying two layers of the ATLAS DCS back-end hierarchy (see Fig. 3) taking different roles depending on the layer and type. The local control stations are the systems responsible for handling the hardware systems such as low voltages and high voltage [7].

The SCADA component for the HV Crates is being developed and under initial tests. Data point structures that represent the crate and respective boards were prepared, containing temperature probes, voltages and calibration values. The data arriving from the HVSypply and HVRemote are decoded and mapped to the respective data point element. It was also prepared a set of basic Graphical User Interfaces (GUI) which display the data located in the data points ele-

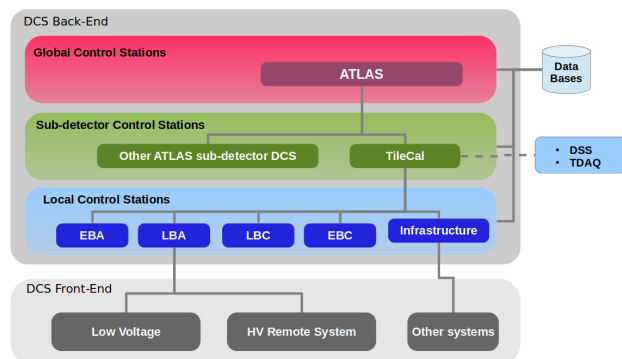

Figure 3: TileCal DCS hierarchy. Image adapted from [7].

ments and execute commands such as switching on/off HV channels (see Fig. 4), board resets (initialization), among others.

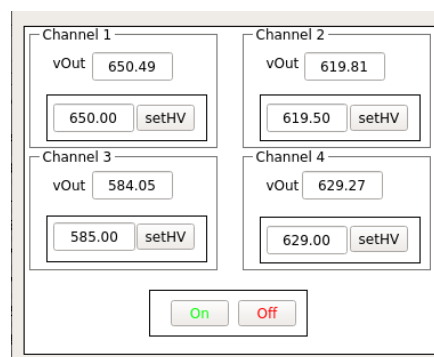

Figure 4: DCS test user interface. The measured HV is shown in the display "vOut" for a group of four channels. It shows the HV for each of the channels. It is also possible to enable or disable the HV for all four channels.

The archiving of the monitored data to the Oracle database is performed according to a set of rules or conditions (smoothing). The smoothing reduces the amount of data stored without losing important data, therefore making the archiving more efficient. For the HVRemote Channels, notifications are available in the form of alerts, which are triggered when the offset between the requested HV and the monitored HV is higher than 4 V (the value can be adjusted channel by channel). Notifications to experts such as emails or a short message service can also be configured, for example in the case of HVSypply failure. Actions can be triggered by alarms conditions as well, for example, in the case of high board temperature, the DCS should power down the HVSypply and HVRemote as a preventive measure.

Figure 5 shows the monitored HV by DCS from source 1 of an HVSypply board, without smoothing.

## CONCLUSIONS AND FUTURE WORK

A new control is being prepared for the HV remote system which will consist on control software running on the crates and supervision software which is part of the TileCal DCS. As for the next steps the crate control software will be ported

Figure 5: Plot of the output voltage (without smoothing) of one HV source located at the HVSupply during a test beam period with realistic data taking conditions.

to the ZYNQ controller and fully tested with the interface board and the other components of the system.

# EPICS DAQ SYSTEM OF BEAM POSITION MONITOR AT THE KOMAC LINAC AND BEAMLINES

Young-Gi Song<sup>†</sup>, Jae-Ha Kim, Sung-Yun Cho

Korea Multi-purpose Accelerator Complex, Korea Atomic Energy Research Institute, Korea

## Abstract

The KOMAC facility consists of low-energy component, including a 50-keV ion source, a low energy beam transport (LEBT), a 3-MeV radio-frequency quadrupole (RFQ), and a 20-MeV drift tube linac (DTL), as well as high-energy components, including seven DTL tanks for the 100-MeV proton beam [1]. The KOMAC has been operating 20-MeV and 100-MeV proton beam lines to provide proton beams for various applications. Approximately 20 stripline beam position monitors (BPMs) have been installed in KOMAC linac and beamlines. A data-acquisition (DAQ) system has been developed with various platforms in order to monitor beam position signals from linac and beamlines. This paper describes the hardware and software system and test results.

## INTRODUCTION

Ten stripline BPMs and nine stripline BPMs were installed in the 350MHz pulse KOMAC Linac and beamline, respectively. Figure 1 shows the BPM installed in Linac and beamlines.

Figure 1: Layout of KOMAC Linac and Beamline.

In addition to the transverse beam position, the BPM is used to measure the beam phase for energy calculation based on flight time measurement. VME-based board was adopted as a major platform for high-performance subsystems. The MVME3100 CPU board has been adopted as a standard control system and is used in beam diagnosis, timing system, and LLRF control systems [2][3].

The DAQ system for BPM measures beam position and phase in pulse mode through IQ-based RF signal measurement. It used a single type of electronic product for all BPMs so that the design of the front electronic device is applied to all type of single-board computers

through minor modifications. Table 1 summarizes the main specification of the Linac BPM and beamline BPM. The fabricated BPMs are shown in Fig. 2.

Table 1: Design Parameters of the BPMs

Type	Linac BPM	Beamline BPM
Electrode aperture	20 mm	100 mm
Electrode thickness	2 mm	2 mm
Electrode angle	60 deg.	456 deg.
Electrode length	25 mm	70 mm
Electrode gap	3.5 mm	15 mm
Feedthrough	SMA	SMA
Signal frequency	350/700 MHz	350 MHz

Figure 2: Linac BPM (left) and beamline BPM (right).

The BPM frontend that receives, levels down, and filters BPM signals includes analog parts of some sensitive electrical devices. The signal that has passed the frontend is sampled by the digitizer board and accumulated in memory. The sampled data extracts valid values such as beam position, beam phase, and beam current. KOMAC BPM DAQ has been upgraded to be integrated using EPICS [4] after collecting and processing BPM signals.

## SYSTEM CONCEPT

As part of the available electronics platform and electronics standardization strategy, VME has been adopted and used as a major device for KOMAC's high-performance electronics, including BPM, timing and LLRF systems. The main reasons for adopting VME are excellent performance, durability, and cost reduction. In particular, by unifying the platforms of various control system, short development processes and simple maintenance become the biggest advantages.

Figure 3 shows a schematic diagram of the BPM system manufactured by KOMAC for accuracy and calibration.

tion measurement. The original plan was to measure the beam phase and position using a log ratio BPM electronic device. However, only the beam phase of the BPM is currently being measured. The upgrade plan is to directly measure the four signals of the BPM electrodes and simultaneously generate beam phase, beam position, and beam current from four signals.

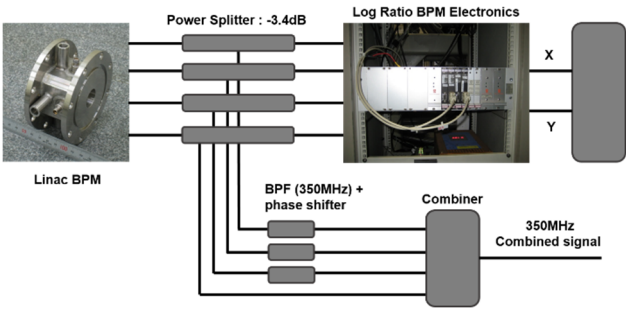

Figure 3: Original plan for beam phase and position.

The induced voltage of the BPM is transmitted to the DAQ system installed in the KOMAC klystron gallery by four coaxial cables. The DAQ contains several electronic modules, such as digitizer board for processing analog signals and VME CPU board with EPICS middleware installed on vxWorks operating system.

The accuracy and calibration of the BPM were performed on the test stand as shown in Fig. 4. After checking the signal processing results of BPM's test stand and DAQ, the calibration value is obtained by measuring the BPM position mapping data using the actual BPM signal line in the tunnel.

Figure 4: BPM test stand for accuracy and calibration measurement.

A wire containing RF power is passed through the BPM instead of the actual beam. The ADC board measures the X and Y output voltages of the BPM. The X and Y voltages sampled by the ADC are processed in driver support of EPICS IOC and serviced using Channel Access (CA).

### BPM DAQ SYSTEM

The data acquisition board consists of a Linac BPM and beamline BPM. The MVME3100 baseboard and PENTEK7142 board for beam signal acquisition have been adopted as Linac BPM as shown in Fig. 5. For beamline BPM, Libera spark HL products have been adopted [5]. PENTEK7142 is a PMC type board with a 14-bit, 125MHz/s/channel sampling function for four

independent analog inputs with Xilinx Virtex-4 FPGA. At the KOMAC facility, 10 DAQ boards for Linac BPM and 9 DAQ boards for beamline BPM are installed. Since the BPM DAQ must be synchronized with the beam timing, all DAQ system for beam diagnosis equipment must be synchronized with the KOMAC timing system.

Figure 5: MVME3100 and PENTEK7142 for Linac BPM.

One of the reasons for choosing the MVME3100 board is to match the PCI bus transmission rate with the PEN-TEK board. Table 2 describes the PCI bus specifications. The PENKEK board supports a PCI bus transmission rate of 64 Bits/66 MHz. The PCI bus of the MVME3100 may select 32bits and 64bits of bus width at 66 MHz.

Table 2: Specifications of PCI Bus

Type	Clock	Bus Width	Data Rate
PCI	33MHz	32bits	132MB/s
		64bits	265MB/s
PCI or PCI-X	66MHz	32bits	264MB/s
		64bits	528MB/s
PCI-X	133MHz	32bits	532MB/s
		64bits	1064MB/s

Figure 6: Schematic diagram of BPM DAQ System for measuring beam phase, position, and current.

The analog frontend consists of RF components including a mixer, 4-way splitter, 350MHz band pass filter, low pass filters. The 350MHz beam signal is mixed with the 300MHz LO signal for signal conversion and is down-converted to 50MHz IF signal in the analog frontend. The IF signal is sampled by the PMC ADC board. Figure 6 shows BPM DAQ System for measuring beam phase, position, and current with a 350MHz signal generator and

a DAQ digitizer board used in the BPM test stand. The DAQ system for the Linac BPM is classified into two parts: MVME3100 baseboard and PMC digitizer board. In PMC, data is sampled using ADC and the sample IQ data is stacked in the FIFO memory. When the stored data reaches a specified memory size, an interrupt is generated and the data is transferred to the baseboard through a PCI bus. The data block transmission between the baseboard and the PMC digitizer board uses the DMA method. DMA uses burst address mode, which repeats read/write indefinitely from start to end. The burst address mode reduces the counter by 1 and proceeds until it reaches zero, and when it is done, it informs the CPU using DMA\_INT as shown in Fig. 7.

Figure 7: Transfer the data block between two-hardware devices.

Figure 8: User interface of BPM using CSS.

### EPICS Driver Support

The VME baseboard has a built-in EPICS IOC server and generates PV data, and serves it. The ADC data is supplied to the FPGA. The FPGA stacks the data in the FIFO memory in an IQ arrangement and hands over the data to the CPU board after one pulse. The EPICS driver support is implemented to extract the beam position, phase, and current. The beam position is different of sum and log ratio. Position mapping data of BPM is measured to obtain a calibration value, and application to the DAQ system is completed. The beam phase is vector sum of four signals from four electrodes in a beam chamber. The beam current is amplitude sum of four signals from four electrodes. Primary data processing is performed in the driver support area of the EPICS layer. Amplitude and phase are generated from IQ data. The FPGA code must

be general and flexible, so it can be used for all BPM types with little modification.

The final value calculated and obtained from the driver support is registered in the EPICS PV. BPM data is monitored in real time through the Control System Studio (CSS) and Channel Access (CA) in shown Fig. 8.

## CONCLUSION

The BPM DAQ system for KOMAC Linac and beam-line has been developed. The MVME3100 and PEN-TEK7142 ADC board have been adopted to directly collect signals from the BPM 4 channels and process data. EPICS IOC for MVME3100 has been developed with the PENTEK driver. The BPM data processing is performed by EPICS driver support, and beam position, phase and current values could be checked in real time for each beam pulse. Libera spark HL products have been adopted and installed for beamline BPM. Libera is judged to be a user-friendly system in beam position electronics based on system on chip platform.

The VME baseboard has been adopted and used as a major device for KOMAC's high-performance electronics, including BPM, timing and LLRF systems. By unifying the platforms of various control system, short development processes and simple maintenance become the biggest advantages.

## ACKNOWLEDGMENT

This work has been supported through KOMAC (Korea Multi-purpose Accelerator Complex) operation fund of KAERI by MSIT (Ministry of Science and ICT).

## Device Control and Integrating Diverse Systems

representation of equipment to higher layers through which the equipment can be monitored and controlled. The elementary entity on this level is called an Input Output Controller (IOC).

The gigabit Ethernet (GigE) Local Area Network (LAN) allows the communication between the IOCs, Archivers, and OPIs.

The software architecture of the control and archiving system is shown as in Fig. 1. The EPICS IOC software package are dealing with the low-level input and output controls to the devices, while the GUI (Graphical User Interface) for HLA (High-Level Application) and the GUI for Archiving system are taking care of the High-level user operations.

### Design of the Control System

The control of the Beam Profile Station for Gamma Beam diagnostics includes one Mclellan PM600 motor controller and two Trius-SX674 CCD cameras.

**IOC Design for the Motor Controller** The Mclellan PM600 is a powerful single axis motion controller which has been selected for the beam profile station to move the scintillators in and out of the gamma beam.

Figure 2: The hardware and software structure for the motion control.

The motor controller Mclellan PM600 is connected to the PC via a RS232 serial cable, and to the linear bellows drive via the dedicated Motor and Limit/Datum cables.

The diagram showing above (Fig. 2) is the hardware and software structure for the motion control which includes a Mclellan PM600 controller, connected via RS232 serial cable to an IOC running EPICS and motor related software. The IOC is connected to the operator's workstations via the Ethernet network.

Mclellan PM600 controller is supported by the EPICS device support module motor record. By using the motor record, the IOC can read motor position from the controller's readback register, can get readback information while the motor is moving, and can trigger a forward link when a complete motion is finished.

**IOC Design for the CCD Cameras** The image acquisition of the Beam Profile Station for Gamma Beam diagnostics includes two Trius-SX674 CCD cameras which are connected to the PC via USB cables.

The goal is to provide a functional EPICS application using the required Python device support and device drivers for the Trius-SX674 CCD camera.

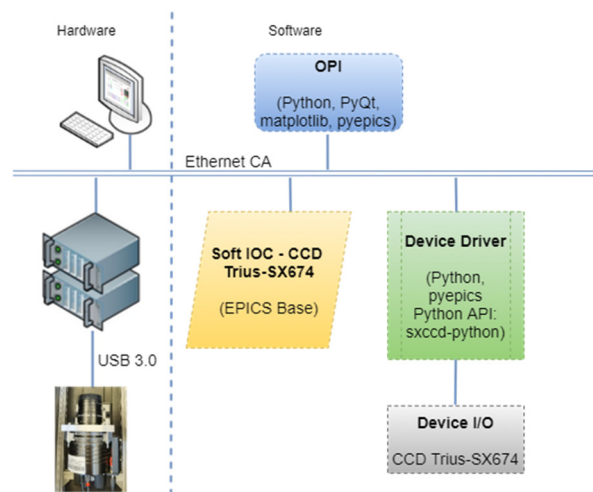

Figure 3: The hardware and software structure for the CCD camera.

The Hardware and Software structure design for the Camera (Fig. 3) includes a Trius-SX674 CCD camera, connected via USB 3.0 to an IOC running EPICS and camera related software. The IOC is connected to the operator's workstations via the Ethernet network.

Trius-SX674 CCD camera is not a standard genicam camera, so the most common used EPICS device support modules aravisGigE and areaDetector cannot be used as the Linux camera driver. We use Python API sxccd-python as device support module, and implement a driver wrapper based on this device support module. Besides, a soft IOC will deal with the EPICS databases for the CCD camera control.

**Design of the OPI (GUI)** Typically, areaDetector plugins are used to save images and to provide arrays used for displaying images acquired by cameras using the GUI. Since the Trius-SX674 CCD camera is not supported by EPICS areaDetector, the GUI need to be implemented individually.

The EPICS device support module motor record provides a CSS BOY-based GUI to perform the device-layer control and troubleshooting for the Mclellan PM600 controller. Moreover, a Python and PyQt based GUI for the motion control and the image acquisition for the Beam Profile Station will be implemented.

The goal is to provide a functional EPICS based GUI to control the Mclellan PM600 controller and to acquire image from the Trius-SX674 CCD camera.

### Design of the Archiving System

The architecture of the archiving system (as shown in Fig. 4) consists of an archive engine, the MySQL RDB, a web server and the web-based GUI.

The Archive Engine samples Process Variable (PV) data, time stamp etc., from EPICS IOCs via Channel Access (CA), and places them in a Relational Database. Users can then access the historic data from the database as well as the live data from the PV channels using the CSS Data Browser. Config.xml and settings.ini are the two basic configuration files needed to configure the database by using the provided ArchiveConfigureTool. Besides, PhpMyAdmin is used as the tool for the database maintenance and configuration.

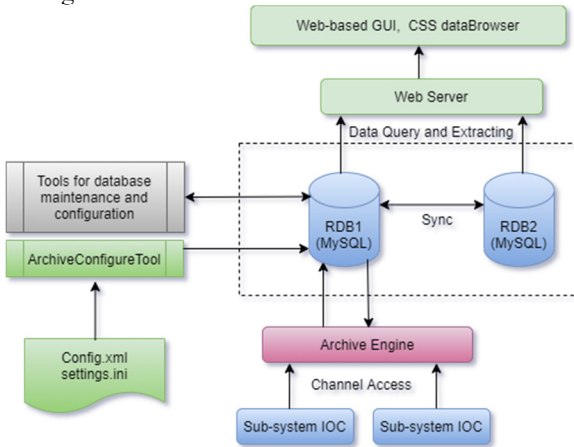

Figure 4: The structure and data flow of the archiving system.

## IMPLEMENTATION

### Implementation of the IOCs

To integrate the Trius-SX674 CCD cameras, we use Python API sxccd-python [3] as the device support module. Based on the sxccd-python module, a driver wrapper has been implemented for the communication with the soft IOC which deals with the EPICS databases for the CCD camera control.

The IOC for the CCD camera starts with an initialize module to deal with the USB connection and soft IOC initialization. The read-out loop detects when the image acquisition toggle is on, then the image will be captured and the waveform data will be put into the PV of image.

McLennan PM600 controller is supported by the EPICS device support module motor record [4]. To integrate the PM600 controller, we use the version of the motor record motorR7-1, as well as other related modules in EPICS SynApps5-8.

The IOC for the motor controller is implemented following the standard steps for an EPICS motor IOC. The IOC start file st.cmd is configured to clarify the support module, to establish the serial connection, and to generate the database by the file motor.substitutions and motorUtil.db

### Implementation of the OPIs

The operator interface, the GUI is implemented using python3 and PyQt5. Some other python modules, such as numpy, pyepics, threading, and matplotlib etc., are also imported for the development.

A screenshot of the GUI has been shown in Fig. 5.

The left part of the GUI is dealing with the following motion controls:

- Turn on/turn off the motor remotely.
- Move the motor for a certain distance.
- Set the velocity.
- Update the feedback in real-time.
- Calibrate the motor to the home position.

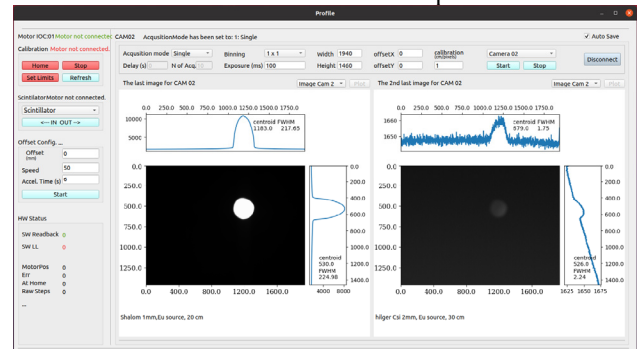

Figure 5: The GUI for the control of the motor and CCD.

The rest part of the GUI is able to deal with the image capturing controls as following:

- Turn on/turn off the camera remotely, to acquire image remotely from the client user interface.
- Set the width, height, exposure time, offset, and acquisition mode (single/continuous).
- Monitoring the status of the camera, to set the exposure time for the camera.
- Provide real-time processing of the images, e. g., profile for X and Y axis, centroid, and FWHM.
- Save images in different formats for the image analysis.
- Save the waveform data of the images.
- Save the parameters for the image capturing.

### Implementation of the Archiving System

The EPICS Archive Engine Service in CS-Studio has been chosen as the software tool for the archiving system development. To configure the archive engine, Phoebus [5], the latest version of CS-Studio has been chosen as the archive engine configuration tool to read samples from PVs and write them to the RDB. The data browser has been chosen also to browse the historical or monitoring data from the RDB.

The Archive Engine has been configured using the ArchiveConfigTool. PhpMyAdmin has been used as the database management tool.

Besides, we stored on the database server all the images which are acquired from the Beam Profile System, as well as the image data, and the image related parameter files in the file system.

### Implementation of the Web Server and Web-Based GUI

Figure 6 shows the scheme used to implement the web-based system using the MVC (model-view-controller) pattern. With this implementation, the system can serve requests in two ways: by using the embedded views and also via API's fetching and sending raw data.

Figure 6: MVC representation.

The web server and the web-based GUI for the archiving system is implemented based on Node.js, Express, MySQL, Sequelize, Javascript, Pug, HTML, and VS code.

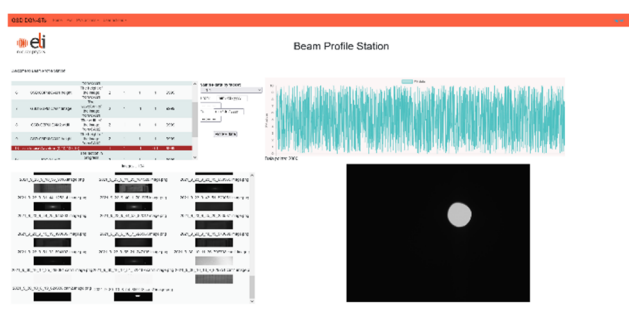

Figure 7: EPICS-based archive application GUI.

Figure 7 shows the results of HTTP requests using the embedded view (GUI). By using the web-based GUI, users can connect to the archive RDB which stores the data fetched by the archive engine. Users can also browse the data by choosing a PV from the PVs-list and then plot the data immediately. Moreover, the GUI allows users to choose an image from the images-list and to display it immediately with the parameters associated to the image.

## CONCLUSION

The EPICS based control and archiving system has been implemented for the Beam Profile Station at ELI-NP. The devices have been integrated into the control system, and the archive engine has been configured for the archiving system.

The IOC for the CCD camera has been configured based on sxccd-python. A driver wrapper has been implemented for the communication with the soft IOC of the camera. The IOC for Mclennan PM600 controller has been configured using the version of the motor record motorR7-1, as well as other related modules in SynApps5-8. The GUI for the control has been implemented using python3 and PyQt5.

The archive engine has been configured using CSS Phoebus. The web server and the web-based GUI have been implemented using the MVC pattern.

This implementation of the control and archiving system for Beam Profile Station has been proved as a professional programming structure that helps in maintenance and readability of the whole system, moreover, it is reliable enough for scaling up in the future implementation for other diagnostics stations such as Beam Energy Station and Beam Polarization Station at ELI-NP.

# REDESIGN OF THE VELO THERMAL CONTROL SYSTEM FOR FUTURE DETECTOR DEVELOPMENT

S. A. Lunt\*, University of Cape Town, Cape Town, South Africa  
L. Zwalinski, B. Verlaet, CERN, Geneva, Switzerland

## Abstract

The Detector Technologies group at CERN has developed a Two-Phase Accumulator Controlled Loop (2PACL) [1] test system for future detector development, using reused hardware from the LHCb Vertex Locator (VELO) Thermal Control System [2]. The fluid, electrical and control systems have been redesigned and simplified by removing redundant components because it is no longer a critical system. The fluid cycle was updated to allow both 2PACL and integrated 2PACL [3] cycles to be run and the chiller was replaced with an air-cooled unit using hot gas bypass to achieve a high turndown ratio. The electrical systems were upgraded to improve usability and practicality. The control system logic is being developed with the CERN's Unified Industrial Control System (UNICOS) framework. This paper presents the details of the design and implementation.

## INTRODUCTION

The Vertex Locator (VELO) Thermal Control System (VTCS) is the first CO<sub>2</sub> detector cooling system used at CERN to cool LHCb's VELO sub-detector. Following the successful use of CO<sub>2</sub> cooling in the VTCS and AMS-02 [4] on the International Space Station the number and capacity of CO<sub>2</sub> based detector cooling systems has increased significantly with installations in the LHCb, ATLAS and CMS experiments at CERN. The VTCS was retired and replaced with a new system in 2019 [5]. The Detector Technologies (DT) group decided that the system could be refurbished and used for the development and testing of future detectors for ATLAS on the surface.

The system was partially redesigned to prepare it for the new role. The electrical system was replaced to ensure it met the department's standards. The control logic has been rewritten with a new program developed under the Unified Industrial Control System (UNICOS) framework [6]. The fluid systems have remained largely unaltered with only the position of the accumulators being changed. All redundant components have been removed and a mode that runs the integrated two-phase accumulator controlled loop (I2PACL) [7] have been added. The chiller has been replaced to make it more suitable for surface applications without available underground infrastructure.

## FLUIDIC SYSTEM

The original fluid systems were designed with redundancy in each layer to make sure no single failure would cause the

detector's cooling supply to stop because the silicon tracking sensors of the detector degrade quickly at temperatures above 0 °C after they have been exposed to radiation. These redundant elements have been removed from the new system because a failure of the cooling system in a test environment is acceptable because the sensors have not been exposed to radiation [8].

The VELO detector consists of two halves that sit on either side of the beam. The VTCS was designed with two independent, two-phase accumulator controlled loops (2PACL), one for each side. A third pump was installed to act as a backup for either side in the event of a pump failure [2]. This pump along with the pipes and valves that supplied it have been removed. Two valves were left in because they provide mechanical support for the surrounding pipes and convenient access for maintenance of the system.

The new system will retain the two independent 2PACL, shown in Fig. 1, loops to maximise its versatility and minimise the changes that need to be made to the CO<sub>2</sub> system. To improve the responsiveness of the controllers to changes in the process, in-flow temperature sensors are being added. The accumulator heat exchanger previously connected to the backup chiller will be used to allow the system to run in the simpler Integrated 2PACL (I2PACL) mode [7].

## Integrated 2PACL

Since the development of the VTCS the DT group has made improvements to the two-phase process: integrated 2PACL. This removes the need to actively cool the accumulator, reducing the complexity of the fluid and control systems. In an I2PACL system, the sub-cooled CO<sub>2</sub> leaving the pump flows through a heat exchanger in the accumulator, shown in Fig. 2.

Removing the need for a controlled external cooling source simplifies the control of the accumulator's saturation pressure, thus allowing the saturation temperature of the accumulator to be controlled with the heater alone. The heater provides the energy equal to the heat capacity of the liquid CO<sub>2</sub> and by controlling the power the pressure is regulated (Fig. 3).

The accumulators contain two condensing spirals, which were used by the main and backup chillers. One of these condensing spirals will now be used for the I2PACL mode; the other will be supplied from the chiller to control pressure in 2PACL mode.

## Chiller

The primary water-cooled chiller and backup air-cooled chiller, will not be reused. Cold water is a service supplied in the caverns at CERN but is not readily available in other

\* Intstu001@myuct.ac.za; slunt@cern.ch

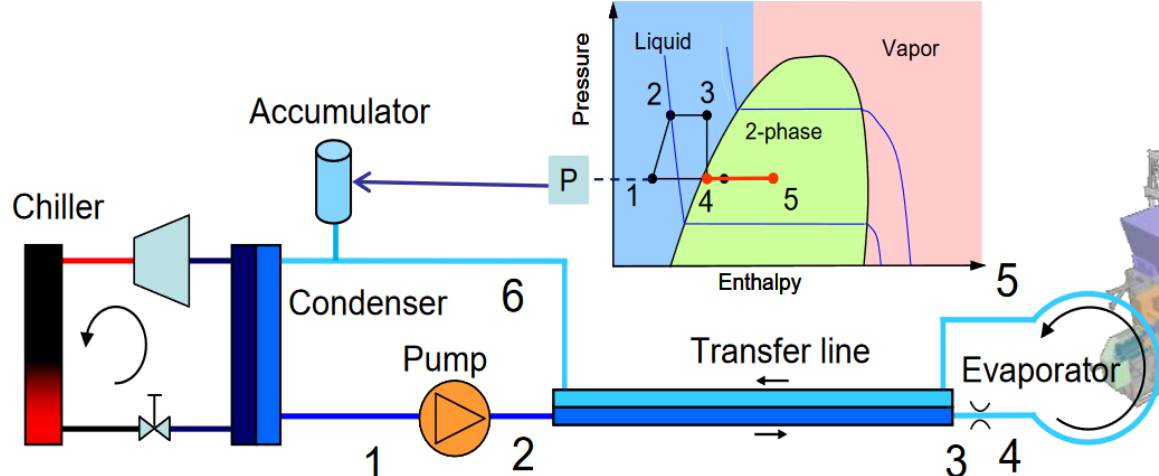

Figure 1: 2PACL system diagram [9].

Figure 2: I2PACL system [10].

parts of the site, making the old primary chiller problematic to re-use on the surface. The backup chiller's capacity is only 1 kW which is too low. They will be replaced with a new 3.15 kW air-cooled chiller.

The chiller is based on a commonly used design that the group first developed for the Light Use Cooling Apparatus for Surface Zones (LUCASZ) systems, shown in Fig. 4 [10]. Hot gas bypass and cold liquid injection valves allow the chiller to continue running when varying or low loads are applied to it. This is unusual in refrigeration systems as they are typically designed to operate at a fixed load. In this case, the load will be variable and the chiller needs to be capable of running normally at any load that is applied to the system.

The chiller will use R449a to replace R404a which is prohibited from being used in new systems from 2020 by the European Fluorinated Gas Regulation to reduce the climate impact of refrigeration systems [11]. The adaptation to R449a required some minor modifications to the design and control to accommodate the differences in the characteristics of the two refrigerants.

## ELECTRICAL SYSTEM

The electrical systems were examined to determine what could be re-used from the original system and what would require upgrading. The electrical hardware in VELO was installed in rack mounted boxes with connectors on the back. These boxes were replaced with a simplified electrical system where all the electrical components are mounted vertically in the cabinet behind the front door, as shown in Fig. 5.

This design is advantageous because it makes the components more visible and accessible. The status of circuit breakers can be seen and set or reset without disconnecting any cables or removing components from the cabinet. The flat layout also allows for signal cables and power cables to be more easily isolated from each other, reducing the impact of electrical noise on other components. A new electrical design was developed using the original system as a base-line. The design was constrained by the available area of the panel, 500×1500 mm, and by the project budget. Using components that are in good condition from the VTCS or were in spare stock at the time will reduce the cost.

## CONTROL

The control architecture has been completely redesigned using CERN's UNICOS continuous process control framework [6] to make sure it meets CERN's standards and will be easily maintainable and modifiable in the future. The system will be controlled through Siemens WinCC OA for supervisory control and data acquisition (SCADA) which will operate on CERN's Technical Network (TN) as shown in Fig. 6.

The PLC is a Siemens S7-400 station that will be reused with changes to some modules. The CPU was upgraded to one with a greater work memory to accommodate the larger size of programs developed using UNICOS. An incompatible controller card was removed and replaced with an analogue output (AO) module. The current system configuration is shown in Table 1.

The spare channels were retained because we already had all the IO modules apart from the analog outputs and

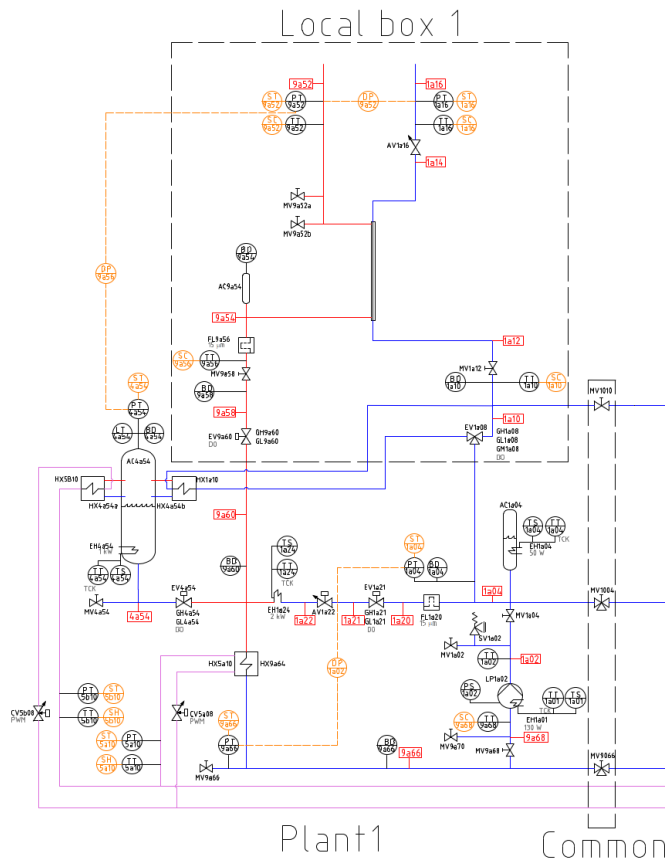

Figure 3: CO<sub>2</sub> P&ID diagram.

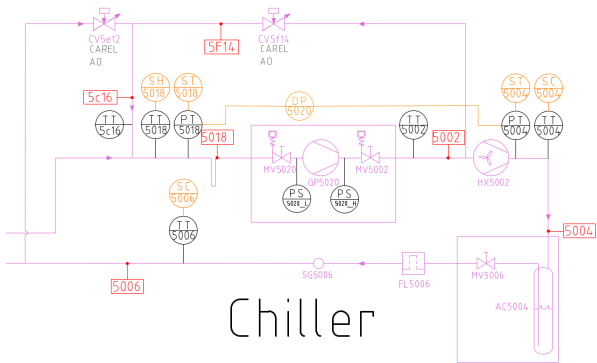

Figure 4: Chiller P&ID.

Table 1: PLC IO Channels		
IO type	Used	Total
Digital input	63	96
Digital output	41	96
Analog input	47	64
Analog output	2	8

they were connected to IO terminals in the cabinet. They also provide a comfortable buffer against the failure of an individual card. The S7-400 platform is reaching end of life,

if a IO card failed it would be possible to switch to a spare unit and continue operating while a replacement is found.

Figure 5: New power distribution panel.

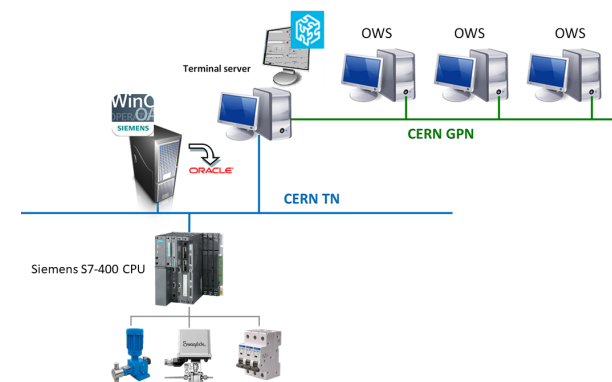

Figure 6: Control system architecture.

## Program Structure

UNICOS applications are made up of process control objects (PCO) each representing a separate unit within the system. A PCO can be made up of actuators or other PCOs as shown in Fig. 7. This system has a top-level PCO called CO<sub>2</sub>. The chiller is its own PCO containing all its actuators. Each 2PACL system is identical and has its own PCO which contains the CO<sub>2</sub> actuators and allows the systems to operate independently. Each local box has its own PCO which is contained by the respective plant PCO and controls the flow of CO<sub>2</sub> from that PCO.

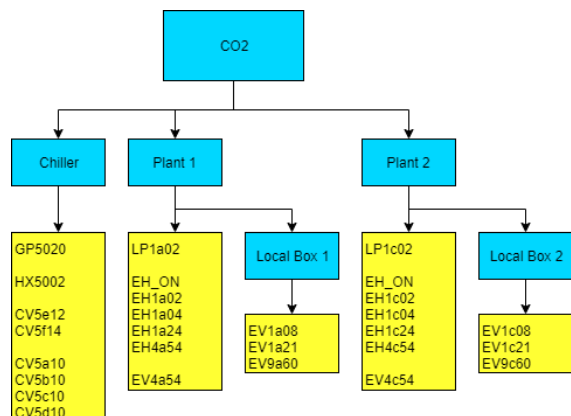

Figure 7: PCO structure.

The state of a PCO will be determined by the state of the parent PCO. If this is in Stop mode then the dependant PCO's will also be stopped. If a parent PCO is in Run mode, the dependant PCO's will be allowed to run subject to its normal run conditions. The two CO<sub>2</sub> plants can run independently of each other. The chiller will start when one or both CO<sub>2</sub> plants are requested to run.

## Safety

The use of liquid CO<sub>2</sub> in a closed system introduces several important safety concerns which the system design must mitigate. The control system must ensure that no cold liquid CO<sub>2</sub> is trapped in a confined space. If this happens the pressure will increase dramatically as the CO<sub>2</sub> heats and

boils, causing the pipe to burst or safety systems to activate and the CO<sub>2</sub> will be vented from that section. This could cause damage to the system and harm anyone who is in the vicinity.

Experiments will be manually connected to and disconnected from the local box. This process requires manual intervention by the operator. The design must protect both the operator and the hardware from potential operator error. If the operator opens a local box valve at the improper time CO<sub>2</sub> could be vented into the atmosphere. This poses an asphyxiation hazard to the operator.

The Stop or Safe position of controlled valves is set to open except for the local box shutoff valves, which will close. This ensures that there is always a path for CO<sub>2</sub> to return to the accumulator, but isolates the local box from the rest of the system. When an experiment is disconnected, the PLC will wait until only vapour is present in the transfer line before allowing the operator to continue.

If the system is stopped without disconnecting the experiment or an emergency stop is triggered, the local box shut-off valves will close with liquid still inside. This is important to simplify the shutdown procedure and allow an experiment to remain connected. A pressure vessel, AC9a54 shown in Fig. 3, will be added to allow any liquid CO<sub>2</sub> trapped in the local box to pressurise without causing any damage. It will have the same volume as the tubing in the local box and be placed above the accumulator and transfer line. This ensures that there is only vapour present at all times.

## Start-Up and Experiment Connection

The chiller and both CO<sub>2</sub> plants have no start-up sequences. They start running when that state is requested and any interlocks are cleared. The Local Box has a more detailed process depending on the mode it is running in. These are shown in Fig. 8 with the transitions explained in Table 2.

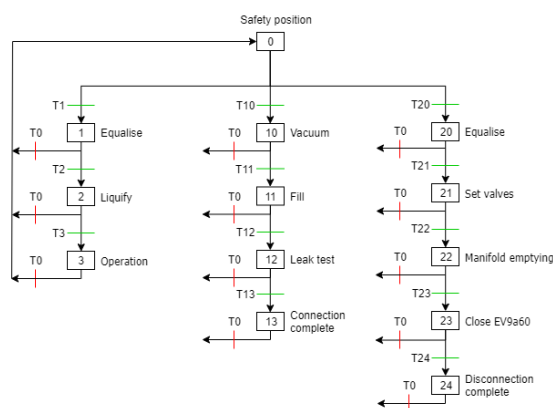

Figure 8: Stepper for the Local Box PCO.

**Normal operation** For normal operation of the local box the local box PCO changes the set point of the CO<sub>2</sub> plant to equalise the pressure difference across the valves before opening. Following this, the loop is liquefied before the set point is changed back to the user set point.

Table 2: Transition Condition Descriptions

Transition	Condition description
T0	Stop request
T1	Device connected and run mode
T2	Pressure difference within limits
T3	Liquid CO <sub>2</sub> is circulating
T10	Device disconnected and connect mode
T11	Vacuum applied
T12	Device filled with CO <sub>2</sub>
T13	Leak test OK
T20	Device connected and disconnect mode
T21	Pressure difference is within limits
T22	CO <sub>2</sub> return valve open
T23	Super-heating in the local box
T24	Plant valves closed

**Connection procedure** The connection process is a manual process that is performed by the user. The PLC uses the sensors in the Local Box to monitor the steps that the user performs and ensures that they are all followed properly.

**Disconnection procedure** To disconnect an experiment, the Local Box is first emptied of liquid CO<sub>2</sub>. This is done by reducing the accumulator set point to its minimum allowable value and waiting for super-heating to be detected in the local box. This removes as much CO<sub>2</sub> from the local box as possible and allows the user to vent and disconnect the local box safely.

## CONCLUSION

The VTCS has been significantly simplified and optimised to fulfil its new role for the group. The new design follows the most recent norms and standards of CERN and the DT group to ensure that it can be maintained or modified as needed to continue supporting the group's research.

## ACKNOWLEDGEMENTS

I would like to thank Lukasz Zwalinski, Bart Verlaat, Michal Zimny and Wojciech Hulek for their continuous guidance on this project. Eric Thabuis and Loic Curtat from the gas workshop for their assistance with technical elements of the rebuilding of the system. Pawel Bak contributed to the development of the electrical schematics.

## APPENDIX

The system documentation will be uploaded to the Engineering Data Management System (EDMS) and will be avail-

able at: <https://edms.cern.ch/>. The project is named DTCS and can be found under: CERN-0000219585.

# LHC VACUUM SUPERVISORY APPLICATION FOR RUN 3

Sebastien Blanchard<sup>†</sup>, Ivo Ambrósio Amador, Nikolaos Chatzigeorgiou, Rodrigo Ferreira,  
Joao Diogo Francisco Rebelo, Paulo Gomes, Christopher Viana Lima, Gregory Pigny,  
Andre Paiva Rocha, Lampros Zygaropoulos  
CERN, Geneva, Switzerland

## Abstract

The LHC Vacuum Supervisory Control and Data Acquisition application has been upgraded to fulfil the new requirements of Long Shutdown 2 and Run 3.

The number of datapoint elements has been increased from 700k to 1.5M, which constitutes a challenge in terms of scalability. The new configuration of pumping station control hardware has led to an increase in the number of permanently connected PLCs – from 150 to almost 300. A new concept has been developed and deployed, in which the PLC configuration is updated online. The goals were to automate, and to speed up periodic updates of the control system. Integrating of the wireless mobile equipment had led to the acquisition of expertise in dealing with temporary connections and dynamic insertion of device representation in the synoptic.

Other new features include: the introduction of an innovative remote control and representation in synoptic panel of hardware interlocks, the development of a pre-configured notification system, and the integration of asset management into the user interface.

## VACUUM SYSTEMS

The Large Hadron Collider (LHC) has two types of vacuum systems:

- The beam vacuum system, which reaches ultra-high vacuum (below  $1 \times 10^{-9}$  mbar).
- The insulation vacuum system, used for thermal insulation of cryogenic components, and which reaches high vacuum (below  $1 \times 10^{-5}$  mbar).

Both systems are divided into sectors delimited by vacuum valves or windows. Vacuum sectors will reduce or entirely prevent the propagation of sudden pressure increases. They also allow for independent venting and interventions.

The beam vacuum system of the LHC has 321 sectors. Only a few sectors have pumping group stations [1] permanently installed. For most sectors, pumping group stations – and sometimes, bake-out cabinets [2] – are temporarily installed during installation or interventions. Pumping group stations achieve high vacuum, after which bake-out cycles decrease the outgassing rate of the vacuum vessel and activate the NEG thin-film coatings. Finally, the permanently installed pumps are started. These include, for example – ion pumps. In addition, every sector has a full set of vacuum gauges.

The insulation vacuum system of the LHC has 235 sectors. These sectors have pumping group stations [1] and vacuum gauges permanently installed.

Table 1: List of Remote-controlled Instruments

Type	System	Count
Sector Valves	Beam	324
Sector Valves	Insulation	68
Fixed Pumping Groups	Beam	10
Fixed Pumping Groups	Insulation	193
Ion pumps	Beam	906
Pirani Gauges	Beam	455
Pirani Gauges	Insulation	343
Penning Gauges	Beam	803
Penning Gauges	Insulation	343
Ion Gauges	Beam	196
Membrane Gauges	Insulation	237

Table 1 lists the individual quantities of remote-controlled vacuum instruments in the LHC.

## HARDWARE ARCHITECTURE

The automation layer of the vacuum control hardware architecture is PLC-based. Figure 1 shows the hardware architecture.

PLCs and controllers are installed in radiation-free areas of the LHC's underground, while the radiation-tolerant measuring cards [3], for gauges, are installed in the tunnel – close to the instruments. Table 2 lists the individual quantities of PLCs, controllers, measuring cards and hardware interlocks installed in the LHC.

Table 2: List of Controllers

Type	System	Count
PLCs	Beam	40
PLCs	Insulation	253
PLCs for mobiles	Beam/Insul.	350
Commercial controllers	Beam/Insul.	654
Valve controllers	Beam	324
Radiation tolerant cards	Beam/Insul.	881
Hardware Interlocks	Beam	282
Hardware Interlocks for Cryogenics	Insulation	539

After a successful Run 2, the LHC entered into Long Shutdown 2 (LS2). This will have lasted from the end of 2018, to the beginning of 2021.

<sup>†</sup> sebastien.blanchard@cern.ch

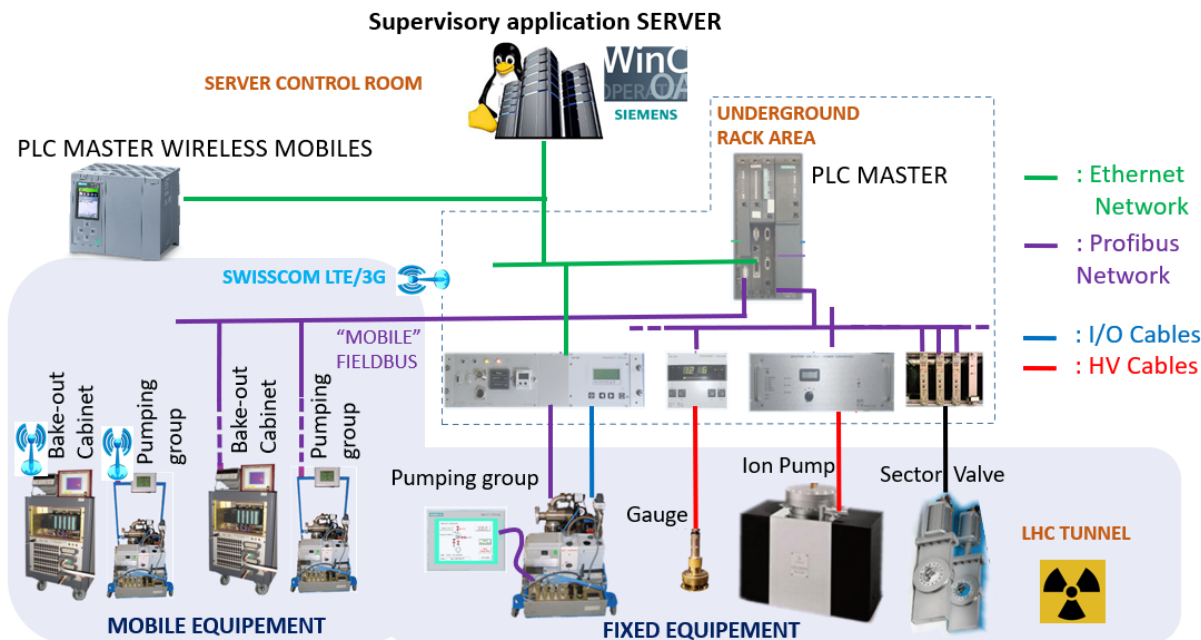

Figure 1: Control hardware architecture.

The following hardware has been upgraded during Long Shutdown 2:

- The permanently installed pumping group controllers (120 models of S7-300, to be replaced with 219 models of S7-1200)
- The insulation vacuum gauges and PLC interlocks (120 models of S7-300, to be replaced with 34 models of S7-1500)
- Mobile pumping groups and bake-out cabinets have been fitted with a 3G/LTE communication solution (55 units).
- New, radiation-tolerant measuring cards (881 units) have been installed for membrane, Pirani and Penning gauges.

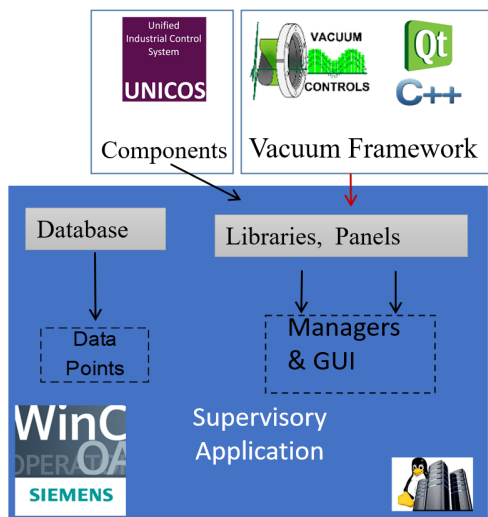

Figure 2: The supervisory application and its components.

## THE SUPERVISORY APPLICATION

The Supervisory Control and Data Acquisition of the LHC vacuum system is based on a commercial product: WinCC OA™ by Siemens™. The Figure 2 shows the application components: managers, drivers and libraries. These come from either WinCC OA™ native components, or from CERN standard frameworks such as UNICOS [4], JCOP [5], and the Vacuum Framework [6].

The Vacuum Framework (libraries, panels, and components) customises the application to facilitate vacuum devices and features required for operating the LHC vacuum system.

### Proof of Scalability

During the period of Long Shutdown 2, the vacuum supervisory application of the LHC had seen successful growth on an unprecedented scale. The number of data points has increased from 700k to 1.5M due to:

- Integration of 3G/LTE communication solution.
- Integration of new, highly parameterised controllers such as the Agilent™ Ion pump controller.
- Increase of device number, vacuum sectors number and layout complexity.
- Increase of PLC connections, from 150(before Long Shutdown 2) to 290.

## DEVELOPMENT OF NEW DEVICE TYPES

Three major control types have been completely refactored (pumping group, ion pump and rough to high vacuum gauge).

## Pumping Group Device Type

A pumping group station is, at minimum, composed of a primary pump and a valve. Depending on the subtype, it can contain a turbo-molecular pump, four additional valves, one or two gauges, an integrated bakeout system, a heated exhaust system, etc. The process is controlled by a PLC, which also manages the interlocks.

The pumping group can be either permanently installed, or temporarily connected to the vacuum vessel (the so-called mobile pumping group). Mobile pumping groups are remote-controlled – either through a Profibus network deployed during the LHC installation in the 2000s, or through the new 3G/LTE communication solution [7].

Altogether, it represents a very large number of subtypes due to all the possible combinations. The development guideline was to standardise the behaviour of the device representation in the synoptic panel and the layout of the device details panel. For all the temporary (mobile) or permanently installed pumping group in the LHC accelerator, a single device type (set of libraries) has been developed.

Process specifications did not change since LHC Run 2. There were, however, significant changes to pumping group control. During LHC Run 2, every instrument (pumps, valves, gauges, etc.) had been controlled individually, and the pumping group had been managed globally, by a process. This allowed the switching of instruments to manual operation, and to drive them independently. As a result of the pumping group controller upgrade, the control becomes global-only, without the possibility of switching individual instruments to manual operation.

At first, development of the supervisory device libraries started in absence of new specifications. Indeed, the instrument itself had not changed; therefore, new specifications had not been requested. As mentioned above, however, the pumping group control method was very different. Choices regarding the new behaviour and standardisation had to prioritise speed over consensus, considering the strict deadline for first deployment.

The first deployment – even though it had allowed for perfect remote control of the pumping groups – was not a success. Mainly due the lack of status information in the synoptic panel, which confuse an operator who had been accustomed to the previous behaviour. A new version must be developed – this time with proper specifications, approved by the operators responsible. The next development and deployment fixed all the issues.

The 3G/LTE communication mobile pumping group is managed by the same device type as the permanently installed pumping group. A new dynamically built synoptic panel has been developed [8] and deployed. The synoptic library inserts or removes the widget representation of the mobile device changing dynamically the length and organisation of the synoptic panel according to the device connection state. The first deployment of the new, dynamically built synoptic panel experienced some issues. The rebuild and display of the synoptic takes a couple of seconds, which is acceptable in normal conditions. Unfortunately, however, the application had suffered continuous

disconnection and re-connection cycles, resulting in the synoptic rebuilding all the time. This issue has been fixed by, first, invalidating the device (with a blue colour animation), then introducing a ten-minute timeout, before finally removing the device representation and rebuilding the synoptic.

## New Strategy for Pumping Group Updates

Concerning the new hardware, each pumping group has its own PLC controller. This means 219 PLCs that may require updating during LHC Shutdowns and Technical Stops.

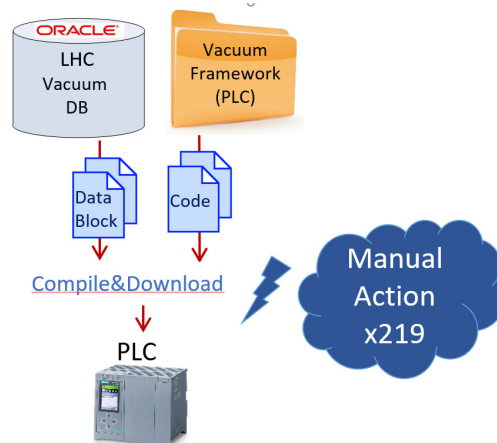

Figure 3: PLC update procedure, following the old/standard strategy.

The update describes in Figure 3, following the standard procedure (as was common before the new strategy) would have taken a very long time. 219 compilations and downloads – each performed manually – usually undertaken for the trivial purpose of changing equipment names or process parameters. Furthermore, this procedure also requires that pumping groups be vented and stopped.

Figure 4: New strategy update procedure.

The new strategy delegates the update of parameters and names (defined in a database) to the supervisory application – making this procedure automatic.

As shown in Figure 4, the configuration step (i.e., the updating of names and parameters coming from the LHC

vacuum database) is included in the supervisory application update. This is the most common type of update required during Technical Stops. Technical Stops are already short (three-to-four days long), and the time allotted to the control software update is even shorter (half a day). The much faster update and the suppression of manual intervention errors are two obvious advantages. In addition, this procedure does not require for pumping to be stopped, nor does it interrupt the remote control and logging - also very important points.

Updates of the PLC code baseline still require a standard update procedure, but such intervention is rarely scheduled during Technical Stops.

### New Ion Pump Controller and Sector Valve Interlock Animation

The ion pump controller measures the current of the power supply. This current is a function of the pressure in the vacuum vessel. The controller is therefore used to provide hardware interlocks to the sector valves with ion pump pressure level thresholds. The new ion pump controllers, installed during Long Shutdown 2, compliment a complete communication interface with remote control of all the parameters and access to all the statuses, including parameters and statuses of the interlock outputs.

To make use of this information, a new animated interlock hardware widget has been developed. Hardware interlock widgets are represented in the synoptic by an arrow pointing in the direction of the target valve. The arrow is represented either in green (no interlock) or in purple (valve interlocked). Sources of the interlock can be changed with the new remote control from one ion pump to another. As shown in Figure 5, the operator can now change the interlock schema on-the-fly and shift the interlock source from a faulty ion pump, to an intact one, and so maintain the level of protection even when a component of the interlock schema fails. This is not such a rare occurrence in a vacuum system as large as the LHC's.

Figure 5: Hardware interlock animation in the synoptic.

### I/O Gauge Device Type

Measuring and control cards for I/O gauge are installed in the arcs of the LHC tunnel (for both insulation and beam vacuum). Anticipating increased levels of radiation in the tunnel, the cards have been replaced with a radiation-resistance version. The software framework team took the

opportunity to develop a new unified device type for all I/O gauges with a thorough protection scheme.

The Penning gauge is an on/off vacuum gauge to measure pressure ranges between  $1 \times 10^{-5}$  and  $1 \times 10^{-11}$  mbar. If this gauge were switched on or operated at pressures above approximately  $1 \times 10^{-5}$  mbar - it may be damaged, or at least see its lifetime reduced. To avoid such damage, the gauge is protected either by the controller - or, in case of an I/O gauge - by the PLC. With the new I/O gauge device type, the protection schema has default parameters that can be changed on-the-fly from the supervisory application.

Figure 6 shows all of the protection parameters:

- “Protection Source Gauge”: the third-party gauge used to protect the Penning gauge. This is the standard protection scheme that interlock/switch-off the Penning gauge in case of high pressure.
- “Self Protection OFF Threshold”: same as above, but the source is the Penning gauge itself. It does not replace the above protection - it acts as a redundancy.
- “Self Protected Mode Threshold”: above this pressure threshold, the gauge is switched on for only 16 seconds (duration required for a valid measurement) every 8 minutes. This advanced protection behaviour increases the lifetime of the Penning gauge.

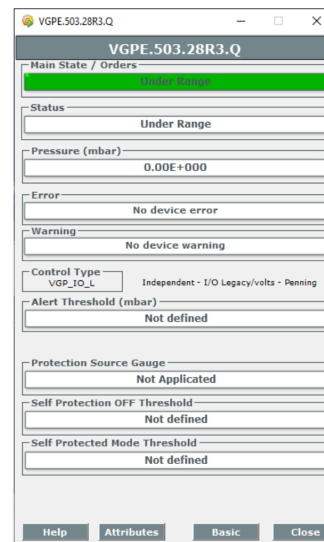

Figure 6: Details panel of an I/O Penning gauge.

## NEW NOTIFICATION SYSTEM

The notification system sends e-mail/SMS message according to its criteria. The notification system already existed before Long Shutdown 2. The first version was working well and had already been used on a large scale, but it required advanced user skills and quite a long time to configure parameter criteria.

The new system offers predefined criteria according to the vacuum sector state. The default available modes are:

- Operation beam vacuum: the criteria are based on sector valve positions and the high vacuum gauge pressure value (threshold  $1 \times 10^{-7}$  mbar)

- Operation insulation vacuum: the criteria are based on the cryogenic alarm signal and rough vacuum gauge pressure value (threshold  $1 \times 10^{-3}$  mbar)
- On work/intervention: the criteria are based on the sector valve position and pumping group state (not pumping or disconnected)
- Bakeout/NEG Activation: the criteria are based on the sector valve position and pumping group states (not pumping or disconnected), the Bakeout controller state, and the gauge pressure value (threshold  $1 \times 10^{-2}$  mbar).

Additional predefined modes and their criteria can be easily defined on-the-fly by the software engineer in charge of the application, simply by adding ASCII text parameters in the supervisory application resources and configuration file. This file is parsed by the notification library during initialisation of the supervisory application client session.

## ASSET MANAGEMENT

A functionality to directly manage assets [9] has been deployed to the supervisory application. It requires up-to-date synchronisation of the functional position names between the vacuum database and the CERN Enterprise Asset Management database. It offers an interface from the widget menu to create maintenance or repair requests. This functionality saves a lot of time and encourages proper equipment asset management. It has been largely used by the vacuum operators during the Long Shutdown period.

## CONCLUSION

The Vacuum Supervisory application is one of the biggest industrial control applications at CERN with 1.5 million data points, more than 290 PLCs for fixed equipment, and more than 250 PLCs for mobile equipment. The main concern of the application upgrade has been device type standardisation. The layout changes for LHC Run 3 have been properly integrated in the supervisory application with significant changes in more than 40 vacuum sectors. The migration of the new controllers has been successfully integrated, taking the opportunity to increase functionality.

The new features and developments have increased the protection of the vacuum system, reduced effort required for its operation and monitoring, and improved diagnostic capability.

# CHALLENGES OF AUTOMATING THE PHOTOCATHODE FABRICATION PROCESS AT CERN

Cédric Charrondiere, Eric Chevallay, Thomas Zilliox, CERN, Geneva, Switzerland

## Abstract

The CERN Photoemission Laboratory was founded in 1989 with the goal of studying laser-driven electron sources, for producing high-brightness electron beams within the framework of the Compact Linear Collider (CLIC) study. To produce these photocathodes, two processes run in parallel. The first process, which is slow and asynchronous, controls and monitors the evaporation of photoemissive material. For this first step several power supplies are controlled to evaporate different metals through the Joule effect, with the power maintained constant in time and the thickness deposited monitored. The second process is synchronized with a laser trigger ranging from 0.1 to 50Hz, where the photocurrent and laser energy are measured to calculate the Quantum Efficiency.

The control system for these processes has recently been renovated to benefit from the modularity of a PXI-based real-time environment using the standard CERN MiddleWare communication layer (CMW). This paper describes the challenges of the fabrication process as well as the flexibility introduced by using a PXI system.

## INTRODUCTION

The CERN Photoemission Laboratory [1] was built with the goal to study and supply the CLIC Test Facilities (CTF 1 and 2) [2] with electron bunches of a few ps in time with a high electrical charge in the range up to 100 nC.

The CERN Photoemission Laboratory apparatus is divided in three parts:

- The Preparation Chamber where the fabrication of our photocathodes (the electron source) is done
- A DC Gun coupled with a beam measurement line for the characterisation of the cathode properties with a real, powerful, electron beam.
- A laser which is used to illuminate the electron sources during the fabrication and characterisation phases.

In the middle of the years 1990, after a few years of R&D, and the validation of the Cs-Te deposition technology, the laboratory received an important upgrade which enable the possibility to supply the CTF, our first client, with electron sources.

## FABRICATION PROCESS

### Physical Process Involved

The fabrication of the photocathode (Fig: 1) is the process of coating a substrate, the Cu photocathode plug, with a mixture of alkali metals and another element, tellurium or antimony. During this process the cathode is illuminated with a laser. A photoemission reaction occurs and produces

an electron current, collected and measured to quantify the cathode's performance. The goal is to maximize the photocurrent and the quantum efficiency of the cathode while ensuring a very good source lifetime.

Figure 1: Cs-Te coating visible on the photocathode head.

In order to optimize the process, the system needs to be able to control several power supplies used to heat the evaporators and monitors the applied electrical power, temperature, laser energy, intensity produced by the photoelectron current, thickness of the coatings and vacuum pressure.

### Instrumentation

- The Inficon XTM/2 deposition monitor is dedicated to monitor the alkali coating.
- The Inficon XTC/2 deposition controller is used to monitor the thickness of the tellurium coating.
- The Inficon XTC/3S is a spare deposition controller
- The TPG300 is a vacuum gauge controller to monitor the pressure in the vacuum vessel.
- The VIONIC 159 is the vacuum gauge controller for hot cathode gauge.
- The Heidenhain ND 780 is a positioning ruler, as a milling machine gives the position of the evaporator arm and the cathode arm in um.
- The Radiometer RM6600a is used as Joulemeter to monitor the laser energy when the light hits the cathode.
- Power supplies (Delta Elektronik + CERN made electronics) heat the evaporator (Cs or Te) by the Joule effect (control and instrumentation)
- Temperature monitoring with thermocouple and dedicated electronics
- Photocurrent acquisition with a precise laser synchronous timing system and fast sample/hold electronics.

## CHALLENGES

Photocathode fabrication in laboratories like CERN is not reproducible because installations were designed for R&D and not for industrial production. Furthermore, with

each fabrication we often change parts of the process for learning purposes. Lots of parameters can affect the final result and we need to have a good knowledge and control of each of them:

- Deposition Flow Rate of Cs or Te (called Stoichiometric Ratio Control)
- Caesium availability in the evaporator
- Vacuum Quality
- Temperature (Alkalic Antimony Cathode only)
- Mechanical positioning of the Evaporators (ruler)

We learned how to upgrade the mechanical engineering aspects of the project to reach reproducible results and a fully automated process is now mandatory to assist the operator in controlling the process. All the tools are now available to start a real automatic process.

## AUTOMATION

### Architecture

The user should be able to monitor and control the main parameters with a refresh rate of approximately 1 Hz and plot them as a function of time. The entire process can take more than half a day and should not be stopped. Some intelligent devices like the laser energy meter or the thickness monitors communicate via GPIB or RS-232. The other devices are controlled by analog signals (between  $\pm 10$  V) and digital signals. To separate the GUI and the real-time process, a standard 3 tier design (Fig. 2) has been chosen. The communication between the real-time task and the GUI is done using the CERN Controls Middleware framework (CMW) [3]. Each equipment is abstracted by a dedicated software module.

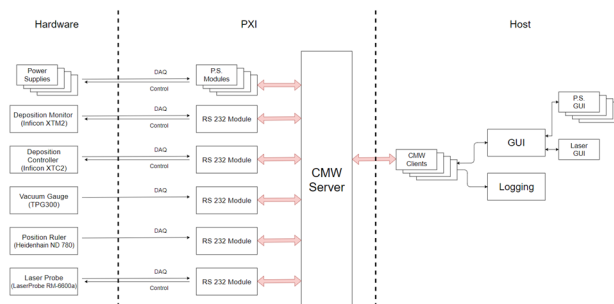

Figure 2: Automation software architecture.

The software is implemented using the Actor Framework [4], which abstracts the communication between the different modules, thereby increasing development efficiency. This framework is object-oriented, which allows us to add several layers of abstraction. Each serial device is a child of the RS-232 module class (Fig. 3).

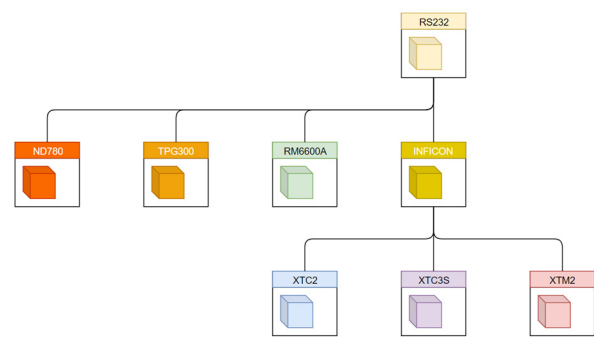

Figure 3: Class hierarchy of the RS-232 module.

Each serial device has maximum 3 features:

- Live streaming of the current data
- Getting the current settings
- Reacting to user commands

The RS-232 devices class abstracts all these features and has a common communication interface with the main module. The INFICON devices, being similar to each other, share a common parent. The addition of a new device and the maintenance of the current ones benefit from this implementation.

The most challenging part of the real-time software was the power supply implementation (Fig. 4).

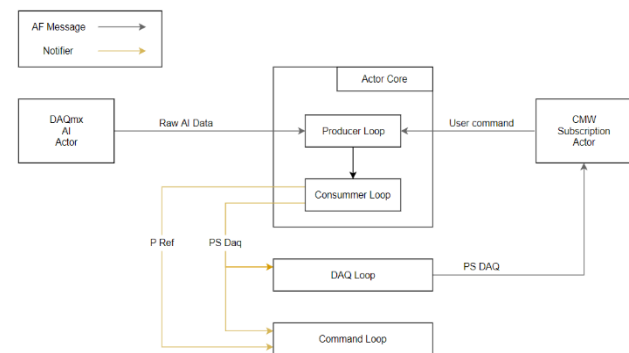

Figure 4: Power supply internal communication actor.

Each power supply is handmade at CERN and therefore has its own behaviour. To regulate the power supplies, an adaptive controller could also have been implemented but the idea was discarded due to a lack of time and the difficulty to make a system identification.

The actor framework's main drawback on LabVIEW real-time targets, is that each actor is re-entrant. This means they cannot be debugged using standard LabVIEW tools. To cope with this limitation, the RADE-logger [5] was heavily used to track errors. To be able to test the actor framework properly on real-time targets, additional support modules had to be developed, adding overhead compared to standard OOP LabVIEW implementations. In hindsight, using the Actor Framework on a real-time target might not have been the best design choice for this project, however it proved both scalable and adequate for the job.

### Hardware Chosen for the Automation

The process doesn't require high speed acquisition or control, however it does require stability during a long run. To benefit from a Real-Time OS, a timing input and a robust CPU, the PXI controller NI PXIe-8821 with a PXIe-1082 chassis, was used. To communicate with the serial devices, a PXIe-8430/8 was used. To communicate with power supplies, a PXIe-4302 for the analog inputs, a PXIe-6738 for the analog outputs, and a PXIe-6535 for the digital inputs and outputs were used (Fig. 5).

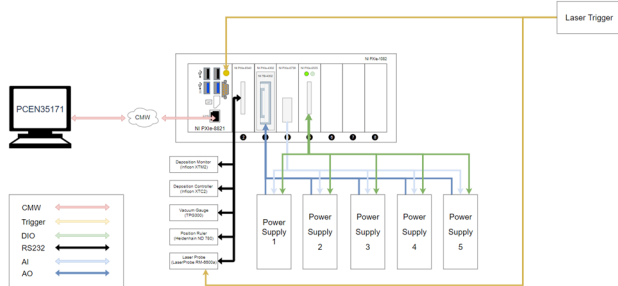

Figure 5: Automation hardware architecture.

### Power Supply Control

In the application, the power supplies are controlled for power, but physically in the hardware, only the current parameter is controlled at the power supply. We use the voltage of the evaporator to compute the power of the evaporator as shown in Eq. (1).

$$P_{Evaporator} = U_{Evaporator} * I_{Power Supply} \quad (1)$$

This power must be regulated in real time within a few hundreds of ms via the application. Up to five power supply values can be regulated in parallel.

### Continuous Process

The power supply feedback is made with a 100ms cycle to comply with the control system design. Therefore, the analog and digitals inputs are acquired at 10 Hz. They following the power supply current, voltage and states and also the temperature of the fabrication bench as shown in Fig. 6.

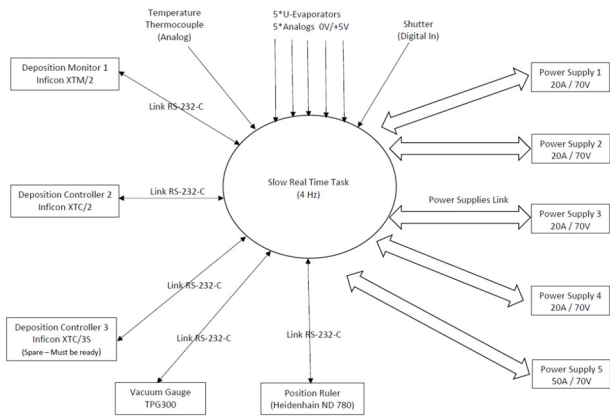

Figure 6: Slow process communication layer.

Several devices are connected to the control system using RS-232. As the fabrication of the photocathodes is a relatively slow process, it is sufficient for the feedback of the deposition of the different metals to be followed on the timescale of one second. The use of serial communication is therefore acceptable. The readings of the different devices are made at 4 Hz. 10 to 20 seconds are needed to get a proper deposition, and within this time we can pass from a good to a bad cathode. A precise quantity of matter needs to be deposited to maximize the quantum efficiency (QE), which is given by Eq. (2) [6].

$$QE = K \frac{Laser Energy}{U_{Electrode}} \quad (2)$$

Where K is a coefficient.

### Triggered Process

The electrode voltage and the laser energy are monitored at 10Hz. This value allows us to compute the quantum efficiency that the operator will maximise to improve the quality of the photocathode. The acquisition of the radiometer, measuring the laser energy, and the electrode voltage are synchronized using the TTL trigger from the laser as shown in Figure 7.

Figure 7: Fast process communication layer.

## RESULTS

To optimize the stoichiometric ratio of the Cs-Te (Cs<sub>2</sub>Te) alloy, you need to optimize the flow rate of the Caesium vapor. This optimization is a function of the (not constant) tellurium vapor flow and of the level of quantum efficiency. This is done by fine tuning the evaporator power.

This allows the QE to achieve record values greater than 20% (Fig. 8) but the process remains delicate. The key to achieve this is the monitoring of parameters such as photo-current, laser energy, deposited thickness and a good control of the power.

The high quantum efficiency allows us to produce a cathode with longer lifetime (between weeks and months depending on the electrical charge produced and the frequency of use) addressing what is probably the main issue of these cathodes.

Figure 8: Quantum efficiency result.

Even if the process is not very fast, it requires both a flexible and deterministic control solution. The NI PXI systems provide both things. Moreover, the PXI platform opens the possibility to add additional cards and/or more mathematical processes in the future.

## FUTURE IMPROVEMENTS

To improve the quantum efficiency, and further automate the solution, we need a deeper understanding of the physical process itself. This could be done via increased monitoring and perhaps, using machine learning, further optimising the process itself.

In general, adaptive controllers could be implemented after proper system identification. Interlock monitoring on the mechanical pieces could be added. The motors of the cathode holders and the vertical arms holding the evaporators could be controlled automatically. This will still require a deeper understanding of the manual process itself which today relies entirely on the experience of the operator.

## CONCLUSION

Even though an operator is still required to monitor and control the photocathode fabrication process, the automation of various tasks such as the evaporator control, the synchronization of each device and the reproducibility introduced by this new implementation allows CERN to be technologically ready for full automation of this process in the future. In addition, the accuracy of the power regulation as well as the availability of the data gives us more flexibility in the automation.

# DISTRIBUTED TRANSACTIONS IN CERN'S ACCELERATOR CONTROL SYSTEM

F. Huguin, S. Deghaye, P. Manton, J. Lauener, R. Gorbonosov, CERN, Geneva, Switzerland

## Abstract

Devices in CERN's accelerator complex are controlled through individual requests, which change settings atomically on single Devices. Individual Devices are therefore controlled transactionally. Operators often need to apply a set of changes which affect multiple devices. This is achieved by sending requests in parallel, in a minimum amount of time. However, if a request fails, the Control system ends up in an undefined state, and recovering is a time-consuming task. Furthermore, the lack of synchronisation in the application of new settings may lead to the degradation of the beam characteristics, because of settings being partially applied. To address these issues, a protocol was developed to support distributed transactions and commit synchronisation in the CERN Control system, which was then implemented in CERN's real-time frameworks. We describe what this protocol intends to solve and its limitations. We also delve into the real-time framework implementation and how developers can benefit from the 2-phase commit to leverage hardware features such as double buffering, and from the commit synchronisation allowing settings to be changed safely while the accelerator is operational.

## DISTRIBUTED TRANSACTIONS: INTRODUCTION

In CERN's accelerator control system, clients address devices individually with a request made on a property of a device. To modify a property across multiple devices, requires as many requests as there are devices. Until all the requests are made, an accelerator is in an undefined state. Moreover, if any of the requests fail, additional actions are required to understand why it failed and how to fix it, leaving the accelerator in an undefined state for a potentially large amount of time.

In order to solve this problem, distributed transactions were designed and implemented in CERN's accelerator control system.

## GOALS, LIMITATIONS, AND DESIGN OF DISTRIBUTED TRANSACTIONS

The goal of distributed transactions is to ensure that a set of modifications occurring on distributed nodes are either completely recorded, or not at all. A node can be anything, but the first example that comes to mind is a database. This behaviour is typically achieved by using a two-phase commit. The generic workflow is as follows:

- A transaction is opened with the different participating nodes;
- Modifications are made on the different nodes in any order and over an unspecified period of time;

- The commit then occurs in two steps:
  1. A commit is sent to all the nodes which perform the required checks and ensure that locally there are no errors;
  2. If no errors are reported by the first commit, a second one, confirming the wish to commit is sent. From then onwards, the modifications are permanently recorded;
  3. If, on the other hand, errors are reported during the first-phase commit, the transaction is rolled back on all the nodes and no modifications are recorded.

## DISTRIBUTED TRANSACTIONS IN ACCELERATOR CONTROLS

In the context of CERN's accelerator controls, the nodes are the low-level equipment controllers, the so-called Front-End Computers (FECs). The modifications are changes of the underlying equipment settings. A nominal transaction for CERN accelerator controls contains the following steps:

- The client opens a transaction with a unique transaction ID on all the devices it plans to modify, via a synchronous middleware call to a standardised property;
- The client modifies the settings via a synchronous middleware call. Again, the order and period of time are unspecified;
- The client asks the devices to test their new settings via a synchronous middleware call to a standardised property (TRANSACTION.TEST);
- If all the devices report a successful test, the client commands the timing system to broadcast a commit event for the transaction. Upon reception, the FECs permanently commit the new settings;
- Otherwise, if one or more devices report an error during the test, the client asks the timing system to broadcast a roll-back event which will trigger the discard of the settings set with the corresponding transaction ID.

In the workflow described above, several implementation choices are already visible. One key element is the way to transport the final commit and roll-back. CERN's timing system, whose purpose is, among other things, to distribute events to the whole accelerator complex, is used to trigger a commit or rollback of a transaction. Even though the transactions are not meant to synchronise the moments at which the commits are performed, by using the timing system to transport these two events, we combine the possibilities offered by a global commit event with the synchronisation possibilities of the timing system.

In addition, mainly for test purposes, the client may trigger a commit or rollback event without using the timing system. This is done by telling every device in the transaction to commit or rollback via another middleware call to the TRANSACTION.COMMIT or TRANSACTION.ROLLBACK properties. It is acknowledged that in this case, the commit loses its atomicity, since the client is limited to regular TCP connections to do this, without any multicast possibility.

It should be highlighted that, on the low-level equipment controllers (FECs), a single server typically handles many devices. Clients do not use this information in any way and must treat each device regardless of the FEC they are handled by. However, this has some implications on the design of the server-side commit process. The implementation of the transaction protocol in a device server, where a transaction is processed as a whole entity (in opposition to device by device), is explained in the following sections. Why such a design choice was made, its constraints, and how the technical challenges were solved are also described.

## DISTRIBUTED TRANSACTIONS IMPLEMENTATION IN FESA

The Front-End Software Architecture (FESA) framework is used to do real-time programming to control accelerator hardware in CERN's control system. It offers the possibility to react to specific events through an API giving access to all the concerned devices at once. Many systems developed with FESA are a composition of multiple devices, and if settings are changed on multiple devices within a transaction, this must be seen as one change of all the settings, rather than multiple changes of individual devices.

Since clients are not aware of this (they always treat devices as individual entities), this must be transparently implemented in FESA. In addition, a FESA device server can be run either as a single process (see Fig. 1) or as two separate processes, called server process and real-time process, which interact through a shared memory and several message queues (see Fig. 2).

Figure 1: FESA server running as a single process.

Figure 2: FESA server running as two processes.

This has several implications:

- FESA must be able to uniquely identify and pass the data from a transaction across processes.
- Since the transaction is opened sequentially on all the devices by the client, FESA cannot know in advance the size of the settings that will be modified in the transaction.
- When a transaction is tested by the client, test requests will happen sequentially on every device. FESA must test the full transaction on the first received test request and ignore subsequent test requests on other devices.

Many failures can happen during a distributed transaction (hardware error, device server crash, network issue, timing system issue). A commit event is thus not guaranteed to be processed by all the devices in the transaction. Because of this, the processing of the commit event by the devices should be as small an operation as possible, e.g., a buffer swap. Devices must use the test request to prepare for an upcoming commit or rollback. Consequently, the implementation does not guarantee the state of the system in case of a failure during the commit. Furthermore, due to the nature of the timing system, it is difficult to provide feedback to the client in such a case. Some solutions exist to mitigate this problem [1], at the cost of an increased complexity.

Finally, in order to provide a transaction implementation across as many devices as possible, it was decided that FESA would offer two modes:

- A transparent mode, with no code modification required by the users, but without the possibility to leverage some hardware capabilities such as double buffering. This is intended for cases where validation of settings is done entirely in software, which guarantees that commit events will successfully apply the new settings unless an unpredictable hardware error occurs.
- An advanced mode, which requires the user to implement entry points for test, commit, and rollback. In this mode, the test event can be used to prepare the hardware, for example by preparing a

buffer containing the new settings to apply, and the commit event can be used to trigger a buffer swap, applying the new settings atomically in a very short time.

These two modes are mutually exclusive in a FESA process.

## TRANSACTIONS IMPLEMENTATION IN FESA: TRANSPARENT MODE

In order to fully understand the implementation of transparent transactions, it is first necessary to understand how a normal modification of a setting works (outside of a transaction):

- The client sends a new setting.
- Its validity is checked by some user code, which may accept or reject the new value.
- If the new setting is valid, the memory containing the setting values is updated with the new value [2]. If the setting needs to be applied immediately, an event is sent to the real-time FESA process, possibly across process boundaries if running in split mode.
- The event is received and processed by the real-time part, which applies the new setting on the hardware.

If the setting is instead modified within a transaction, the sequence is as follows:

- The client sends a new setting.
- Its validity is checked by some user code.
- If the new setting is valid, its value is saved in a buffer dedicated to this transaction. If the setting needs to be applied as soon as the transaction is committed, an event is prepared and saved in the transaction buffer.
- The client sends other settings, and the same process is repeated until a commit or rollback event happens (in transparent mode, the test event is ignored, as the validity of settings has been checked already).
- If a commit event happens, the memory containing the setting values is updated with the buffered setting values. All the buffered events are triggered.
- The events are received and processed by the real-time part, which applies the new settings on the hardware.

Thus, in transparent mode, the modification of settings within a transaction are equivalent to modifying all the settings in rapid sequence.

While the transparent mode offers the main advantage of being usable without user code modification, it does not cover one key element of the nominal sequence which is the possibility for Sets to be done in an unspecified order. To support this, a more sophisticated implementation is required, the advanced mode.

## TRANSACTION IMPLEMENTATION IN FESA: ADVANCED MODE

The goal of advanced mode is to allow the user to benefit from the 2-phase commit (test, then commit) to test new settings only after they have all been set, and to leverage the capacity of the controlled hardware to prepare for a commit.

A fictitious but simple example (which can be applied to many other use cases) can demonstrate why this is important:

Consider a lab-bench power supply, which has a power output limit of 300 watts. It is connected to a FESA process which can modify its voltage and maximum current through a serial connection.

When a new voltage or maximum current is requested by a client, the user code must check that the product of the two does not exceed 300 watts. Assume that it is currently configured to 5V and a maximum of 20A.

If a client wants to set it to 30V and 5A, without the transactions, it must be careful to first set the maximum current, otherwise the maximum power will exceed 300W in the transition (30V times 20A). This requires the client to know about this logic, which is not feasible in the case of automated settings management.

The transaction implementation in advanced mode solves this problem by delaying the validation of the settings until the test request happens. The user code can still reject a setting value as soon as it is sent if it is invalid on its own (e.g., setting a voltage of 10000V), and in addition, it can check the validity of the settings combination in the code that is called when a test event happens. The API provided by FESA in that case transparently provides the values stored in the transaction buffer if present, or previously known otherwise.

Now also assume that the power supply can receive its new voltage and maximum current settings but wait for a further command to apply them. In addition to ensuring the settings validity, the implementation of the test event would then send the new values to the power supply. If anything goes wrong at this point, it is still possible to signal a test failure to the client, who can roll back the transaction, or try with other setting values.

Finally, when the commit event arrives, the only thing left to do is to tell the power supply to apply the new settings. The possible failure surface has thereby been reduced to the strict minimum, allowing the clients to cancel the transaction if anything else goes wrong.

While this example is voluntarily simple, it applies to a lot of hardware used in accelerators, such as power converters, digital oscilloscopes, and much more.

## ADVANCED MODE OUTSIDE OF A TRANSACTION

As explained above, transactions in advanced mode require the user to adapt their code to handle the test, commit and rollback events. However, the settings can still be changed outside of a transaction, in which case they need to be applied immediately.

For such cases, FESA simulates a transaction: the request to modify a setting will cause FESA to generate a test event, and if it is successful, a commit event. If the test event fails, the new setting value will not be applied, and the client will receive the test event error message, informing why the new setting could not be applied.
