Also previous trials showed that the best results are obtained using a band-pass filter with two bands centered on the transverse tunes ν_x and ν_y (a 99% uncertainty is reached if only one tune band is used without noise). Table 1 presents the frequencies (ω) used to built the filter, where (N.) is the number of the case, the dots are the complementary values, such as an increment of 0.0005 in $\Delta\omega$ is

always made. The band centered at ν_x corresponds to the ω labeled with I, while the band for ν_y is labeled II. The bandwidth of the two bands are the same.

The filtered signal is the addition of the signals obtained with the two single band-pass filters, whose frequency response looks like Fig. 1.left, and in case of overlapping, the addition of the filtered signals is followed by the subtraction of a band-pass signal with the overlapping frequencies as the band, the frequency response looks like Fig. 1.right.

CHANGE IN THE APJ CODE

The phase obtained from the BPM measurements (eq.(14) in [2]) is implemented with the appropriate sign in the APJ computer code, in order to count on the four quadrants of a Cartesian coordinate. This and the fact that the trajectory function has a sinusoidal behavior allow to select 2 maximal and 2 minimal (i.e. negative maximal) orbits, for each transverse plane, and not only 1 as before.

The selection of the orbits is such as the final orbit has a maximum amplitude at the error position. As reported in [3] the selection is based on the phase of the trajectory. In this study the information from the two transverse planes is necessary, therefore 8 orbits are obtained, and the phase dispersion is 0.15 rad. Each orbit, called a formable orbit, is the average of the TBT orbits that have the maximum.

Also, an initial reformulation of the error position estimation is done in the PYTHON APJ code. The transverse error position is taken as:

$$z_{error} = \sqrt{2\bar{J}_0\beta_{z,error}}\sin\left(\psi_{z,error} - \bar{\delta}_0\right) \qquad (2)$$

where $\bar{J}_0$ and $\bar{\delta}_0$ are the average of the Action and Phase in a region before the error (generally the arc before the IR), respectively, and $\beta_{z,error}$ and $\psi_{z,error}$ are the beam β-function and phase advance, at the longitudinal position of the magnetic error, respectively.

To obtain the magnetic errors A_1 and B_1, the APJ uses the relations reported at [4] or [2]. Including different combinations of the orbits, new relations are obtained as reported in the *Appendix* of this paper. For more precise and exact results an implementation of a 2D independent fit is done. This allows to get A_1 and B_1 directly from:

$$\theta_x = -xB_1 + yA_1 \quad \text{and} \quad \theta_y = xA_1 + yB_1 \qquad (3)$$

where θ is the kick produced by the error, x and y are the estimate coordinates of the trajectory at the error. This is assuming that there is not other type of magnetic error.

RESULTS AND DISCUSSION

Figure 2 contains the beam y-trajectory in the frequency space for one BPM of the LHC. Four signals are plotted in the same axis, the FFT of: the simulated, with noise, and filtered, trajectories. This representation allows to observe how the amplitude of the noise signal is reduced in the filtered signals. The difference of the noise type used implies a higher amplitude of noise for the Gaussian case,

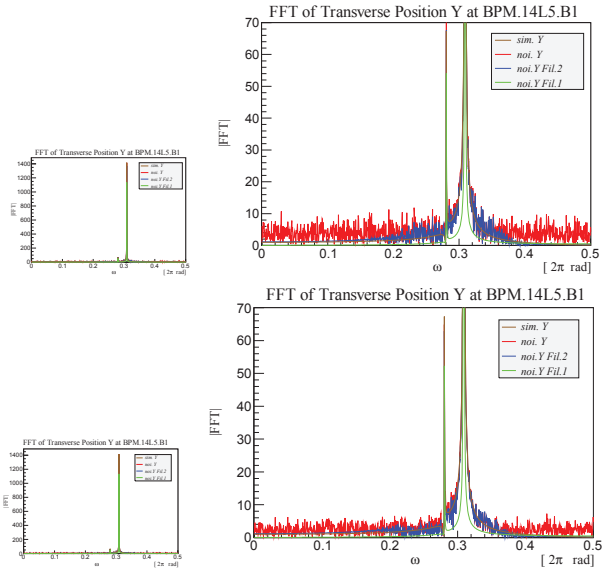

Figure 2: FFT of the Vertical Positions at BPM.14L5.B1 after 2000 turns, with Gaussian (top) and Uniform (bottom) noise. The left plots are the complete spectrumwhile the right plots is a close-up for the bottom of the spectra. All are a superimpose of a simulated (sim.) trajectory, a sim. with noise added (noi.), and a noise filtered signal for the cases N.1 (Fil. 1) and N.8 (Fil. 2) on Table 1.

observed as well in the plane x. This contrast the fact that the Gaussian distribution has a $\sigma_{Gauss} = 0.1$ mm while the Uniform distribution is up to 0.3 mm. [1].

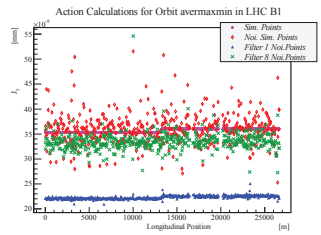

Figure 3: Action (J) along the LHC ring for one orbit type. Obtained from the simulation, without noise (Sim.), with Gaussian Noise (Noi. Sim.), and the filters N.1 and N.8 on Table 1. The magnetic errors are at 13271 m.

The Action (J) and Phase (δ) are modified with the presence of noise. Figure 3 contains J against s, without noise, for Gaussian noise and filtered, for y. The value of J is affected after the use of the filter Fil N.1, due to the difference of the trajectories amplitudes explained by the Frequency response of Fig. 1 (left). The Phase for the same orbit is in Fig. 4a. For both variables in x or y, the filter reduce the dispersion of their values. Something similar occurs with uniform noise, Fig. 5a shows δ against s, for the same type of orbit that is analyzed before, and the observations are the

[1] For both noise distributions, the BPMs resolution of 0.3 mm is the reference [7]. Because the beam distribution is Gaussian, we assumed that it is less probable to have particles of the bunche extremes affecting the BPM signal, therefore it is enough to have $\sigma_{Gauss} = 0.1$ mm.

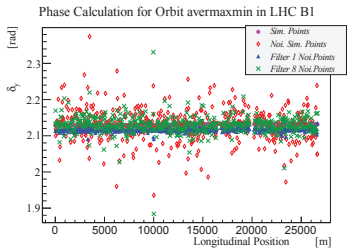

Figure 4a

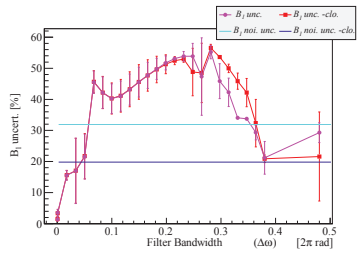

Figure 4b

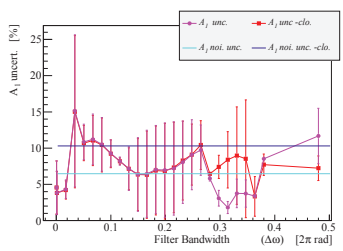

Figure 4c

Figure 4: Results for Gaussian Noise. Figure 4a contains the Phase (δ) along the LHC for the cases discussed in Fig. 3. The Uncertainty (uncert.) for B_1 and A_1 are showed in Fig. 4b and Fig. 4c, respectively, for the different bandwidths. The uncert. for the noised orbit is plotted as a horizontal line. A Low-pass filter to get the closed-orbit implies the -clo results.

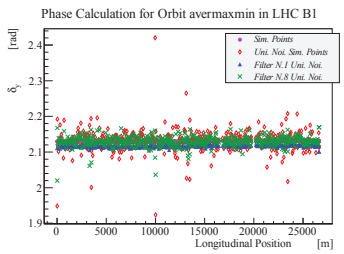

Figure 5a

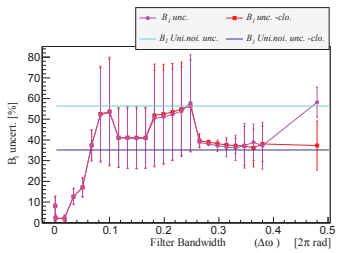

Figure 5b

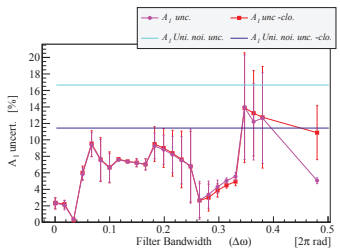

Figure 5c

Figure 5: Results for Uniform Noise in the same quantities as Fig. 4. Figure 5a contains δ while Fig. 5b and Fig. 5c contain the Uncertainty of B_1 and A_1. In the plots the precision and exactness is clearly lost for very small $\Delta\omega$.

same. Comparing the two distributions, the uniform noise implies a less dispersion.

To obtain A_1 and B_1, the selection of orbits implies that 8 points are available for the fit of Eq. 3. The magnetic errors uncertainty (taked as the Absolute Error of the measurements) of the two values obtained from the fit of Eq. 3., obtained from the fit with its dispersion (error bars), is plotted in figures Fig. 4b, Fig. 4c, Fig. 5b and Fig. 5c, against $\Delta\omega$.

Results using a low-pass band filter ($\omega_{cut} = 0.075$) for the closed-orbit calculation are reported with the line labeled as -clo. In the others, the closed-orbit is the average of the TBT trajectories. When there is noise at many frequencies, a discrepancy on the results is observed.

Also, the noise distribution affects the magnetic components in a different way. The horizontal lines, which are the uncertainty average on noised orbits (no filter used), have different values in Fig. 4b, Fig. 4c, Fig. 5b and Fig. 5c. The precision change according $\Delta\omega$ and the error.

The lesser uncertainty value for B_1 and A_1 with Gaussian and Uniform noise is obtained when $\Delta\omega = 0.0174$. This bandwidth has also a very high precision in the Uniform noise results. Diference on the noise reduction at the different bandwidths at the middle region could be corrected by setting an overlapping bandwith higher than the common ω values. In here, we are interested to take the lesser bandwidth that gives the lesser uncertainty.

CONCLUSION

A dual band-pass filter with a bandwidth of 0.0174 around the transverse tunes can be use to highly decrease Gaussian and Uniform noise in LHC orbits, when measure A_1 and B_1 at the same quadrupole using the APJ method as presented. Differences on how the closed-orbit is calculated are observed when there is noise at many frequencies.

APPENDIX

To obtain the magnetic errors, Equations (21) in [2] are used for every orbit. Other possibility is taking two orbits $(x^{(1)}, y^{(1)}, \theta_x^{(1)}, \theta_y^{(1)})$ and $(x^{(2)}, y^{(2)}, \theta_x^{(2)}, \theta_y^{(2)})$ to obtain one error, for example for B_1:

$$B_{1,x}=\frac{\theta_x^{(1)}y^{(2)} - \theta_x^{(2)}y^{(1)}}{x^{(2)}y^{(1)} - x^{(1)}y^{(2)}} \text{ and } B_{1,y}=\frac{\theta_y^{(1)}x^{(2)} - \theta_y^{(2)}x^{(1)}}{y^{(1)}x^{(2)} - y^{(2)}x^{(1)}} \quad (4)$$

The precision reached in this way is not as good as the presented results, but it could imply a faster and good measurement.

Abstract

Transverse laser cooling is pursued at an ion storage/cooler ring, S-LSR, Kyoto University. An RF bunched Mg^+ beam was cooled transversely through synchro-betatron resonance coupling by a co-propagating laser. We investigated peaks of synchrotron oscillation spectroscopically so that we can observe them stably. Oscillation signals from a parallel-plate pickup were observed by a spectrum analyzer. We also observed the coherent synchrotron modes. As the beam temperature decreases, the ion beam would be in space charge limited region. According to the computer simulation, in the case the beam turns to be space charge limited, the disappearance of peaks of synchrotron oscillation is expected. We would like to propose a capability of detecting space charge limited region by observing such a frozen synchrotron oscillation.

INTRODUCTION

In Small Laser-equipped Storage Ring (S-LSR) at ICR, Kyoto University, a frequency tuneable laser of ~280 nm is co-propagating with a 40keV Mg^+ beam, as shown in Fig.1. It was cooled in the transverse direction through resonant coupling method [1]. The Horizontal and longitudinal oscillations are coupled by an RF voltage applied at the position with a finite dispersion when a synchro-betatron resonance coupling condition (SBRC) is satisfied: a cooling force in the longitudinal direction is transferred to the transverse direction [2].

The ion beam was bunched by the RF wave of frequency 2.5192MHz. Since the revolution frequency was 25.192kHz, it corresponded to the harmonic number 100. Frequency spectra, which were obtained from preamp signals of a parallel-plate pickup in the ring, were observed by a spectrum analyzer [3]. We hope to use these frequency spectra for diagnostic purpose of ultra cold ion beams.

The RF frequency of 2.5192MHz will be printed as 2.5MHz for abbreviation, which corresponds to 0Hz in Figure 2, 3, and 5. In Figure 4, 0Hz represents 2×2.5MHz. At this stage of transverse laser cooling where the beam temperature was not yet ultra-cold to be in space charged limited region, there was no clear difference in frequency spectra whether the ion beam was laser cooled or not.

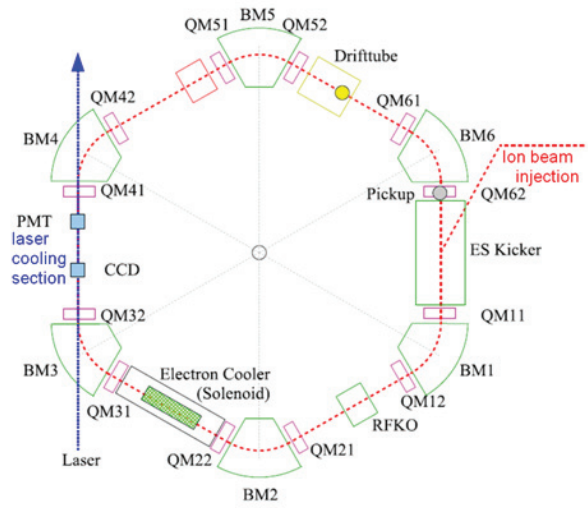

Figure 1: Layout of S-LSR.

Table 1 shows the main parameters of S-LSR.

Table 1: Main Parameter of S-LSR

Circumference	22.557 m
Average Radius	3.59 m
Length of straight section	1.86 m
Radius of curvature	1.05 m
Revolution frequency	25.192 kHz
Super periodicity	6
Ion species	$^{24}Mg^+$
Kinetic beam energy	40 keV
Transition wavelength	280 nm

EXPERIMENTAL RESULTS

The frequency spectra of around 2.5MHz, which is located at the centre, are shown in Fig. 2. To erase sidebands (2 peaks about ±1kHz, and about±2kHz from the centre), the RF frequency was varied ∓ 0.5kHz (Fig.2-a and 2-c) when SBRC was satisfied (Resonance tune ν_s=0.066、ν_h=2.066). However, we could not erase them. They were not noises. In fact the sidebands are small enough since the ordinate is the unit of dBm.

In Fig. 3 and 4, sidebands of synchrotron frequencies were observed at both sides of each harmonic of the revolution frequency when SBRC was satisfied. These peaks were not observed under no beam. Therefore the ion beam caused them.

In Fig. 3, five peaks are recognizable. They correspond to frequencies of harmonic number h=98, 99, 100, 101, and 102 from the left. At h=98, 99, 101, and 102, synchrotron sidebands are accompanied in both sides of each harmonic. The 1st harmonic of RF frequency 2.5MHz is observed at the centre (h=100). An enlargement of the central peak is identical to Fig. 2-b.

In Fig.4, five peaks are also recognizable. They correspond to frequencies of harmonic number h=198, 199, 200, 201, and 202 from the left. At h=198, 199, 201, and 202, synchrotron sidebands are accompanied in both sides of each harmonic. The second harmonic of RF frequency (2 × 2.5MHz) is observed at the centre (h=200). The peak between 199 and 200 (about −1.6kHz from the centre 200) is a noise since it was observed under no beam.

The RF voltage was varied in Fig.5, which was recorded in higher resolution. Peaks indicated by blue arrows, of which synchrotron frequencies were shown, were moved among 5 peaks of +0kHz, about ±1kHz, and about±2kHz from the centre. Unexplainable low peaks were observed at ±1.7kHz in Fig5-a and ±1,5kHz in Fig5-b. They were not noises. Those low peaks were not observed under no beam.

Because of higher resolution, these peaks looks a little bit slender compared to those in Fig. 2. Synchrotron frequencies were evaluated according to the frequency formula of small amplitude synchrotron oscillation [4].

THE COHERENT SYNCHROTRON MODES

Fig. 2 manifests that sidebands are the coherent synchrotron modes (4 peaks about ±1kHz, and about± 2kHz from the centre), which occur when the RF frequency is a not exactly an integral multiple of the revolution frequency of each of circulating ions: this is the case when ions are circulating in bunches. A bunch is made of ions with different synchrotron amplitudes and phases. The coherent synchrotron modes of the bunch can be obtained by averaging synchrotron motions over the bunch distribution [5]. The coherent frequency spectra are located at harmonics of the RF frequency. Fig. 5, in which the RF voltage was varied, shows that the coherent synchrotron modes are independent of the RF voltage.

DISCUSSION

The computer simulation expects dumping of synchrotron oscillations when the ion beam is in space charge limited region [6]. When an ion beam is cooled to space charged limited region, it would be very difficult to detect it directly since the number of ions in the cold Mg^+ beam is very limited. In fact, the number of ions is estimated much less than ~10^4 [7]. A diagnostic method using scraping is already applied in a ultra-cold Mg^+ beam, which, however, was not sensitive enough to be usable in space charged limited region [8].

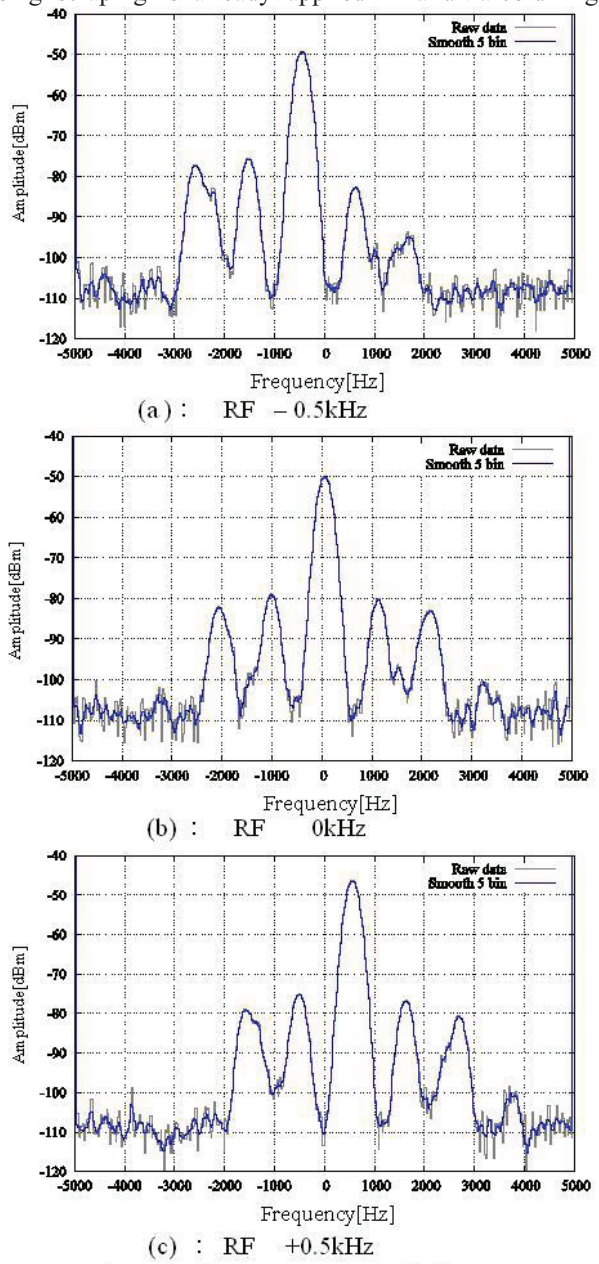

Figure 2 : Frequency spectra RF frequency was varied relative to RF frequency 2.5MHz (centre 0Hz).

We have observed synchrotron frequencies stably in frequency spectra. Observation of synchrotron frequencies would be helpful to confirm space charge limited ion beam since peaks of synchrotron oscillation would disappear in frequency spectra. Therefore we hope frequency spectra are usable as a diagnostic method of ultra cold ion beams.

It is also our great interest what will happen to the coherent synchrotron modes in space charged limited region, which we want to investigate with the use of the indirect transverse laser cooling when SBRC is satisfied in a near future.

LUMINOSITY ESTIMATION AND BEAM PHASE SPACE ANALYSIS AT VEPP-2000*

A. Romanov, I. Koop, E. Perevedentsev, D. Shwartz
BINP SB RAS and Novosibirsk State University

Abstract

Luminosity is the main output of colliders, so it is very important to measure it with speed and accuracy. VEPP-2000 has 16 beam profile monitors (BPM) which use CCD-cameras to register synchrotron light in the visible spectrum. Two luminosity estimation methods are presented, both based on beam size analysis. Although the luminosity measurements by particle detectors CMD-3 and SND are slow and have low statistical accuracy for low beam currents, their data can be used to test new faster methods. Additionally, an attempt of the phase space tomography is presented using the simulated BPM measurements of the particle distribution in a strongly non-gaussian beam.

INTRODUCTION

VEPP-2000 is used for hadron cross section measurements in the energy range of $0.4 \div 2$ GeV [1], hence it takes luminosity at several dozens of energies every season, thus emphasizing the tuning tools' importance. The collider has a two-fold symmetry lattice with 16 CCD cameras that take beam images using synchrotron light (Fig. 1). 8 CCDs are aimed at electrons and 8 at positrons.

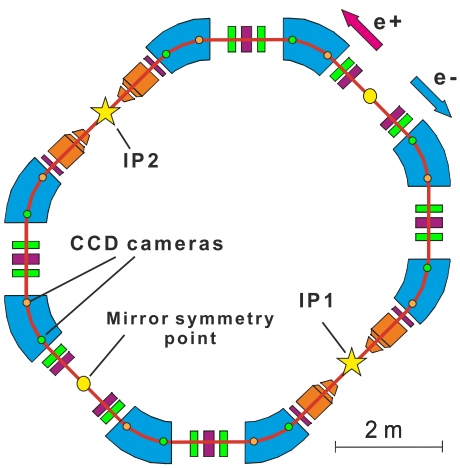

Figure 1: VEPP-2000 layout.

There are a number of theoretical and empirical considerations regarding lattice configuration depending on the energy [2], but the last step of the final tuning is almost always unique and done manually. To get the best luminosity output, the operator should tune parameters such as beta-functions at the IPs, closed orbit position, betatron tunes, chromaticity, betatron coupling and others. The crude effects such as "flip-flop" can be noticed by the naked eye, however fine tuning requires the fast and reliable luminosity estimation tools. Unfortunately, the speed and precision of the luminosity measurements from the detectors are not sufficient, especially at low energies.

Both presented methods of luminosity estimation assume that accurate optics model of the real accelerator ring is available. Assuming no focusing perturbations in the lattice other than those caused by the collision, and thus located at the IP, one can use known transport matrices to evaluate the beam sizes at the IP from the beam size measurements by CCDs.

FIRST LUMINOSITY ESTIMATION METHOD

Eight measurements are available for either transverse coordinates of the two beams, while there is only a pair of strongly indeterminate parameters - beam emittance ϵ and $\beta*$ - for each mode and each beam.

For the parameters fitting procedure, it is convenient to transport all the measured beam sizes to the point of mirror symmetry where Twiss $\alpha = 0$. The center of technical straight section is chosen since this point is not perturbed by the beam-beam focusing. The beta-function for $i-th$ profile monitor is transported as:

$$\beta_i = \beta_0 \cdot t_{11,i} + \beta_0^{-1} \cdot t_{12,i}, \quad (1)$$

where t_{kl} are the elements of known transport matrix. The fitting minimizes the difference between the model and measured beam sizes:

$$F = \sum_i \frac{\left(\sqrt{\epsilon\left(\beta_0 \cdot t_{11,i} + \beta_0^{-1} \cdot t_{12,i}\right)} - \sigma_i\right)^2}{\sigma_i^2 + o_i^2}. \quad (2)$$

Here, o_i is the size measurement error with a typical value of $3-5\mu m$, while the beam size σ_i is a pure betatron part of measured transverse size with excluded dispersion contribution

$$\sigma_\beta = \sigma - D \cdot \frac{\sigma_E}{E} \quad (3)$$

The fitted beta-function β_0 is transported to the IP together with the emittance that gives the size needed. The luminosity can be easily calculated as:

$$L = \frac{N_1 N_2 f_0}{2\pi\sqrt{\left(\sigma_{1x}^2 + \sigma_{2x}^2\right)\left(\sigma_{1y}^2 + \sigma_{2y}^2\right)}}. \quad (4)$$

The model is extremely simple, it uses several assumptions. 1) Well-known unperturbed optics between the IPs

* This work is supported by the Ministry of Education and Science of the Russian Federation.

Copyright © 2013 CC-BY-3.0 and by the respective authors

without betatron coupling. Strictly speaking it is not the case for VEPP-2000 but the rotation produced by the final focusing solenoids can be ignored. 2) Both arcs and IPs are identical. 3) All particle distributions remain Gaussian. This is not true in the case of very intensive beams close to the beam-beam limit. 4) Energy spread is not perturbed and formed by synchrotron radiation. Recently the bunch lengthening in the low energy range was observed, indicating the microwave instability for the beams that are intensive enough (Fig. 3). This phenomenon would modify the dispersion contribution to the beam sizes.

The comparison of this luminosity estimation technique is in good agreement with measurements from the detectors (Fig. 2).

SECOND LUMINOSITY ESTIMATION METHOD

General Outline

This method is also model dependent, but it is based on the second moments (SM) of the particles' distribution, some of which are obtained from the imaging BPMs. The idea is to transport the set of SM for both bunches over the ring and by adjusting initial values of the SM matrices and some other parameters fit the traced moments to the measured sizes. Given that the ring lattice is perfectly known, there are still interaction regions that have unknown effect on the distribution of particles in the bunches. To handle this problem the ideal ring lattice is appended with thin IP transformations.

Each IP is divided in two equal thin lenses to be able to find second moments in the center of the IP. The strength of the IP lens is calculated based on the size of the opposite bunch. First tests of this approach reveal discrepancies of the fitted and experimental second moments at large currents, when bunches became strongly non-Gaussian. The calculated luminosity also became unrealistic. To fix this effect, an additional set of fitting coefficients was introduced to adjust the counter beam focusing kick.

The final focus solenoids in the present VEPP-2000 lattice configuration cancel the rotation of the betatron oscillation planes after passage through the interaction straight. Since all the CCDs are located outside the IP's straight sections, the solenoids could be treated as axially symmetrical lenses without rotation. Due to the two-fold symmetry of the VEPP-2000 and by omitting the rotation from the solenoids, the SM in the center of each IP should be diagonal. Second moments of the electron and positron bunches in the first IP form the main part of the fitting parameters.

$$M_{IP1} = Diag[m_{1,00}, m_{1,11}, m_{1,22}, m_{1,33}, m_{1,44}, 0] \quad (5)$$

The longitudinal distribution has been set to zero because it has no effect on transverse beam size in VEPP-2000.

The total number of fitting parameters p_j is 18: 10 second moments and 8 from beam-beam force fitting parameters (2 IPs, 2 bunches, 2 dimensions). Experimental data from 16 working CCD cameras gives 32 points, which provides enough information to keep the task well overdetermined.

The target function is:

$$F = \sum_i \left(\frac{M_{exp,i} - M_{fit,i}}{M_{exp,i}} \right)^2 = \sum_i V_i^2. \quad (6)$$

The beam sizes vary strongly from CCD to CCD and this form gives equal weight to all data points.

Minimization Algorithm

To minimize F, the set of variations of parameters Δp_j must be found that leads to the cancellation of the V_i. Linearizing the $\Delta V_i(\Delta p_j)$ this goal can be written as:

$$\Delta V_i(\Delta p_j) \simeq \sum_j \frac{1}{k_j} \frac{\partial V_i}{\partial p_j} k_j \Delta p_j = -V_i, \quad (7)$$

here, k_j are normalization coefficients that can be used to adjust impacts of different model parameters. To find the desired set of parameters, the rectangular matrix $\frac{\partial V_i}{\partial p_j}$ should be inverted. The flexible way to find a pseudo-inverse matrix is provided by the singular value decomposition (SVD):

$$\Delta p_j = \sum_i \left(\frac{\partial V_i}{k_j \partial p_j} \right) \Big|_{SVD}^{-1} \frac{-V_i}{k_j}. \quad (8)$$

Implementation of the found corrections finishes the iteration that should be repeated several times, since the model depends nonlinearly on the parameters. After convergence of the fitting, luminosity is calculated with Eq. (4). The comparison of the second luminosity estimation method with others is shown in Fig. 2.

One of the differences between two algorithms is that latter has the energy spread in the beam as the fitting parameter. First runs supported the presence of microwave instability, first observed with phi-dissector – optical tool for bunch length measurements (see Fig. 3) [3, 4].

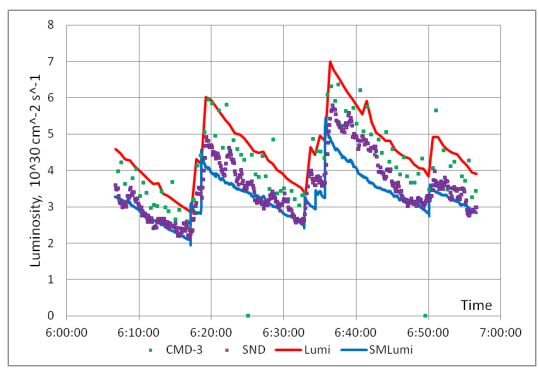

Figure 2: Comparison of the luminosity from different measurements: green dots – CMD-3, purple dots – SND, red and blue lines – estimation methods

PHASE SPACE TOMOGRAPHY

Relatively small number of CCDs – 8 for electrons and 8 for positrons – led to pessimistic estimations of classical approach to the beam phase space tomography methods which use several tens of projections [5]. Therefore, the feasibility study regarding this task was started after the shutdown of VEPP-2000.

The success in solving the inverse problems using the SVD inspired its use in the beam phase space tomography method. The fitting parameters p_j in this case describe the distribution of the particles in the phase space at some point. The experimental data $V_{exp,i}$ is composed of all projections' points from all the CCDs. For the known optics model, the transportation of the particles' distribution to the CCDs locations and calculation of the projections $V_{mod,i}$ is straightforward. To simplify the test problem, several assumptions were used: no transverse coupling; no energy spread; no lattice errors; no counter beam.

To describe the particles' distribution in the tested method the mesh in phase space is set so that values p_j describe the density in the mesh pointsand intermediate values are calculated by linear interpolation. One of the disadvantages of the method is that negative density is allowed. The main clue is to setup the mesh evenly with respect to the phase space. To do so, the point is selected where the Twiss parameter $\alpha = 0$. In this case, the phase trajectories represented in the normalized coordinates $(x/\sqrt{\beta}, x' \cdot \sqrt{\beta})$ form circles, and the mesh points' coordinates could be selected as (r_n, ϕ_m) plus $(0, 0)$ forming a polar mesh. The normalization coefficients k_j in Eq. (8) are proportional to the area related to the corresponding node.

Figure 4 demonstrates results of the fitting for three types of distributions with 5% noise level in the "experimental" projections. For the tests the real VEPP-2000 lattice in the horizontal plane was taken with 8 electrons' CCDs. The real lattice was taken for the tests. Except for some areas with very small negative densities, it is obvious that in general the reconstructed distributions are in good agreement with the original. Also, the integral of the negative density could be used to test the plausibility of found distributions.

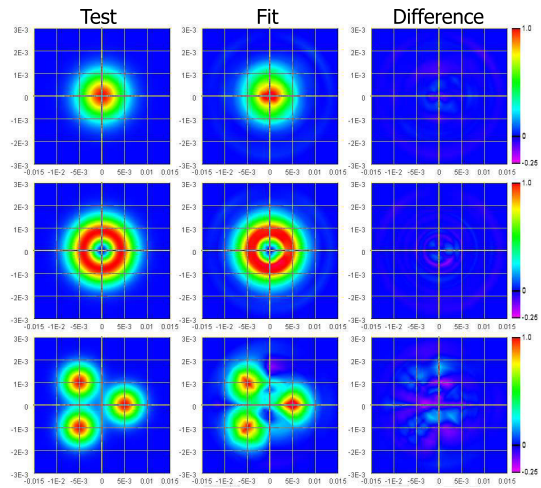

Figure 4: Test distribution, its fit and their difference for the Gaussian, ring-shaped and triple-Gauss distributions.

Further studies will include comparison of the tested method to the commonly used methods, such as inverse Radon transformation. Additionally, influences of various errors and mesh configurations should be thoroughly investigated.

The main practical goal of the beam phase space tomography at VEPP-2000 is to accurately estimate luminosity at high currents when the beam become strongly nongaussian and simpler methods may give unreliable results.

COMBINING MULTIPLE BPM MEASUREMENTS FOR PRECESSION AC DIPOLE BUMP CLOSURE*

BNL, Upton, NY 11973, USA

Abstract

For the RHIC spin flipper to achieve a rotating field, it requires operating five AC dipoles as a pair of closed orbit bumps. One key requirement is to minimize the remnant AC dipole driven betatron oscillation outside of the spin flipper by 50 dB [1]. In the past, due to its inherent sensitivity, a single pickup with a direct-diode detector (3D) [2] and dynamic signal analyzer (DSA) were used to measure bump closure by measuring the remnant oscillations. This however proved to be inadequate, as the betatron phase advance between the AC dipoles is non-zero. A method of combining multiple BPMs into a sensitive measure of bump closure has been developed and was tested during RHIC polarized proton operation in 2013. This technique as well as the experimental results will be presented.

INTRODUCTION

A spin flipper for RHIC (Relativistic Heavy Ion Collider) has been developed for RHIC spin-physics experiments. It is needed to cancel systematic errors by reversing the spin direction of the two colliding beams multiple times during a store [3].

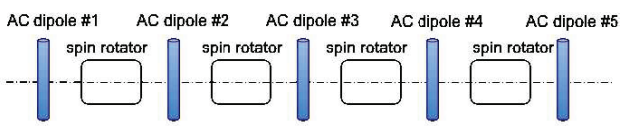

Figure 1: Spin flipper configuration.

The spin flipper system consists of four DC dipole magnets (spin rotators) and five AC dipole magnets (see fig. 1). The aim of this configuration is to produce a rotating field. Multiple AC dipoles are needed to localize the driven coherent betatron oscillation inside the spin flipper [1, 4]. While results from the 2012 run did suggest the presence of a rotating field, the polarization lifetime was degraded with the AC dipoles on. This suggested incomplete bump closure and/or incorrect phase between bumps [1] which lead to reinvestigating the method used to close the AC dipole bumps.

Operationally the AC dipoles form two bumps that minimize the effect of the AC dipoles outside of the spin flipper. The central AC dipole, #3 in figure 1, is common to both bumps. Both AC-dipole bumps operate at the same frequency, but are phase shifted from each other. The convention used when expressing closure in dB is to make the 0 dB reference the strongest AC dipole. In case of the dual bump, AC dipole #4 is used.

BBQ 3D AFE & DSA

Up until the 2013 run the closure was only trimmed using the pickup and direct-diode detector (3D) analog front end (AFE) of the RHIC baseband tune meter (BBQ) processed via a DSA.

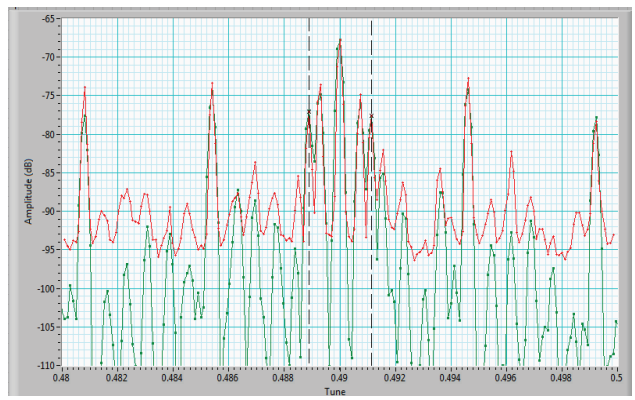

Figure 2: Closed bump DSA beam spectrum (green plot). The red plot is the fitted AC dipole magnet currents.

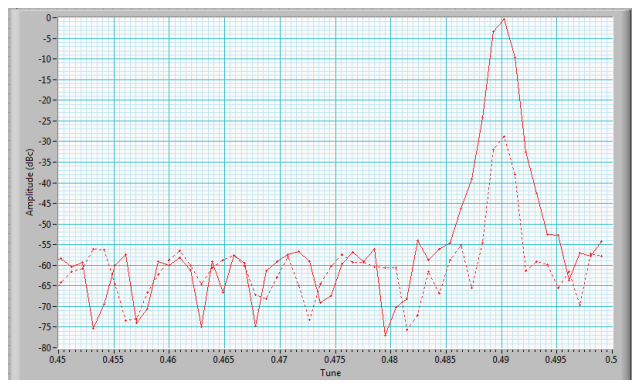

Figure 3: AC dipole #4 alone (solid) and closed bump (dotted) BPM beam spectrum of the most sensitive BPM.

The DSA spectrum in figure 2 (green plot) shows that the closure for the AC dipole bumps was 67 dB. However, the spectrum of the most sensitive BPM (fig. 3, dotted plot) shows a closure of only 28 dB. This nearly two order of magnitude difference clearly shows that it's not possible to determine closure using a single pickup (at a single frequency). The possibility of using a single pickup at multiple frequencies has not yet been fully explored.

COMBINING BPM MEASURMENTS

Even though discrete Fourier transform (DFT) spectrums, which typically are calculated using the fast Fourier transform (FFT) algorithm, are used here, these

Copyright © 2013 CC-BY-3.0 and by the respective authors

methods are not strictly DFT/FFT methods. As a matter of fact the BPM magnitude and phase used by software calculations used a sine/cosine fit, which can be thought of as the evaluation of the discrete time Fourier transform (DTFT) or z-transform at a single frequency.

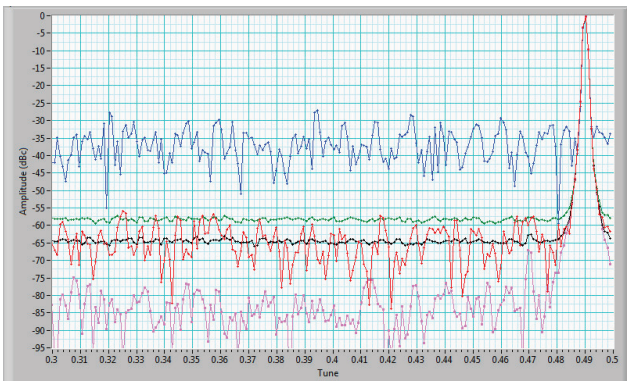

Figure 4: BPM spectrums of weakest (blue), strongest (red), average (green), weighted average (black) and vector average (purple) for AC dipole #4 at 90 A_{pk} (76 G·m) for PP at injection (23.8 GeV).

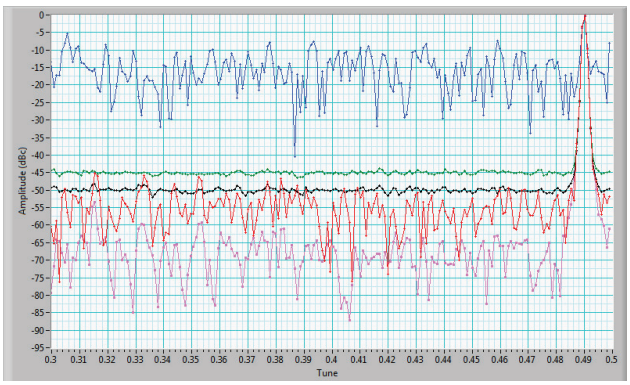

Figure 5: BPM spectrums of weakest (blue), strongest (red), average (green), weighted average (black) and vector average (purple) for AC dipole #4 at 117.9 A_{pk} (100 G·m) for PP at store (255 GeV).

Figures 4 and 5 show the weakest and strongest BPM spectrums and the spectrums for different methods of combining BPMs for polarized proton beam at injection and store respectively when excited by a single AC dipole (#4). In all cases the response is normalized to place the AC dipole peak at the driven frequency (0.49) at 0 dB. This is done as convenient way to visualize the signal to noise ratio. BPM data was taken with 1024 turn data records. For the 2013 run, 4096 turn records were available and these longer records would improve the signal to noise ratio by 6dB. Also note that the AC dipole excitation is 2 dB stronger for the data taken at store. The weakest BPM responses (blue traces) do change proportionally with the change in energy or magnetic rigidity (~20 dB). The strongest response (red traces) changes less (~12dB), which is just a direct result of the optics also being different. The weakest and strongest responses were also produced by different BPMs.

The average response (green trace) is just a simple magnitude average:

$$k_s \sum_{n=1}^{N} |Y_n| \tag{1}$$

Y_n is the frequency response for BPM n and k_s is a scale factor which normalizes the average to 1 (0 dB) when excited by a single AC. Since this is a magnitude response of all BPMs, all need to be zero for this to be zero and this would only happen for a closed bump. The noise floor for 1024 turn data at store was ~45 dB.

The weighted average (black trace) is a magnitude average weighted by each BPM's normalized signal to noise ratio squared:

$$\sum_{n=1}^{N} a_n |Y_n| \tag{2}$$

Software calculations for a_n use the mean magnitude of the DFT/FFT bins from 0.025 to 0.48 as the estimated noise value. The RMS error from a fit could also be used. The noise floor for 1024 turn data at store was ~50 dB.

The vector average (purple trace) scales frequency response of each BPM by the normalized signal to noise ratio squared, just as the weighted average, but also counter rotates the phase by measured phase:

$$\sum_{n=1}^{N} a_n \, e^{-i\phi_n} \, Y_n \tag{3}$$

Phase ϕ_n is the measured phase of BPM n when it was excited by a single AC dipole. The noise floor for 1024 turn data at store was ~70 dB. While this might look like a good candidate for determining bump closure, because this is a linear combination of BPMs, it is possible for it to be zero for combinations of only two AC dipoles and therefore not useful for definitely trimming bump closure (see eqn. 6 of next section).

Frequency Response of Multiple AC Dipoles

From previous treatments of transverse beam motion due to a single AC dipole [5] the basic equation of motion can be thought of as a discrete sampled time system, but the actual sampling is done by a particle or bunch.

Extending the model for an arbitrary number of AC dipoles in the time domain is:

$$\begin{pmatrix} y_0[n] \\ y_0'[n] \end{pmatrix} = \mathbf{M} \begin{pmatrix} y[n-1] \\ y'[n-1] \end{pmatrix} + \begin{pmatrix} e[n] \\ e'[n] \end{pmatrix} \tag{4}$$

$$\begin{pmatrix} e[n] \\ e'[n] \end{pmatrix} = g_{acd} \sum_{k=1}^{N} \mathbf{M}_{kN} \begin{pmatrix} 0 \\ i_1[n] \end{pmatrix} \tag{5}$$

Copyright © 2013 CC-BY-3.0 and by the respective authors

Functions $y_0[n]$ and $y'_0[n]$ are the beam position and slope at center of the last AC dipole, e[n] and e'[n] are the effective stimulus of all AC dipoles, matrix **M** is the transport matrix for a full turn, g_{acd} is a constant which converts magnet current into deflection (units A^{-1}) and matrix $\mathbf{M}_{kN}$ is the transport matrix from AC dipole k to the last AC dipole (N).

These equations illustrate that superposition can be used and that each AC dipole stimulus includes the path or optics to the reference point (center of last AC dipole).

Although not presented here, eqns. 4 and 5 can be transformed into the frequency domain. However, since this is a linear time invariant (LTI) system, certain assumptions can be made. The first is that the BPM position is a superposition of AC dipole currents:

$$Y_n(z) = \sum_{m=1}^{M} H_{nm}(z) I_m(z) \qquad (6)$$

$H_{nm}(z)$ is the transfer function from AC dipole m to BPM n, with M the number of AC dipoles.

Similarly, based on eqn. 5, BPM position is also a superposition of the error signals:

$$Y_n(z) = G_n(z)E(z) + G'_n(z)E'(z) \qquad (7)$$

$G_n(z)$ and $G_n'(z)$ are the transfer functions from AC dipole stimulus (or bump error) signal to BPM position n.

While both eqns. 6 & 7 were shown as continuous functions in z-transform form, actual calibrations are done at a fixed frequency ($z=e^{i2\pi Q_{acd}}$). The calibration process then just becomes a matter of multiplying complex constants. The transfer functions H_{nm} are also not calculated from a model, but a result of BPM position and AC dipole current measurements. For a single AC dipole on one at a time (superposition) eqn. 6 becomes:

$$H_{nm}(z) = \frac{Y_n(z)}{I_m(z)} \qquad (8)$$

Not shown, but it's also possible to derive these transfer functions from stepped AC dipole data.

Closing AC Dipole Bumps Using Calculated Correction Factors

Once the transfer functions have been determined, eqn. 6 can be used to solve for the precise currents needed to close a bump by setting $Y_n=0$ and solving for currents (or correction factors). Since the spin flipper contains two bumps, both need to be calculated separately using:

$$H_{n3} = 2k_2 H_{n2} - k_1 H_{n1} \qquad (9)$$

$$H_{n3} = 2k_4 H_{n4} - k_5 H_{n5} \qquad (10)$$

These equations assume a value for the shared AC dipole (#3) and calculate correction factors (k_1, k_2, k_4, and k_5) for the other four magnets assuming ideal settings.

Two methods have been used to calculate these correction factors. One involves a matrix operation using all BPMs at once for eqn. 9 and 10. The other method is a cutting method that involves iteratively calculating average correction factors for all combinations of BPM pairs and removing BPM pairs that produce correction factors that deviates more than four standard deviations from the average.

Measuring Bump Closure by Estimating AC Dipole Stimulus Components

A direct consequence of eqn. 7 is that the total AC dipole stimulus or bump error components (E, *E'*) can be calculated using pairs of BPMs using:

$$E = p_n Y_n + p_m Y_m \qquad (11)$$

$$E' = p'_n Y_n + p'_m Y_m \qquad (12)$$

The E and *E'* used are the ideal values calculated from the magnet current (based on eqn. 5). The scaling convention used is to make both E and *E'* equal 1 when excited by AC dipole #4 alone. Constants p_n, p_m, p'_n, and p'_m are then calculated using matrix operations while iterating over all BPM pairs (each of BPM n and m). These constants are summed and scaled to produce coefficients for each BPM so that producing the E and *E'* response only requires a single pass over the BPM data. The scaling used depends on which BPM pairs were used. When using all BPM pairs, the scaling should use the normalized signal to noise ratio squared to improve the resultant signal to noise ratio. When only using the final pairs used to calculate the bump correction factors, then the coefficients only need to be normalized by the number of pairs.

CONCLUSION

It is possible to combine multiple BPM measurements to close the AC dipole bumps. Using the calculated correction factors produced good results during the 2013 run. There are also numerous ways to verify closure, and this still includes the 3D pickup and DSA.

STRIPLINE BEAM IMPEDANCE*

A. Blednykh#, W. Cheng, S. Krinsky
BNL, Photon Science, NY 19973-5000, USA

Abstract

We discuss the Lambertson and Shafer formalisms for the longitudinal and transverse beam impedances of a stripline. The required characteristic impedances and the geometric factors are determined by the solution of Laplace's equation in 2-dimensions, which we find using the 2-D POISSON code. Lambertson's equations are compared with numerical results obtained using the 3-D electromagnetic simulation code GdfidL. Good agreement is found at low frequencies. The results differ at high frequencies, since the analytic results do not take into account higher order modes.

INTRODUCTION

Striplines [1-4] are often used in accelerator systems to serve as either pick-ups or kickers. These devices are comprised of the conducting surfaces of the vacuum envelope and inner conducting electrodes as illustrated in Fig. 1. An important issue in the design of a stripline is the impedance that it presents to the particle beam traveling along the axis through the device.

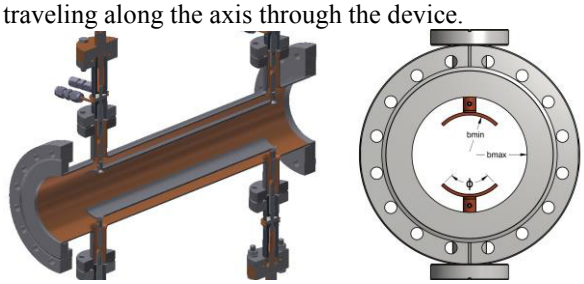

Figure 1: One half of the stripline kicker geometry. Two electrodes are located inside of the round pipe with $b_{min} = 24.1mm$ and $b_{max} = 38mm$ radii. The length of electrodes is 300mm. The electrode thickness is 2mm.

Lambertson [2,3] has presented a very interesting and comprehensive discussion of pick-ups and kickers. Following his formalism, one can express the longitudinal and transverse (vertical) beam impedances for a stripline in the form

$$Z_{||}(k) = g_{||}^2 Z_{ch,||}[sin^2(kL) + j\, sin(kL)cos(kL)] \quad (1)$$

$$Z_{\perp}(k) = \left(g_{\perp}^2 Z_{ch,\perp}/kb^2\right)[sin^2(kL) + jsin(kL)cos(kL)] \quad (2)$$

where k is the wave number, L is the longitudinal length of electrodes, b_{min} is the minimum distance between the beam axis and the electrodes, $g_{||}$ and $g_{\perp}$ are longitudinal and transverse geometric factors, and $Z_{ch,||}$ and $Z_{ch,\perp}$ are longitudinal and transverse characteristic impedances of the stripline. The geometric factors and the characteristic impedances are for the full structure containing all electrodes. We note that for a device comprised of two identical electrodes symmetrically placed as in Fig. 1, $Z_{ch,||} = Z_L/2$, where Z_L is the characteristic impedance of a single electrode.

At low frequency the longitudinal shunt impedance is related to the longitudinal beam impedance by [3]

$$R_{sh,||} = ReZ_{||}(k) \times 4, \quad (3)$$

and the transverse shunt impedance is related to the transverse beam impedance by

$$R_{sh,\perp} = ReZ_{\perp}(k) \times 4/k \quad (4)$$

To determine $Z_{ch,||}$ and $Z_{ch,\perp}$ for a given geometry, one needs to solve Laplace's equation in 2 dimensions. For this, we use the 2D POISSON electrostatic code [5]. The characteristic impedance is given by [6]

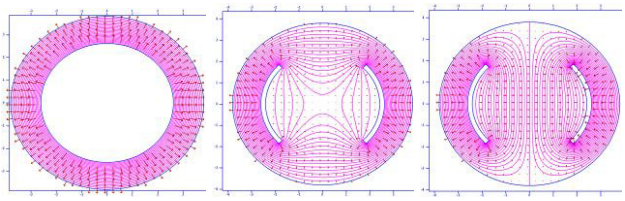
$$Z_{ch} = \frac{1}{cC}, \quad (5)$$

where c is the velocity of light and C is the capacitance of the stripline structure. For the longitudinal mode, both electrodes have voltage V_p, while for the transverse mode they have voltages of opposite polarity $\pm V_p$. In both cases, the capacitance is related to the stored energy W_e and voltage V_p via

$$C = \frac{2W_e}{V_p^2} \quad (6)$$

Given the magnitude of the voltage V_p, we calculate the stored energy using POISSON and in this manner determine the capacitance and thus the characteristic impedance for each mode.

First, as an illustration, we consider the ideal coaxial transmission line with geometric parameters $b_{min} = 24.1mm$ inner and $b_{max} = 38mm$ outer radius (Fig. 2a). The characteristic impedance determined from the stored energy computed by POISSON and using Eqs. (5 and 6) with specified positive voltage ($V_p = +1Volt$) on inner conductor is $Z_{ch}^{+} = 22.53\Omega$. This agrees with the well-known result, $Z_{ch}^{CXL} = \frac{Z_0}{2\pi} Log(b_{max}/b_{min})$ for the coaxial (CXL) transmission line.



Next, we consider the longitudinal and transverse characteristic impedances for the round stripline geometry shown in Fig. 2b,c. The electrode radius b_{min} and outer radius b_{max} are fixed. The angle subtended by an electrode is varied from $\phi = 10^{\circ}$ to $\phi = 170^{\circ}$. The longitudinal and transverse characteristic impedances of the structure with the two electrodes as a function of the electrode angle are shown in Fig. 3. The longitudinal characteristic impedance tends to 23Ω for $\phi \to 180^{\circ}$, approaching the result for the coaxial transmission line, as it must.

As can be seen from Fig. 3, for electrode angle $\phi \to 180^{\circ}$, the transverse characteristic impedance $Z_{ch,\perp}$ is about a factor of two less than the longitudinal $Z_{ch,||}$. For electrode angle $\phi \to 90^{\circ}$, their difference becomes

less but the fact that they are not equal means that a pair of electrodes matched to 25Ω transversally (50Ω single electrode) are mismatched longitudinally ($Z_{ch,||} = 18.2\Omega$) and vice versa.

a) b) c)

Figure 2: a) Coaxial transmission line with inner and outer radii of $b_{min} = 24.1mm$ and $b_{max} = 38mm$ respectively. b) Longitudinal excitation for $\phi = \pi/2$: two electrodes inside the round pipe at equal positive voltages V_p. c) Transverse excitation for $\phi = \pi/2$: two electrodes inside the round pipe at $\pm V_p$. Magenta lines are lines of constant scalar potential. Arrows are proportional to electric field strength.

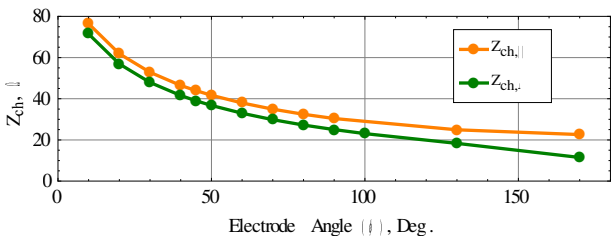

Figure 3: For the structure of Fig. 2b,c, we plot the longitudinal (orange) and transverse (green) characteristic impedances as a function of electrode angle ϕ calculated using the POISSON code.

The geometric factors for a pair of electrodes as a function of the electrode angle ϕ are shown in Fig. 4 (other geometric dimensions fixed). For $\phi \to \pi$, the longitudinal geometric factor $g_{||} \to 1$, while the transverse geometric factor, $g_{\perp} \to 4/\pi$.

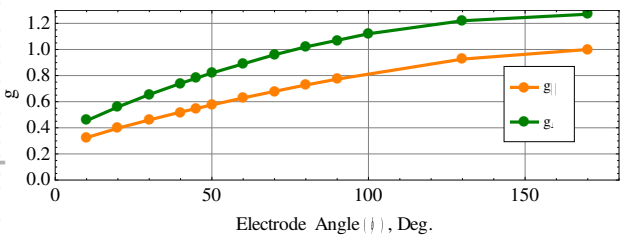

Figure 4: For the structure of Fig. 2b,c, we plot the longitudinal (orange) and transverse (green) geometric factors as a function of electrode angle ϕ calculated using the POISSON code.

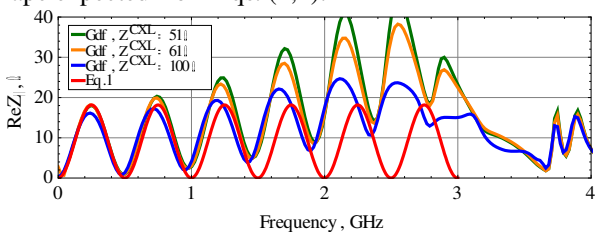
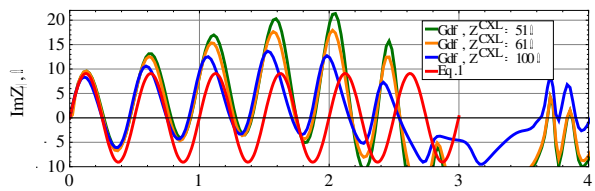


BEAM IMPEDANCES, $Z_{||}(k)$ AND $Z_{\perp}(k)$

The real and imaginary parts of the longitudinal beam impedance at low frequencies are shown in Eq. (1) [1].



In Figs. 5a and 5b, we compare Eq. (1) with calculated data obtained using the 3D GdfidL electromagnetic simulation code [7] for the stripline geometry with 90° electrode angle, as shown in Fig. 1. The simulated longitudinal geometric factor and longitudinal characteristic impedance are $g_{||} = 0.774$ and $Z_{ch,||} = \frac{Z_L}{2} = 30.5\Omega$ (for two electrodes).

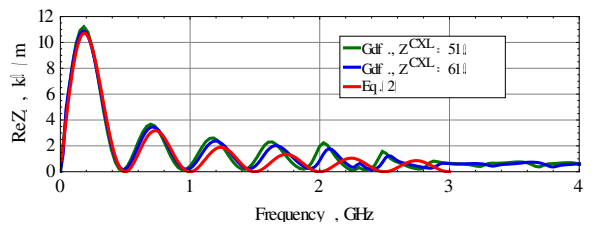
We varied the geometric dimensions of the coaxial feed-thru connectors to obtain three different longitudinal characteristic impedances of the external coaxial line, Z_{ch}^{CXL} =51Ω, 61Ω and 100Ω. This was done in order to check the deviation of the GdfidL calculated longitudinal beam impedance from Eq. (1), when electrodes are matched or mismatched to Z_{ch}^{CXL} of the feed-thru connectors.

First, we consider the characteristic impedance of feed-thru connectors $Z_{ch}^{CXL} = 51\Omega$. In this case, there is a good match to the transverse characteristic impedance ($Z_{ch,\perp}$) of each stripline electrode with 90° angle and a mismatch to the longitudinal characteristic impedance ($Z_L = 2Z_{ch,||} = 61\Omega$) of single electrode for the same angle. From Figs. 5a and 5b, we see that the longitudinal beam impedance (real and imaginary parts) agree well with Eq. (1) at low frequencies. The longitudinal impedance spectrum starts to deviate at high frequencies from the shape expected from Eqs. (1,2).

a)

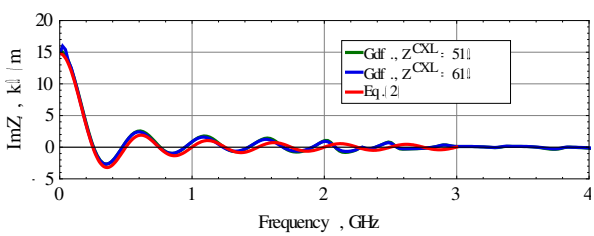
b)

Figure 5: Real (a) and Imaginary (b) part of the longitudinal impedance for the stripline kicker with two 90° angle electrodes inside. The feed-thru connectors are matched to three different characteristic impedances $Z_{ch}^{CXL} = 51\Omega$ (green curve), $Z_{ch}^{CXL} = 61\Omega$ (orange curve) and $Z_{ch}^{CXL} = 100\Omega$ (blue curve). The longitudinal characteristic impedance of two 90° angle electrodes is $Z_{ch,||} = 30.5\Omega$. The red curves are the results of Eq. (1), with $Z_{ch,||} = 30.5\Omega$ and $g_{||} = 0.774$.



Next, we consider the characteristic impedance of feed-thru connectors to be $Z_{ch}^{CXL} = 61\Omega$. In this case the feed-thru connectors are matched to the longitudinal characteristic impedance of each individual electrode. The difference between the numerical results (orange curves in Figs. 5a and 5b) and the analytic results [Eqs. (1)] is reduced at high frequencies (below 3GHz) since matching is improved, but still there is significant

Copyright © 2013 CC-BY-3.0 and by the respective authors



deviation. This can be explained due to gradual increase of the reflection coefficient (S_{11}-parameter) at higher frequencies. The coaxial feedthru connectors and electrode pair are perfectly matched at low frequencies. The reflection of the TEM-mode in the coaxial waveguide is around 10% for considered geometry at low frequencies and 50% at frequency ~2GHz (determined from a GdfidL calculation). Due to larger reflection of TEM-mode from output feed-thru connectors at high frequencies, electromagnetic fields radiate more into the vacuum chamber and the real part of the longitudinal coupling impedance $ReZ_{||}(k)$ deviates from quadratic sinusoidal wave. If the longitudinal characteristic impedance is over-matched ($Z_{ch}^{CXL} = 100\Omega$), then we observe frequency shift and reduction of $Z_{||}(k)$ at low frequencies.

The discussed equations provide a good approximate description of the beam impedance. We found excellent agreement between equation Eq. (1) and numerical calculations at low frequencies, when the electrodes and feed-thru connectors are matched or even slightly mismatched to each other

The real and imaginary parts of the transverse beam impedance are shown in Eq. (2). This equation is compared with GdfidL results for the stripline geometry as shown in Fig. 1. We analysed the effects of two electrodes with an angle of 90° each. The calculated transverse geometric factor and transverse characteristic impedance are $g_\perp = 1.1$ and $Z_{ch,\perp} = 25\Omega$ (for two electrodes). The transverse beam impedance is calculated for two different characteristic impedances of the feed-thru coaxial connectors, $Z_{ch}^{CXL} = 51\Omega$ and $Z_{ch}^{CXL} = 61\Omega$ (Fig. 6a and Fig. 6b).

a)

b)

Figure 6: Real (a) and Imaginary (b) part of the transverse impedance of the stripline kicker with two 90° angle electrodes inside. The feed-thru connector has two different characteristic impedances, $Z_{ch}^{CXL} = 51\Omega$ (green) and $Z_{ch}^{CXL} = 61\Omega$ (blue). The red curves are the result of Eq. (2).

As a result the electrodes are well matched in first case and slightly mismatched in the second. The real and imaginary parts of the transverse beam impedance agree well with Eq. (2) up to 2GHz. The imaginary part of the beam impedance at $\omega \to 0$ is $ImZ_\perp = 15k\Omega/m$. The small mismatch of electrodes with connectors has small effect on the transverse beam impedance.

TRANSVERSE SHUNT IMPEDANCE

The transverse shunt impedance has been calculated via Eq. (4). The real part of the transverse beam impedance of Eq. (2) with simulated transverse geometric factor and the transverse characteristic impedance has been implemented into Eq. (4) (green) and the result is shown at low frequency in Fig. 7. It agrees with $R_{sh,\perp}$ data obtained due to implementing the GdfidL data $ReZ_\perp(k)$ from Fig. 6a in to Eq. (4).

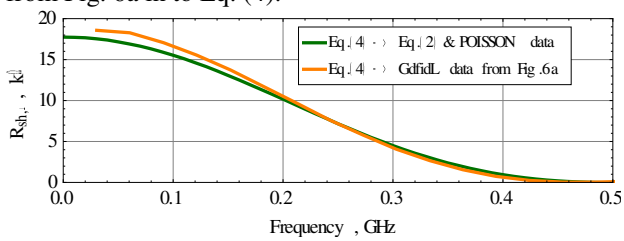


Figure 7: Transverse shunt impedance calculated via Eq. (4). Green curve is $R_{sh,\perp}$ due to Eq. (2) and numerically obtained vertical geometric factor and transverse characteristic impedance. Blue curve is the GdfidL data implemented in to Eq. (4).

SUMMARY

Analytical equations at low frequency for the beam impedances as well as the ratio between $Z(k)_{||,\perp}$ and $R_{sh,||,\perp}$ have been presented. Good agreement is found between the analytical results and 3D GdfidL simulations at low frequencies.

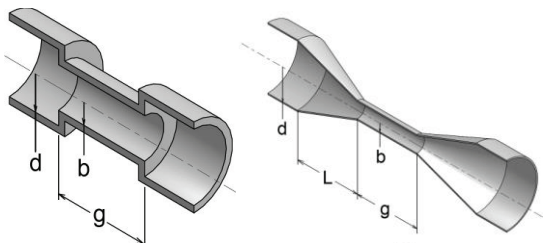
LONGITUDINAL WAKEFIELD FOR AN AXISYMMETRIC COLLIMATOR*



A. Blednykh# and S. Krinsky,
BNL, Photon Science, NY 11973-5000, USA

Abstract

We consider the longitudinal point-charge wakefield, *w(s),* for an axisymmetric collimator having inner radius *b*, outer radius *d*, inner length *g* and taper length *L*. The taper angle α is defined by $\tan\alpha = (d-b)/L$. Using the electromagnetic simulation code ECHO, we explore the dependence of the wakefield on a collimator's geometric parameters over a wide range of profiles: from small-angle tapers to step-function transitions.

INTRODUCTION

In this paper, using the 2-D electromagnetic simulation ECHO code [1,2], we carry out an investigation of the longitudinal short-range wakefield due to an axisymmetric collimator. More detail on this subject can be found in ref. [3].

a) b)

Figure 1: a) Step Collimator. b) Tapered Collimator.

We consider the highly relativistic limit in which a particle traveling at the speed of light *c*, passes through a step-function or tapered collimator illustrated in Figs. 1a,b. We denote: the smaller pipe radius by *b;* the larger radius by *d*; the length of the inner section of the collimator by *g;* and the length of the taper by *L*. The taper angle α is defined by $\tan\alpha = (d-b)/L$. The longitudinal wakefield produced by a point charge is denoted *w(s)*, where *s* is the distance of the test particle behind the driving particle.

Podobedov and Stupakov [4] have noted that the point-charge wakefield for a collimator can be written in the form,

$$w(s;b,d,g,L) = \frac{c\,Z_0}{\pi} log(d/b)\delta(s) + D(s;b,d,g,L), \quad (1)$$

where Z_0 is the impedance of free space. The delta function term corresponds to the result in the optical regime [5]. The causal function *D(s)*, vanishes for *s<0*, and is discontinuous at *s=0*. Since the impedance vanishes at zero frequency, it follows that

$$\int_0^\infty ds\, D(s) = -\frac{cZ_0}{\pi} log(d/b). \quad (2)$$

In this paper, in order to facilitate the illustration of the behavior of the wakefield over a wide range of parameters and for larger *s*, we prefer to introduce the normalized causal function $u(s)$, via

$$w(s;b,d,g,L) = \frac{c\,Z_0}{\pi} log(d/b)[\delta(s) - u(s;b,d,g,L)], \quad (3)$$

where

$$\int_0^\infty ds\, u(s) = 1. \quad (4)$$

Using this normalized function, the ratio of the loss factor k_{loss} to that in the optical regime [5,6] k_{loss}^{opt} is easily expressed. For a Gaussian bunch of rms width σ, this ratio is given by

$$k_{loss}(\sigma)/k_{loss}^{opt}(\sigma) = 1 - \int_0^\infty ds\, u(s) exp(-s^2/4\sigma^2), \quad (5)$$

where $k_{loss}^{opt}(\sigma) = \left(cZ_0/2\pi^{3/2}\sigma\right) log(d/b)$.

For a small-angle tapered collimator *(sat)*, it is shown in ref. [4] that,

$$D^{sat}(0) \cong -\frac{cZ_0}{\pi b\alpha}, \quad (6)$$

and for a step collimator *(st)*, it follows from the work of Okamoto, Jiang and Gluckstern [7] that

$$D^{st}(0) \cong -\frac{0.6\,cZ_0}{\pi b(\pi/2)}. \quad (7)$$

We now note that to within $\pm 10\%$ accuracy,

$$\frac{1}{\pi b} \cong \frac{log(d/b)}{d}, \quad (for\ 1.5 \leqslant d/b \leqslant 6). \quad (8)$$

In this paper, we shall restrict our attention to collimators with parameters within the range $1.5 \leqslant d/b \leqslant 6$. In this case, Eqs. (6,8) imply that for small-angle tapers,

$$u^{sat}(0) \cong \frac{\pi}{d\alpha}, \quad (9)$$

and Eqs. (7,8) show that for a step collimator,

$$u^{st}(0) \cong \frac{0.6\,\pi}{d(\pi/2)}. \quad (10)$$

The short-range wakefield depends predominantly on the two length scales $b\alpha$ and $d\alpha$. In illustrating its behavior, one can plot the wakefield versus the variable $s/b\alpha$ or $s/d\alpha$. In this paper, in order to illustrate more clearly the behavior of the wakefield at longer distances, we prefer to utilize the variable $s/d\alpha$.

For the short-range wakefield $(s/d\alpha \lesssim 0.3)$, our numerical calculations demonstrate that the dependence on g is very weak and they support the approximate validity of the scaling relation,

$$w(s;b,d,g,L) \cong \frac{c\,Z_0}{\pi} log\left(\frac{d}{b}\right)\left[\delta(s) - \frac{1}{d\alpha} f\left(\frac{s}{d\alpha}, \frac{b}{d}\right)\right]. \quad (11)$$

With the wakefield approximated by Eq. (11), it follows from Eq. (5) that the departure of the loss factor from the optical approximation for short bunches $(\sigma/d\alpha \lesssim 0.15)$ can be estimated by

$$k_{loss}(\sigma)/k_{loss}^{opt}(\sigma) \cong 1 - \sqrt{\pi} f\left(0, \frac{b}{d}\right)\frac{\sigma}{d\alpha}. \quad (12)$$

with $f\left(0, \frac{b}{d}\right)$ varying from ~3 for small-angle tapers to ~1.8 for step collimators. Eq. (12) is a more accurate expression for the loss factor than the similar relation given in Eq. (12.26) of ref. [8].

DIMENSIONAL ANALYSIS

We motivate our discussion by using dimensional analysis and the longitudinal scaling relation introduced in ref. [9]. From dimensional analysis, we can write,

$$u(s;b,d,g,L)=\frac{1}{d}u_1\left(\frac{s}{d};\frac{b}{d},\frac{g}{d},\frac{L}{d}\right). \quad (13)$$

In the special case of a step collimator, for which L=0,

$$u^{st}(s;b,d,g)=\frac{1}{d}u_1^{st}\left(\frac{s}{d};\frac{b}{d},\frac{g}{d},0\right). \quad (14)$$

We have determined that when g is not too the wakefield depends very weakly on g, so we can simplify Eq. (14) to read,

$$u^{st}(s;b,d,g)\cong\frac{1}{d}u_2^{st}\left(\frac{s}{d};\frac{b}{d}\right). \quad (15)$$

The corresponding weak dependence of the impedance of a step collimator on g was found in the analysis of Ref. [7].

Our ECHO calculations have uncovered the surprising result that in the parameter range we are considering [see Eq. (8)], and for $s/d\gtrsim 0.5$, the dependence on b/d is very weak (see Fig. 2), so to a reasonable approximation,

$$u^{st}(s;b,d,g)\cong\frac{1}{d}u_3^{st}\left(\frac{s}{d}\right), \quad (16)$$

Clearly, in Eq. (13), we could have chosen to set the length scale with any of the lengths in the problem. Eq. (16) provides one motivation for our choice to single out the dependence on the larger radius d.

For a small-angle tapered collimator, it has been shown [9] that an important longitudinal scaling relation holds for the short-range wakefield,

$$w^{sat}(s;b,d,g,L)=\lambda\, w^{sat}\left(s\lambda;b,d,\frac{g}{\lambda},\frac{L}{\lambda}\right), \quad (17)$$

where λ is a dimensionless parameter. The scaling relation (17) holds trivially for the delta function term in Eq. (3). It therefore follows from Eqs. (13) and (17) that

$$u_1^{sat}\left(\frac{s}{d};\frac{b}{d},\frac{g}{d},\frac{L}{d}\right)=\lambda\, u_1^{sat}\left(\frac{s\lambda}{d};\frac{b}{d},\frac{g}{\lambda d},\frac{L}{\lambda d}\right). \quad (18)$$

We now choose $\lambda=L/(d-b)$, obtaining

$$u_1^{sat}\left(\frac{s}{d};\frac{b}{d},\frac{g}{d},\frac{L}{d}\right)=\frac{L}{d-b}\,u_1^{sat}\left(\frac{sL}{d(d-b)};\frac{b}{d},\frac{g(d-b)}{Ld},\frac{d-b}{d}\right) \quad (19)$$

and hence,

$$u^{sat}(s;b,d,g,L)=\frac{L}{d(d-b)}u_2^{sat}\left(\frac{sL}{d(d-b)};\frac{b}{d},\frac{g(d-b)}{Ld}\right). \quad (20)$$

Recall that the taper angle α is defined by $\tan\alpha=(d-b)/L$. We can rewrite Eq. (20) in the form

$$u^{sat}(s;b,d,g,L)=\frac{1}{d\tan\alpha}u_2^{sat}\left(\frac{s}{d\tan\alpha};\frac{b}{d},\frac{g\tan\alpha}{d}\right). \quad (21)$$

Based on the ECHO calculations, we have found that the dependence on g is weak for $s/d\alpha\lesssim 0.3$. Neglecting the dependence on g, and replacing $\tan\alpha$ by the angle α in the first argument of u_2^{sat}, we obtain the approximate scaling relation

$$u^{sat}(s;b,d,g,L)\cong\frac{1}{d\alpha}u_2^{sat}\left(\frac{s}{d\alpha};\frac{b}{d}\right). \quad (22)$$

Let us note that Eq. (22), which we have just introduced for the tapered collimator, has a form consistent with Eq. (15) found for the step collimator ($\alpha=\pi/2$). Therefore, we can hope that Eq. (15) will have an approximate validity for large collimator angles. Our numerical calculations show that replacing the tangent by the angle extends the range of usefulness of Eq. (15). In the context of the derivation of the scaling relation of Ref. [9], replacing $\tan\alpha$ by the angle α corresponds to moving out of the region of validity of the paraxial approximation, which is only applicable for a smooth, slowly-varying wall. Once the taper angle approaches $\pi/2$, the scaling is broken and the function f begins to depend also on the angle α itself. The special case of the wakefield of the step collimator ($\alpha=\pi/2$) turns out to exhibit very interesting behavior deserving individual attention.

APROXIMATE CALCULATION OF THE POINT-CHARGE WAKEFIELD

Using ECHO, we cannot directly calculate the point-charge wakefield. In Ref. [4], an approximate method for determining the point-charge wake has been introduced. Following this approach, we use ECHO to calculate the wakefield $W^{\sigma_0}(s)$ produced by a Gaussian bunch of rms width σ_0. We choose σ_0 small enough so that the wake is resistive. We then approximate Eq. (3) by

$$W^{\sigma_0}(s;b,d,g,L)=\frac{cZ_0}{\pi}log(d/b)\left[\frac{1}{\sqrt{2\pi}\sigma_0}exp\left(\frac{-s^2}{2\sigma_0^2}\right)-U^{\sigma_0}(s;b,d,g,L)\right]. \quad (23)$$

For $s\gg\sigma_0$, the point-charge wake is well-approximated by Eq. (23), hence

$$u(s;b,d,g,L)\cong U^{\sigma_0}(s;b,d,g,L)\qquad (s\gg\sigma_0). \quad (24)$$

In this manner, we approximate the scaling function introduced in Eq. (11) by

$$f\cong d\alpha\cdot U^{\sigma_0}(s;b,d,g,L)\qquad (s\gg\sigma_0). \quad (25)$$

STEP COLLIMATORS

In Fig. 2, we plot $f\cong d\alpha U^{\sigma_0}$ versus $s/d\alpha$ for step collimators with b=3mm and d=6mm (black), 12mm (green) and 18mm (orange), and with b=6mm and d=12mm (red). The rms length of the charge distribution $\sigma_0=50\mu m$ is chosen to be small enough to assure that the wake field is resistive. The close agreement of the wakefields for these different parameters is striking. These results clearly show that the dependence of the scaling function f on the ratio b/d is surprisingly weak, as noted in Eq. (16).

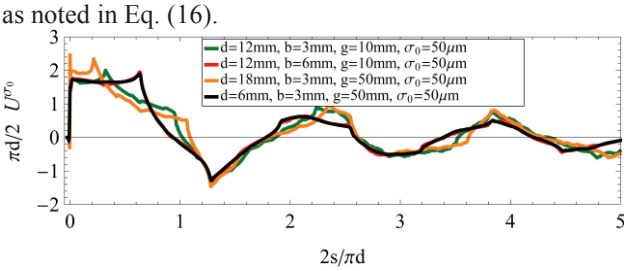

Figure 2: For step collimator, we plot $(\pi d/2)U^{\sigma_0}(s;b,d,g)$ versus $2s/\pi d$ for σ_0=50μm and: d=12mm, b=3mm, g=10mm (green); d=12mm, b=6mm, g=10mm (red); d=18mm, b=3mm,g=50mm (orange); d=6mm, b=3mm, g=50mm (black).

TAPERED COLLIMATOR

We note that for $s/d\alpha\lesssim 0.3$, f is quite independent of g. In Fig. 3, we plot the function $f\cong d\alpha U^{\sigma_0}$ versus $s/d\alpha$ for collimators with d=6mm and b=3mm. The cases with taper length $L\gtrsim 6.25mm$ (red, blue, orange) satisfy the

Copyright © 2013 CC-BY-3.0 and by the respective authors

longitudinal scaling (17) very accurately. The longitudinal scaling is seen to be broken when $L \lesssim 3.125mm$. The accuracy of the approximation of Eq. (11) for the cases of L=3.12mm (aqua) and L=1.56mm (green) has been significantly improved by the replacement of $\tan\alpha$ by the angle α as suggested following Eq. (21). Even in the case of the step collimator (black), Eq. (11) provides a rough approximation for small s. In Fig. 4, we plot the function $f \cong d\alpha U^{\sigma_0}$ versus $s/d\alpha$ for collimators with d=12mm and b=3mm. The cases with taper length $L \gtrsim 12.5mm$ (pink, black, orange) satisfy the longitudinal scaling (17) very accurately. The longitudinal scaling is seen to be broken for the cases of $L \lesssim 6.25mm$ (red, aqua, green). In Fig. 5, we plot the function $f \cong d\alpha U^{\sigma_0}$ versus $s/d\alpha$ for collimators with d=6mm, b=3mm, L=25mm (red); d=12mm, b=3mm, L=50mm (black); and d=18mm, b=3mm, L=50mm (green) for values of L sufficiently large to assure longitudinal scaling (17) is accurately satisfied. We see that for $s/d\alpha \lesssim 0.3$, there is approximate agreement between the curves corresponding to different values of b/d, illustrating the weak dependence on the ratio b/d in the approximate scaling relation (11).

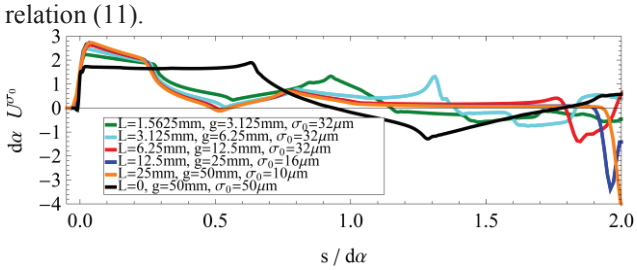

Figure 3: For tapered collimators, we plot $d\alpha U^{\sigma_0}$ versus $s/d\alpha$ for **d=6mm, b=3mm** and: g=3.12mm, L=1.56mm, σ_0=32μm (green); g=6.25mm, L=3.12mm, σ_0=32μm (aqua); g=12.5mm, L=6.25, σ_0=32μm (red); g=25mm, L=12.5mm, σ_0=16μm (blue); g=50mm, L=25mm, σ_0=8μm (orange). The black curve corresponds to a step collimator. We see that longitudinal scaling is only accurately satisfied for $L \gtrsim 6.25mm$.

SUMMARY

For a tapered collimator, we have shown that the short-range wakefield, for $s/d\alpha \lesssim 0.3$ and $\alpha \lesssim \pi/3$, is well-approximated by Eq. (11). Having factored out the $log(d/b)$ term, we have found that in the range $1.5 \leqslant \frac{d}{b} \leqslant 6$ of Eq. (8), the scaling function f depends only weakly on b/d. For small taper angle, $\alpha \lesssim \pi/4$, the ECHO calculations confirm that the longitudinal scaling [9] relation (17) is accurately satisfied. The approximation of Eq. (11) properly satisfies Eq. (17) for small taper angle. The longitudinal scaling is broken for angles large compared with $\pi/4$. We have found that using the taper angle α in Eq. (11), rather than its tangent, allows Eq. (11) to remain a good approximation for larger angles ($\alpha \sim \pi/3$), beyond the regime where Eq. (17) is satisfied. As the taper angle increases further, Eq. (11) becomes less accurate, and the function f begins to depend on the angle α itself.

The case of a step collimator ($\alpha = \pi/2$) is quite interesting. For the parameters that we have considered, its wakefield is well-approximated by,

$$w^{step}(s;b,d,g,L) \cong \frac{c\,Z_0}{\pi} log\left(\frac{d}{b}\right)\left[\delta(s) - \frac{1}{d}F^{step}\left(\frac{s}{d},\frac{b}{d}\right)\right], \quad (26)$$

where the dependence on b/d is very weak for s/d > 0.5 (see Fig. 2). The very weak dependence of F^{step} on b/d is quite remarkable, and we did not anticipate this simple behavior.

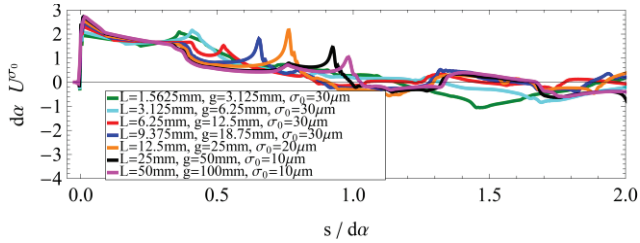

Figure 4: For tapered collimators, we plot $d\alpha U^{\sigma_0}$ versus $s/d\alpha$ for **d=12mm and b=3mm** and: g=3.12mm, L=1.56mm, σ_0=30μm (green); g=6.25mm, L=3.12mm, σ_0=30μm (aqua); g=12.5mm, L=6.25, σ_0=30μm (red); g=18.8mm, L=9.4mm, σ_0=30μm (blue); g=25mm, L=12.5mm, σ_0=20μm (orange); d=12mm, g=50mm, L=25mm, σ_0=10μm (black); g=100mm, L=50mm, σ_0=10μm (purple).

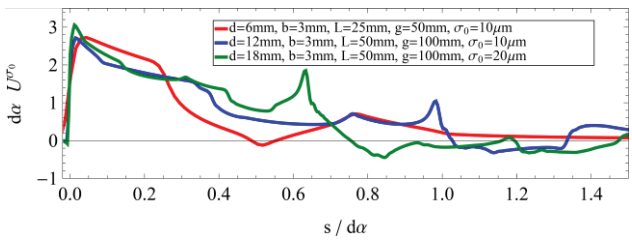

Figure 5: For small-angle tapered collimators satisfying longitudinal scaling, we plot $d\alpha U^{\sigma_0}$ versus $s/d\alpha$ for: d=6mm, b=3mm, L=25mm (red); d=12mm, b=3mm, L=50mm (black); and d=18mm, b=3mm, L=50mm (green).

WAKE FIELDS DUE TO WALL ROUGHNESS FOR REALISTIC SURFACES*

A.V. Fedotov#, I. Pinayev , BNL, Upton, NY 11973, USA
A. Novokhatski, SLAC National Accelerator Laboratory, Menlo Park, CA 94025, USA

Abstract

Wake fields due to the wall roughness of the vacuum chamber can catch up to the bunch causing energy spread and emittance growth. Several theoretical models were developed in the past which showed rather different importance of this effect. Some models suggest that the wall roughness effect can be minimized if the vacuum chamber surface is characterized by a large aspect ratio of the surface roughness (characteristic length to the height of the surface bumps). To explore these effects several surfaces were measured and direct numerical simulations were performed for such realistic surfaces. The studies were done both for the long bunches to provide estimates of this effect for parameters of the eRHIC project, as well as for very short bunches to explore parameter space of the wall roughness experiment proposed at BNL's ATF.

INTRODUCTION

This work was originally motivated by beam dynamics studies for the eRHIC project [1-3], which is a proposed upgrade of the Relativistic Heavy Ion Collider (RHIC). The present eRHIC design is based on the multi-pass electron beam transport in existing tunnel of RHIC. As a result of a high peak current and a very long beam transport, consideration of various collective beam dynamics effects becomes important [2, 3]. The contribution of the wall roughness to the coupling impedance (wake potential) can become significant, especially when the size of the vacuum chamber is small and length of the electron bunch is short.

Some models indicate that the wall roughness effects can be minimized if the vacuum chamber surface is characterized by a large aspect ratio of the surface roughness (characteristic length to the height of the surface bumps). We attempted to explore these effects for realistic surfaces by means of the direct numerical simulations. Several surfaces were measured, including extruded aluminium, for which such roughness aspect ratio is expected to be very large. The measured surface data was then used as an input parameter in electrodynamics code NOVO [4] to simulate the wake field.

Studies were done both for the long bunches (for the eRHIC parameters [2-3]) with the bunch length longer than a typical correlation length of the rough surface and for short bunches with bunch length much smaller than the correlation length of the surface roughness. In this paper, only results for the case of the short bunches are presented, as an illustrative example of our studies.

WALL ROUGHNESS

An effect of the wall roughness was first estimated based on the impedance of small protrusions of different configurations and orientations in Ref. [5]. Such an "inductive" model can lead to a very strict requirement on the surface polishing. The longitudinal wake potential in this model scales as h/b, where h is the height of the protrusion and b is the radius of the beam pipe.

Another model for the wall roughness was introduced in Refs. [6-7]. In this model the presence of roughness is equivalent to a pipe with a thin dielectric layer or periodic corrugation on the smooth wall surface. This model is typically referred to as the "dielectric" or "resonator" model. In the "resonator" model the coupling impedance also has a resistive part. A detailed comparison of the "resonator" and "inductive" models was given in [7]. The "resonator" model becomes invalid when the correlation length (or period of corrugation) is significantly larger than the height of the protrusion. This happens to be the case for realistic wall surfaces [8] and especially for the surfaces produced with extrusions.

The length of the protrusions along the surface (referred to as the "correlation length" l_c) was taken into account in the model developed in Refs. [8-9], which reduced the coupling impedance significantly for typical surfaces with the large correlation length, resulting in the scaling of the wake potential as $h \cdot h/(b \cdot l_c)$. A comparison of such model with the "inductive" model was given in Ref. [10].

In the eRHIC design, we relied on a significant reduction of the wall roughness effects due to the large aspect ratio of the wall roughness by choosing extruded aluminium vacuum chamber. Measurements of several surfaces were performed to allow systematic study of wake field dependences on the height and length of the roughness. In addition, rather than using measured surface data in approximate models for the estimates, we attempted to study wake fields directly, using numerical simulations with the code NOVO [4].

MEASURED SURFACES

In this paper, we limit our discussion to three measured surfaces: 1) "surface-1": sample of an extruded aluminium surface from the NSLS-II vacuum chamber; 2) "surface-2": rough aluminium surface without extrusions; 3) "surface-3": extruded aluminium surface from the superconducting undulator provided by ANL [11].

Copyright © 2013 CC-BY-3.0 and by the respective authors

NUMERICAL SIMULATIONS

Numerical calculation of wake fields due to real surface roughness is extremely demanding task. For this purpose, we used computer code NOVO which was specifically developed to handle calculation of wakes for very short bunches in very long accelerator structures. For solving Maxwell's equations in time domain, the NOVO code uses finite-difference method with improved characteristic of the dispersion curve in the region of minimum critical wavelength [4]. This code was used before to study effects of wall roughness for artificially created surfaces [6-7]. Here we performed simulations of wake fields with real measured surface data.

Although measured surface maps are three dimensional, the NOVO code is a 2-D code. For each numeric simulation, we took a single 1-D slice from the measured surface. Based on such a slice, the code generates azimuthally symmetric protrusions. The net effect of such 2-D simulation is that magnitude of the wake is somewhat over estimated compared to the real structure in 3-D [12]. Therefore, such 2-D simulations can be used for a conservative estimate.

The primary goal of our studies was to study wakes resulting from real surfaces produced with an extrusion technique, and thus very long correlation length. In addition, we studied dependences on the correlation length and height of the surface bumps; as well as different beam distribution from Gaussian to a more uniform bunch profiles. Due to a limited space in this paper, only few results for the case of bunches with a short edge are presented. Shown results are for the bunches with the flat centre region of 0.3 mm and bunch edges of 0.03 mm rms.

EXAMPLES AND RESULTS

Figure 1 shows 3-D measurement of extruded aluminium "surface-1".

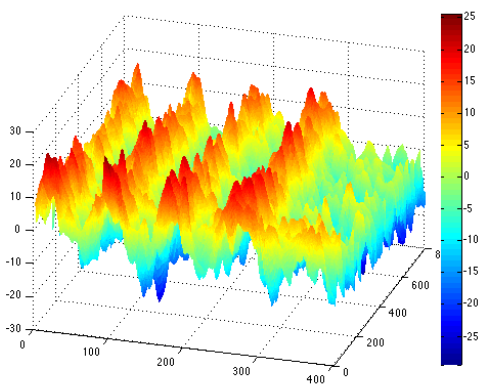

Figure 1: Measurement of "surface-1". Extrusions are along the mountain ridges (red). Vertical axis in μm; horizontal axes in pixels.

Due to a very large height of the roughness, resulting wake potential for "surface-1" is also large. Figure 2 shows a 1-D slice from the surface in Fig. 1 used in simulations. Figure 3 shows the bunch profile, the resulting wake potential and the loss factor.

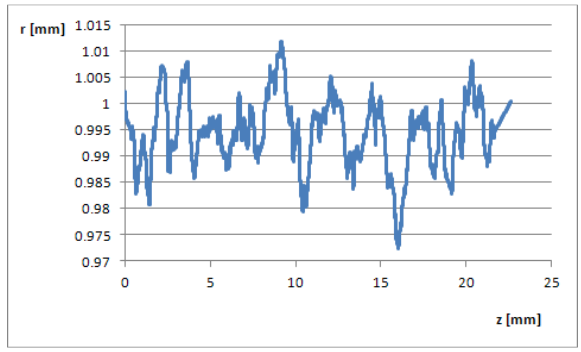

Figure 2: Slice from measured "surface-1" along one of the "mountain ridges" (along extrusion, beam direction z) added to the beam pipe radius of r=1 mm.

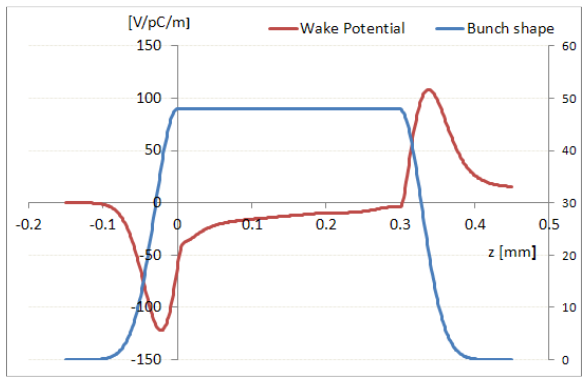

Figure 3: Blue: bunch profile; red: wake potential for "surface-1", radius r=1mm. Loss factor k=16 V/pC/m.

Simulations using "surface-1" data but with the characteristic length l_c artificially scaled by some factor showed that energy spread scales as $1/l_c$, as suggested in [8-9]. However, we did not observe expected h^2 dependence when the height h of the surface was also scaled by a factor. A possible scaling (more studies are needed) could be similar to $h \cdot g/(b \cdot l_c)$, where g is some additional surface parameter, describing the characteristic distance between the protrusions. For comparison, one obtains such $h \cdot g/(b \cdot l_c)$ dependence for a periodic structure with the depth h, gap size g and period l_c.

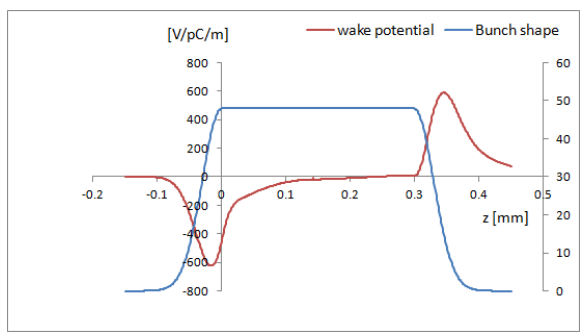

Figure 4: Blue: bunch profile; red: wake potential for "surface-1" with the correlation length 4 times smaller than in Figs. 2-3, r=1mm. Loss factor k=64 V/pC/m.

Copyright © 2013 CC-BY-3.0 and by the respective authors

As an example, Figure 4 shows resulting wake potential for the "surface-1" with the longitudinal structure of the surface in Fig. 1 compressed by a factor of four.

In further studies, a small-gap extruded aluminium vacuum chamber with a very smooth surface (Fig. 5), without applying possible polishing techniques, was provided by ANL [11]. The calculated wake potential and loss factor for such surface are shown in Fig. 6.

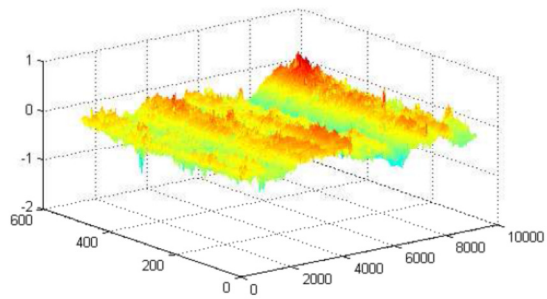

Figure 5: Measured surface for extruded aluminium "surface-3" provided by ANL. Vertical axis in μm; horizontal axes in pixels.

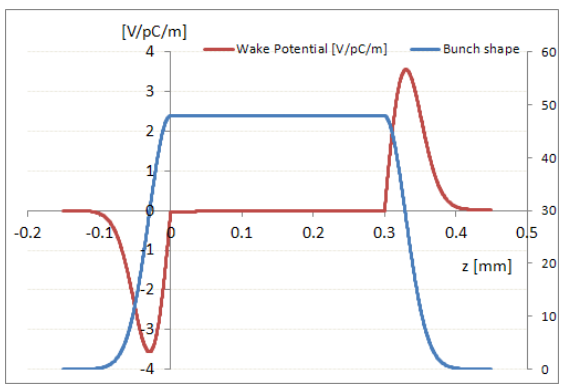

Figure 6: Blue: bunch profile; red: wake potential for "surface-3", r=1mm. Loss factor k=0.05 V/pC/m.

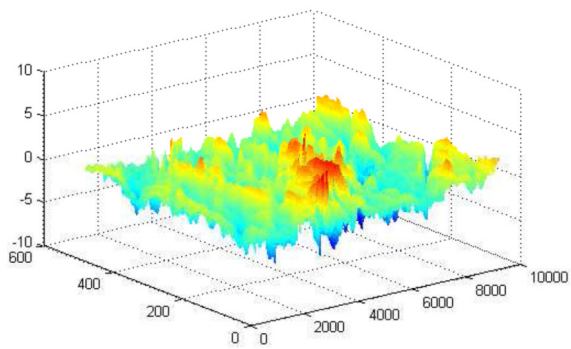

Figure 7: Measurement for aluminium surface without extrusions ("surface-2"). Vertical scale in μm.

We also studied wake potential for several aluminium surfaces without extrusions. Although these surfaces did not have large correlations lengths the height of the roughness bumps was not as large as for "surface-1". As a result, computed wake potential was of the same order as for "surface-1" with the extrusions, as shown in Figs. 7-8.

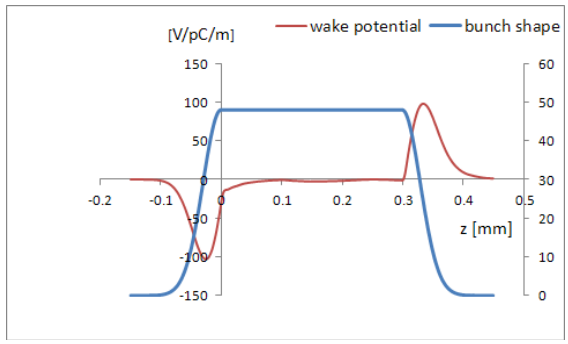

Figure 8: Blue: bunch profile; red: wake potential for "surface-2", r=1mm. Loss factor k=4 V/pC/m.

SUMMARY

In these studies we simulated wake potentials due to a wall roughness using real measured surface data. Some dependences on the correlation length and height of the surface bumps were examined. Several examples from our studies are reported in this paper.

Our simulations confirmed that the effect of the wall roughness can be strongly suppressed with the smooth extruded surfaces like the "surface-3". Simulation of wakes for the eRHIC parameters (not presented in this paper) showed that such a surface would be satisfactory for the eRHIC design.

ACKNOWLEDGMENT

We are indebted to Peter Takacs from the Instrumentation Division of BNL for surface measurements used in these studies. We would also like to thank I. Ben-Zvi, V. Litvinenko, E. Trakhtenberg and V. Yakimenko for help and useful discussions.

CHANGES IN ELECTRON CLOUD DENSITY WITH BEAM CONDITIONING AT CESRTA*

J.P. Sikora†, J.A. Crittenden, D.O. Duggins, Y. Li, X. Liu, CLASSE, Ithaca, New York 14853 USA

Abstract

We compare measurements of electron cloud (EC) buildup in uncoated and TiN-coated aluminum vacuum chambers as a function of integrated beam dose up to 1140 amp-hours. The EC density in newly installed bare aluminum chambers increases with beam dose, while the EC density in the TiN-coated chambers decreases with dose under the same beam conditions. Several techniques are used to monitor EC buildup. These include shielded pickups that measure the flux of cloud electrons onto the beam-pipe wall, and a TE wave resonance technique that measures the EC density within the volume of the beam-pipe. These measurements were made at the Cornell Electron Storage Ring, which has been reconfigured as a test accelerator CESRTA, providing positron and electron beams with energies ranging from 2 GeV to 5 GeV and a variety of bunch train configurations.

INTRODUCTION

New chambers were installed at three locations in the Cornell Electron Storage Ring Test Accelerator (CESRTA) in August 2012 as shown in Fig. 1. We have previously reported on the effects of beam conditioning measured immediately after chamber installation and then again after a significant beam dose of up to 1140 amp-hours [1]. Data with beam dose that is between these two extremes is presented here in order to estimate the dose required to obtain this conditioning. Table 1 shows the number of amp-hours for each beam. The chambers in L3 were let up to atmosphere as part of a separate project in January 2013, but the chambers at 15W and 15E have been under vacuum throughout this period. The table shows two values for the beam dose in April 2013 to reflect this.

Using the TE wave technique, data was collected in the TiN and bare aluminum chambers in L3 as well as the bare aluminum chamber at 15E. The raw data is in the form of phase modulation sideband amplitudes from which the peak electron cloud (EC) density can be calculated [2, 3]. The 10-bunch TE wave data taken in this study use 14 ns spaced bunches.

Shielded pickups (SPU) collect data from the TiN chamber at 15W and the bare aluminum chamber at 15E. This data is in the form of an oscilloscope trace as the SPU samples the flux of cloud electrons onto the vacuum surface [4]. For the purpose of plotting, the averaged scope trace is integrated to obtain the charge into the 50 Ω scope input for each turn (including the preamplifier voltage gain of 100). The data presented here is from two bunches of equal charge spaced by 14 ns. A turn at CESRTA is 2.5 μs and data is recorded with a 100 ns span, which is enough time to capture the non-zero signal from two bunches.

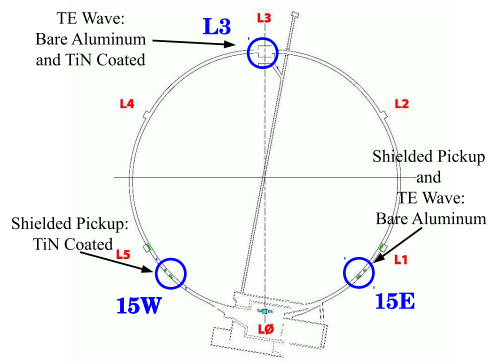

Figure 1: This sketch of the CESRTA storage ring shows the location of detectors used in this study: SPU in a chamber with TiN coating at 15W; SPU and TE wave measurements in the same aluminum chamber at 15E; TE wave measurements in the grooved TiN and bare aluminum chambers of L3.

CONDITIONING OF TITANIUM NITRIDE

There are two TiN-coated chambers in this study: the grooved chamber at L3 where there is TE wave data and the 15W chamber with SPU data. Figure 2 gives examples of the recorded 2-bunch SPU data at 8 mA/bunch. The signal from the first bunch peaks before 20 ns and is mostly composed of photo-electrons produced in the empty chamber. The larger second bunch signal at about 30 ns includes

photo-electrons, but is dominated by the cloud electrons produced by the first bunch that are accelerated into the detector by the second bunch.

As a guide for interpretation of the SPU signals, simulations with ECLOUD [5] have shown that an increase in both the first and second bunch signal generally indicate an increase in the quantum efficiency for producing photoelectrons. Changes in the second bunch signal for the same first bunch signal generally indicate a change in the secondary emission coefficient. The data from April 2013 of Fig. 2 suggest a reduction in quantum efficiency with extensive conditioning, since there is a reduction in both the first and second bunch signals. The very early conditioning from August 22-23, 2012 (0.5 amp-hours) on the other hand appears to have an unchanged first bunch signal, while the second bunch signal is reduced by ten percent or so.

The integral of traces such as those shown in Fig. 2 become data points of Fig. 3 giving the SPU signal versus total beam current. The 2-bunch SPU data from the TiN chamber of Fig. 3 shows a noticable reduction in the SPU signal between the first beam in the storage ring on August 22nd and measurements taken the following day. Records also show that the vacuum improved under the same conditions from 100 nT to about 30 nT with a total beam dose of 0.551 amp-hours. The later measurements show small progressive reductions in the SPU signal with beam dose.

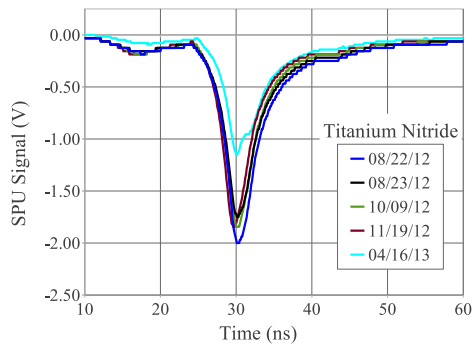

Figure 2: These plots are part of the 2-bunch SPU data that was taken in the TiN-coated chamber at 15W with 16 mA total positron current (8 mA/bunch = 1.28×10^{11} positrons/bunch).

The 10-bunch TE wave data from the L3 grooved TiN chamber in Fig. 4 is somewhat different. There is a step change in the EC density between the August 2012 data and all of the remaining measurements. The EC density measurement in October at 334 amp-hours is only slightly higher than the remaining measurements. This chamber was let up to atmosphere during maintenance in January 2013, so the April 2013 data in L3 corresponds to 521 amp-hours for that chamber. The TiN chamber at 15W (Fig. 3) had a total of 1140 amp-hours.

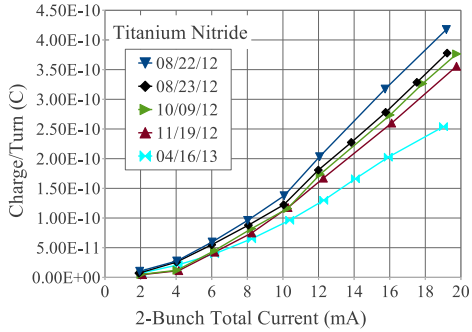

Figure 3: 2-bunch SPU data from the TiN-coated chamber at 15W (see Fig. 2) is integrated to obtain charge/turn. The data shows monotonic conditioning with beam dose. This includes the earliest conditioning with less than 0.5 amp-hours.

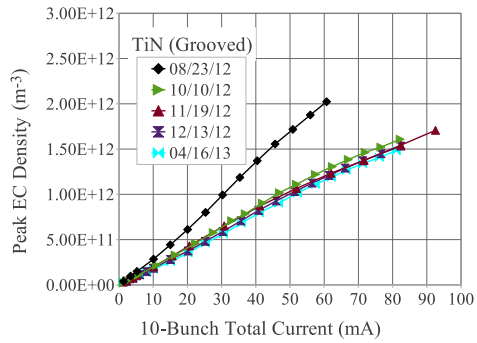

Figure 4: TE wave data with ten bunches from the grooved TiN-coated chamber at L3.

CONDITIONING OF BARE ALUMINUM

There are two bare aluminum chambers in this study: the grooved aluminum chamber in L3 with TE wave measurements and the 15E chamber where both TE wave and SPU measurements are made. Figure 5 shows some of the SPU data taken in the bare aluminum chamber at 15E. Following the interpretation used in the previous section on TiN SPU signals, Fig. 5 shows an overall increase in the signal from August 2012 to April 2013. There is an increase in both the first and second bunch signals, suggesting that this is due to an increase in quantum efficiency. The very early conditioning data (in the first 0.5 amp-hours) from August 22-23, 2012 shows a decrease in both the first and second bunch signals, suggesting a decrease in quantum efficiency. There were also substantial changes in the vacuum during the measurements on these two days, from 300 nT down to 30 nT at the peak currents. So it is possible that some of the electrons were produced by ionization.

Integrating the SPU signals, the charge/turn values are plotted versus total current in Fig. 6. As with the individual scope data plots, the trend of SPU signal versus current shows a decrease in signal amplitude with less than

Copyright © 2013 CC-BY-3.0 and by the respective authors

0.5 amp-hours, but after this, there an overall increase of EC density in the aluminum chamber with dose.

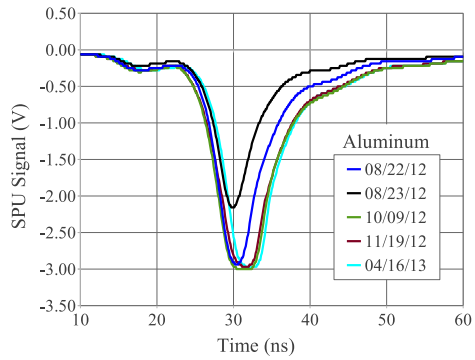

Figure 5: These plots are part of the 2-bunch SPU data in the aluminum chamber at 15E that was taken with 16 mA total positron current (8 mA/bunch = 1.28×10^{11}positrons/bunch). The preamplifier output is limited to 3 V resulting in some flattening of the highest amplitude signals.

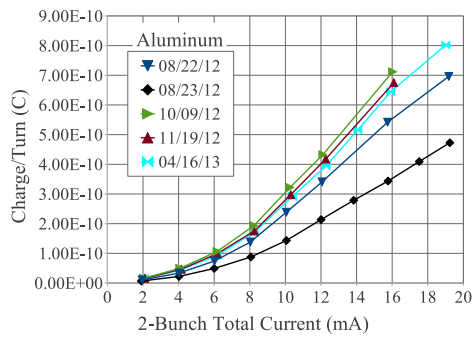

Figure 6: SPU two bunch data from the bare aluminum chamber at 15E shows an overall increase in signal with dose.

The 10-bunch TE wave data from the aluminum chamber at 15E is shown in Fig.7 and agrees with the SPU data in that the EC density becomes higher than its initial value after less than 170 amp-hours. No very early (less than 0.5 amp-hour) TE wave data is available in this data set. Data from the L3 grooved aluminum chamber in Fig. 8 shows a similar increase in EC density of about 40 percent after the earliest data.

CONCLUSIONS

Data taken using two very different techniques give similar information about the conditioning of bare aluminum and TiN-coated chambers. Bare aluminum shows a significant increase in EC density after modest conditioning and is mostly unchanged thereafter. There is some disagreement between the two techniques in data from TiN-coated chambers as to whether or not these chambers continue to

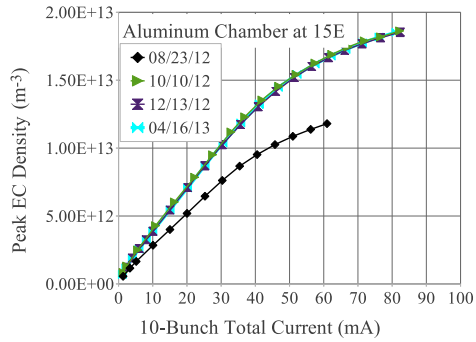

Figure 7: TE wave ten bunch data from the bare aluminum chamber at 15E shows a step increase of about 40 percent in EC density after the earliest measurement.

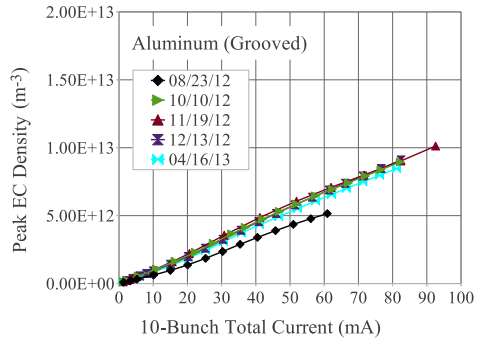

Figure 8: TE wave data from the grooved aluminum chamber in L3 also shows a step increase in EC denstity after the earliest measurement.

condition with beam dose. Interpretation is more difficult in this case because the TiN chambers have different photon dose and vacuum histories.

3D TOROIDAL FIELD MULTIPOLES FOR CURVED ACCELERATOR MAGNETS*

L. Brouwer †, S. Caspi, D. Robin, W. Wan, LBNL, Berkeley, CA 94720, USA

Abstract

Curved magnets producing continuously rotating field multipoles along the length of the bend can provide strong and continuous transverse focusing, making them of interest for accelerator systems such as compact ion beam gantries and synchrotron light sources. Evaluating the utility of such rotating multipole systems requires an accurate description of field behavior for beam physics calculations. This paper presents a helical scalar potential solution in 3D toroidal harmonics relevant to boundary conditions on the surface of a torus. The resulting fields are evaluated for a curved helical quadrupole channel to illustrate field rotation and the effect of magnet curvature.

INTRODUCTION

Previous analysis and use of accelerator magnets producing helical fields have focused on straight, cylindrical designs [1]-[5]. There is interest in studying the extension of this concept to curved magnets [6], requiring expressions for allowable fields rotating around the bend of torus. Previous work on field description and measurement of curved magnets is specific to cases of axial symmetry where the assumption of no field variation along the bend is made [7]-[9].

In these references Schinzer *et al.* present a method for finding scalar potential solutions in local polar coordinates using approximate R-separation of the scalar Laplace equation (expansion in the aspect ratio of the torus). In this paper a similar approach was taken to obtain expressions relevant to rotating fields on the bend of a torus, with the difference being the use of toroidal coordinates and full R-separation in 3D toroidal harmonics.

TOROIDAL COORDINATES

The right hand toroidal system of η, ξ, ϕ is formed by the rotation of bipolar coordinates η and ξ about the vertical axis (Fig. 1). Surfaces of constant η are tori, making toroidal coordinates a natural choice for problems with boundary conditions on the surface of a torus. Scale factors for this system are

$$h_\eta = h_\xi = \frac{a}{\cosh\eta - \cos\xi}$$
$$h_\phi = \frac{a\sinh\eta}{\cosh\eta - \cos\xi} \qquad (1)$$

where $(\pm a, 0)$ are foci of the bipolar system.

† lnbrouwer@lbl.gov

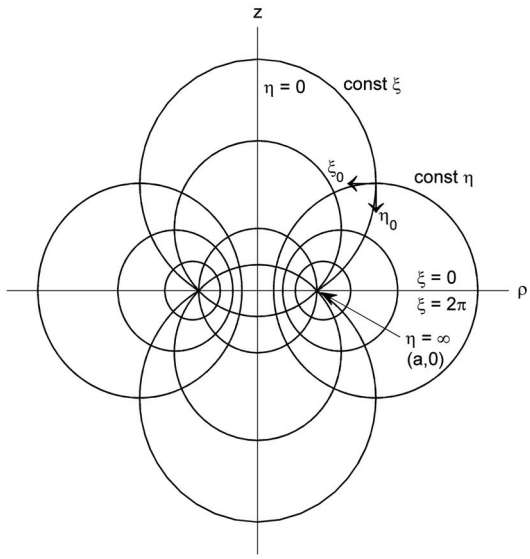

Figure 1: Bipolar coordinates $0 < \eta < \infty$ and $0 \le \xi \le 2\pi$ forming toroidal coordinates when rotated about the z-axis.

SCALAR LAPLACIAN

In a current free region the magnetic field can be expressed using only the gradient of a scalar potential $\vec{B} = -\nabla\psi$. The divergence of this field produces Laplace's equation for the scalar potential $\nabla\cdot\vec{B} = -\nabla^2\psi = 0$. In toroidal coordinates the scalar Laplace equation is

$$\nabla^2\psi = \frac{1}{h_\eta h_\xi h_\phi}\left[\frac{\partial}{\partial\eta}\left(\frac{h_\xi h_\phi}{h_\eta}\frac{\partial\psi}{\partial\eta}\right) + \frac{\partial}{\partial\xi}\left(\frac{h_\eta h_\phi}{h_\xi}\frac{\partial\psi}{\partial\xi}\right) + \frac{\partial}{\partial\phi}\left(\frac{h_\eta h_\xi}{h_\phi}\frac{\partial\psi}{\partial\phi}\right)\right] = 0. \qquad (2)$$

Substitution of the coordinate dependent scale factors (1) produces

$$\frac{k^2}{a^2}\left[\frac{\partial^2\psi}{\partial\eta^2} + \frac{\partial^2\psi}{\partial\xi^2} + \coth\eta\frac{\partial\psi}{\partial\eta} - k^{-1}\left(\sinh\eta\frac{\partial\psi}{\partial\eta} + \sin\xi\frac{\partial\psi}{\partial\xi}\right) + \frac{1}{\sinh^2\eta}\frac{\partial^2\psi}{\partial\phi^2}\right] = 0, \qquad (3)$$

where the simplification $k(\eta,\xi) = \cosh\eta - \cos\xi$ is made. The technique of R-separation is used, producing

$$\frac{k^{5/2}}{a^2}\left[\frac{\partial^2 u}{\partial\eta^2} + \frac{\partial^2 u}{\partial\xi^2} + \coth\eta\frac{\partial u}{\partial\eta} + \frac{1}{4}u + \frac{1}{\sinh^2\eta}\frac{\partial^2 u}{\partial\phi^2}\right] \qquad (4)$$

Copyright © 2013 CC-BY-3.0 and by the respective authors

which can be separated to obtain expressions for the substituted function $u = k^{-1/2}\psi$.

GENERAL HELICAL SOLUTION IN TOROIDAL HARMONICS

With u separable in each variable $u(\eta,\xi,\phi) = G(\eta)H(\xi)L(\phi)$, sinusoidal behavior in ξ and ϕ is assumed such that

$$L(\phi) = \sum_{m=0}^{\infty} \left[A_m \cos(m\phi) + B_m \sin(m\phi)\right] \quad (5)$$

$$H(\xi) = \sum_{n=0}^{\infty} \left[C_n \cos(n\xi) + D_n \sin(n\xi)\right]. \quad (6)$$

With these assumptions the separated "radial" equation for $G(\eta)$ can be obtained from (4) as

$$\frac{d^2G}{d\eta^2} + \coth\eta \frac{dG}{d\eta} + \left[\frac{1}{4} - n^2 - \frac{m^2}{\sinh^2\eta}\right] G = 0. \quad (7)$$

If a change of argument $Z = \cosh\eta$ is used, (7) can be reformulated into the associate Legendre differential equation

$$(1-Z^2)\frac{d^2G}{dZ^2} - 2Z\frac{dG}{dZ} + \left[\nu(\nu+1) - \frac{m^2}{1-Z^2}\right] G = 0 \quad (8)$$

with degree $\nu = n - \frac{1}{2}$ and order m. General solutions for $G(\eta)$ are the associate Legendre polynomials P_ν^m and Q_ν^m with argument $Z = \cosh\eta$.

$$G = \sum_{m=0}^{\infty}\sum_{n=0}^{\infty}\left[E_{n,m}P^m_{n-\frac{1}{2}}(\cosh\eta) + F_{n,m}Q^m_{n-\frac{1}{2}}(\cosh\eta)\right] \quad (9)$$

Combining the solutions of separable equations and the R-separation substitution, the general form of the helical potential is

$$\psi = k^{\frac{1}{2}}\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}\left[E_{n,m}P^m_{n-\frac{1}{2}}(Z) + F_{n,m}Q^m_{n-\frac{1}{2}}(Z)\right]\times \left[C_n\cos(n\xi) + D_n\sin(n\xi)\right]\left[A_m\cos(m\phi) + B_m\sin(m\phi)\right] \quad (10)$$

which is in agreement with similar separable solutions of Laplace's equation in toroidal coordinates (see [10] for example).

BOUNDARY CONDITIONS ON A TORUS

A surface of constant $\eta = \eta_0$ forms a torus. If the minor and major radius of a torus are respectively R_c and R_0, the constants producing this surface are

$$\eta_0 = \cosh^{-1}\epsilon^{-1} \quad (11)$$

$$a = R_c\sinh\eta_0 = R_0(1-\epsilon^2)^{\frac{1}{2}}, \quad (12)$$

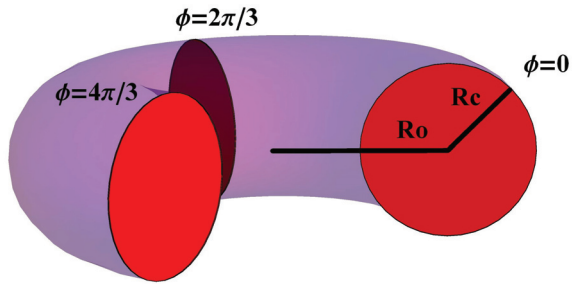

Figure 2: A partial torus of $\epsilon = 50/100$ is shown with bore cross sections at $\phi = 0$, $\frac{2\pi}{3}$, and $\frac{4\pi}{3}$ marked in red. The rotation of transverse fields through similar cross sections for a helical quadrupole channel is shown in Fig. 3.

where $\epsilon = R_c/R_0$ is the aspect ratio of the torus (Fig. 2). The potential inside and outside the torus' surface is given by

$$\psi^{in}(\eta_0 < \eta < \infty) = k^{\frac{1}{2}}A^{in}_{n,m}Q^m_{n-\frac{1}{2}}(\cosh\eta)\sin(n\xi - m\phi) \quad (13)$$

$$\psi^{out}(0 < \eta < \eta_0) = k^{\frac{1}{2}}A^{out}_{n,m}P^m_{n-\frac{1}{2}}(\cosh\eta)\sin(n\xi - m\phi), \quad (14)$$

where the Legendre polynomials are required to remain finite, and phase in ϕ and ξ is chosen such that $B_\xi(\eta,\xi,\phi = 0)$ is symmetric about the $\xi = 0$ axis.

Bore Fields

The fields inside the bore from $\vec{B} = -\nabla\psi^{in}$ (13) are,

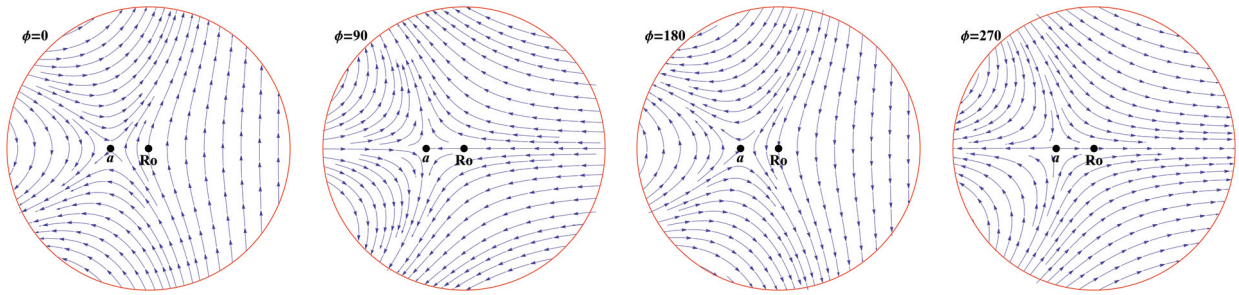
$$B^{in}_\eta = -\frac{A^{in}}{a}k^{3/2}\left[\left(\frac{n-\frac{1}{2}}{\tanh\eta} + \frac{k^{-1}}{2}\sinh\eta\right)\times Q^m_{n-1/2}(\cosh\eta) - \frac{m+n-\frac{1}{2}}{\sinh\eta}Q^m_{n-3/2}(\cosh\eta)\right]\times \sin(n\xi - m\phi) \quad (15)$$

$$B^{in}_\xi = -\frac{A^{in}}{a}k^{3/2}Q^m_{n-1/2}(\cosh\eta)\left[n\cos(n\xi - m\phi) + \frac{k^{-1}}{4}\left[\cos((n-1)\xi - m\phi) - \cos((n+1)\xi - m\phi)\right]\right] \quad (16)$$

$$B^{in}_\phi = \frac{mA^{in}}{a\sinh\eta}k^{3/2}Q^m_{n-1/2}(\cosh\eta)\cos(n\xi - m\phi), \quad (17)$$

with use made of the properties of associate Legendre polynomials found in [11]. For the evaluation of the Legendre polynomials using the DTOR algorithms see [12].

Copyright © 2013 CC-BY-3.0 and by the respective authors



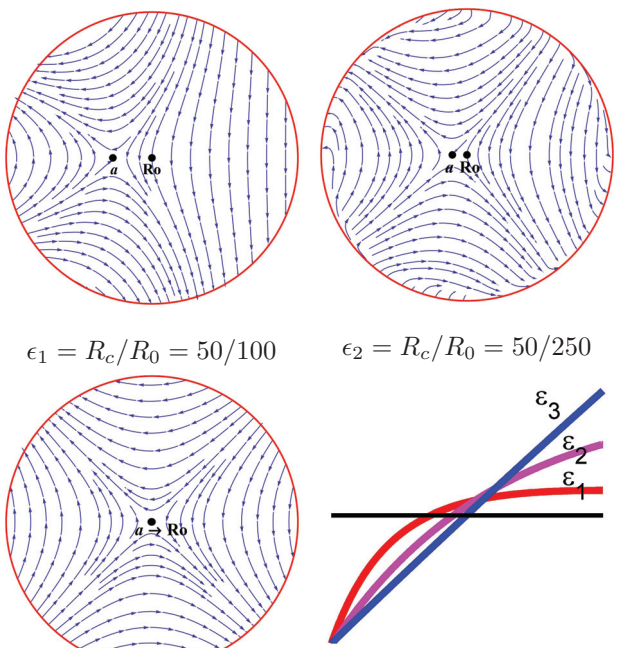


Figure 3: Transverse field rotation within a helical quadrupole channel ($n = 2$, $m = 1$) is shown for a torus of aspect ratio $\epsilon = 50/100$. The coordinate ϕ is the angle around the bend of the torus (see Fig. 2).

CURVED HELICAL "QUADRUPOLE" FOCUSING CHANNELS

The n=2 toroidal multipoles resemble quadrupole fields twisting along the length of the torus with m total rotations. This is illustrated in Fig. 3 for a curved quadrupole channel with one full period around the torus (m=1). The aspect ratio ϵ and field period length $2\pi R_0/m$ of the magnet determine the deviation of the helical toroidal field multipoles from traditional cylindrical multipoles. As the aspect ratio of the torus approaches zero and field period length approaches infinity, the fields approach those produced by a straight non-twisting quadrupole (see Fig. 4).

$\epsilon_1 = R_c/R_0 = 50/100$ $\epsilon_2 = R_c/R_0 = 50/250$

$\epsilon_3 = R_c/R_0 = 50/5000$ Normalized vertical field gradient along midplane

Figure 4: Axially symmetric quadrupole-like fields (n=2, m=0) are shown for a fixed bore radius R_c and increasing major radius R_0. As the aspect ratio of the torus $\epsilon = R_c/R_0$ tends to zero, the fields are seen approaching those of a straight cylindrical quadrupole.

CONCLUSION

A 3D scalar potential obtained through R-separation of Laplace's equation in toroidal coordinates was presented. This potential can be used to describe magnetic fields rotating helically along the length of a curved magnet in terms of toroidal harmonics. The deviation of these toroidal harmonics from straight cylindrical multipoles is influenced by the period of field rotation and the aspect ratio of the magnet (torus). This deviation tends to zero in the limit of no rotation and a aspect ratio of zero. A curved helical quadrupole channel was used to illustrate this behavior.

RETRIEVAL OF EFFECTIVE PARAMETERS OF METAMATERIALS FOR ACCELERATOR AND VACUUM ELECTRON DEVICE APPLICATIONS *

Z. Y. Duan[1, 2, #], M. A. Shapiro[1], J. S. Hummelt[1], and R. J. Temkin[1]

Abstract

In this paper, we propose a new method to retrieve the effective material parameters, *i.e.*, the effective permittivity and permeability. We first obtain the effective permeability analytically and then retrieve the effective permittivity numerically from the structure's dispersion curve. This method is different from that one which is based on the scattering parameters for metamaterial slabs. The approach presented here offers an effective parameter retrieval for metamaterial-based accelerator and vacuum electron device applications.

INTRODUCTION

Metamaterials are artificial electromagnetic materials comprised of sub-wavelength elements. Metamaterials offer many new options for the design of components that use electromagnetic materials. A Double-Negative Metamaterial (DNM) has both negative permittivity and negative permeability and can be described by an effective medium theory [1, 2]. We investigate metamaterials at microwave, millimeter wave, and THz frequencies for application as accelerator structures, as interaction circuits of high-power microwave vacuum electron devices, and as beam diagnostics tools.

The present parameter retrieval method based on the scattering parameters (S_{11} and S_{21}) [3] is not suitable for the metamaterial-loaded waveguide case due to the waveguide dispersion and the anisotropy of the metamaterials as well as the complex mode. Up to now, the parameter retrieval method is only suitable for metamaterial slabs interacting with TEM mode in free space.

In this paper, we propose a metamaterial-loaded rectangular waveguide which is described by the effective medium theory and provide a method for the retrieval of the effective material parameters from the dispersion relation. The method presented here can offer a theoretical foundation for developing novel metamaterial-based accelerators and high-power vacuum electron devices [4]

RETRIEVAL METHOD

A square waveguide operating below the cut-off frequency which is loaded by split-ring resonators (SRRs) was first proposed by Marques et al. [5] The empty waveguide can be considered as a negative permittivity medium only when the TE mode is excited, and the SRR array forms the effective negative permeability medium. As stated in [6], when metallic rods or stripes are loaded in the transverse direction of the waveguide operating below the cut-off frequency, the TM mode can be excited. Since TM modes are of interest in accelerator and vacuum electron device applications, we propose to use a rectangular waveguide loaded by complementary split-ring resonators (CSRRs) as shown in Fig. 1 (a). As opposed to SRRs on a dielectric in a waveguide where dielectrics can easily induce breakdown or damage [5], a CSRR-loaded waveguide is also completely composed of metallic elements and thus suitable for high-power applications.

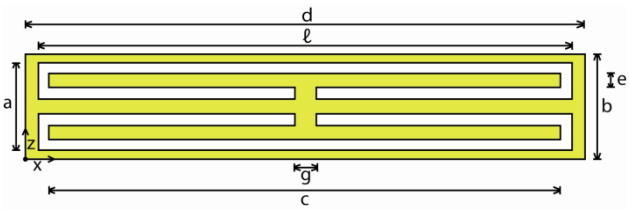
The CSRR array can be characterized by an effective negative permittivity in the y direction. In addition, when the loss of the proposed waveguide is not considered, the corresponding empty rectangular waveguide operating below the cut-off frequency can be considered as a "magnetic" plasma and its relative permeability is given by [6]

$$\mathrm{Re}(\mu_{r,eff}) = 1 - \frac{\omega_c^2}{\omega^2}, \tag{1}$$

$$\omega_c = \frac{\pi}{\sqrt{\varepsilon_0 \mu_0}} \sqrt{\frac{1}{d^2} + \frac{1}{h^2}}. \tag{2}$$

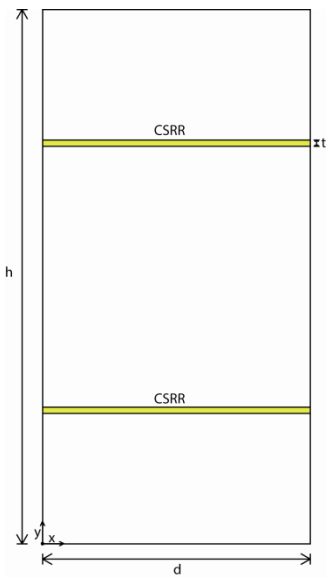
Here ω_c is the cut-off frequency for the TM_{11} mode, ω is the angular frequency, and ε_0 and μ_0 are the vacuum permittivity and permeability, respectively, and d and h are the cross-section dimensions of the rectangular waveguide.

In Fig. 1 (b), two CSRR-loaded metallic plates are placed inside a rectangular waveguide and the beam is located between the two CSRR layers. In this waveguide, there is a TM-dominated hybrid mode. This mode is not pure TE or TM mode, but is a complex hybrid mode with field components both perpendicular and parallel to the electron beam direction. From the point of view of the effective medium theory, the "*macroscopic*" mode is



Copyright © 2013 CC-BY-3.0 and by the respective authors

approximately a "TEM" mode because the integrals of the longitudinal electric- and magnetic- fields in a period approximately vanish, respectively. Thus, from the simple physical model, once the dispersion is obtained, the phase velocity is determined. Therefore, for the approximate "macroscopic TEM" mode, the phase velocity can be easily written as



$$v_p = \frac{c_0}{\sqrt{\mathrm{Re}(\varepsilon_{r,eff})\,\mathrm{Re}(\mu_{r,eff})}}, \quad (3)$$

where c_0 is the light velocity in vacuum. Thus we can write the real part of the negative relative permeability as:

$$\mathrm{Re}(\varepsilon_{r,eff}) = \frac{c_0^2}{v_p^2\,\mathrm{Re}(\mu_{r,eff})}. \quad (4)$$

(a)

(b)

Figure 1: (a) a CSRR unit-cell, a=7.25 mm, b=8 mm, c= 39.18 mm, d=43.18 mm, e=0.75 mm, g=2.5 mm, l=41.38 mm; (b) the cross section of the proposed CSRRs-loaded rectangular waveguide, h=86.36 mm, t=1 mm.

Therefore, knowing the dispersion of the proposed waveguide and using the permeability given in Equation 1 we can completely determine the effective permittivity and permeability for the CSRR-loaded rectangular waveguide.

SIMULATIONS AND RESULTS

The two CSRR layers are symmetrically located in the waveguide along the z direction and the distance between the two CSRR layers is set to be 42 mm. The CSRRs are periodically placed along the axis of the structure with period 8 mm. Using the Eigen-mode solver of HFSS [7], we can get the dispersion curve for this structure which is shown in Fig. 2. Note that the material loss is not considered in the HFSS simulation. The cut-off frequency is ~3.89 GHz for the TM_{11}mode in the empty rectangular waveguide, as shown in Fig. 3. From the dispersion curve the phase velocity can easily be obtained by $v_p = \mathrm{Re}(\omega)/\beta$. For example, we can see that the double-negative frequency band is only from ~2.3 to 2.84 GHz for the l=41.18 mm case, where the directions of $\bar{v}_p$ and $\bar{v}_g = d\omega/d\beta$ (group velocity) are opposite. Here β is the phase constant.

Applying the parameter retrieval method presented here, the effective permeability can be found according to Equations (1) and (2), and it is shown in Fig. 3. Also, using Equations (3) and (4) and simulation results of the dispersion (from Fig. 2), we can retrieve the effective permittivity in the double-negative frequency band which is shown in Fig. 4. In the simulations d is kept as a constant and $c = l - 2$ is varied for three different values. Decreasing the resonator length l increases the resonant frequency of the CSRRs and thus the dispersion curve moves to the high frequencies (Fig. 2). The retrieved effective permittivity is dramatically changed (Fig. 4).

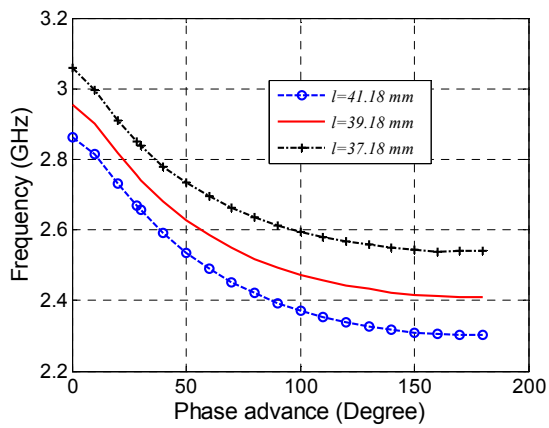


Figure 2: The dispersion curve for the proposed CSRR-loaded rectangular waveguide.

Here we are not interested in the frequencies beyond the double-negative frequency band, since this method is based on the effective medium concept and the dispersion characteristics. Note that this method is not rigorous, but it is approximately correct for the effective material parameters. Currently, we are developing another method based on the field analysis to retrieve the effective permittivity for the CSRRs which are filled in the waveguide.

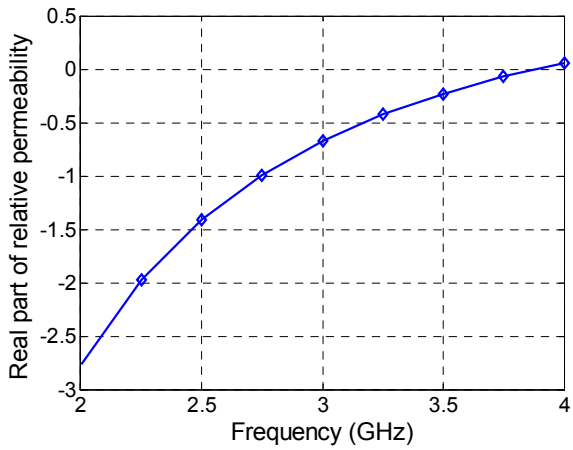

Figure 3: The real part of relative permeability vs. frequency.

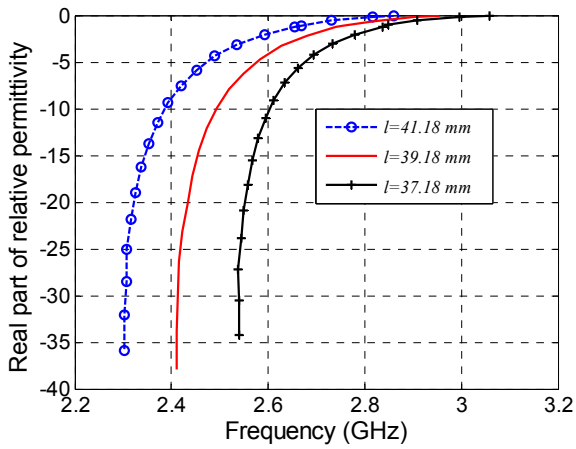

Figure 4: The real part of relative permittivity vs. frequency.

CONCLUSIONS

In this paper, we have proposed a CSRR-loaded waveguide. Using the effective medium theory and setting up a simple physical model, we have developed a method to retrieve the effective parameters for the CSRR-loaded waveguide. This method is based on the "magnetic plasma" concept and the structure's dispersion characteristics. It is different from the widely used scattering parameter method which is suitable for metamaterial slabs excited by TEM mode, but is not suitable for the metamaterial-loaded waveguide, where the waveguide affects the electromagnetic behaviour of the metamaterial.

Abstract

A metamaterial waveguide is proposed for use in a linear accelerator. The waveguide walls are made of a metamaterial structure composed of complementary split-ring resonators (CSRRs). In such a metamaterial waveguide, a TM-like mode exists that can be excited by an electron bunch. A complementary split-ring resonator is formed by slots machined in a metallic plate. The fact that the metamaterial waveguide is both planar and composed of elements that are direct machined makes it both easy to build and easily scalable to higher frequency linear accelerators. The metamaterial waveguide is coupled to single mode rectangular waveguides. These waveguides can then be connected to a microwave network to couple power into or out of the waveguide. The metamaterial waveguide that is presented was designed using electromagnetic simulations in HFSS, and wakefield as well as PIC simulations of the structure were carried out using the CST Particle Studio code.

INTRODUCTION

Metamaterial (MTM) structures [1] are periodic structures that are both sub-wavelength and operate in a frequency range in which the structures are resonant. In contrast to the disk-loaded waveguides used as accelerator structures, spatial harmonics do not play a role in the accelerating properties of MTM structures. Basic studies of MTMs for use in or as accelerator structures, beam diagnostics, and interaction structures of higher power microwave sources are of interest due to the potential benefits of using frequency selective materials in microwave generation and the advances in MTM fabrication that may allow for high frequency design.

A complementary split-ring resonator (CSRR) with negative permittivity has been introduced [1]. A medium formed of an infinite array of parallel plates with CSRRs machined into them was proposed as an accelerator structure [2,3]. This system can be considered as an infinite array of electric dipoles, and the effective permittivity and permeability of this MTM were determined and simulations showed that this MTM has a negative refractive index.

The CSRR MTM has been modified to be used as an accelerator structure. Instead of using an infinite medium, a MTM waveguide is formed by placing the CSRRs in a waveguide that is below cutoff. In this paper we study the dispersion properties of the MTM waveguide and the electron beam interaction with its field.

METAMATERIAL WAVEGUIDE

The MTM waveguide proposed (Fig. 1) is an assembly of four rectangular waveguides that have each had CSRRs machined into one of their faces as shown in Fig. 2. The waveguides are assembled such that the waveguide walls into which the CSRRs have been machined divide a 'cross' shaped pipe into four outer waveguide regions and one central waveguide region through which the electron beam passes. One period of the structure along the axial direction of the waveguide includes two split ring slots with openings facing each other, with total period p = 7 mm (Fig. 2). The MTM waveguide is designed in the S-band operating at 2.6 GHz. As the period is 7 mm, it is sub-wavelength at this frequency along the axial direction. The transverse dimension of the split rings is 41 mm. The slot width is g=2 mm and the CSRR thickness is 1.6 mm. In addition to the cross shaped structure shown in Fig. 1 we have investigated square, hexagonal, and triangular geometries as well.

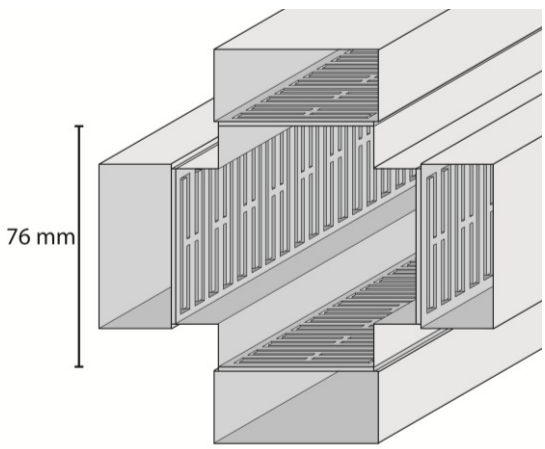

Figure 1: Metamaterial waveguide assembled from four WR187 waveguides (47.55 x 22.15 mm) with CSRRs machined into inner face of assembled structure.

Copyright © 2013 CC-BY-3.0 and by the respective authors

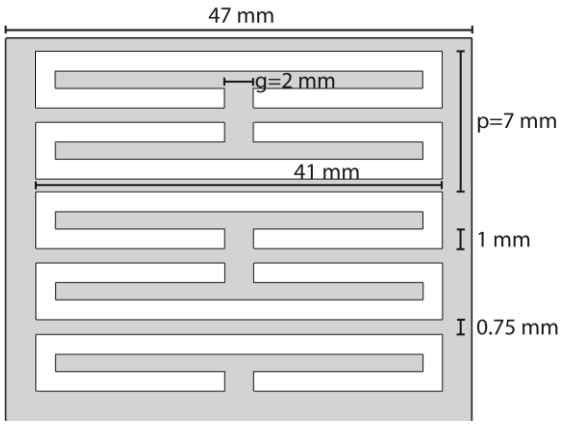

Figure 2: Metamaterial waveguide made from standard WR187 waveguide with CSRRs machined into one face of the guide.

Because of the electric response of the CSRRs, the MTM waveguide formed by the assembled waveguide structure has negative permittivity at 2.6 GHz. The structure's negative permeability is caused by the operation of the waveguide below its cutoff frequency for TM (HE) modes. The cutoff frequency of a waveguide with the same dimensions as the central region is near 5 GHz. The combination of negative permittivity and negative permeability provides a negative refractive index.

The HFSS simulation results showing the dispersion of the MTM waveguide are presented in Fig. 3. The frequency is shown as a function of phase advance per one period in degrees.

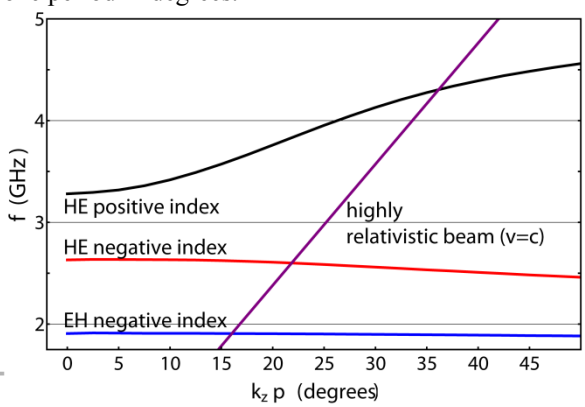

Figure 3: Dispersion curves of TM modes in the metamaterial waveguide. Two modes exist that couple to the electron beam, a negative refractive index mode at 2.5-2.6 GHz (red) and a positive index mode at 3.5-4.5 GHz (black). The relativistic electron beam dispersion line is also shown ($2\pi f = k_z c$, purple).

The negative group velocity, negative refractive TM-Hybrid mode is found at the frequency range of 2.5-2.6 GHz. In addition to this mode, the presence of the CSRRs also supports a lower group velocity mode at 1.9 GHz. The differences between these two modes have to do with the symmetry of fields between adjacent split rings. There is antisymmetry between split rings in the lowest order mode, which results in field cancellation and a very small axial field in the structure. Therefore, this mode is not expected to couple to the electron beam as well as the HE modes. At higher frequencies (3.5-4.5 GHz) a positive index mode is found. Shown in Fig. 3 is the dispersion line of a highly relativistic ($v \approx c$) electron beam. The beam excites the MTM modes at the frequencies where this beam line intersects the modal dispersion curves.

WAKEFIELD SIMULATION

The CST Particle Studio wakefield solver was employed to simulate the wakefield created from a single impulse bunch travelling through the structure. While the wakefield solver lacks the ability to characterize the full beam-wave interaction as a PIC code would, it is an efficient way to estimate the relative coupling of an electron beam to any particular mode in a structure when we examine the wake impedance as a function of frequency. The wake impedance as a function of frequency $Z_z(\omega)$ is found by taking the Fourier Transform of the wake potential $W_z(s)$, which is defined by the relation

$$Z_z(\omega) = -\frac{\int_{-\infty}^{\infty} W_z(s) e^{-i\omega s} ds}{\int_{-\infty}^{\infty} \lambda_z(s) e^{-i\omega s} ds}$$

where λ_z is the longitudinal charge distribution and s is the distance behind the impulse bunch. The wake potential created by the test bunch, shown in Fig. 4, is displayed in Fig. 5 as a function of s.

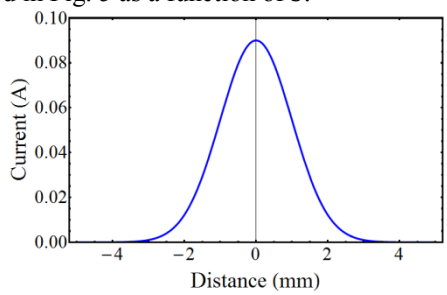

Figure 4: Test bunch current profile used in the wakefield simulations.

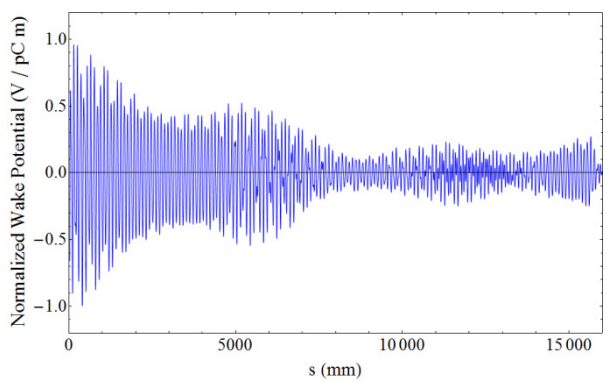

Figure 5: Longitudinal wake potential as a function of the distance behind the impulse bunch (s).

Copyright © 2013 CC-BY-3.0 and by the respective authors

For this simulation the bunch length used is much shorter than the wavelength of interest. Fig. 6 shows the longitudinal wake impedance as a function of frequency. The on-axis bunch excites the TM modes in the MTM waveguide and the longitudinal wake impedance indicates narrow band excitation at the frequencies of 2.6 GHz and 4.5 GHz. In addition to these two modes, there is slight excitation of the mode at 1.9 GHz because it does have a small, but nonzero axial field. The frequencies of each mode are in good agreement with the HFSS electromagnetic simulations.

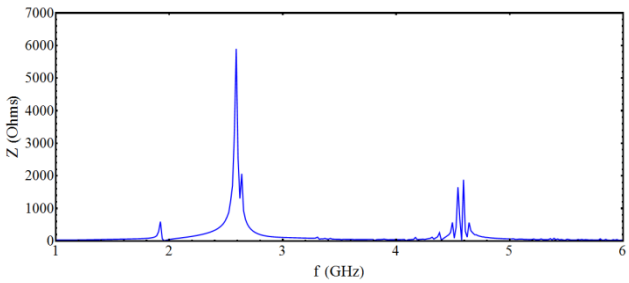

Figure 6: Longitudinal wake impedance shown as a function of frequency.

RADIATION OF A TRAIN OF BUNCHES

PIC simulations of a train of bunches in the 2.6 GHz MTM waveguide were performed using the CST Particle Studio code. This research is of interest for potential application at the beam line of the Haimson Research Corporation (HRC)/MIT 17 GHz linear accelerator, where the MTM waveguide simulated at 2.6 GHz is easily scalable to 17 GHz due to the frequency selectivity and planar geometry of the MTM. The HRC/MIT accelerator produces a train of sub-picosecond bunches with the repetition rate of 17.14 GHz. Radiation from this 17 GHz train of bunches has been used for bunch diagnostics, particularly bunch length measurement [4]. Radiation of the train of bunches in a photonic band gap structure was characterized in Ref [5].

These simulations were done for the S-band MTM waveguide and a train of bunches with a repetition rate of 2.6 GHz, an injected energy of 500 keV, and a time average current of 1 Amp. Fig. 7 shows the 1.1 m length of MTM waveguide with the electron bunches injected from the left.

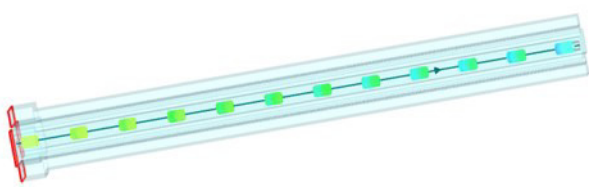

Figure 7: CST simulation of metamaterial waveguide structure with a train of bunches.

The radiation output is at the injection end of the structure because the radiation propagates backward, as predicted from the negative dispersion of the HFSS simulation. The energy distribution along the length of MTM waveguide in the train of bunches is shown in Fig. 8. Bunches give up their energy to radiation and the energy spread increases as the energy decreases.

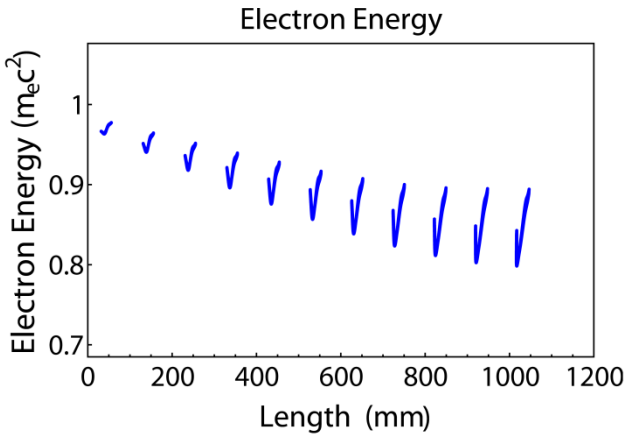

Figure 8: Electron energy distribution of the train of bunches as they travel through the structure. The bunches are injected at an energy of 500 keV (0.98 m_ec^2).

CONCLUSIONS

A metamaterial waveguide is proposed for use in an accelerator as a diagnostic or accelerating structure. The MTM waveguide is designed at the S-band but can be scaled to higher frequencies due to the simple and easily machined planar elements that give the waveguide its frequency response. A negative refractive index mode was identified for this MTM waveguide using the code HFSS, and this mode was also confirmed to both exist and couple strongly to the electron beam using the wakefield solver of CST Particle Studio. The excitation of the MTM waveguide by the electron beam was modelled and studied using the PIC solver of CST. A possible experiment using the HRC/MIT linac is presented.

RIBBON ELECTRON BEAM SOURCE FOR BUNCHED BEAM PROFILE MONITOR AND TOMOGRAPHY

V. Dudnikov, Muons, Inc., Batavia, IL 60510, USA
A. Aleksandrov, ORNL, Oak Ridge, TN 37831, USA

Abstract

Ribbon electron beam source with a strip cathode has been designed, fabricated and tested. Image of the ribbon electron beam with width up to 15 cm has been registered on the luminescent screen. This ribbon beam can be used for the large proton bunch profile monitoring in the Spallation Neutron Source (SNS) proton storage ring. Advanced beam diagnostics are essential for high performance accelerator beam production and for reliable accelerator operation. It is important to have non-invasive diagnostics which can be used continuously with intense beams of accelerated particles.

INTRODUCTION

Beam profile determination at high intensity ion accelerators requires the use of non-destructive methods. The basic physics and recent technical realizations of important non-intercepting profile diagnostics are summarized in Ref. [1]. Transverse electron beam scanners were realized recently for use in the SNS storage ring by Aleksandrov et al. [2, 3].

In the electron beam profile monitor (EBPM) developed at the SNS, a transverse beam profile is reconstructed from the deflection of electrons crossing the proton or ion beam after being influenced by the beam's space charge, as schematically shown in Fig. 1 [1]. A pencil electron probe is formed by an electron gun and scanned through the proton beam by the electric field of deflectors as in an oscilloscope tube. The position of the scanning electron probe after crossing the proton beam is visualized by a fluorescent screen and the image is captured by a camera for further processing. Assuming the electron beam has a much lower diameter than the proton or ion beam and the scan duration is much shorter than the ion bunch passage, the space charge field can be treated as constant. The beam profile can be reconstructed from the electron beam trace using the mathematical formalism given in Ref. [2].This method was considered for high energy synchrotrons and recently commissioned at the SNS [3]. A significant part of the scanner hardware is used for the extension of the scanning e-beam. Large quadrupole magnets also complicate the magnetic shielding of this version of scanner. For these reasons, electron beam profile monitors (EBPM) with electron beams formed by the deflection of pencil e-beams can be long, and fairly complex. Potentially more practical e-beam profile monitors that are more suitable for proton beam tomography can be developed using a strip cathode for formation of a ribbon beam as discussed below [4]. The analysis of the data for beam bunch transverse profiles for the system that we are proposing will be very similar to what has been developed for the EBPM as described below.

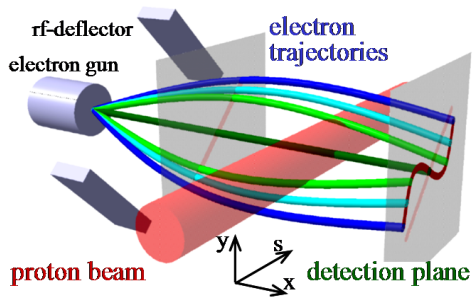

Figure 1: Schematic of an electron scanner for the vertical beam profile [1].

RIBBON ELECTRON BEAM PROFILE MONITOR (REBPM)

The ribbon electron probe beam profile monitor (REBPM) using a strip cathode is proposed as shown in Fig. 2. The electron ribbon (6) is generated by the strip cathode (1) with extractor (2). The transverse dimensions of the ribbon are defined by the collimator with two slits (3) and (5). The width or duration of the ribbon electron probe (6) is formed by the deflection of the ribbon electron beam across slit (5) by a pulsed voltage on the deflecting plates (4). Electrons of the ribbon electron probe after deflection by electric field of the proton bunch are visualized on the luminescent screen (7) and recorded by a fast CCD camera for further processing by the corresponding software discussed above.

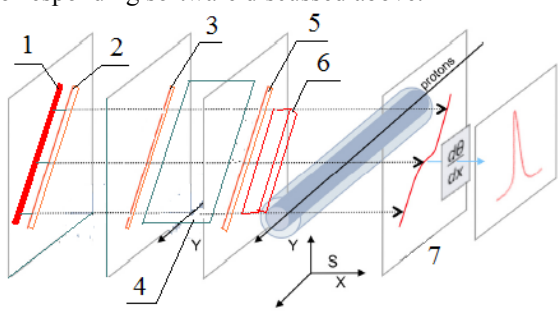

Figure 2: Electron probe beam profile monitor with a strip cathode.

The mechanical design of the system is shown in Fig. 3, the 3D models of the of the strip cathode electron gun with insulators and support insulators are shown in Figs. 4-6.

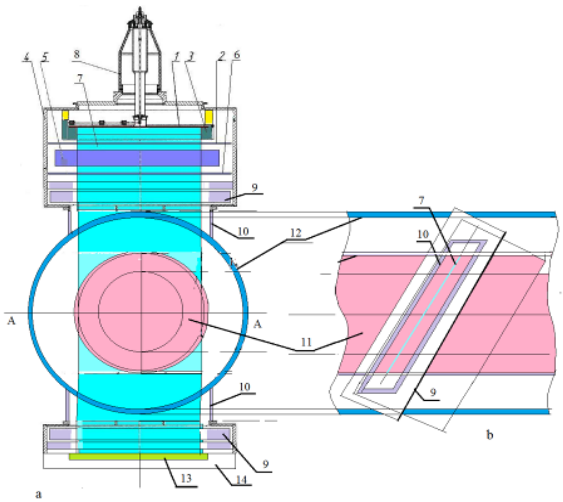

Figure 3: Mechanical design of the RBPM. a-cross-section in the plane of the ribbon electron beam; b- view of cross section in plane A-A. 1-strip cathode; 2-anode with slit; 3-extraction electrode with a slit; 4-vacuum vessel; 5-deflection plates; 6-beam forming electrode with collimating slit; 7-ribbon electron beam (up to 15 cm wide); 8-high voltage insulator; 9-slit valves for proton tube vacuum insulation (need slit ~50x180 mm^2); 10-electron beam vacuum chamber joined with proton vacuum tube 12; 11-proton bunch; 12-proton storage ring vacuum tube (OD=254 mm, ID=248 mm); 13-luminescent screen for electron beam observation; 14-vacuum window.

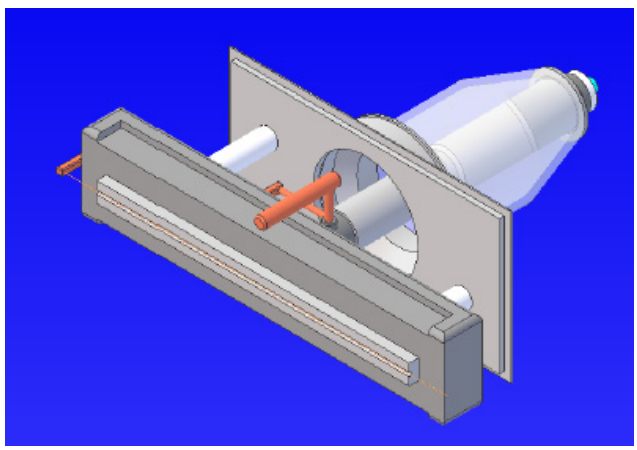

Figure 4: Design of Ribbon strip cathode electron gun.

Ribbon electron beam formation was optimized using the computer simulation code PBGUNS. The study below shows the optimization to reduce the electron beam divergence in the plane orthogonal to the ribbon. This is necessary to keep the image of the ribbon focused on the phosphor screen. The cross section of the electron gun for ribbon beam production is shown in Fig. 7. The scale of this drawing is 1 mm per division. The simulation grid step-size near the emitter can be up to 16 times smaller than the regular grid and the emission area can be simulated with high accuracy in an acceptable simulation time. The extracted electrons escape from the gun through a slit with width h=1 mm.

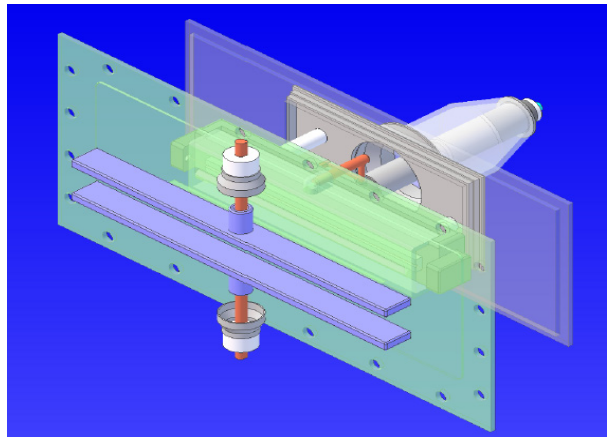

Figure 5: 3D design of RB electron gun with extraction electrode, accelerating anode, and deflection plates.

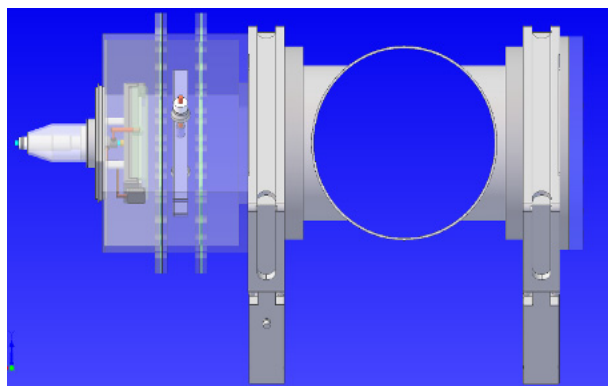

Figure 6: Adaptation of RB e-gun on the vacuum tube of the proton storage ring with vacuum valves.

The escaping electrons are accelerated by an anode (4) with voltage Ua= 100 kV located at coordinate Z_4=8 mm. Deflecting plates (5) with coordinates between Z4=9 mm and Z_5=13 mm are located between the anode (4) and electrode (6) with coordinate Z_6=14 mm. The ribbon electron beam can be deflected by the transverse electric field created between these plates and can be focused by electric fields near ends of these plates. This simulation was made with the potential of deflecting plates Ud=95 kV, which corresponds to the focusing voltage of a cylindrical (one dimensional) Einzel lens Uf=-5 kV.

The simulation was conducted with a space charge current limitation and with emission current limitation at the level of Je=100 mA/cm^2 ~ 1.5 mA per cm of the cathode filament (the simulation used a 1 m long filament). As can be seen from Fig. 7 the emitted flux of electrons is very divergent because of the cylindrical emission surface. The extraction electrode (first anode) intercepts a linear current density J1~0.23 mA/cm and J2~0.08 mA/cm is emitted from the gun. The central part of the beam has a regular divergence of α=40 mr/mm which must be compensated by additional focusing. This additional focusing was provided by the Einzel lens made by the fields between the deflection plates and the collimating slits.

Copyright © 2013 CC-BY-3.0 and by the respective authors

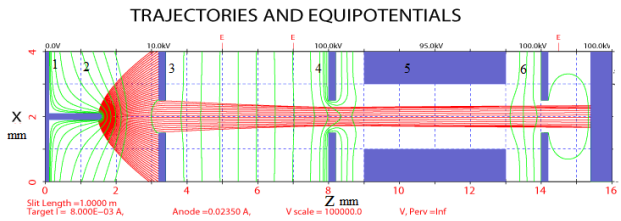

Figure 7: Edge view of the strip cathode electron gun showing the simulation of ribbon electron beam extraction, acceleration, and focusing by the deflector plates (extraction voltage Uex=10 kV, accelerating voltage Ua=100 kV, focusing voltage on the deflector system is Uf=-5 kV). Red lines are electron trajectories, green lines are equipotentials. The scale is 1 mm/division. The flat electrode (1) at Z_1=0 mm has zero potential, the same as the cylindrical emitter (2) with radius r=0.05 mm, located at coordinate Z_2=1.5 mm from the flat electrode. The electrons are extracted from the cylindrical emitter (2) by extraction electrode (3) located at coordinate Z_3=3.2 mm with potential Uex=+10 kV relative to the emitter.

A strip cathode with strong filament tension have been built and tested (see Fig. 8). The filament (1), (0.11 mm diameter thorium doped tungsten) has been attached to insulated holders (3) by spark welding with nickel foil interface and has been kept straight by a system of springs. The right holder is fixed on insulator 8. The left holder (3) can slide along a rod (4). Two direction plates with a glassy carbon inserts (5) can keep the left holder from rotating. The spring (6) can press the left holder to the left direction to keep the filament (1) straight. The filament (1) is positioned along the slit (2) of extractor (9). The anode (10) is used for further electron beam acceleration. The cathode is assembled on the base plate (7).

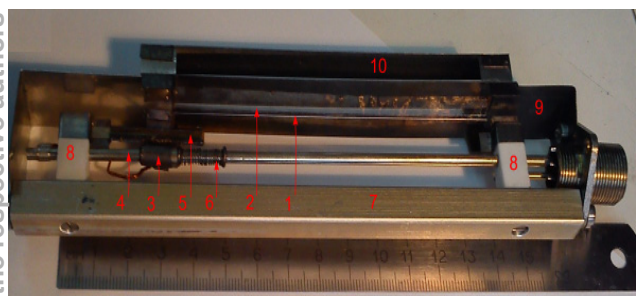

Figure 8: Design of a strip cathode gun with a tension by a spring. 1-filament thorium doped tungsten; 2-slit of extractor electrode; 3-cathode holder, sliding along support rod (4); 4- support rod; 5-plates for direction a cathode holder with a glassy carbon sliders; 6-spring 7-insulated base plate; 8- high voltage insulators;

The image of the ribbon beam from the e-beam gun prototype hitting the phosphor screen is shown in Fig. 9. The filament was heated by current Ih=1 A. The electron beam was extracted from the filament by pulsed extraction voltage Ue~ 1kV with the pulse duration T=1 μS and repetition up to f=10 Hz transmitted through an insulating transformer.

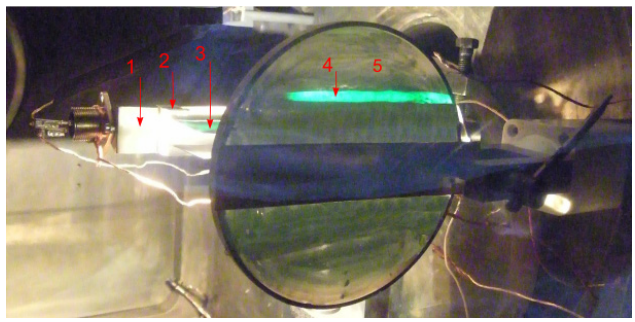

Figure 9: Ribbon electron beam on the luminescent screen deflected by deflection plates. 1-extractor electrode; 2-anode; 3-deflecting plates; 4-image of the ribbon electron beam on the screen; 5-luminescent screen. Diameter of luminescent screen is 110 mm, the shielding plate width is 25 mm.

The green line (4) on the screen (5) in Fig. 9 is an image of deflected ribbon electron beam. In this experiment, the beam line image was ~3 mm wide because the beam focusing by the deflecting plate electrostatic lens, as described in the section above on computer simulations, was not used. The beam trace visible on the screen can be seen and registered after one pulse.

With the electron beam energy increased to 100 keV, the luminescent screen trace can be seen with lower beam current. More-efficient luminescent screens with metallization will be used for the regular RBPM developed in Phase II. Increased accelerating voltage and fine focusing by the deflecting plates will produce a finely focused ribbon beam with thickness less than 1 mm, which is enough for good RBPM accuracy.

POSSIBLE EXPERIMENTS ON WAVE FUNCTION LOCALIZATION DUE TO COMPTON SCATTERING

V. Danilov, A. Aleksandrov, J. Galambos, T. Gorlov, Y. Liu, A. Shishlo, ORNL, Oak Ridge, TN 37831, U.S.A.

Abstract

The reduction of a particle's wave function in the process of radiation or light scattering is a longstanding problem. Its solution will give a clue on processes that form, for example, wave functions of electrons constantly emitting synchrotron radiation quanta in storage rings. On a more global scale, it may shed light on wave function collapse due to the process of measurement. In this paper we consider various experimental options using Fermilab electron beams and a possible electron beam from the SNS linac and lasers to detect electron wave function change due to Compton scattering.

INTRODUCTION

The first dedicated experiments to measure the wave function of an electron in accelerator were started in Novosibirsk about two decades ago and described in [1, 2]. The experiments showed that the wave function of an electron in a storage ring is very localized, and its motion is similar to the motion of a classical particle with random kicks without any sign of phase space dilution due to the potential well (RF) nonlinearities.

The experiments were performed in the VEPP-3 storage ring with a single circulating electron [2] and the light from an undulator that was detected by photomultipliers. The standard Brown-Twiss intensity interferometer scheme used a splitter to send the photons to two photomultipliers. The basic idea to measure the longitudinal wave function size was to detect two photons by different photomultipliers during one passage of an electron through the undulator and the rms difference in time, multiplied by velocity of light, was supposed to give the wave function size. Unfortunately, the photomultipliers were slow – their response time (called the dispersion in [2]) was around 160 ps. The signal time difference from two photomultipliers was well within this number, therefore it was concluded that the wave function size is much shorter than the available resolution.

Here we pursue another approach. Using scattered instead of radiated quanta, and knowing the precise energy of electrons and photons, we can measure the resulting energy distribution (and, consequently, the electron wave function) after the scattered photon is measured by a detector and after we employ coincidence scheme, i.e. take only pairs of related electrons and Compton photons with very small angle with the beam velocity vector. This results in a very small transverse recoil and the electrons have mostly longitudinal momentum (or energy) change. This is possible if the resolution of detectors is high and the repetition rate of events is low. If the repetition rate is high, the electron beam energy spread in its left shoulder (see Figure 1) gives the energy spread of scattered electrons even without precise knowledge of the measured gamma quanta if the quanta don't introduce a large angular spread for electrons (we discuss this in the next sections).

An experiment outline is shown schematically in Figure 1. An electron beam with very small energy spread from a linac with energy in the range of hundreds of MeV collides with a laser beam producing rare Compton quanta. The backward scattered quanta are measured in a small scattering angle range (to have precise knowledge of their energy) by an X-ray detector and the electron that scattered the quanta is measured in an energy analyser that separates this electron from the rest of the beam by, e.g., magnetic field.

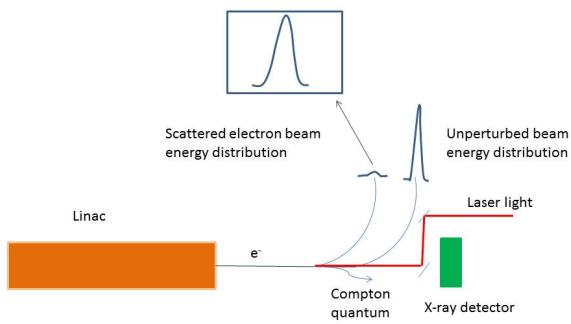

Figure 1: Experiment outline.

If the separation is larger than the width of the electron beam after the magnets, it is possible to measure the width of the energy distribution of the scattered electrons. This distribution, if different from the beam distribution, will give us the wave function width, or its localization, after the process of scattering and measurement of the photon. One has to notice that Figure 1 two-peak discontinuous distribution of electrons can be obtained if we cut out all electron-photon scatterings with large angles of Compton quanta with respect to beam axis pointing toward beam velocity. This procedure will eliminate the scattered-electron angular spread contribution to the left shoulder distribution and as a

Copyright © 2013 CC-BY-3.0 and by the respective authors

result will give more accurate details on the localization process.

In the next section we present calculations for the process probability and accuracy of the measurement. Last section presents simple estimations for the resulting wave package width – the technique is simple and related to the Heisenberg uncertainty principle.

ESTIMATIONS OF THE MAIN PROCESS PARAMETERS

Here we are interested in estimating for a given Compton quanta flux, the required laser and electron beam parameters, accuracies of the beams alignment, etc.

First of all, the electron beam should be as monochromatic as possible and the Compton quanta energy spread has to be minimal. The energy spread of the scattered electrons includes the energy spread of the incident electron beam and Compton quanta plus energy spread increase due to localization process. The smaller the first contribution is, the larger the accuracy of the energy spread increase measurement will be. In the limit of zero energy spread of the electron beam and Compton quanta energy, the energy spread of the scattered electrons (left screen in Figure 1) is a result of localization process and the Fourier image of the square root of the distribution gives us the localized electron wave function after the Compton quantum measurement (see the discussion of its physics in the last section).

Let's estimate separation of the beams – scattered (left trajectory in Figure 1) and unperturbed (right trajectory in Figure 1). Assuming a head-on collision, for backscattered quanta the energy ε_s is:

$$\varepsilon_s = 4\gamma^2\varepsilon, \quad (1)$$

where ε_s is the Compton quanta energy, and γ is the relativistic factor of the electron beam (here and below we assume that we are in Thompson regime, i.e. photon energy in the electron rest frame is much less than the electron rest energy). Assuming the electron energy E=405 MeV for SNS [3] and E=150 MeV for Fermilab IOTA injection line [4] we have roughly 8.8 MeV and 1.2 MeV backscattered quanta for these facilities, respectively, for readily available 355 nm light. More important is the relative energy change that is 2.2 % and 0.67 %, respectively. The typical relative electron beam energy spread is 0.01%. It shows both Fermilab and SNS electron beam energy separation could be made almost two orders of magnitude larger than the spread which gives us opportunity to make clean experiments on wave function localization.

The next step is to calculate the angle for quanta registration to reach the desired accuracy of scattered electron spread and the detection rates. The Compton cross section σ in electron rest frame in the Thompson regime is:

$$d\sigma = \frac{r_e^2}{2}(1+\cos^2\chi)d\Omega, \quad (2)$$

where r_e is the classical radius of the electron, and χ is the angle of the scattered photon with respect to the initial angle that is assumed to be exactly (or very close to) 180 degrees with the electron beam direction. We have to register backscattered photons very close to beam axis and, once a photon is registered, detect the scattered electron. In this way we minimize spread of scattered electron energies. If we want it to be small, the angle $\theta=\pi-\chi$ has to be small also. Recalculating the photon energy ε_s from the electron rest frame to laboratory frame yields:

$$\varepsilon_s = 2\gamma^2\varepsilon(1+\beta\cos\theta) \approx 4\gamma^2\varepsilon(1-\frac{\theta^2}{4}). \quad (3)$$

The spread of photon energies is about $\varepsilon_s\frac{\theta^2}{4}$, and has to be less than the electron beam energy spread δE which yields:

$$\theta \le 2\sqrt{\frac{\delta E}{E}\frac{E}{\varepsilon_s}}. \quad (4)$$

The rough estimate for both facilities (assuming $\frac{\delta E}{E} \approx 10^{-4}$) for 355 nm light is $\theta \le 0.2$ radians. Only photons within this angle have to be collected. We have to recall here that the Compton photon with a large angle gives a transverse kick (around 10^{-3} angle for our maximal angle of 0.2 rad in the beam's rest frame) and this reduces the accuracy of measurement because the electron separation due to dispersion and energy drop of scattered electrons will be smeared by the spread of the horizontal coordinates that appear due to Compton photon transverse momenta. We just have to reduce beta function at interaction region to mitigate this effect. In addition, the dispersion function after the magnets has to be as large as possible and the beta function at the electron position measurement has to be minimized – we leave these details for future work on more detailed design of the beam and laser optics.

At this point we have to estimate the needed electron flux and the detection rates for reasonable lasers. In the laboratory frame this photon angle becomes:

$$\theta_L \approx \frac{\theta}{2\gamma}, \quad (5)$$

that is around $0.3\text{x}10^{-3}$ for the Fermilab parameters. It means that the gamma detector, placed 10 meters from the beam, has to have an aperture diameter only 0.6 cm for the Fermilab case. SNS parameters have the similar values. For this small angle the cross section (2) becomes:

$$\sigma = \pi r_e^2\theta^2, \quad (6)$$

And the rate f of Compton quanta detection is:

$$f = \sigma f_{ph} N_e / S, \quad (7)$$

where f_{ph} is the number of photons per second, N_e is the number of electrons in the interaction volume, and S is the area of beams overlap.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Estimation for the simplest SNS experiment can be done under following assumptions:

1) Electrons come from H^- stripping by a Q-switch laser with duration around 10 ns with repetition rate 30 Hz;
2) Only a small fraction (1%) of ions are stripped to prevent electron beam blow-up due to space charge force, therefore the total number of electrons per one laser shot is N_e=2x10^7;
3) The laser for interaction is also a 30 Hz Q-switch laser with the number of photons = 1.5x10^{18} per pulse assuming 25% efficiency conversion into 355 from 1064 nm light;
4) The area of overlap can be made around 1 mm^2;
5) We assume the electron beam spread can be reduced to 10^{-4} or below – either naturally or using some collimation.

The SNS events rate for 100% efficiency of gamma detector is $f \approx 0.9\,kHz$. This number is too high in order to use coincidence registration for electrons and gamma quanta. Probably, it is not necessary. But we can collimate the beam to reduce the energy spread and number of electrons will go down two orders of magnitude or so. That means the detection rate of around 9 Hz would be less than 30 Hz laser rate (0.3 Compton photons per shot), and we can use coincidence scheme to make clean measurements of electron energy distribution.

The Fermilab linac needs special low current injector producing monochromatic beam for such experiment. In the IOTA channel it is desirable to increase the dispersion as much as possible after the bend and reduce the betatron horizontal size. The counters for Gamma quants can be chosen different to see if the results of experiment depend on the boundary conditions for absorbed scattered photons.

Typical accuracies of the laser beam alignment have to be about 10^{-4}. The angular spread of the electron beam angles has to be about the same. All misalignments have to be less than acceptable angle of Compton quanta that is 0.3x10^{-3} for the typical beam parameters (see eq. [5]).

WAVE FUNCTION SIZE EXTRACTION

The expected result is that Compton energy spectrum for electrons doesn't change after the quantum measurement and we don't see any broadening of scattered electron distribution. The wave function localization is very weak then and can't be measured. If we see broadening of the left distribution in Figure 1, it will indicate that some localization took place.

Here we would like to speculate on how we calculate wave function size from a measured image on the screen (see Figure 1, left distribution). We assume that the dispersion function D can be made large enough so that the betatron size of the beam can be made much smaller than the energy spread-related size, that is $D\frac{\delta E}{E}$. In addition, we assume the electron spin doesn't influence its motion much, and ignore the rest mass of the electron. In this case its motion is similar to the light and the Fourier transform of the energy spectrum (taken as square root of the measured distribution) produces the wave function in time-space representation. There is always a question of wave function slow phase that can't be determined from the measurement of this type – we assume it is close to being a constant.

Simple arguments give us the following picture: if the wave function gets localized after the measurement to one photon wave length, the energy spread will be equal to the photon energy meaning the left image in Figure 1 will overlap the right one. If the localization is about 10 wave lengths, the energy spread is around 10% of the photon energy (the width of the right distribution is about 10% of the distance to the right one), etc.

The parameters, chosen in this paper, allow us to see the localization size if it is below 100 backscattered photon wave lengths. If the localization length is larger, meaning the increase of the energy spectrum width is not seen, one needs to decrease the electron beam and backscattered photons energy spread further.

SUMMARY

In this paper we have presented examples of possible experiments at SNS and Fermilab on electron wave function localization due to Compton quantum scattering and its measurement by a detector. It is shown that if the localization of the electron wave function is below 100 wave lengths of backscattered photons, it will be possible to measure it with moderate modifications of existing and future facilities at SNS and Fermilab.

Abstract

Fermilab's Integrable Optics Test Accelerator (IOTA) is an electron storage ring designed for testing advanced accelerator physics concepts, including implementation of non-linear integrable beam optics and experiments on optical stochastic cooling. In this report we describe the contribution of RadiaBeam Technologies to the IOTA project which includes non-linear magnet engineering, prototype fabrication and measurement.

INTRODUCTION

IOTA is an electron ring designed as a proof-of-principle of non-linear integrable optics [1] at the ASTA facility [2]. Nonlinear optics are predicted to increase stability of the electron beam through Landau damping [3] and the natural tune spread of the electron beam will also increase dynamic aperture [1], leading to more intense beams in high-energy physics machines. The goal of the project is to study single particle dynamics in the non-linear regime using a 150 MeV electron beam in a ∼40 m circumference ring with 4 non-linear inserts that are each 2 m long [4]. While the beam dynamics of the non-linear optics system is being studied at Fermilab, the magnetic inserts are being designed and manufactured at RadiaBeam Technologies.

In this paper we discuss the magnetic design and tolerance requirements of the IOTA inserts and the measurement system being built to measure the first prototype of these unique magnets. The goals of the prototype magnet insert are to gain experience manufacturing a complex geometry, determine the cross-talk between adjacent magnet segments, and measure the field of a challenging insert that is tens of centimeters long with a sub-centimeter aperture.

DESIGN

The approach to this problem is the standard magnetostatic approach [5]: find the equipotential surfaces and choose one to fill with iron, correct the edge fields for the finite extent of the real magnets and then magnetize that iron via a current carrying coil on a "far off" yoke. The magnetostatic problem is defined in terms of the magnetic vector potential for a 2D object:

$$A_z(x,y,s) = \frac{B\rho\, c^2\, t}{\beta(s)} \sum_{n=1}^{\infty} \frac{2^{2n-1} n!(n-1)!}{(2n)!} \times \left(\frac{x^2+y^2}{\beta(s)\, c^2}\right)^n \cos\left[2n \arctan\left(\frac{y}{x}\right)\right]. \quad (1)$$

Where $B\rho$ is the magnetic rigidity of the particles, c is a scale factor with units $m^{1/2}$, t is a unitless strength parameter, x, y and s are the horizontal, vertical and longitudinal coordinates, respectively, and $\beta(s) = \beta^* + \frac{s^2}{\beta^*}$ is the beta-function in the non-linear insert with $\beta^* = 0.727$ m at the longitudinal center of the insert.

The vector potential (and as we will see, the scalar potential) is clearly continuous in the longitudinal coordinate but it would be very difficult to create a single 2 m long device that varies continuously to produce the desired scaling. Accordingly, the 2 m device is divided into 20 sections of constant parameters that are 6.5 cm long, between each section is a 3.5 cm long non-magnetic block (or air gap) used to separate the different segments. Because of the symmetry around the longitudinal center of the device, there are 10 different segments. The segments are labeled 1 through 10 with 1 being nearest the center of the 2 m device and 10

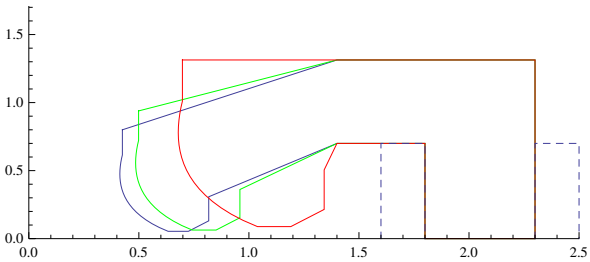

Figure 2: Real space outline of the 2D IOTA design for segments 1 (blue), 5 (green) and 10 (red), including a continuous return yoke. The dashed lines show the outline of the excitation coils. All dimensions are in centimeters.

being the outer most segment.

To lowest order, the problem is limited to a 2D plane, so the scalar potential is related to the vector potential via a $\pi/2$ rotation about the longitudinal axis [6]:

$$\phi(x_N, y_N) = t \sum_{n=1}^{\infty} \frac{2^{2n-1} n!(n-1)!}{(2n)!} \times \left(\frac{x_N^2 + y_N^2}{c^2} \right)^n \sin\left[2n \arctan\left(\frac{y_N}{x_N}\right)\right]. \quad (2)$$

Here, the scalar potential has been normalized such that $\Phi(x, y, s) \equiv \frac{B\rho c^2}{\beta(s)} \phi(x/\beta^{1/2}, y/\beta^{1/2})$ with $x_N \equiv x/\beta^{1/2}$ and $y_N \equiv y/\beta^{1/2}$. Because we know the scaled form of the potential and how the beta-function evolves through the non-linear magnet, we can solve for the pole face once and then scale it via the beta-function for all of the magnets. Further, because of the four-fold symmetry of the problem, we need only find the solution in one quadrant. The equipotential lines of the scalar potential in Eq. 2 are shown in Fig. 1. The green line in Fig. 1 shows the contour that will be used to define the pole faces. Because the solution is scaled by $\beta(s)$, this is the face for all of the magnets.

We note here that the potentials given by Eqs. 1 and 2 have singularities at ($x_N = \pm c$, $y_N = 0$), so whatever solution is found can never include normalized coordinates greater than c. Further, because the singularities are located on the $y = 0$ line, the vertical aperture is larger than the horizontal aperture.

In order to make the design easier to produce we have decided to make a single yoke design for all of the different pole tips. This way, the yokes can be produced en masse while the tighter tolerance pole tips are made for each of the segments separately. Fig. 2 shows a 2D outline of poles 1 (the smallest pole, it is the pole closest to the longitudinal symmetry point), 5 and 10 (the largest pole) of the IOTA insert design along with a continuous return yoke and a single excitation coil. The curved surface of each segment is given by the green line in Fig. 1.

Above the curved pole tip, a straight face is extended to 1.3 times the height of the highest point on the curved face. This straight corner improves the agreement between the simulation results and the desired field. The value was found via 2D optimization of the field using the code Poisson [7]. The height of the yoke is defined by the height of the pole face extension for the number 10 segment. On the lower side, the curved face is cut off by a flat section that is "chamfered" on the outside edge (to the right in Fig. 2) to prevent field concentration there. These underside changes are made in the scaled coordinate system, so they are different for each magnet.

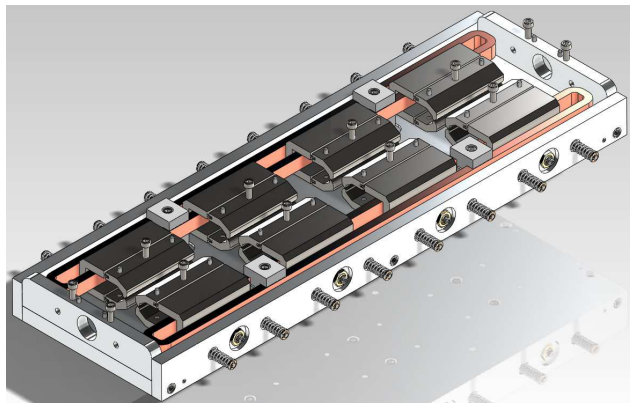

Figure 3: Isometric view of the IOTA insert prototype. A plate on top has been hidden to show detail below. The copper items are the excitation coils, the dark grey items are the steel poles and return yokes and light grey items are aluminum.

An isometric view of the prototype insert can be seen in Fig. 3. The prototype insert will contain 4 complete segments. Because the smallest aperture comes from the number 1 pole, the prototype insert will have the following segments (in order): 1, 1, 2, 3. This combination of segments allows us to measure the smallest aperture magnets and the coupling between segments. 3D simulation using the code Maxwell [8] has shown that the longitudinal symmetry point of a full length insert will be faithfully reproduced between the two number 1 poles in the prototype.

NONLINEAR MAGNET REQUIREMENTS

Figure 4: Close up image of the tongue and groove reluctance gap.

The magnets shown in Fig. 2 are closed yoke magnets. However, because the beta-function of the electron beam evolves along the length of the insert, each of the 10 segments requires a different excitation magnitude. To reduce the number of power supplies needed, we have decided to

Copyright © 2013 CC-BY-3.0 and by the respective authors

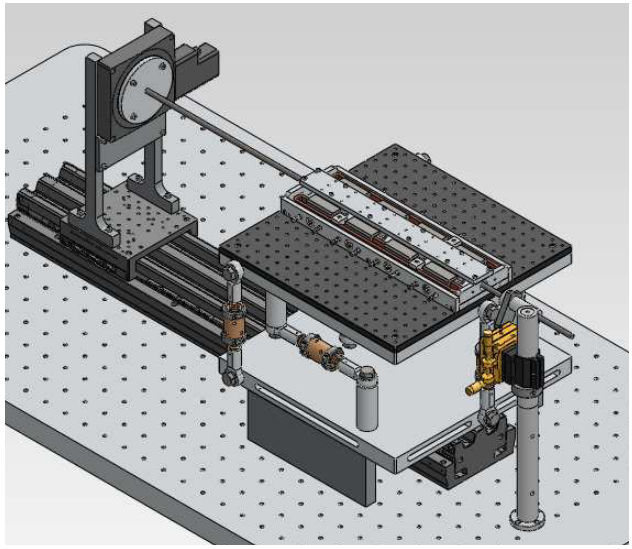

Figure 5: View of the IOTA insert measurement system.

use a single excitation coil for all of the yokes and to tune the field in each segment using a reluctance gap that can be set by moving the return yoke of each segment individually. If the reluctance gap were comprised of two flat faces, the required precision of the position of the yoke relative to a fixed pole tip is very tight, a few micrometers. To reduce the required tolerance we opted for a tongue and groove approach, this results in a required positional tolerance of $\sim$50 μm. A close up of the tongue and groove reluctance gap can be seen in Fig. 4.

The field quality requirements were defined using a frequency map analysis [4], the analysis indicates that a good field region of $|y| \approx c$ and $|x| \approx c/2$, with good being defined as difference from the ideal field by less than 1%, is required. Further, the magnetic center of the segments must be placed along the same line with an accuracy of 50 μm or less. To compare the magnetostatic simulations to the theoretical field, the simulated field is compared to the ideal field on the y-axis (B_x) and x-axis (B_y). Of the above defined magnets, the number 1 pole has the worst field quality: the difference is less than 0.5% at all points within ($x < 0.6c$,$y < 0.8c$). Therefore, simulations show that all magnets are potentially within the desired tolerance. Harmonic analysis of the fields produced by Poisson shows that the field faithfully reproduces the quadrupole and octopole moments with 0.1% of the desired values while the dodecapole moment is within 3% of the desired value (r_N = 0.5). The fields in the aperture are quite small at $B \leq$ 100 G, using t=0.45, c = 0.009 m$^{1/2}$ and $B\rho$ = 0.502 T-m, which are the design parameters for the prototype.

MEASUREMENT SYSTEM

To measure the magnetic field of the prototype insert requires that we design a measurement system with over 40 cm of travel in the longitudinal direction that can fit within circular gap of $\sim$10 mm diameter within the number 1 pole

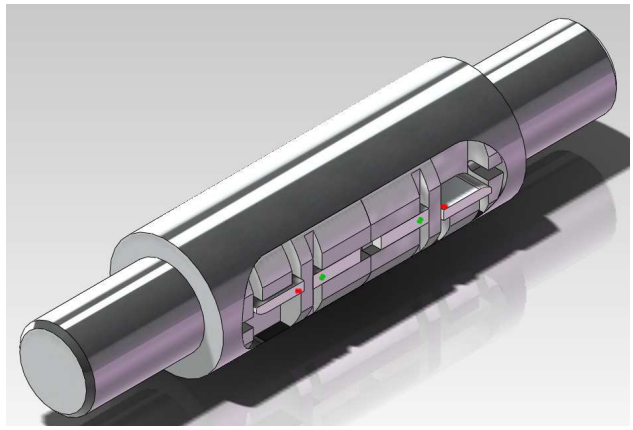

Figure 6: View of the hall probe holder showing the custom mechanics to allow probe motion in the radial direction. The red and green crosses are the locations of the hall probes.

(see Fig. 5). Additionally, the hall probe must be able to move within this 10 mm diameter gap. To accomplish this, we have designed a "rod and radius" system wherein a set of miniature hall probes [9] are mounted in a custom holder in a rod of the specified diameter (see Fig. 6). The rod is moved longitudinally via a linear motion stage and rotationally via a rotational stage. The radius is set manually with a set screw. This design will allow us to measure a large fraction of the desired aperture. We will use 4 hall probes that are separated longitudinally in the probe holder, such that two different radii within the IOTA insert aperture can be measured in a single, automated longitudinal scan (see Fig. 6). We intend to zero and measure each of the probes in a pair of common standards and to have an overlap region that can be measured by both sets of probes for direct comparison. At the time of publication, the IOTA insert is being manufactured and the measurement design is being completed.

PERFORMANCE OF PLANAR RADIATOR IN THE RADIABEAM-IAC EXPERIMENT*

A. V. Smirnov#, R. Agustsson, S. Boucher, J. J. Hartzell, S. Storms, RadiaBeam Technologies Inc., Santa Monica, CA 90404, USA and Y. Kim Idaho Accelerator Center and Idaho State University, Pocatello, ID 83209, USA

Abstract

Planar gratings structure for generation of mm-sub-mm wavelength long-range wakefields is analysed. The rugged, side-open, slow wave structure can sustain substantial beam loading including long multi-bunch trains up to CW operation. Electromagnetic performance of the structure is characterized numerically vs. experiment with emphasis to application to flat beams. It is shown that such an electrically wide, wavelength-gap structure can operate at significantly reduced tolerances whereas substantial flatness of the wakefield can be obtained at essentially non-flat eigenmode profile.

INTRODUCTION

In the experiment [1] conducted at Idaho Accelerator Center (IAC) a side-open gratings planar structure (see Fig. 1) was used to generate and partially extract mm-sub-mm wave radiation induced by wakefields. Since the structure is relatively new the radiator performance needs more detailed characterization as well as to substantiate the measurements made and to support other potential applications such as compact THz sources [2], energy dechirping [3] and collinear wakefield acceleration.

We analyse here the structure performance with GdfidL code [4] in eigen- and time domains. The side opening has been modelled as a large space enclosed by low conductivity walls (see Fig. 1) with negligible influence on the frequencies of the modes of our interest.

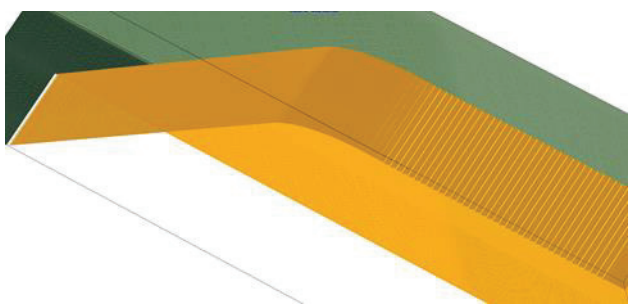

Figure 1: GdfidL model of one-quarter structure with horn antenna. Interaction gap: 1.26 mm, width: 6.3 mm, grating length L=30.4 mm (130 periods), period: 0.23 mm, and groove depth: 0.081 mm.

EIGENMODES

We analyse here eigenmodes that are in synchronism with the relativistic beam (v/c=0.996) using only one period of the regular part of the structure. Several modes with different horizontal variations can potentially interact with the beam in such an oversized structure. Field patterns for lowest modes are shown in Fig. 2. Side opening provides modal selection for the wakefield energy radiated forward [2,5] due to the side radiation losses via the factor $F = \left((1-\exp(-\alpha L))/\alpha L\right)^2$, where $\alpha = \pi f / Q v_{gr}$ is the modal attenuation. Simulation results for the first few eigenmodes are shown in Table 1.

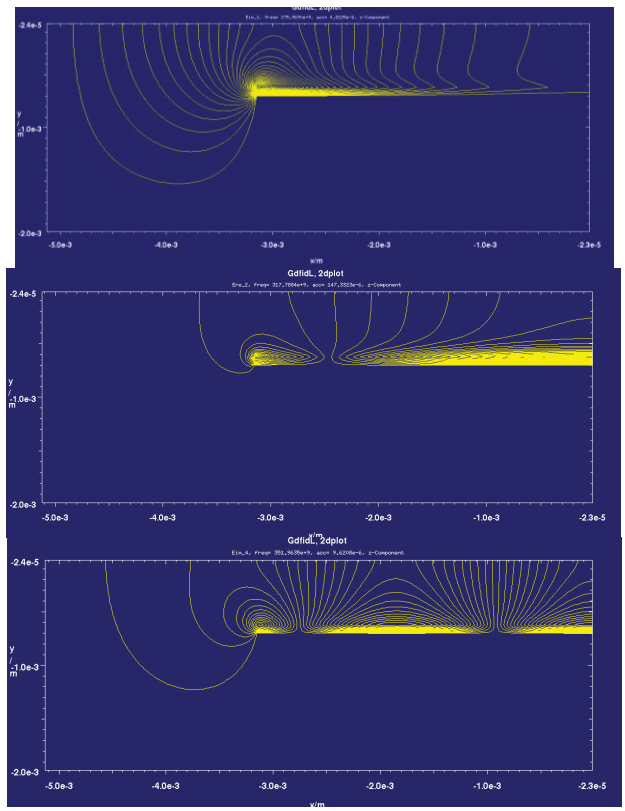

Figure 2: Contour plots in transverse XY plane for the Ez field for three lowest modes which are synchronous to 5MeV beam at 276, 312 and 352 GHz (one quarter model).

Table 1: F, group velocity, and r/Q [Ω/m] for different widths w [mm] of the beam filling the vertical gap.

f, GHz	F	r/Q, w=0	r/Q, w=2	r/Q, w=4.76	βgr
276	0.05	11	14.3	94	0.81
312	0.53	2450	2201	1343	0.844
352	0.27	1076	721	112	0.72
401	5e-4	459	180	23	0.79

One can see from Table 1 that with the absorbing periphery (having as low as 1 Sm/m surface conductivity) the factor F reduces fast as the modal order increases. This effect is similar to the spectrum rarefaction in open cavities and waveguides. One can see that mode #2 (at 312 GHz) strongly dominates in beam interaction due to radiation losses and higher r/Q at finite beam width.

TIME DOMAIN SIMULATIONS

Wakefield simulations have been performed here for filament and ribbon bunches having 30 pC charge at 500 and 700fs rms durations in various configurations: grating structure only, with horn attached, horn only (without the structure), and also in the structure with randomized geometrical parameters:

Wakefields induced by flat (ribbon) and filament bunches are illustrated in Fig. 3. Note the radiation patterns seen in Figs 3, 7 is significantly modified ("flattened") by the beam width.

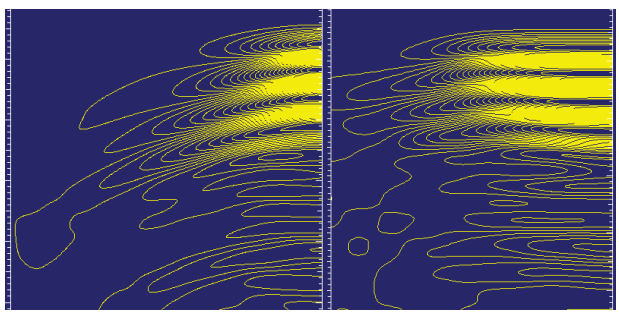

Figure 3. Ez field pattern in median XZ plane induced by a σz=150 μm bunch along 40 periods structure at t=31 ps for filament (left) and 4.8 mm wide (right) bunch filling the vertical gap.

Field spectra shown in Figs. 4, 5 confirm the dominant mode at ~300 GHz. Line splitting is caused by partial reflection of the power from the horn.

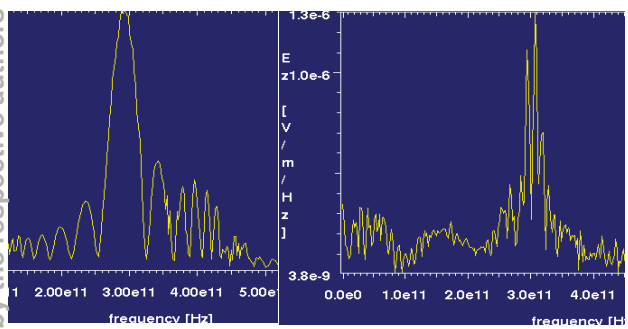

Figure 4: Ez field spectra on the output edge of the gratings (left) and on the horn opening (right) forσz=150 μm and w=2 mm bunch.

Longer bunch causes appearance of spectrum lime at lower frequencies (tens of GHz, see Fig. 5, right) and magnitude reduction at 300 GHz (compare to Fig. 4, right). We observed very similar behaviour experimentally [1], when we obtained signals from fast oscilloscope (~20 GHz bandwidth) whereas the pyrodetector signal was weak or not registered yet. That occurs when the chicane and RF phases were tuned incompletely.

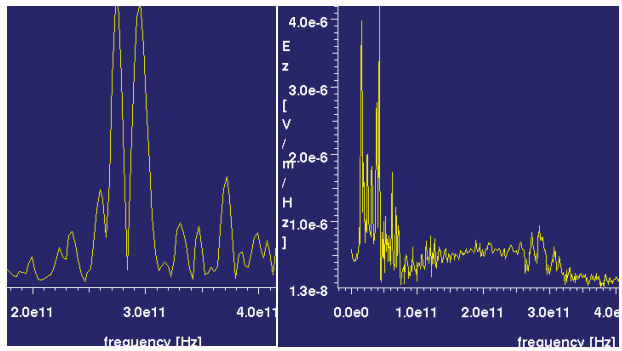

Figure 5: Ez field spectra on the output edge of the gratings (left) and on the horn opening (right) for a σz=210 μm, w=2 mm bunch.

Flux integral that determines radiated energy is plotted in Fig. 6 for full system and horn only. One can see that the radiated energy without gratings is negligible compared to that with gratings that occurs at ~ 310 GHz (see Fig. 4, right).

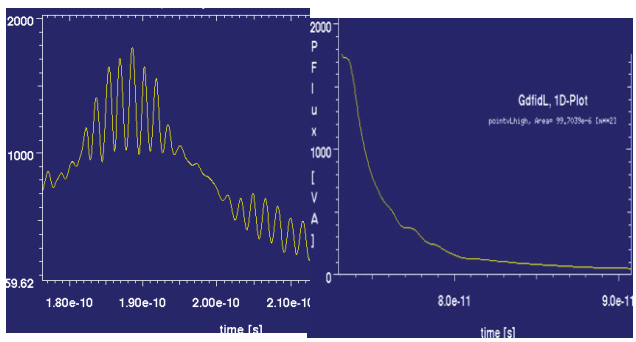

Figure 6: Total flux integral [W] (including quasi-static charge-induced fields) vs. time on the horn output with (left) and without the gratings (right) for a σz=150 μm, w=2 mm bunch.

From Fig. 6, left one can estimate the radiation micropulse time ~20 ps which corresponds well to the 18ps drain time determined as difference between slow wave structure filling time and time-of-flight. The tail of the plot corresponds to the bouncing caused by partial reflection.

One can also estimate from Fig. 6, left, ~40 nJ energy radiated by a 500 fs microbunch. For 1.3 GHz RF frequency and 2 μs pulse length it corresponds to ~100 μJ energy radiated per macropulse or ~3mW average power at 30 Hz rep rate. That corresponds well to pyrodetector measurements [1] and previous analytical estimations. From the analytical model and the simulations above we also estimate the rms bunch duration about 600-700 fs.

Wider bunches change field because of generation of higher and lower order modes (see Figs 7, 8).

From the field pattern induced by the bunch in the horn (Fig. 9) one can assume lobe direction angle about half of

Copyright © 2013 CC-BY-3.0 and by the respective authors

the opening angle. This is in agreement with preliminary far-field simulations.

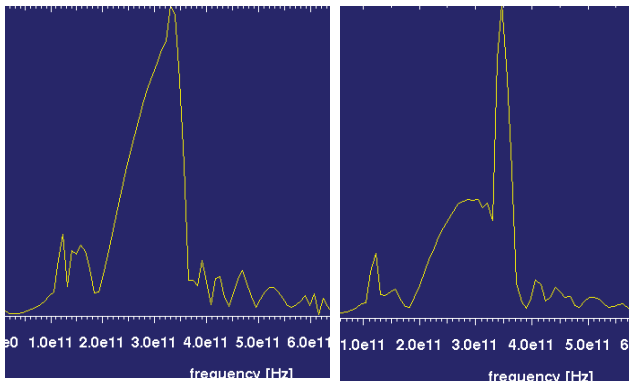

Figure 7: Ez field spectra induced in the 40-period gratings for 2 mm (left) and 4.76 mm (right) wide bunch at σz=150 μm.

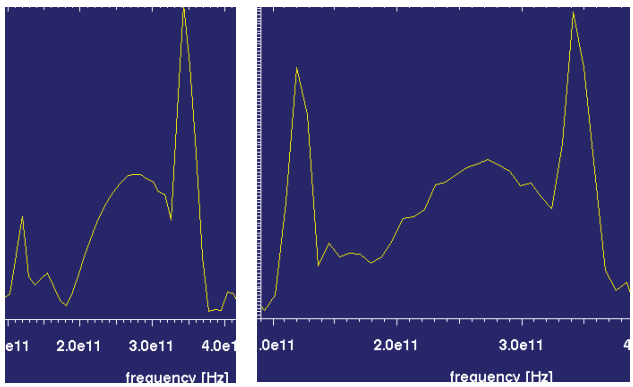

Figure 8: Ez field spectra induced in the 40-period gratings for 4.76mm (left) and 7 mm (right) wide bunch at σz=210 μm.

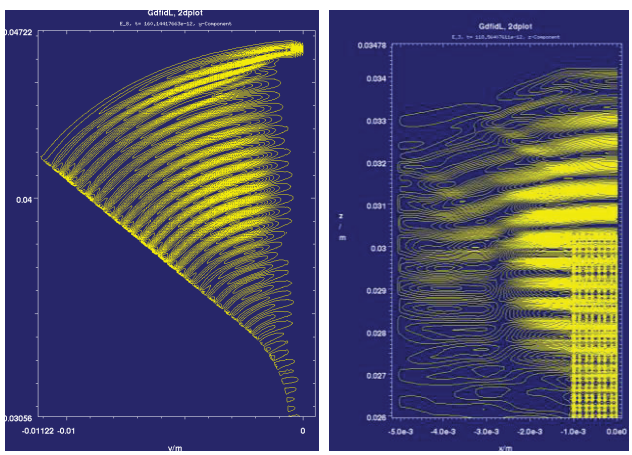

Figure 9: Ey in YZ (left, t=160ps) and Ez field plotted in XZ plane (right, t=118ps) forσz=150 μm bunch. The rectangular region on the right corresponds to the 2mm bunch width.

To model effect of CNC milling tolerances we introduced 0.5 mill randomization into the gratings parameters (period, groove depth, and thickness) in the full-length model (with the horn). The results for power and spectrum shown in Fig. 10 to be compared to Figs 4, 6.

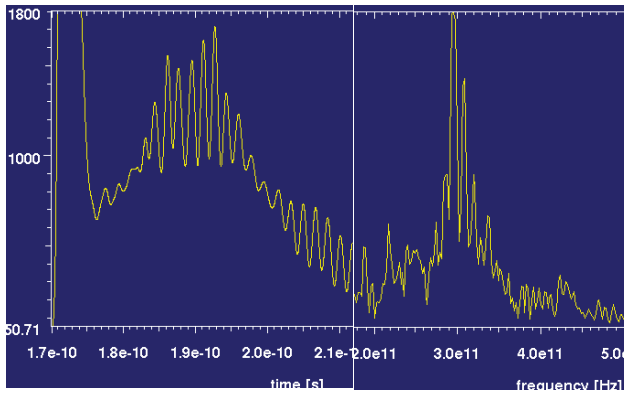

Figure 10: Full power [W] (left) and Ez field spectrum (right) for radiator with randomized gratings for 2 mm wide, σz=150 μm bunch.

CONCLUSION

Simulation confirmed ~mW power radiated from the insertion device at sub-THz frequency estimated earlier from measurements at negligible contribution of geometric wake induced by the antenna horn.

Flat beam considerably modifies wakefield pattern and can make it "flat" even if the eigenmode is not flat.

Wider beam (>5 mm) also results in appearance of ~120 GHz line and shift of the main peak to higher frequency (340 GHz at 7 mm width).

Radiation from longer bunches (≥650 fs) is dominated in the insertion device by lower frequencies (10-100 GHz) that was effectively used in the experiment for the pre-tuning of the beam compression system with fast oscilloscope.

At shorter bunches the radiation is strongly dominated by a single mode at ~310 GHz. That validates analytical simulations made previously to design the experiment [1].

Gratings randomization (~a mill) does not change much the coherent part of the wake making the high group velocity structure exceptionally attractive for applications.

WAKEFIELD CALCULATIONS FOR SEPTUM MAGNET IN LCLS–II*

K.L.F. Bane, T. Raubenheimer, SLAC, Menlo Park, CA 94025, USA

INTRODUCTION

The LCLS-II would have delivered low emittance beams with an energy in the range 7–13.5 GeV to one of two undulators, one for generating soft x-rays (SXR) and the other for hard x-rays (HXR) [1]. To allow for flexibility in the distribution of the beams to the two undulators, a fast kicker and Lambertson-type septum magnet would be installed just upstream of the undulator region. The septum itself is 2 m long and the beam is meant to traverse it while passing within millimeters of metallic walls, which will induce resistive wall wakefields. The longitudinal wakes will take energy from the beam and add a longitudinally correlated energy variation—an energy chirp. The transverse wakefields can increase the beam's projected emittance.

In this report we perform calculations of the longitudinal and transverse wakefields of the septum, find their effects on the beam, and put the results in the context of the wakes of other objects in the downstream part of LCLS-II.

Figure 1 gives the layout of the LCLS-II beamlines upstream of the undulators, showing the location of the fast kicker and septum magnets. The septum magnet geometry we consider is shown in Fig. 2. The design orbit for the unkicked (free) beam is 1.6 mm above a curved SS surface; the (horizontally) kicked beam moves in the middle of a flat, rectangular chamber with a vertical aperture of 5 mm.

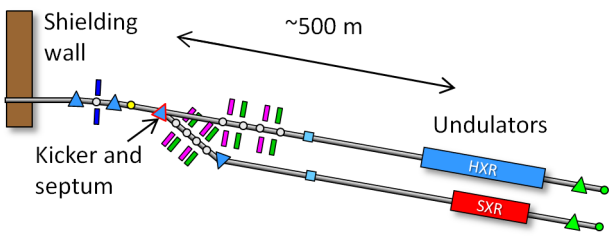

Figure 1: Layout of the LCLS-II beamlines in the vicinity and downstream of the fast kicker and septum magnet [2].

WAKES OF SHORT BUNCHES

Four bunch scenarios are considered for the operation of LCLS-II: short, relatively flat distributions with bunch charge $eN = 250$, 60, 12, 50 pC; peak current $\hat{I} = 3$, 3, 3, 4 kA; full width $t_{fw} = 70$, 15, 3, 10 fs. With the peak current (relatively) fixed and the bunches quite short, the wake strength of a bunch tends to vary $\sim t_{fw}$—since the wake is normalized to total charge eN. Thus it is the first scenario, the so-called "high charge" case with $eN = 250$ pC that will induce the largest wake effects by far, and

* Work supported by the U.S. Department of Energy under contract DE-AC02-76SF00515.

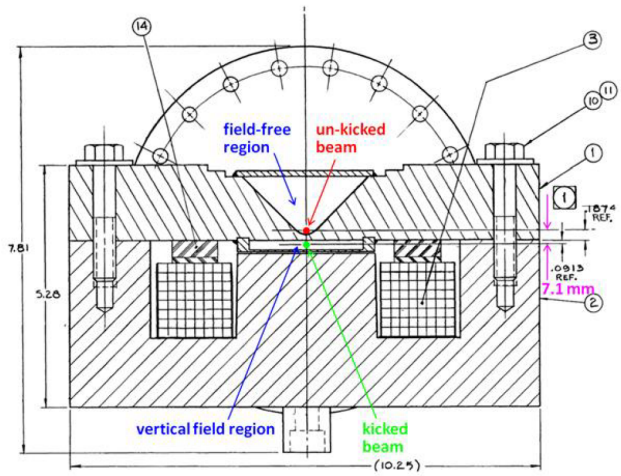

Figure 2: Cross-section the horizontally deflecting Lambertson septum magnet, "HLAM", considered in this report. The length of the chamber is 2.2 m. (Dimensions in the figure, unless otherwise specified, are in inches.)

in this report we limit our study to this case. The bunch distribution $I(s)$, to be used in calculations, is taken from the LCLS and is shown in Fig. 3 (the blue curve); note that the head is to the left, at positions $s < 0$. The distribution is double-horned, with an rms length $\sigma_z = 6.1$ μm; its core can be approximated by a uniform 3 kA (the red curve). Presumably, for the FEL we would like the entire beam core to reach saturation in the undulator together; thus the wake effects over the bunch core are most important.

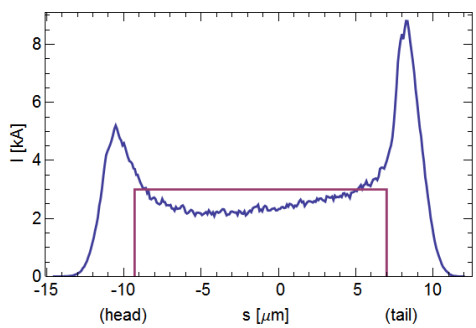

Figure 3: The bunch distribution used in the simulations, which represents the "high charge," 250 pC case (blue), and a uniform approximation of the core at 3 kA (red).

The energy variation induced in a bunch by the wake is

$$E_w(s) = -\frac{L}{c}\int_0^\infty W_z(s')I(s-s')\,ds' \,, \qquad (1)$$

Copyright © 2013 CC-BY-3.0 and by the respective authors

with L the structure length, c the speed of light, and $W_z(s)$ the longitudinal point charge wake ($W_z > 0$ means energy loss). The point charge wake of a periodic structure has a maximum value at $s = 0^+$. In a round structure that value is $W_z(0^+) = Z_0 c/(\pi a^2)$, with $Z_0 = 377\ \Omega$ and a the minimum radius of the boundary [3]. Similarly, for the dipole wake, for which $W_y(0) = 0$, the slope at origin is limited to $W_y'(0^+) = 2Z_0 c/(\pi a^4)$. For non-round structures the scaling will be the same but the constant factor will differ.

For bunches that are short compared to the zero-crossing distance of the wake, Eq. 1 can be approximated by $E_w(s) \approx -LW_z(0^+)Q(s)$, with $Q(s) = \int_{-\infty}^{s} I(s')\,ds'/c$. If, in addition, the core of the distribution is uniform, then over the core, $Q(s) \sim s$ and the wake-induced energy chirp will be approximately linear, with negative slope.

SEPTUM MAGNET

Free Beam

The resistive wall wakefields are weak forces for long bunches, *i.e.* when $\sigma_z \gg s_0 \equiv (2a^2/Z_0\sigma_c)^{1/3}$, where a is the offset of the beam from the wall, and σ_c is the conductivity of the wall metal. For the free, HXR beam, we find that $\sigma_z \ll s_0 = 21\ \mu$m ($a = 1.6$ mm, $\sigma_c = 1.4 \times 10^6\ \Omega^{-1}\mathrm{m}^{-1}$ for SS), and the effect is strong. In a round chamber, the longitudinal point charge wake (in the dc approximation) is given by [4]

$$W_z(\zeta) = \frac{4Z_0 c}{\pi a^2}\left(\frac{e^{-\zeta}}{3}\cos\sqrt{3}\zeta - \frac{\sqrt{2}}{\pi}\int_0^\infty \frac{x^2 e^{-x^2\zeta}}{x^6+8}dx\right) \quad (2)$$

with $\zeta = s/s_0$.

However, the chamber surrounding the free beam is only partially round, at the bottom (see Fig. 2). K. Yokoya has found the solution of the resistive wall wake for any boundary shape [5]. The solution is given in terms of an integral equation that he then solves numerically in a computer program. We use his program to find the wakes excited by the beam. In Fig. 4 we show in cross-section the lower part of the actual chamber shape (in red), the modified chamber that we use as boundary in our calculation (in blue), and the nominal position of the free beam (the olive dot).

The calculation results are given in Fig. 5. In frame (a) we present the point charge wake $W_z(s)$ for the model structure (blue), and the wake if the entire boundary were a circle of radius $a = 1.6$ mm (blue dashed, Eq. 2). Because of the vertical asymmetry in geometry, the energy loss varies linearly with vertical offset. However, for reasonable offsets ($\Delta y < 100\ \mu$m) Yokoya's program finds that the change in wake is small.

Using Eq. 1 we obtain the energy variation in the bunch, $-E_w(s)$[Figure 5(b)]. We see that the energy varies rather linearly over the bunch core, with a total $\Delta E_w = 1.3$ MeV; over the entire bunch the variation is $\Delta E_w = 2.6$ MeV. In the two frames we show also the wake and its effect if the surface were plated with Cu (the red curves). This reduces $\Delta E_w$to 0.4 (0.7) MeV over the core (the entire beam).

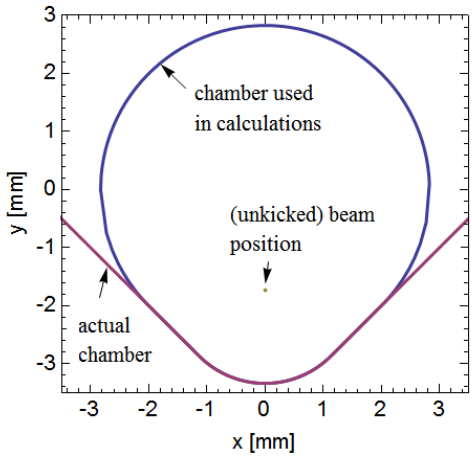

Figure 4: Position of unkicked beam, its relation to the chamber wall, and the model chamber used in calculations.

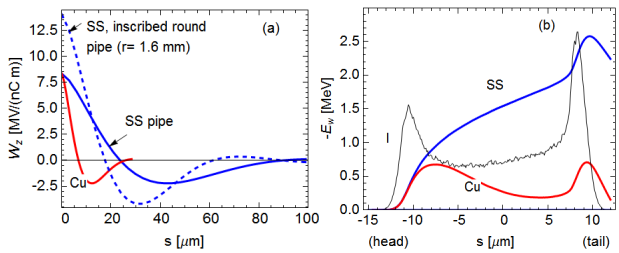

Figure 5: For the free beam: (a) Point charge wake in the SS structure (blue), if it were Cu plated (red); for an inscribed round pipe with SS, shown for comparison (dashes). (b) Total wake energy change for $eN = 250$ pC case. Bunch shape I is also shown (gray).

Transverse Wake

For our structure, with mirror symmetry in x and no symmetry in y, the transverse wake between two particles can be written as

$$\begin{aligned} W_y(s,y_1,y_2) &= W_{y0}(s) + y_1 W_{yd}(s) + y_2 W_{yq}(s) \\ W_x(s,x_1,x_2) &= x_1 W_{xd}(s) - x_2 W_{yq}(s) \end{aligned} \quad (3)$$

where x, y, indicate (small) offsets from the design orbit, and subscript 1 (2) refers to the leading (trailing) particle. Even on the design orbit, the vertical wake induced by the beam, $W_{y0}(s)$, will kick the beam downward and increase its projected emittance. The other wake functions $W_{xd}(s)$, $W_{yd}(s)$, $W_{yq}(s)$, are dipole and quad wake components. Yokoya's program finds all these components.

In Fig. 6(a) we plot the numerically obtained $-W_{y0}(s)$ (the blue curve). Convolving again like in Eq. 1 and dividing by the energy E, we obtain the kick angle $\Delta y'$. With normalized emittance $\epsilon_n = 0.4\ \mu$m, $E = 7$ GeV, $\beta_y = 30$ m, then $\sigma_{y'} = 1\ \mu$r. The normalized kick $\Delta y'/\sigma_{y'}$ is plotted in Fig. 6(b) (the blue curve); the average and rms values are 0.74, 0.54. The projected emittance growth on

Copyright © 2013 CC-BY-3.0 and by the respective authors

the design orbit is comparable to the slice emittance! Plating the septum wall with Cu can greatly reduce the effect (the red curves in Fig. 6). The relative average and rms kick values become 0.21, 0.11.

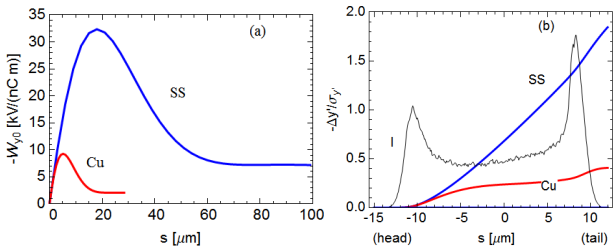

Figure 6: For the free beam: (a) Point charge vertical wake (on the design orbit) in the SS structure (blue) and if it were Cu plated (red). (b) Relative total vertical kick angle for $eN = 250$ pC case. Bunch shape I is also shown (gray).

The dipole wake functions W_{xd}, W_{yd}, were also computed. In an FEL the allowable pulse-to-pulse variation in orbit is similar to the beam size, which in the septum region is $\sigma_y = 30$ μm. Repeating the previous exercise with W_{yd} for a beam offset by σ_y, we find that the average and rms values of $\Delta y'/\sigma_{y'}$ are 0.01, 0.01, for SS, which are negligible (the results for W_{xd} are similar). As to the quad wake W_{yq}, it defocuses in y and is weak: the minimum effective focal length (near the tail of the bunch) is 6.5 km.

Kicked Beam

The SXR beam passes near the center of a rectangular chamber of width 76 mm and height 5 mm; its trajectory is bent horizontally. The bottom and sides are SS, the top is low carbon steel ($\sigma_c = 10^7\ \Omega^{-1}\mathrm{m}^{-1}$). For simplicity we will take as model parallel SS plates. The results will be slightly pessimistic for the longitudinal effect, and will miss the vertical kick on the symmetry plane (which we expect to be small).

The point charge wakefields between parallel, resistive plates have long been known [6, 7]. However, for convenience, we use Yokoya's program here again. In the flat case, the longitudinal wake at the origin, for plates separated by $2a$, is smaller than for the round case (with radius a) by the factor $\pi^2/16$. Performing the same calculations as for the free beam we find that the induced energy change E_w is similar to that given in Fig. 5(b) (the blue curve), though the amplitude is here about half as large. The energy variation over the bunch core (entire bunch) $\Delta E_w = 0.7$ (1.3) MeV.

The transverse wake for the parallel plate model follows Eq. 3, with $W_{y0} = 0$, $W_{xd}(s) = W_{yq}(s)$. In flat geometry $W_{yd}(s) \approx W_{yq}(s)$ over short distances. For a beam offset by σ_y, the maximum wake kick $\Delta y'/\sigma_{y'}$ (at the back of the bunch) is 0.02, with an average of 0.01, again a small effect. The quad wake defocuses vertically and is weak: the minimum focal length (at the back of the bunch) is 1 km.

The dispersion for the kicked beam can turn the wake induced energy spread into emittance growth as: $\delta\epsilon_x \approx \beta_x \eta_x'^2 \sigma_{\delta w}^2/(2\epsilon_x)$, with η_x' the derivative of the dispersion function and $\sigma_{\delta w}$ the relative rms energy spread due to the wake. Taking $\beta_x = 36$ m, $\eta_x' = 7 \times 10^{-3}$, $\sigma_{\delta w} = 0.7\ \mathrm{MeV}/(2\sqrt{3E}) = 3 \times 10^{-5}$, we obtain $\delta\epsilon_x = 0.03$, a negligible growth.

DISCUSSION

In Table 1 we show how the wake-induced energy variation ΔE_w in the septum compares with that in other vacuum chamber regions of LCLS-II downstream of the last bunch compressor, BC2: in the 580 m of Linac 3, the bypass line (1200 m), the linac-to-undulator transfer line (LTU) (300 m), and the undulator blank (in the HXR beam line) (170 m). Considering the septum is only 2.2 m long, its wake effect is relatively strong (assuming SS)—due to the extremely small chamber aperture. Note that for the septum as well as for the other regions in the table, the chirp is negative and mostly linear. In the LCLS-II the total wake-induced chirp serves an important function—to compensate the energy chirp left in the beam in BC2.

Finally, an important conclusion of this work is that, in order to avoid wake induced emittance growth, the septum surface in the vicinity of the free-beam orbit should be plated with a good conductor like Cu, even if the longitudinal wake adds a small nonlinearity to the energy chirp.

Table 1: Wake-induced Energy Variation ΔE_w in Different Regions of LCLS-II after BC2, for the High charge Case, $eN = 250$ pC [8]. Results are Given for the Core of the Beam, and the Entire Beam. The Septum Results Assume SS.

Region	Core	Total
Linac 3	19.8 MeV	36.0 MeV
Bypass	7.1	12.5
LTU	5.9	10.0
Septum, Free Beam	1.3	2.6
Undulator Blank	2.6	7.8
Total	36.7 MeV	68.9 MeV

ACKNOWLEDGEMENT

We thank K. Yokoya for supplying us with his Fortran program for calculating resistive wall wakes, and Y. Ding for providing the bunch shape used in the calculations.

NEW TECHNIQUE TO MEASURE THE EMITTANCE OF BEAMS WITH SPACE CHARGE

K. Poorrezaei, R. B. Fiorito, and R. A. Kishek
Institute for Research in Electronics & Applied Physics,
University of Maryland, College Park, MD 20742, U.S.A.

Abstract

Characterization of the transverse phase space of electron beams with space charge is an important requirement for high brightness particle accelerators. We present a novel technique to measure the transverse rms emittance. The method uses the beam divergence, measured, e.g. with optical transition radiation interferometry, and the beam radius, obtained by imaging the beam, to determine the cross correlation term and thus all the terms in the equation for the rms emittance. The experimental data is obtained with a lens-drift-screen setup similar to what is used in a quadrupole scan. However, the analysis of the scan data is unique. It involves taking the cross-correlation term as a control variable in a procedure which matches the beam envelop radius and its derivative calculated from the envelope equation, with the measured radius and divergences at the screen. A linear space charge model is used in the envelope equations, hence the errors in the measurement relate to the nonuniformity of the beam transverse distribution. The technique is tested using simulated data.

INTRODUCTION

It is important to measure the transverse beam emittance in accelerators to quantify the beam quality and match the optics in an accelerator beam line. Most beams of interest are space-charge-dominated near the source and low energy transport section, where the beam dynamics are mostly determined by interparticle forces rather than the beam pressure represented by emittance. Space charge usually modifies and degrades the performance of emittance measurement methods such as quadrupole scan techniques [1]. Reference [2] presents a comprehensive analysis of space charge force effects on such measurements. Several amendments have been proposed in literature to enhance the accuracy of quadrupole scan method for high intensity beams [3].

From the symmetry of the expression for the rms emittance

$$\tilde{\epsilon}^2 = < x^2 >< x'^2 > - < x \cdot x' >^2$$

it is obviously possible to determine emittance with a quadrupole scan technique using measurements of either the beam radius or divergence . The usual implementation of the method is to perform a quadrupole scan of beam size only. However, it is possible to obtain simultaneous, high-quality measurements of beam size and divergence [4]. In this paper, we propose a method for measuring emittance, assuming a linear space charge model, from a small number of measurements of divergence and radius.

In order to use these observables to determine the rms emittance at arbitrary focus points we need a methodology which relates the measured observables, i.e. divergence and beam size to the cross-correlation ($< x \cdot x' >$) term. We will show how this can be done by taking the cross-correlation term as a control variable for matching beam envelopes to their actual envelopes with the constraint that the beam radii and divergences at the screen are same as the measured values.

MEASURING EMITTANCE FOR BEAM WITH SPACE CHARGE

Figure 1 shows a typical quadrupole scan setup. The focal length of the quadrupole (or solenoid) is scanned to achieve a minimum spot size on the screen located downstream at a distance L from the quadrupole.

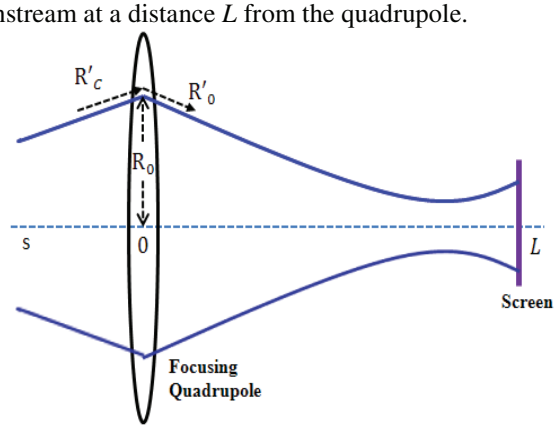

Figure 1: Diagram of a quadrupole scan setup to measure emittance. Beam enters the quadrupole with envelope R_0 and slope R'_C and leaves it with slope R'_0.

For a uniform round beam distribution where space charge is linear, the beam envelope evolution in a drift region is described by the following pair of coupled nonlinear ordinary differential equations (ODE):

$$R_j''(s) - \frac{K}{R_j(s)} - \frac{\epsilon_j^2}{R_j(s)^3} = 0 \quad (1)$$

where j ranges over transverse coordinates x and y, and dimensionless quantity

$$K = \frac{qI_b}{2\pi\epsilon_0 m(c\beta\gamma)^3} \quad (2)$$

is defined as the generalized perveance representing space charge defocusing forces. In Eq. (2), q is charge of the beam particles and I_b is the beam peak current.

Copyright © 2013 CC-BY-3.0 and by the respective authors

We present a method for deriving emittance from two samples of beam radius and divergence for a round beam. As R_x and R_y are equal in this case, we drop the index j and treat all parameters for x.

Multiplying Eq. (1) by R' and then integrating with respect to s leads to the following first order ODE:

$$R'(s) = \pm\left[{R_0}'^2 + \epsilon^2 \cdot \left(\frac{1}{{R_0}^2} - \frac{1}{R(s)^2}\right) + 2K \cdot \ln\left(\frac{R(s)}{R_0}\right)\right]^{1/2}, \quad (3)$$

where R_0 and ${R_0}'$, denote the radius and slope of the envelope at the lens. We need to have the beam envelope relation in terms of at-screen radius and slope quantities. This can be done simply by switching R_0 and ${R_0}'$ with beam quantities at the screen, $R(L)$ and $-R(L)'$, and applying a minus to the LHS of Eq. (3).

Such minuses are necessary as we are treating the envelope evolution along $-s$. Thus, envelope ODE in terms of envelope parameters at screen can be expressed as:

$$R'(s) = \mp\left[R(L)'^2 + \epsilon^2 \cdot \left(\frac{1}{R(L)^2} - \frac{1}{R(s)^2}\right) + 2K \cdot \ln\left(\frac{R(s)}{R(L)}\right)\right]^{1/2}. \quad (4)$$

This form of envelope ODE can easily be solved by numerical integration in packages like MATLAB.

As there is no closed form solution to this equation for large K, we cannot provide a closed form answer for emittance. The following procedure is devised to determine the emittance.

We start with a guess for cross-correlation term and try to infer focal setting applied to the lens by solving Eq. (4). Beam radius and divergence measurements at the screen are translated to $R(L)$ and $R(L)'$ and therefore inferred focal length is going to be a function of the guessed cross-correlation. We use the error between calculated focal length with actual focal length to correct our guess for cross-correlation and reiterate the procedure. Finally, after several steps, as the inferred focal length converge toward the actual one we come within a close vicinity of the actual cross-correlation.

Numerical Procedure

The detailed steps of the procedure are described here. As before we need two sets of beam radius and divergence measurements at two distinct focal lengths f_1 and f_2:

$$\begin{cases} f_1 \\ < x_1^2 > \\ < x'^2_1 > \end{cases}, \quad \begin{cases} f_2 \\ < x_2^2 > \\ < x'^2_2 > \end{cases}$$

Henceforth, we use subscript n, denoting the step number, alone or besides the measurement numbers 1 or 2 on all parameters that change over subsequent steps.

1. $XC1_1$, initial guess for the cross-correlation term at f_1, is chosen according to the discussion in next section.

2. $XC2_n$, the cross-correlation term at f_2, is calculated as:

$$XC2_n = \pm\sqrt{{XC1_n}^2 + < x_2^2 >< x'^2_2 > - < x_1^2 >< x'^2_1 >} \quad (5)$$

3. Next, ϵ_n (not to be confused with normalized emittance) and ${R'}_i(L)$ for two measurement sets ($i = 1,2$) are calculated as:

$$\begin{cases} \epsilon_n = 4[< x_1^2 >\cdot< x'^2_1 > - {XC1_n}^2]^{1/2} \\ {R'}_1(L)_n = 2\dfrac{XC1_n}{\sqrt{< x_1^2 >}} \\ {R'}_2(L)_n = 2\dfrac{XC2_n}{\sqrt{< x_2^2 >}} \end{cases} \quad (6)$$

Note that all three relations are in term of $XC1_n$.

4. ODE Eq. (4) can now be solved for finding at-lens envelope radius and slope conditions of measurements 1 and 2:

$$\begin{cases} R(0)_{1n} \ , & R'(0)_{1n} \\ R(0)_{2n} \ , & R'(0)_{2n} \end{cases}$$

5. For f_{1n} and f_{2n} estimates of focal lengths we have:

$$\begin{cases} f_{1n} = \dfrac{R(0)_{1n}}{{R'}_C - R'(0)_{1n}} \\ f_{2n} = \dfrac{R(0)_{2n}}{{R'}_C - R'(0)_{2n}} \end{cases} \quad (7)$$

Canceling the unknown ${R'}_C$ between these two equations and replacing f_{2n} with its final value f_2 leads to:

$$f_{1n} = \frac{f_2 \cdot R(0)_{1n}}{R(0)_{2n} + f_2 \cdot (R'(0)_{2n} - R'(0)_{1n})} \quad (8)$$

This equation is used to update f_{1n} at each step n. As before, the necessity for two pair of measurements arises from ${R'}_C$.

6. It can be easily checked that f_{1n} is a function of $XC1_n$. i.e. $f_{1n} = g(XC1_n)$. $XC1_n$ should be modified so that reiteration of the procedure from entry 2 makes f_{1n} closer to the target value f_1. In other words, $XC1_n$ is zero of this equation:

$$g(XC1_n) - f_1 = 0 \quad (9)$$

Copyright © 2013 CC-BY-3.0 and by the respective authors

Since derivative of the function g is not known, a modified form of Newton method [5] was used to find $XC1_n$ as zero of this equation.

After updating $XC1_n$ the procedure is repeated from entry 2 until f_{1n} converges with desired precision toward f_1. The process can also be stopped when the variation on emittance calculated at two consecutive steps is less than some $\delta\%$ of the calculated emittance, where δ is usually chosen between 1 and 10. Finally, beam effective emittance is the last ϵ_n calculated in entry 3.

SIMULATION RESULTS

In this section, we present results of tests of our proposed approach with simulated beams. We used the software WARP [6] to simulate the lens-drift experiment. Based on presumed beam parameters ϵ and K and an initial envelope radius at the lens, R_0, WARP generates a set of beam radius and divergence rms values $< x^2 >$ and $< x'^2 >$ at end of the drift section with length L where beam divergence and size are supposedly measured, e.g., using OTRI. The focal length of the lens, f, is calculated according to a hard edge model of the lens. The performance of the method for the several grades of the space charge was tested.

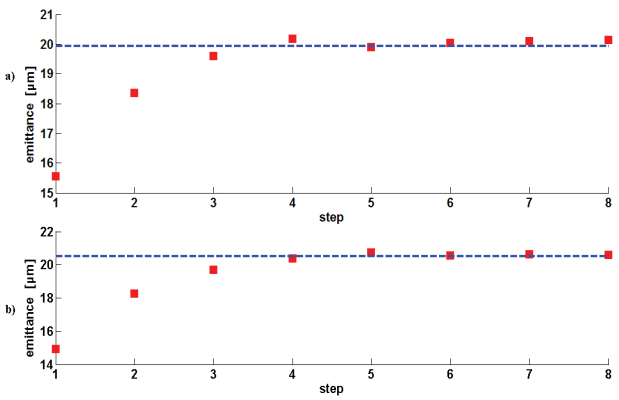

Figure 2: Plot showing convergence of emittance for (a) a medium space charge beam ($K = 2.83 \times 10^{-4}$), and (b) for a high space charge beam ($K = 7.06 \times 10^{-4}$).

Figures 2.a and 2.b show emittance convergence curves for space charge dominated beams with $K = 2.83 \times 10^{-4}$ and $K = 7.06 \times 10^{-4}$ respectively. The convergence is fast and errors in calculation of emittance are satisfactory.

To see effectiveness of the proposed procedure we tried to compare mentioned results with the emittance measured by conventional Courant Snyder (CS) parameter fitting and the minimum beam size method.

In figure 3 we compare the emittance obtained with different methods as a function of the parameter K. As expected the error in determining the emittance obtained using the CS quadratic fitting technique and the minimum beam size method, which are both accurate for emittance dominated beams, becomes increasingly large as space charge increases. In contrast, our two points fit method gives acceptable values for the emittance for all values of the K parameter shown.

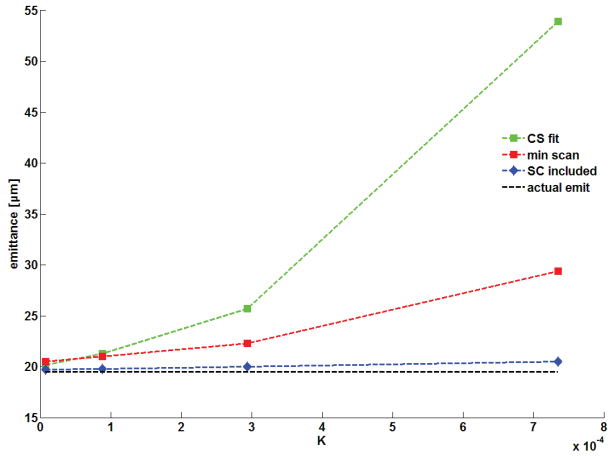

Figure 3: Comparison of the emittance measured using different methods as a function of beam perveance (K): dashed green curve: CS parameter fitting method, red curve: cross-correlation determination at minimum of quad beam size scan, blue curve: two value method including space charge, showing small deviation from the actual emittance.

ACKNOWLEDGMENT

We are grateful for inspiring discussions with J. G. Power, C. F. Papadapoulos, and I. Haber. We also thank J. L. Vay and D. P. Grote for their outstanding support of the WARP code. HIGH POWER RF SYSTEM FOR e-linac FOR TRIUMF

A.K. Mitra, Z. Ang, I. Bylinskii, S. Calic, D. Dale, S.R. Koscielniak, R.E. Laxdal, F. Mammarella
TRIUMF, 4004 Wesbrook Mall, Vancouver, BC, Canada, V6T 2A3

Abstract

The TRIUMF e-linac high power system will be built in stages. For the first phase of installation to be completed by September 2014, the injector cryomodule (EINJ) will be fed by a 290 kW cw klystron at a reduced power level and the accelerating cryomodule (EACA) will be powered by an identical klystron. The first 290 kW 1.3 GHz klystron has been purchased from CPI, USA and the high power supply system has been bought from AMPEGON, Switzerland. The second klystron and second high voltage power supply are being procured from the same manufacturers. The 290 kW cw 1.3 GHz klystron is a factory tuned multi-cavity, high efficiency, high gain, broadband, water cooled tube. The klystron has been tested at the factory. The maximum usable linear range of the rf output power of the klystron is 270 kW and is governed by the incremental gain of 0.5 dB/dB. Thus, rf power required for EACA of 200 kW cw is adequately met by the klystron after taking into account the loss in the waveguide components. and waveguides. The high voltage power supply system (KPS) for the klystron, based on a voltage controlled power module technology, consists of 65 kV beam power supply, focus supply, filament power supply and vacuum ion pump power supply. The klystron will be tested to full power on a dummy load by October 2013. At the same time, the KPS will be tested fully with all controls, interlocks, protections and integration of the klystron and a 300 kW high power circulator.

INTRODUCTION

The TRIUMF e-linac consists of an electron gun, buncher cavity, injector cryomodule, and two main-linac cryomodules [1]. The injector module has one 9 cell cavity whereas each of the accelerating (main-linac) cryomodules contains two 9-cell cavities. The cavities operate at 1.3 GHz at 2 Kelvin. The nominal energy of the e-linac is 50 MeV kinetic with an average current of 10 mA. Each 9 cell cavity has two 60 kW high power couplers. Two 290 kW CW klystrons will be employed to feed injector cryomodule (EINJ) and the accelerating cryomodule (EACA). However, the klystron for the injector will be operated at reduced output power. The linac will be built in stages. In the first stage, to be completed by September 2014, a minimum beam energy of 25 MeV, 4 mA will be obtained using the 290 kW klystrons. In the second stage, to be implemented in 2017, a second accelerating cryomodule (EACB) will be added and a 120 kW rf generator will be procured which will feed the injector. The two 290 kW Klystrons will be restored to full power operation to feed the first and the second accelerator cryomodules, to achieve the final beam power goal of 500 kW.

BASIC SCHEME OF THE HPRF SYSTEM

The basic scheme of the high power rf system for the first accelerating cryomodules is shown in Figure 1. The injector has 1 9-cell cavity and will be powered by one 290 kW klystron at a reduced power level whereas the accelerating cryomodule EACA will be run by the second klystron operating at full power. A variable power divider has been employed to facilitate rf conditioning of the two 9-cell cavities in EACA cryomodule. Also, variable phase shifters are employed to achieve phase balance between two couplers in the same cavity and for phase balance between adjacent cryomodules. The major components of the high power rf system is outlined in the following sections.

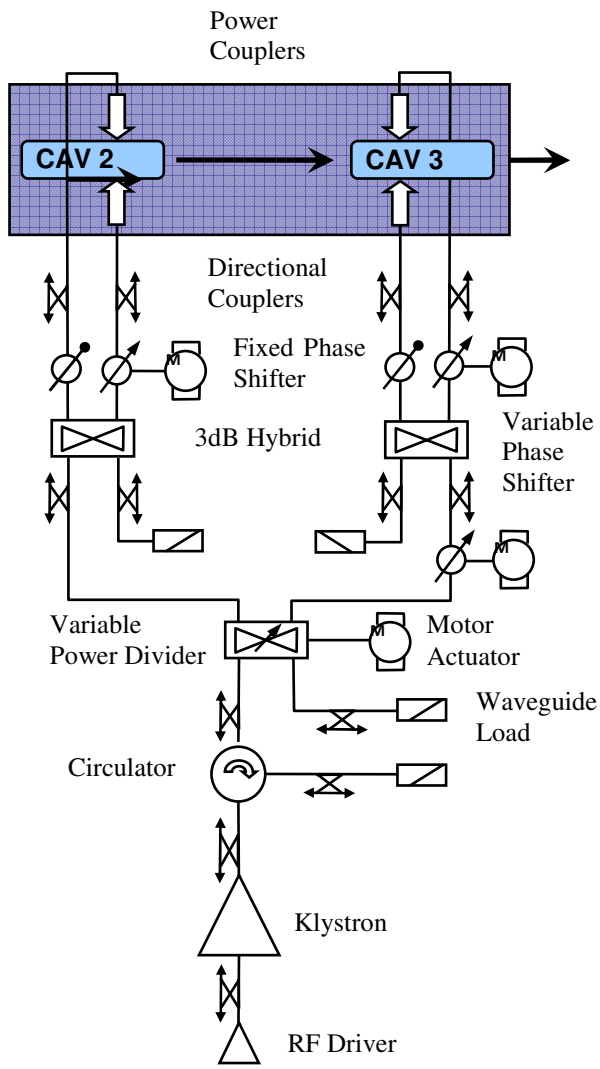

Figure 1: Basic schematic of HPRF system for the first accelerating cryomodule for e-linac

CHOICE OF KLYSTRON

The choice of commercially available high power cw rf sources operating at 1.3 GHz is very limited. Using a 150 kW klystron (available power at the cavity is about 120 kW) for each cavity would have been the ideal choice for e-linac since it would have utilized fully the rf coupler power handling capacity (60 kW operational rating, 75 kW maximum) and provide simple and straight forward low level rf control. Such a system would be very expensive and also a 150 kW klystron is not commercially available. A 290 kW cw klystron, CPI type VKL7967A, shown in Figure 2, has been recently developed jointly with HZB, Berlin and TRIUMF and has been tested at the factory. This solution has been found to be suitable for the e-linac high power rf system and fits to the tight time schedule and available funding of the project. Figure 3 show the measured output power vs drive power for two different operating conditions. The basic parameters of the klystron are listed in Table 1. An oil tank houses the filament and the cathode of the klystron and a snubber is attached to the cathode circuit to limit the stored energy less than 15 joules. Some of the basic parameters for 290 kW and 150 kW operation are, beam voltage 60.5 kV/48.5 kV, beam current 8.1 A/6.8 A, rf drive power 8.0 w/11.0 w, rf efficiency 53%/48% respectively.

Figure 2: CPI type VKL7967A 1.3 GHz cw klystron

HIGH VOLTAGE POWER SUPPLY FOR THE KLYSTRON

A 65 kV, 10 A dc power supply (referred as KPS) has been developed by AMPEGON, Turgi, Switzerland for the CPI klystron. The power supply utilizes 12.5 kV AC 3 phase input and has a transformer with 48 secondary outputs. Each output is connected to a dc switching mode.

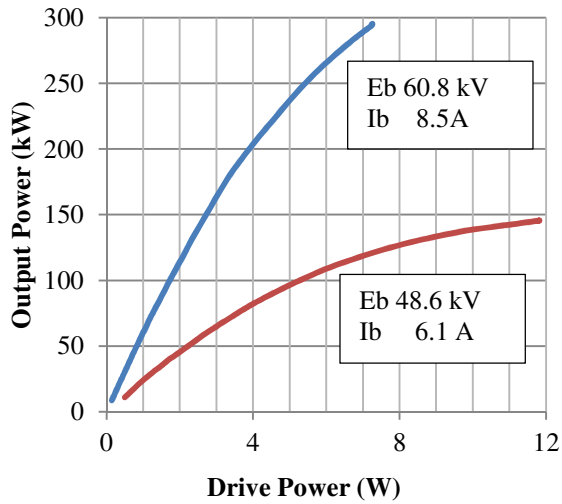

Figure 3: Output power vs drive power of the klystron module.

A novel low ripple enhanced PSM (power switching module) technology has been employed for the cathode power supply [2]. The dc voltage can be varied from 0 to 65 kV with a ripple <0.1% and a efficiency >96%. The KPS contains all required auxiliary power supplies to operate the klystron, rf driver amplifier, amplifier control and fast interlock system. For safety and maintenance of the KPS, a manual disconnect is interposed between the power supply and the Siemens switchgear which supplies all AC power requirement for e-linac. TRIUMF safety system will provide a +24 volt ENABLE control signal for the KPS and will initiate a trip by withdrawing this ENABLE control signal. The power supply has been tested at the factory for all functions, interlocks and local control. Short circuit was applied to a dc cable connected to the dc output of the KPS and the test showed that the output current increases from 0 to 40 amps in 10 µs while output voltage goes from 65 kV to 0 volts. The KPS is now installed at TRIUMF in its final location and is undergoing commissioning Figure 4 shows the photo of KPS being installed at TRIUMF.

Figure 4: AMPEGON KPS at final location at TRIUMF

300 KW CW CIRCULATOR

A high power circulator is connected at the output of the klystron in order to protect it from high reflected power arriving at the klystron output window due to mismatch of the coupler-cavity impedance or arc in the waveguide components. The circulator, rated for 300 kW cw, is water cooled and has an arc protection system. A low-loss glass fiber cable transfers the light of an arc detected with a high sensitive photodiode to the optical input of the arc detector module. The circulator and two 300 kW dummy waveguide loads and system integration is provided by COMARK, USA.

VARIABLE POWER DIVIDER

A variable power divider was chosen to divide power for the two cavities of EACA and was procured from MEGA Industries. During normal operation of the accelerator, the power divider will be set to mid-value so that power from klystron is equally divided and is fed to the two EACA cavities. Since, the cavities are rf conditioned via a self excited mode dictated by low level rf system, the variable power divider will be set for maximum power transfer to the cavity to be conditioned. For rf conditioning the cavities, 2 to 4 kW cw and 5 to 15 kW pulse power may be required depending on the coupling of the power couplers to the cavity. Maximum attenuation of 37 dB of incident power can be achieved with a maximum insertion loss of 0.17 dB.

VARIABLE PHASE SHIFTER

Variable phase shifters are required to balance the phase of the RF input couplers on the same cavity. These variable phase shifters should have more than 120 degrees of phase shift to compensate for tolerances in the waveguide assembly. Also, phase shifter is required to compensate for phase shift between two adjacent 9-cell cavities in the same cryomodule. Multiple solutions were investigated using two stub phase shifter, three stub phase shifter and a hybrid based phase shifter. Simulations were conducted for each case. The two stub phase shifter is not capable of providing the required phase shift; however, the three stub phase shifter can provide the phase adjustment required but requires at least two motors (or three, if two are not ganged together) with independent controllers. The relationship between phase and position of the stubs is not straightforward, so calibration and intelligent control is needed. The hybrid coupler based phase shifter requires significantly more room but has an excellent phase shift characteristic with the movement of the short circuit. The simulation of such a phase shifter shows a phase change of 22.5 degrees occurs for 1 cm change in stub position The simulated insertion less and return loss are <0.1 dB and <-23 dB respectively for the complete range of phase shift.

Table 1: Parameters of CPI Klystron Type VKL 7967A

Operating Frequency Mid-band	1300 MHz
CW Output Power	290 kW
RF Power Gain at nominal beam voltage	42 dB
Usable CW Output Power[1]	270 kW
Usable DC to RF Efficiency[1]	52 %
VSWR Tolerance, maximum	1.2:1
-1 dB Bandwidth	2.0 MHz
-3 dB Bandwidth	6.0 MHz
Klystron Beam Voltage	62.5 to 65 kV
Klystron Beam Current, maximum	9.1A
Beam Perveance, minimum	0.55 μA/V$^{1.5}$
Collector Dissipation, maximum	600 kW
Body Dissipation (without Output)	1% P_{beam}
Tuning	Fixed tune
Beam Focusing	Electromagnet
Phase shift of Output Power to Beam Voltage shift at operating beam voltage	<0.05 degree/volt
Output Wave Guide	WR-650
Cooling	de-ionized water
RF Input, coaxial	Type“N”
Note 1: for incremental gain, IG >0.5dB/dB	

INSTALLATION AND TEST OF THE KLYSTRON

It is proposed to commission the KPS and test the klystron by October 2013. At first, the KPS will be tested for all interlock functions, safety switching on/off procedure with Siemens switch gear and manual disconnect and key sequence for lock out procedure. The front touch panel will be also tested to bring up the KPS in a controlled mode. After short circuit test of the dc output is done, the dc high voltage cables will be connected to the klystron. In the mean time, the klystron will have a snubber installed in the oil tank the focus, filament and vacuum ion power supplies connected and water cooling will installed. The circulator and the two dummy loads will be connected to begin the high power test of the system. EPICS control system interface will be commissioned. This will allow control of the KPS system as well as monitoring the temperature and flow of the water cooling system of the klystron, the circulator and the two loads and the dc parameters of the KPS-klystron system.

THE LAYOUT OF 352 MHz 400 kW RF POWER AMPLIFIER

A. Smirnov, A. Krasnov, I. Rezanov, E. Ivanov, K. Nikolskiy, S. Polikhov, G. Sharkov
Siemens Research Center LLC, Moscow, Russia

Abstract

In this paper, we present the current status of the RF power amplifier under development for European Spallation Source (ESS, Sweden) normal conducting and superconducting accelerating sections based on solid-state architecture. A single 400 kW pulsed machine is represented with four standard 19" cabinets. Brief description and technical solutions regarding 8 kW (Class-AB, Si transistor based) RF modules, different power combiners and control system are shown.

INTRODUCTION

High power RF sources are important elements for most of linear accelerators that have found growing number of applications in science and medicine. Current power amplifier is being designed and developed to fulfil the requirements for superconducting cavities in ESS accelerator facility [1].

Main benefits of the generator under development are its smaller footprint, perspective of lower cost, better reliability and higher efficiency, achieved with class-AB operation, compared to conventional RF power sources like klystrons or other vacuum tubes generators. The solid-state microwave power amplifier modules based on Freescale LDMOS transistors arranged in parallel scheme with use of Wilkinson dividers/combiners are designed on PCB boards.

One machine is planned to be assembled inside set of four 19" cabinets. Each will contain 12 RF power amplifier modules with individual power combiner. All modules are connected to a power combiner with 50 Ohm coaxial cables. The set is terminated with a single common power combiner.

RF POWER MODULES

We have designed and manufactured compact RF power amplifier (RFPA) module prototype. The principal RFPA scheme is shown in Fig. 1. The driver stage is built using Freescale MRFE6VP100H transistor pair. The device is operated in Class-AB. Downstream the driver stage; there is a lumped element 1-to-8 Wilkinson-type splitter with final stage amplifiers at its outputs. All splitter ports have impedances of 50 Ohm.

Freescale MRFE6VP61K25H transistor pairs are being used for the final stage amplifying.

The second Wilkinson 8-to-1 power combiner is located downstream to the final stage amplifiers. The intermediate impedance of this combiner equals to 12.5 Ohms, which results in lower insertion loss. Additionally a lumped element mathing network is used to match the 12.5 Ohm intermediate impedance to output 50 Ohms. In Fig. 2, one of the fabricated RFPA modules is presented.

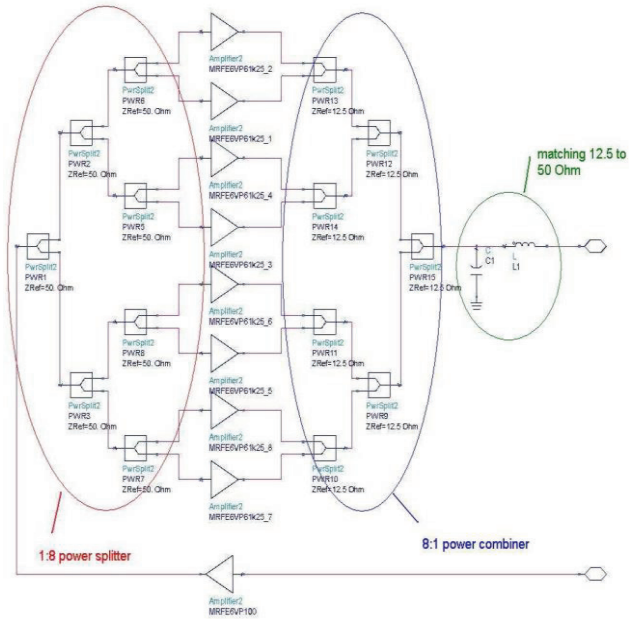

Figure 1: Single RFPA module principal scheme.

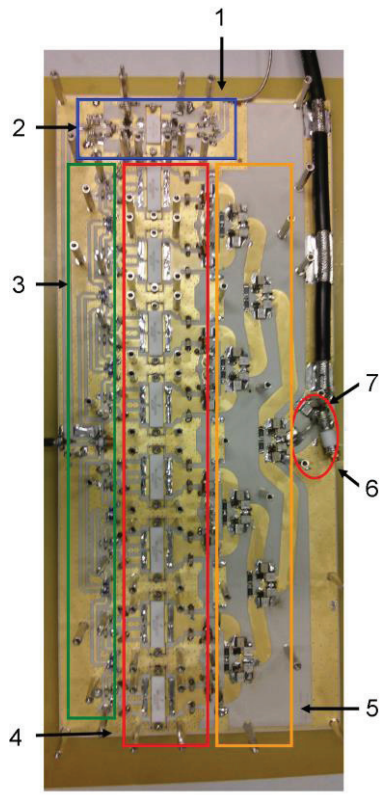

Figure 2: RFPA module: 1 – RF input; 2 – driver stage; 3 – input Wilkinson splitter; 4 – front-end amplifiers; 5 – output Wilkinson combiner; 6 – 12.5 to 50 Ohm matching circuit; 7 – RF output.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Total efficiency dependence on the output RF power is shown in Fig. 3.

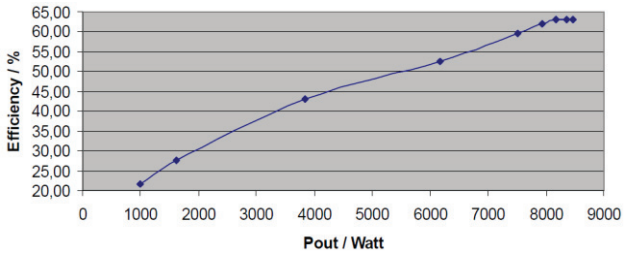

Figure 3: Efficiency vs. output RF power.

This prototype module is lying on a 5 mm thick copper plate that is air cooled, but in future it is planned to replace it with water based heat sink to guarantee heat sink temperature of less than 40°C.

RF performance features of a single RFPA are listed in Table 1.

Table 1: RFPA Specifications

Parameter	Value
Operation Frequency	352.21 MHz
Operation mode	max. 4 ms pulse, 5% duty cycle
Output RF power	8000 W
RF efficiency	~63%
Gain	50 dB
Input RF power	max. 10 W
Supply voltage	50 V
Input/Output impedance	50 Ohm
Dimensions	190×440×80 mm^3

POWER COMBINER

The current amplifier design implies an arrangement of 48 modules (giving required total RF power of 400 kW) in four 19" cabinets with 12 RFPAs and individual 12-to-1 power combiners in each of them. We have designed and fabricated compact power combiner based on rectangular-coaxial line with 12 7/16 input RF connectors and 3-1/8" EIA output flange like shown in Fig. 4. The 12 inputs are arranged in two rows with 6 in each.

The shapes of the copper inner conductor and coupling loops have been optimized to achieve best matching between inputs and 50 Ohm output, low surface fields and equal amplitude and phases of transmission coefficients between every input and output. The inner conductor plate is connected to the same outer case wall on which the inputs are located. This gives an opportunity to easily insert water cooling channels inside this plate as it is the hottest part of the combiner.

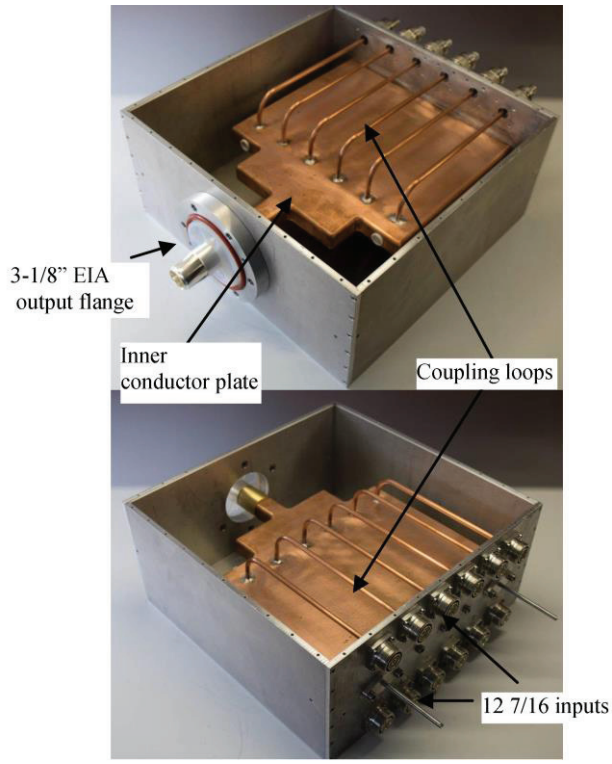

Figure 4: 12-to-1 power combiner prototype.

S11 measurement result referring to the common output port 1 is plotted in Fig. 5; other RF characteristics are listed in Table 2.

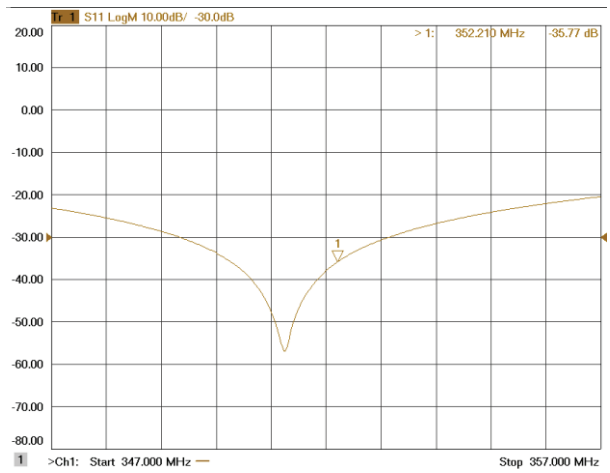

Figure 5: Measured return loss plot.

Table 2: Power Combiner Features

Parameter	Value
Operation frequency	352.21 MHz
Return loss	36 dB
Dissipated RF power ratio	0.5 %
Power splitting equality	~3 %
Dimensions	45×43×16 cm^3

Copyright © 2013 CC-BY-3.0 and by the respective authors

The device showed good performance and can be used in the amplifier. Currently the test bench for high power tests is under development. The next step will be to redesign this combiner so that inputs and output will be on the same side.

GENERATOR FORMFACTOR

All blocks including RFPA modules, power distribution, control, measurement and water-cooling systems will be assembled in four 19" cabinets ending up with a common 4-to-1 power combiner as shown in Fig. 6.

We assume that total height of the final generator assembly would not exceed 42 units (~190 cm) which is less than typical door height.

Figure 6: A row of 4 19" cabinets with common output power combiner.

An arrangement in each cabinet is in the following order from bottom to top: water-flow system, 12 19" racks with RFPAs, control system and 12-to-1 power combiner.

In each rack (see Fig. 7), there is a capacitor bank, supply power distribution system, 2 RFPA modules and water-cooling system with heat exchanger.

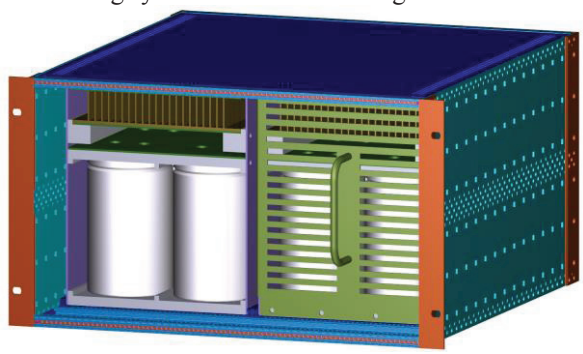

Figure 7: A single 19" rack with 2 RFPA modules arrangement scheme.

As for now the height of the racks is approx. 6 units (~27 cm) and is subject for further ompitimization.

The final 4-to-1 power combiner is assumed to have 4 3-1/8" EIA input flanges and a single 6-1/8" EIA output.

SUMMARY

The 352 MHz 400 kW pulsed machine is now in the design stage. In this paper, class-AB power amplifier modules based on Freescale 50V LDMOS transistors, box-shaped power combiner and the current system topology are described.

We are now working on the flexibility and scalability of the system so that it can be easily adapted to wide variety range of customers requirements on total output RF power, pulse length, duty cycles etc.

THE LAYOUT OF 72 MHz 16 kW RF POWER GENERATOR

A. Smirnov, A. Krasnov, I. Rezanov, E. Ivanov, K. Nikolskiy, S. Polikhov, G. Sharkov,
Siemens Research Center LLC, Moscow, Russia

Abstract

In this paper, we present the current design of the RF power generator for medical cyclotron Eclipse (Siemens Healthcare) based on solid-state architecture. The 16 kW machine operating at 72 MHz in continuous wave regime is being assembled into standard 19" cabinet. Brief description and technical solutions regarding 2 k W (Class-AB, Si transistor based) RF modules, power combiner and control system are shown.

INTRODUCTION

High power RF sources are important elements for most of accelerators that have found growing number of applications in physics and medicine. Current power amplifier will feed Eclipse cyclotron that is being used for PET isotopes production (^{18}F, ^{11}C, ^{13}N and ^{15}O) with H- ions at 11 MeV [1].

The main benefits of the generator under development are its smaller footprint, perspective of lower cost, better reliability and higher efficiency, achieved with class-AB operation, compared to conventional RF power sources like klystrons or other vacuum tubes generators. The solid-state microwave power amplifier modules based on Freescale LDMOS transistors arranged in parallel push-pull circuits, are designed on PCB boards.

All modules are connected to a power combiner with 50 Ohm coaxial cables.

RF POWER MODULES

We have designed and manufactured compact RF power amplifier (RFPA) modules with two pairs of Freescale™ MRF6V2010NR1 (driver stage) and MRFE6VP1K2H (main stage) transistors arranged in push-pull topology as shown on Fig. 1.

The frequency is adjustable between 72 and 73 MHz because cyclotron resonant frequency changes in this range during operation.

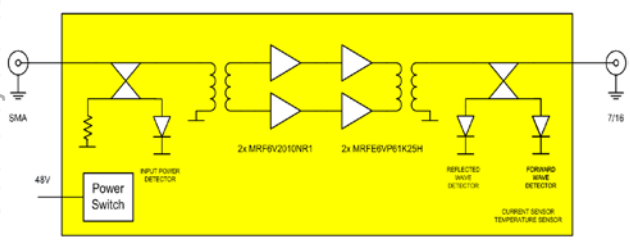

Figure 1: Parallel push-pull circuit.

The manufactured module prototype is presented on Fig. 2. Arlon AD255 with ε=2.55 is used a substrate material. The transistors are fed with 180^0 phaseshift, provided with an RF transformer. Achieved RF performance is shown in Table 1.

Table 1: RFPA Specifications

Parameter	Value
Bandwidth	72..73 MHz
Output RF power	max. 2100 W
RF efficiency	~75% (>80% planned)
Gain	52..55 dB
Input RF power	max. 30 mW
Supply voltage	48 V
Input/Output impedance	50 Ohm
Input/Output VSWR	max 1.3
Dimensions	16×25 cm^2

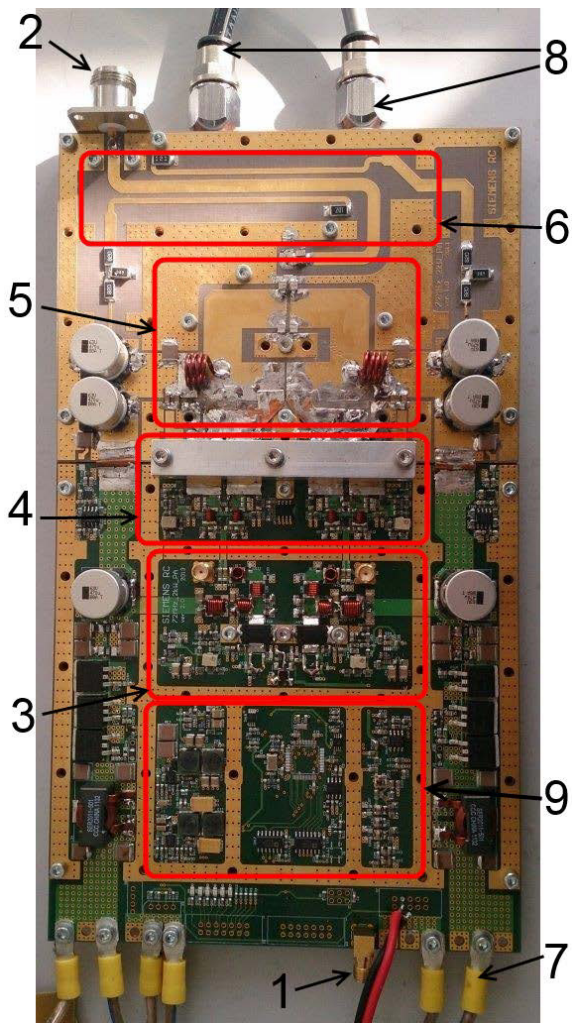

Figure 2: RFPA module: 1 – RF input; 2 – RF output; 3 – driver stage; 4 – main amp stage; 5 – output matching transformer; 6 – output directional coupler; 7 – DC supply; 8 – water cooling tubes; 9 – MCU unit.

MCU (microcontroller unit) is a logic scheme that is able to collect the following measured parameters and and communicates with the external control system:

- Supply voltage and current;
- Input LLRF power level;
- Forward/reflected power at the RFPA output.

A set of nine of these RFPAs (giving total output RF power up to 18 kW) with individual off-shelf 3kW air-cooled AC-DC converters and EMI filters are packaged inside nine 19" racks of 2 units (~90 mm) height as shown on Fig. 3.

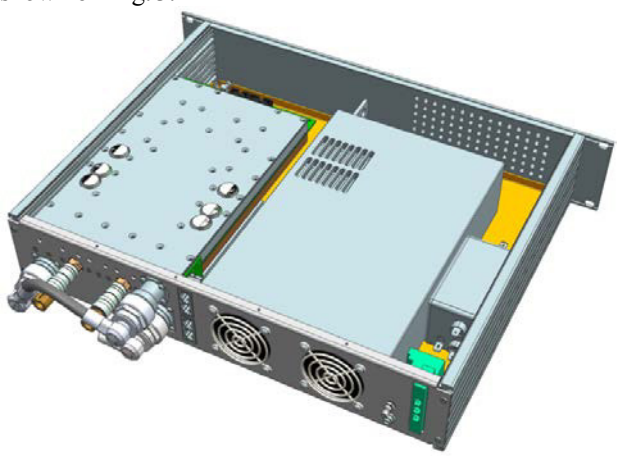

Figure 3: Single RFPA rack.

The RF efficiency dependence on output RF power is plotted on Fig. 4.

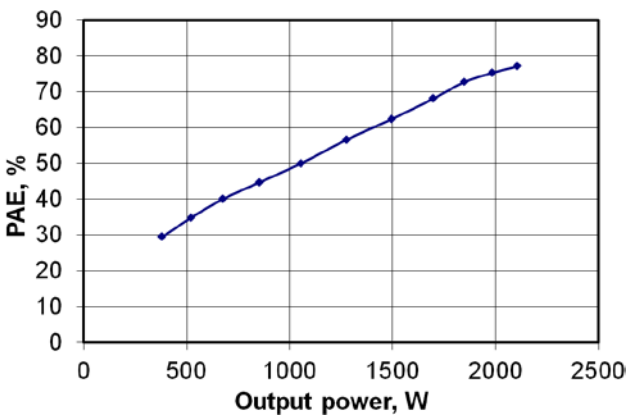

Figure 4: Measured RFPA efficiency vs. output RF power.

POWER COMBINER

Most of power combiners available on the market are based on coaxial geometry and are huge. In order to achieve the best compactness of the generator we have designed and manufactured the planar power combiner of 1 unit (~45 mm) height (see Fig. 5). It has nine 7-16 RF inputs and 1-5/8" EIA output coaxial flange.

Figure 5: 9-to-1 planar power combiner.

The inner conductor with the outer shielding aluminium case forms two sections of rectangular-coaxial serving as pre-combining and matching elements. The oval-shaped hole in the pre-combining part serves for input signals amplitude and phase balancing. The water-cooling tubes shapes have been optimized to introduce low perturbation of the EM fields.

Power combiner S-parameters measurement results referring to the common output port 1 are plotted on Fig. 6, other RF characteristics are listed in Table 2.

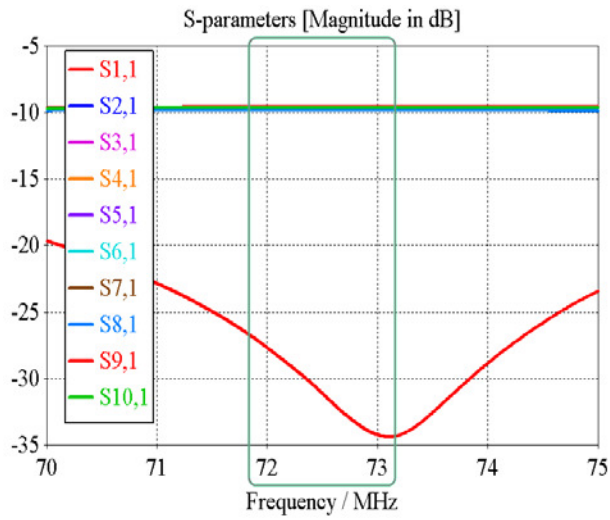

Figure 6: Measured S-parameters plot (operation frequency range is highlighted).

Table 2: Power Combiner Features

Parameter	Value
Bandwidth	72..73 MHz
Return loss	27..34 dB
Dissipated RF power ratio	0.1 %
Power splitting equality	<1 %
Dimensions	45×43×4.5 cm^3

Copyright © 2013 CC-BY-3.0 and by the respective authors

GENERATOR FORMFACTOR

All 12 blocks including power distribution, control, measurement and water-cooling systems will be assembled in 19" cabinet presented with components arrangement on Fig. 7.

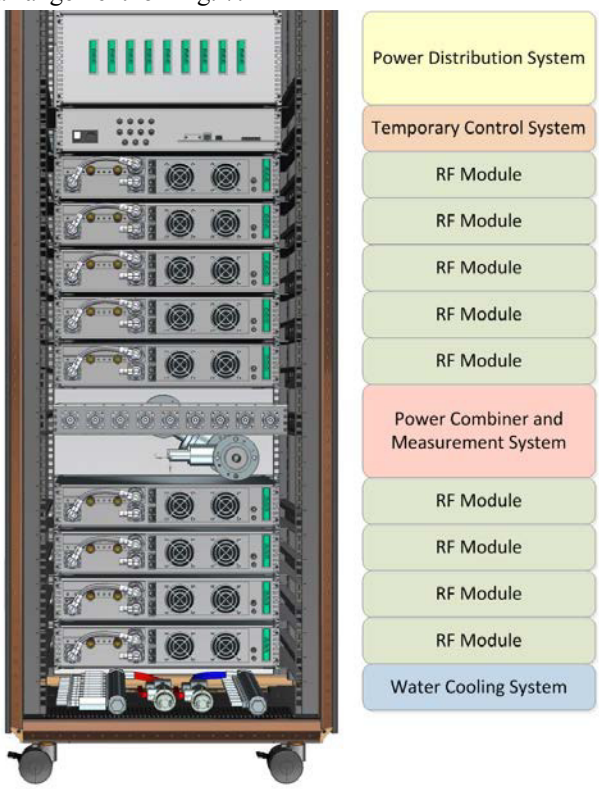

Figure 7: Generator assembly and arrangement scheme.

According to the current preliminary design the total height of the cabinet is 30 units (~1.4 m) and will be reduced down to 18 u nits (~80 cm) by arranging the components closer to each other – especially by putting all RFPAs into a single 4 units (~18 cm) high rack and uniting measurement system with the power combiner, as shown on Fig. 8.

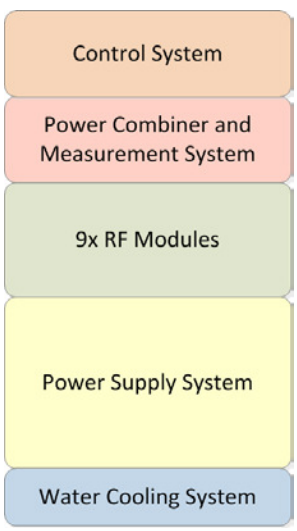

Figure 8: Goal scheme of the generator design.

The following is brief descriptions of the components.

Temporary Control System

The control system creates the reference signal, performs its splitting and amplifying. Each channel provides independent phase shift and adjustment of the transmission coefficients between master oscillator and the RFPA LLRF inputs. It is also possible to use an external reference signal.

Control system also examines the output RF signal and can adjust its phase and amplitude.

Power Distribution System

The generator can be used under 110V or 220V three-phase electrical network. The distribution system equally divides power between three phases by connecting three RFPA modules to each phase.

Cooling system located at the bottom of the cabinet provides the water flow through the RFPA modules and the power combiner.

SUMMARY

We have presented the current design of the 72 MHz 18kW (CW) power generator that is now being assembled and undergoing high power tests. The solid-state class-AB RF amplifiers show commendable efficiency of 75% at the operation output RF power level of 2 kW and will be improved to have over 80%.

As for now, the total height of the prototype device is 1.4 m and we are making efforts to shorten it down to 80 cm.

OVERVIEW OF THE RHIC E-LENS SUPERCONDUCTING MAGNET POWER SUPPLY SYSTEM *

D. Bruno#, A.Di Lieto, G. Ganetis, R.F. Lambiase, W. Louie, C. Mi, T. Samms, J. Sandberg,
Brookhaven National Laboratory, Brookhaven Science Associates, Upton, NY, 11973, USA.

Abstract

A new superconducting solenoid magnet was installed in the yellow ring of RHIC before Run 13 as part of the e-lens project. The second solenoid superconducting magnet will be installed in RHIC after Run 13 is over. There are 6 power supplies required for the solenoid, fringe and anti-fringe coils for both magnets. Commercial off the shelf unipolar power supplies are used to power the solenoid, fringe and anti-fringe coils. There are 24 corrector power supplies required for both magnets. Custom built 50A bipolar power supplies are used to power the correctors. Quench protection and quench detection have also been installed in this power supply system. In addition, 4 new phase shift power supplies have been installed in RHIC which are needed for the new e-lens system. These phase shift power supplies have been installed across the yellow focusing and defocusing arcs as well as the blue focusing and defocusing arcs from sector 8 to sector 10. Power Supply technology, control system, connections, the quench detection/protection system, and status will be presented.

E-LENS POWER SUPPLIES

Power Supplies Description

There are thirty power supplies (p.s.'s) used in the e-lens p.s. system. Fifteen p.s.'s for each magnet. These are all current regulated power supplies with a DC Current Transformer (DCCT) current sensing element.

The two Solenoid p.s.'s are rated at 20Volts and 750Amps dc. The ac input to both Solenoid p.s.'s is 480Vac. The two Fringe and two Anti-Fringe p.s.'s are rated at 15Volts and 534Amps dc. The ac input to the Fringe and Anti-Fringe p.s.'s is 480Vac. The Solenoid and Helical p.s.'s are commercially available voltage regulated switchmode p.s.'s which are used within the BNL designed current regulator. The required p.s. current reproducibility is 0.01% of maximum current.

The twenty four bipolar trim p.s.'s are 20Volts and 50Amps dc. The ac input to the bipolar trim p.s.'s is 208VAc. These are the same bipolar p.s.'s that are used for the RHIC corrector magnets. The required p.s. current reproducibility for the trim p.s.'s is 0.1% of maximum current.

During normal operation these p.s.'s ramp up slowly to a dc level and stay there.

The Solenoid, Fringe and Anti-Fringe p.s.'s are all connected to their own quench protection assemblies (QPA's). These QPA's contain an energy extraction resistor across an IGBT switch as well as a diode across the output of the p.s. The IGBT and energy extraction resistor are connected to the positive output terminal of the p.s. and the magnet. The diode is connected across the dc terminals of the p.s. When a fault occurs in the p.s. or the QPA, or if the magnet quenches, the diode conducts across the p.s. and the IGBT opens so the energy extraction resistor is now in series with the load. The current from the load goes through the diode and through the energy extraction resistor. The supply also trips to the STANDBY-FAULT state. A DCCT was installed in the QPA for the regulation of the e-lens p.s. The trim p.s.'s don't have a separate QPA; they have a crowbar with an energy extraction resistor built into them.

There is a quench detector (qd) for the e-lens p.s. system which monitors the voltage across the magnets and the current of the magnets. The qd trips the p.s. to STANDBY-FAULT if a quench is detected. Whenever the p.s. trips to the STANDBY-FAULT state, the energy extraction resistor becomes part of the circuit.

e-Lens P.S. Magnet Loads

There are 17 superconducting magnets in one cryostat. The main Solenoid is connected to one p.s. The two Fringe magnets are connected in series to one p.s. The two Anti-Fringe magnets are connected in series to one p.s. The 12 trim magnets are connected to 12 individual p.s.'s. The Solenoid magnet has an inductance of 14H. Each Fringe magnet has an inductance of 515mH. Each Anti-Fringe magnet has an inductance of 38.4mH. The two long (vertical and horizontal) trim magnets are 5.34mH each. The 5 short vertical and 5 short horizontal trim magnets are 19.2mH each. The dc resistance of the corrector cables to the magnets is between 74mohms and 120mohms depending on the cable size used.

Quench Detection for e-Lens

The yellow solenoid magnet is made up of 11 double layers (coils). In order to protect the magnet during a quench the coil difference is taken between 5 coils and 6 coils. If this coil difference ever exceeds 125mV the qd will tell the QPA to open the series IGBT, then the energy extraction resistor is connected in series with the load. The p.s. contactor opens after the IGBT in the QPA opens. The blue solenoid magnet is made up of 10 double layers. The coil difference is taken between 6 coils and 4 coils because of the available voltage taps.

There are 2 Fringe coils in each magnet and 2 Anti-Fringe coils in each magnet. Each Fringe coil has dc terminals that come out of the magnet. The Two Fringe coils are connected in series outside of the magnet to one

* Work supported by Brookhaven Science Associates, LLC under Contract No. DE-AC02-98CH10886 with the U.S. Department of Energy
# bruno@bnl.gov

Copyright © 2013 CC-BY-3.0 and by the respective authors

p.s. The coil difference is taken between these two Fringe coils. The qd coil difference trip setting is 125mV. Each Anti-Fringe coil has dc terminals that come out of the magnet. The two Anti-Fringe coils are connected in series outside of the magnet to one p.s. The coil difference is taken between these two Anti-Fringe coils. The qd coil difference trip setting is 125mV.

The gas cooled leads for the Solenoid, Fringe and Anti-Fringe coils are set to trip at 250mV.

The super conducting leads for the Solenoid, Fringe and Anti-Fringe coils are set to trip at 25mV.

The corrector coils do not have qd on the coils, gas cooled leads or superconducting leads. The p.s.'s have an overvoltage interlock which fires a crowbar SCR and connects an energy extraction resistor in series with the magnet coil when the voltage crosses a threshold. The overvoltage trip has been adjusted to make sure that we stay below the Miits rating the corrector coils and superconducting leads when the corrector coil or superconducting leads quench.

Quench Protection for e-Lens

This is the Miits calculation for the solenoid magnet coil.

- The solenoid maximum voltage can see to is 600V across the magnet or +/-300V to ground.
- The maximum current for the magnet is 500A.
- The energy extraction resistor = 600V / 500A = 1.2ohms.
- The inductance of the magnet = 14H.
- The time constant τ = 11.67seconds.
- Miits rating of the solenoid = $I^2(\tau/2)*10^{-6}$=1.46Miits
- The Miits rating of the magnet must be at least 1.46Miits.

The original design of the solenoid magnet showed it could only absorb 0.5Miits. Diodes were added across each solenoid coil in order to raise the magnet's Miits rating from 0.5Miits to 1.5 Miits. These diodes are able to handle 1.5Miits.

The solenoid superconducting leads also had to have their Miits rating raised from 0.5Miits to 1.5 Miits. Stabilizing copper was added to the leads to increase the Miits rating.

The energy extraction resistor for the solenoid magnet was built to absorb 1.75MJ ($E=1/2LI^2$) with a temperature rise of 100C. A stainless steel resistor was used and it was assumed that all of the energy was dumped into the stainless steel. Using q = m x C x ΔT one can solve for m = mass of stainless steel resistor. C= specific heat of material, q=energy dumped into material and ΔT is the desired temperature rise. Once the mass is known the resistor can be constructed.

For the Fringe magnet, the maximum voltage to ground is +/-150V and the maximum current is 500A. For 2 coils in series the Miits rating needs to be at least 0.215 Miits. The Fringe coils are designed for 0.48Miits so no extra protection was required for the Fringe coils.

The energy extraction resistor for the Fringe magnet was built to absorb 128.75KJ ($E=1/2LI^2$) with a temperature rise of 100C. A stainless steel resistor was used.

For Anti-Fringe magnet, the maximum voltage to ground is +/-50V and the maximum current is 400A. For 2 coils in series the Miits rating needs to be at least 0.0215 Miits. The Fringe coils are designed for 0.48Miits so no extra protection was required for the Fringe coils.

The energy extraction resistor for the Anti-Fringe magnet was built to absorb 6.3KJ ($E=1/2LI^2$) with a temperature rise of 100C. A stainless steel resistor was used.

For the corrector the voltage threshold the SCR crowbar circuit is set to fire at 8V (and the current is limited to 45A) which tells us the magnet must absorb at 1847 Miits. The corrector coils, and superconducting leads, Miits rating is 2296 so we are well below the rating.

NEW PHASE SHIFT POWER SUPPLIES

Power Supply Configuration

Four new phase shift ps's (to shift the phase of the beam for e-lens) were installed in RHIC during RHIC runs 12 and 13.

Two new phase shift p.s.'s were installed in RHIC during Run 12. One was installed in the blue ring on the quad defocusing bus from sector 8 to sector 9 across the quad arc magnets. The other p.s. was installed in the yellow ring on the quad defocusing bus from sector 8 to sector 9 across the quad arc magnets.

In Run 13 two more phase shift ps's were installed in RHIC. One was installed in the blue ring on the quad focusing bus from sector 8 to sector 9 across the quad arc magnets. The other p.s. was installed in the yellow ring on the quad focusing bus from sector 8 to sector 9 across the quad arc magnets. All four phase shift p.s.'s were operational for run 13. Each p.s. is connected to 12 quad magnets in each arc. The total inductance each p.s. sees is about 18mH.

All four of the phase shift p.s.'s are located in one service building.

Power Supplies Description

The phase shift p.s.'s are commercially available voltage regulated switchmode p.s.'s which are used within the BNL designed current regulator. These p.s.'s are rated at 16Volts and 185Amps dc. The ac input to these p.s.'s is 208Volts ac and 12Amps rms.

The phase shift p.s.'s each have a QPA which operates in a similar way to the e-lens power supplies QPA's, however, a crowbar SCR was used to short out the p.s. instead of a diode.

Quench Detection Modification for Phase Shift P.S.'s

The qd's for the phase shift p.s.'s reside in two service buildings (1008B and 1010A) and one alcove (9B).

The voltage of the arc quad magnets was already being measured in the alcove 9B qd from the original design of RHIC. The calculation of the arc quad magnets voltage,

Copyright © 2013 CC-BY-3.0 and by the respective authors

using the di/dt method, is also done in the same qd. The voltage calculation had to modified to include the current contribution of the phase shift p.s.'s. This was achieved by sending the p.s. current readback signal from the p.s.'s in the service building (through the tunnel) to the alcove over fiber optics.

The qd voltage tap measurement of the gas cooled lead and super conducting lead was already being done in 2 service buildings (1008B and 1010A) from the original design of RHIC. These voltage taps had to be modified to include the contribution of the phase shift ps current. This was done by sending the p.s. current setpoint over the Real Time Data Link (RTDL) from the p.s. Waveform Generators (WFG's) located in 1010A to the qd's located in 1008B and 1010A.

CONTROL SYSTEM

e-lens and Phase Shift P.S. Control System

Both the e-lens and phase shift p.s.'s use the same 3u chassis control bucket. In this control bucket resides the setpoint card, the current regulator card, the buffer card, the DC overcurrent (DCOC) card, the digital isolation card and the control card. The setpoint card receives a 0-10V analog signal from a fiber optic interface card which resides in another bucket. This analog setpoint is sent over the 3u control chassis backplane to the BNL designed current regulator card. This current regulator card has a removable PC board for adjusting time constants to stabilize the p.s. current loop. The buffer card sends four analog signals back to the Multiplexed Analog to Digital Converter (MADC). These four signals are p.s. current setpoint, output current, output voltage and p.s. current error. The phase shift p.s.'s and the e-lens Fringe and Anti-Fringe p.s.'s use a 0-10V output DCCT head. The e-lens Solenoid p.s. uses a current output DCCT head. This current output is sent to a BNL designed DCCT card which converts the current to a voltage. The DCOC card receives the shunt input from the commercial p.s. shunt and uses this shunt on the DCOC card. The digital isolation card receives commands from a Node card which is external to the p.s. and sends p.s. statuses back to this Node card. The Node card communicates over a MODBUS Plus network to a MODICON Programmable Logic Controller (PLC).

OPERATIONAL EXPERIENCE & STATUS

Phase Shift P.S. Problems During Runs 12 & 13

During Run 12 some problems were encountered with the first two phase shift p.s.'s. We learned from these problems in order to improve the reliability of these p.s.'s for Run 13. The problems during Run 12 included:

- Running a copper BNC cable for the p.s. current readback to the qd through the tunnel. The current readback would move with beam. This was corrected by running a fiber through the tunnel.
- Workmanship problems with the wiring harness which caused a ground fault and other problems. Workmanship was improved to correct this problem and inspections were done.
- The p.s. isolation voltage rating was below the rating required for p.s.'s in the ring. This did not cause any problems but still was corrected. New p.s.'s were purchased with the correct voltage isolation rating.
- Open channels on the qd card picking up a signal from an adjacent channel, which had a p.s. current readback on it, would cause the qd to trip out. These open channels were shorted out.
- A hard reset was required for the yellow qd's to accept changes made for the yellow phase shift p.s.'s.

e-Lens P.S. Testing

The e-lens p.s.'s have not been used by operations for the RHIC runs yet but the yellow e-lens p.s's have been tested during RHIC run 13 and at the end of RHIC run 13.

The solenoid ps. was operated up to 392A maximum. The Fringe p.s. was operated up to 470A maximum and the Anti-Fringe p.s. was operated up to 330A.

One problem encountered with the e-lens p.s.'s was the placement of the DCCT head in the QPA. The DCCT head was placed too close to the energy extraction dc cable. When a quench would occur, and the energy extraction system would kick in, the DCCT head would see a spike on the current during the decay. The DCCT head was moved to correct this problem.

When the p.s.'s are off we have seen that the coil voltage taps pick up a signal when adjacent warm magnets are ramped. Injecting or dumping beam might also affect these coil taps. This has caused the qd to trip. This is currently being investigated.

The correctors were not been tested on the magnet as of yet but they have been tested on short circuits.

ACKNOWLEDGEMENTS

The authors would like to thank the technician's in the Collider Electrical p.s. group who worked very hard on these p.s.'s. 200 KW CW, 350 MHZ MULTIPLE BEAM INDUCTIVE OUTPUT TUBE

R. Lawrence Ives, Michael Read, David Marsden, George Collins, Rasul Karimov,
Calabazas Creek Research, Inc., San Mateo, CA 94404 USA
Takuji Kimura, Edward Eisen, Communications & Power Industries, LLC,
Palo Alto, CA 94304 USA

Abstract

Assembly is nearing completion of a 350 MHz, 200 kW CW, multiple beam, inductive output tube. The device incorporates seven electron beams interacting in a single, fundamental mode, output cavity. A single collector dissipates the spent beam power, and input and output power is transmitted in coaxial waveguide. Simulations predict 70 % efficiency with 23 dB gain. The tube is targeted for ion accelerators.

INTRODUCTION

Calabazas Creek Research, Inc. (CCR), in collaboration with Communications & Power Industries, LLC (CPI), is nearing completion of a 350 MHz, 200 kW CW, multiple beam, inductive output tube (MBIOT). This device is targeted for upgrade of the Advanced Photon Source (APS) at Argonne National Laboratory but will be applicable for a broad range of accelerator systems requiring RF power from 300 to 800 MHz. The MBIOT provides efficiencies higher than klystrons in a dramatically smaller device. The gain is limited to less than 24 dB; however, solid state drivers are commercially available providing several kilowatts of RF power. The principal challenge is designing an input cavity that will drive all electron guns at the same power and phase. This paper describes the design of the MBIOT and status of the assembly.

DESIGN

The MBIOT incorporates a single, coaxial input cavity to drive the seven electron guns. The tube uses electron guns produced by CPI for their single beam IOTs. The gun design is well established, and the performance has been verified through years of operation. Figure 1 shows the gun support plate and two of the guns.

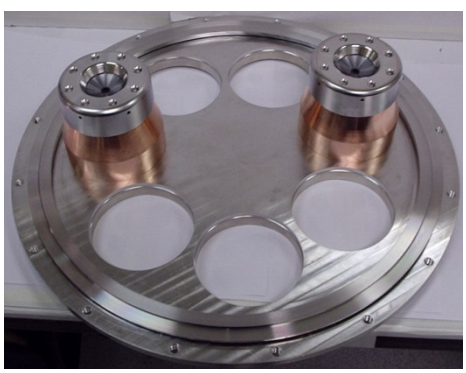

Figure 1: Gun support plate with two guns.

Figure 2 shows an HFSS simulation of the input cavity electric fields. The axis of the device is the Y-axis. Input power enters through a coax waveguide from the right. Heater power is provided by the leads emerging from the back of the gun and coupling to the top wall in the image.

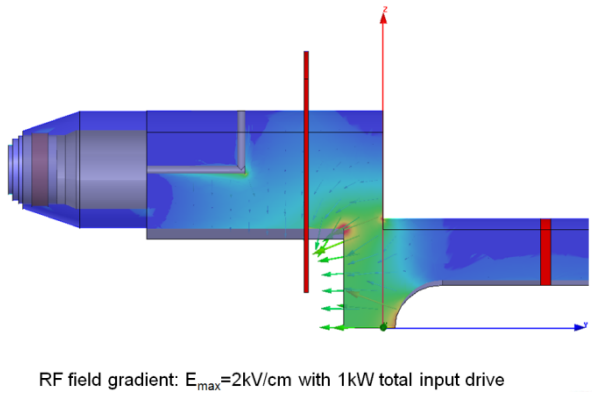

Figure 2: HFSS Simulation of MBIOT input cavity.

Figure 3 shows an HFSS simulation of the output cavity, with the beams entering from the left and the RF output power coupled to a coaxial waveguide on the axis. The external Q is determined by the penetration depth of the coax center conductor, which will be set during cold testing. The seven electron beams exit toward the right into a common collector that surrounds the output waveguide and window.

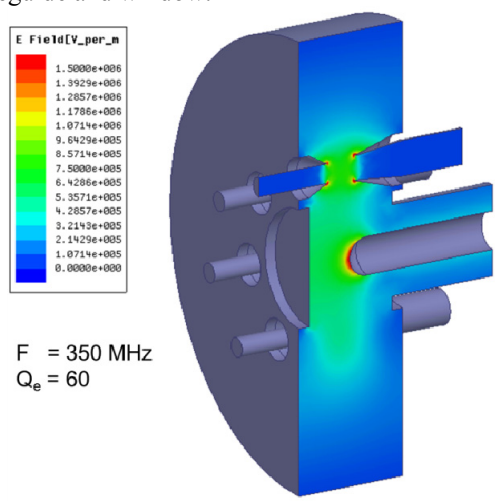

Figure 3: HFSS simulation of the output cavity.

Table 1 provides the performance specifications based on computer simulations. These satisfy the requirements for the APS upgrade and a number of anticipated accelerator systems.

Table 1: MBIOT performance specifications.

Parameter	Value
Frequency	350 MHz
Bandwidth	4 MHz
Output Power	200 kW CW
Gain	23 dB
Operating Voltage	30 kV
Efficiency	70%
Total Current	9.5 A
Number of Beams	7
Average current per beam	1.4 A

FABRICATION

Fabrication is almost complete with only a few assembly steps remaining. The seven guns are complete, as are the input cavity assembly, HV ceramic assembly, collector, and output window. Figure 4 shows a photograph of the input cavity assembly. Tuners behind each electron gun should provide some adjustment of the fields to balance emission from the seven guns. Figure 5 shows a photograph of the collector and output window and waveguide assembly.

Figure 4: Input cavity assembly.

Several issues arose during assembly of the output cavity. Because of the presence of iron and numerous braze joints associated with the electron beams, brazing was a significant challenge. The differential expansion between copper and iron caused significant distortion of the large plates. Sufficient material was incorporated for subassembly machining; however, the distortion also impacted braze alloy flow. Consequently, numerous braze cycles were required before vacuum tight assemblies were achieved. These assemblies are now complete, and final assembly of the output cavity will begin when cold tests are completed. Figure 6 shows a solid model of the completed MBIOT.

Figure 5: Collector and output window and waveguide assembly.

SUMMARY

A multiple beam inductive output tube for accelerator applications is nearing completion. The device is designed to produce 200 KW CW at 350 MHz. The IOT incorporates seven electron beams driven by a single, coaxial input cavity and excites a fundamental mode output cavity. The tube is targeted for ion and proton accelerators and colliders.

DESIGN AND FABRICATION OF A 10 MW, L-BAND, ANNULAR BEAM KLYSTRON*

Michael Read, Patrick Ferguson, R. Lawrence Ives, Robert Jackson, David Marsden, and George Collins
Calabazas Creek Research, Inc., 690 Port Drive, San Mateo, CA 94404

Abstract

Design improvements and fabrication of a 10 MW, 1.3 GHz Annular Beam Klystron are described. The principal improvement is the electron gun. Utilization of a Controlled Porosity Reservoir (CPR) cathode allows the use of a zero-compression gun, resulting in improved beam quality and reductions in the gun and solenoid diameters.

INTRODUCTION

Efforts to achieve a high efficiency 1.3 GHz, RF source for the International Linear Collider (ILC) and similar accelerators are centered on multiple beam klystrons (MBK) and, more recently, on a sheet beam klystron (SBK). CCR is developing an annular beam klystron (ABK) to fulfill the stringent requirements imposed by the ILC. That is, the minimum efficiency should be 65% at an RF output power of 10 MW, and the cathode current density should be less than 5 A/cm^2. The pulse width must be 1.5 milliseconds at a pulse frequency of 15 Hz.

Like the MBK, the ABK perveance can be much higher than in a traditional klystron. In contrast to the MBK, the ABK uses a single beam with simple transverse magnetic (TM) mode resonators. Thus, the tube is similar a traditional klystron and much simpler than an MBK. The ABK length, efficiency and gain are similar to those of an MBK with the same power, perveance and frequency.

The CCR ABK electron beam current is 140 A at 120 kV with inner and outer beam radii of 3.2 cm and 3.6 cm, respectively. The drift tube radius is 4 cm. The tube includes six cavities, and the solenoidal magnetic field is 1.5 kG. A schematic of the ABK electron gun and simulated beam is shown in Figure 1.

As previously reported [1], CCR created a design that met all requirements and was not significantly affected by the diocotron instability. However, the 2 kG magnetic field required more power than desired. With an ideal beam, calculations of the efficiency showed no degradation with fields down to at least 1.5 kG. However, lowering the field increased the beam ripple, which in turn decreased the efficiency. This ripple was due to gun optics.

Design of a gun using compression to create an annular beam is intrinsically difficult, due largely to the fact that there is no radial force on the inside surface of the beam. The original design with a 2 kG field used a complex interaction of the cyclotron motion with the radial fields of the anode to minimize the ripple. Unfortunately, it was not possible to maintain the balance of forces at lower magnetic fields.

Generating an annular beam without compression, i.e. with a uniform axial magnetic field, is much more straightforward. But, for this case, the beam density of 16 A/cm^2 is too high for conventional cathodes. This difficulty is avoided using a CCR Controlled Porosity Reservoir (CPR) cathode. Current densities to 50 A/cm^2 have been demonstrated with this type of cathode. At the required density of 16 A/cm^2, the predicted lifetime is 100,000 hours. This is more than adequate for most applications, including the ILC.

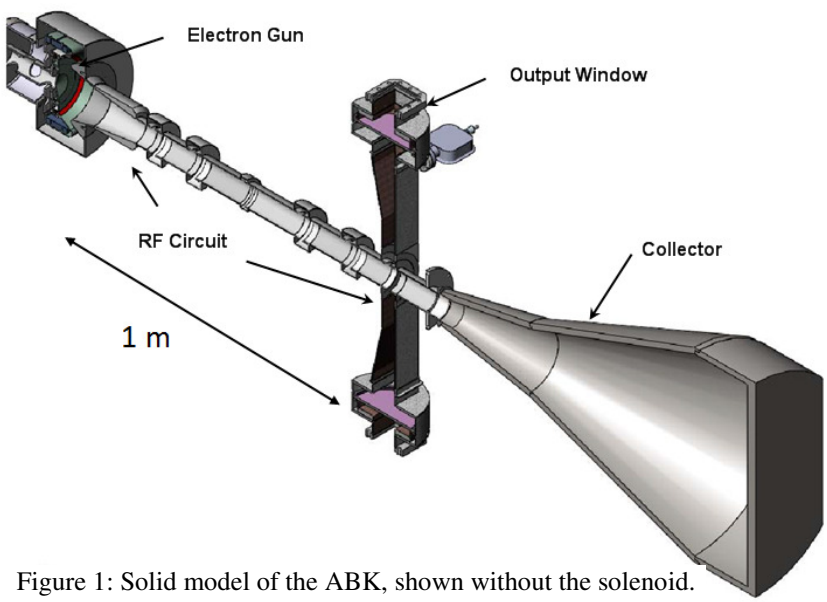

Figure 1: Solid model of the ABK, shown without the solenoid.

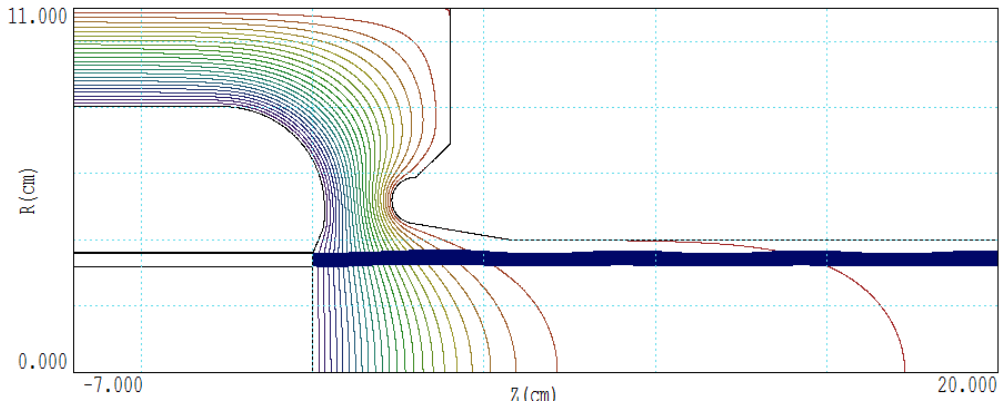

Figure 2: ABK gun with no compression of the beam.

ZERO COMPRESSION GUN

The new design for the gun is shown in Figure 2. There is still a modest ripple due to anode lensing, but, with a 1.5 kG magnetic field, the 4.7 mm peak-peak thickness is less than the original 5.1 mm with a 2 kG field. As with many guns with a high current density cathode, the electric field on the focus electrode was a concern. This, in fact, limited the shape of the focus electrode. In an ideal design, the focus electrode would extend further along an angle of roughly 67.5°, but this would have resulted in unacceptably high electric fields. As shown in Figure 3, the maximum field on the focus electrode is 63 kV/cm. This is under the engineering limit of 66 kV/cm for the design voltage and pulse width.

The average radius of the cathode is 3.4 cm, while the radius of the original cathode was 9 cm. The change in the cathode allowed reduction of the outer radius of the gun from 19 cm to 12 cm. This made it possible to decrease the radius of the solenoid, resulting in a 30% reduction in power required to produce the 1.5 kG field.

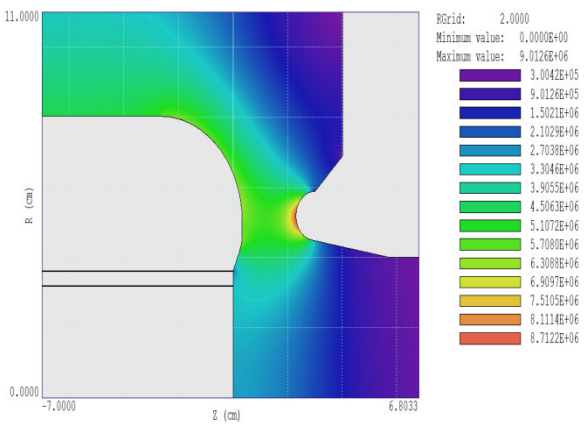

Figure 3: Electric field magnitude in the ABK gun.

FABRICATION

The ABK is being fabricated. Most of the tube uses conventional methods, but the cathode is unusual. Because of the nature of the CPR cathode material [2], the ABK cathode must be made in segments. The arrangement is shown in Figure 4. The cathode will be made in 6 modules,

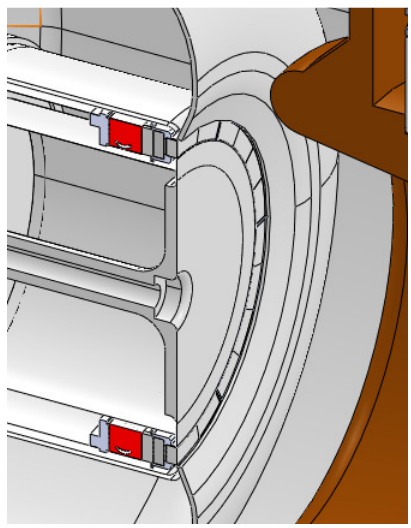

Figure 4: Cathode geometry.

each with 4 cathode segments. There was some concern that the asymmetries introduced by this fabrication method would degrade the beam optics. Simulations using the 3D trajectory code Beam Optics Analyzer (BOA) showed that this is not the case. In fact, even the removal of one of the segments has negligible impact on the beam trajectories. This is shown in Figures 5 and 6.

X-BAND RF POWER GENERATION VIA AN L-BAND ACCELERATOR SYSTEM AND USES

N. Sipahi, T. Sipahi, S. G. Biedron, S. V. Milton, CSU, Fort Collins, Colorado, USA

Abstract

The development of compact, cost effective sources of high-energy electron beams is a major thrust of the Colorado State University Accelerator Laboratory team. In this paper we describe a way to generate usable X-Band RF power suitable for powering an X-Band accelerating structure to overall potentials significantly higher than what we are presently able to obtain from our L-Band photocathode RF gun system. The concept relies on the use of the L-band accelerator beam to generate the X-band power that is then delivered to a suitable X-band structure. Once powered this X-band structure can be used to accelerate an electron bunch to high beam energies.

GENERAL CONCEPT

The CSU Accelerator Facility will serve as a test bed for particle and laser beam research and development. Our major asset is an L-band rf gun system capable of delivering 6-MeV electron bunches [1], these parameters are given in Table 1. We would like to use this L-band linac as a drive source to generate X-band power for accelerating electron beam with an X-band rf structure without the need for an external X-band power source. This system could then be used to accelerate the beam to an even higher energy that possible with the L-band system alone.

Table 1: Parameters of CSU Accelerator Laboratory

Laser Frequency	81.25 MHz
L-Band RF Gun Frequency	1.3 GHz
L-Band RF Gun Energy	6 MeV
L-Band Macro pulse Length	10 μs
X-band Linac Frequency	11.7 GHz
Repetition Rate	10 Hz
RF gun Charge/Bunch	3.5 nC

From our earlier work, we found that although significant gradients could be achieved with an X-band structure powered via our L-band beam system the integrated potential in the X-band structure was fundamentally limited by the drive beam energy loss [2]. This led us to explore an alternative arrangement where power was generated in a TW structure and then transferred to a separate optimized structure used for acceleration of a secondary beam. This basic arrangement is shown in Figure 1.

Using such an arrangement, we would like to achieve the highest possible energies for our given beam parameters and proposed X-band drive system.

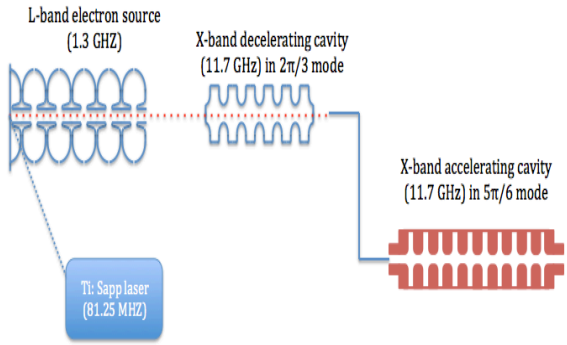

Figure 1: General layout of the two-beam X-band structure.

BEAM STUDIES FOR TWO DIFFERENT CAVITIES

Our study involves two different X-band accelerator structures, one to be used as a decelerating cavity that generates X-band power via the use of the beam from the L-band system, and the second one to be used as an accelerating cavity to achieve the highest practical potential for acceleration of the electron beam.

The one cell geometry for our X-band structures are defined in Figure 2 [3].

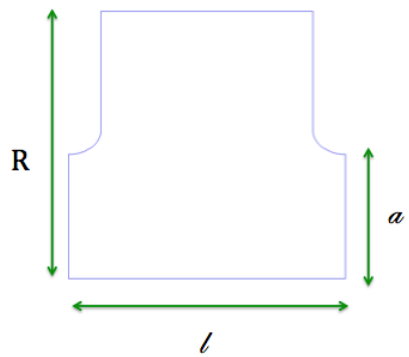

Figure 2: One cell structure of the X-band cavity.

The Beam – Cavity Interaction for the Decelerating Structure

In the decelerating cavity, the aim is to transfer energy from the L-Band RF system to the electron beam, consisting of bunches of charged particles, and then from the electron beam to the RF wave induced in the X-band decelerating structure, thus we design a structure that maximizes this interaction as in ref. 2.

The configuration is unconventional in that the X-band linac does not require a klystron system to achieve high accelerating fields. Rather it uses the power existing in the electron beam to resonantly power the fields in the structure.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Once the X-band structure has been powered up to the full potential a properly phased electron bunch can then be injected and accelerated, and for a properly designed and configured system can raise the beam energy to nearly twice what would have been available from the L-band system alone.

In this decelerating linac geometry, the iris radius (a) is 0.00512466 m, cavity radius (R) is 0.0110955 and the cell length (l) is 0.0085411 m as in ref. 3. The general parameters of this $2\pi/3$ traveling wave (TW) structure are given in Table 2. The X-band power generated with these parameters is 1.4 MW.

Table 2: Beam – Cavity Interaction Parameters for X-band Decelerating Cavity Structure

L-Band Bunch Charge	3.5 nC
L-Band Final Beam Energy	6 MeV
X-band Max. Gradient	62.7 MV/m
X-Band Shunt Impedance	57 MΩ/m
X-Band Eff. Shunt Impedance	33.1 MΩ/m
X-Band Q	6656
Damping Factor (t/τ)	0.1
X-Band Cell length	0.0854 m
Number of X-Band cells	18
Total length of X-Band structure	15.3 cm
Available X-Band Potential	5 MV

The Accelerating Structure

In this design we wish to maximize the energy gain in an optimum length and get highest integrated potential at the end of one or more the cavities; therefore, we chose to design a new geometry, and change the phase advance from $2\pi/3$ to a higher mode, $5\pi/6$. This slows the group velocity and allows us to increase the length of structure and provide more opportunity to increase the integrated potential [4].

The resulting geometry of the accelerating structure becomes (a) is 0.002566233 m, the cell length (l) 0.010676375 m, and the cell radius (R) decreases in this case as in ref 3.The general parameters of this structure are given in Table 3.

Table 3: Beam – Cavity Parameters for X-band Accelerating Cavity Structure

Dec. Cavity Final Beam Energy	11 MeV
Phase Advance	$5\pi/6$
a/λ	0.1
Acc. Cavity Shunt Impedance	185.7 MΩ/m
Acc. Cavity Quality Factor	7474
Acc. Cavity Cell length	0.010676375 m
Group Velocity (v_g/c)	0.95%

This basic configuration, i.e. an L-band gun system beam powering a decelerating cavity used to generate X-band power and all the power fed into a single optimized accelerating cavity achieves an integrated potential significantly higher than our original direct attempt; however, we considered three different scenarios that allowed us to achieve a higher potential with our new proposed system. The two different configurations are shown in Figure 3.

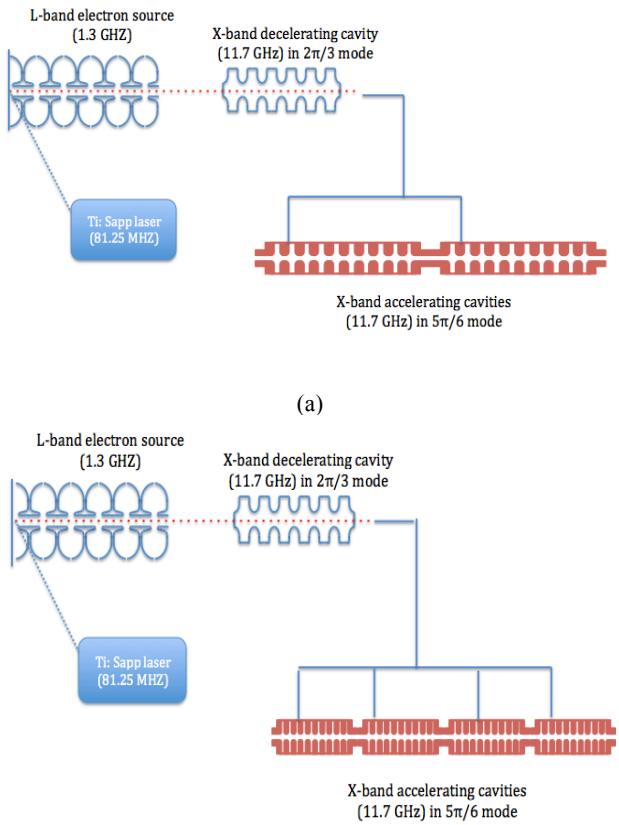

Figure 3: a) Two accelerating structure case b) Four accelerating structure case for the system under study.

In these configurations we divide the power into two or four different linacs to achieve a higher integrated potential than possible with a single structure; furthermore, if the input power and shunt impedance are fixed, the maximum energy gain over a structure of given length depends on maximizing the total attenuation parameter. In this case it becomes 1.26 [5]. Then, by using the quality factor and group velocity parameters from table 3, we can calculate the optimal accelerating cavity length. The beam loading parameters for the accelerating structures are given in Table 4.

Table 4: Available Potential and Maximum Energy Gain values for 0.72 m length accelerating cavity

Total Length of One Section	0.72 m
Number of X-Band cells	69.4

Copyright © 2013 CC-BY-3.0 and by the respective authors

Filling time for 1 Section	259 ns
Available Potential after 1 section	16.2 MV/m
Available Potential after 2 sections	22.9 MV/m
Available Potential after 4 sections	32.4 MV/m
Max. Energy gain after 1 section	12.6 MeV
Max. Energy gain after 2 sections	17.5 MeV
Max. Energy gain after 4 sections	24.8 MeV

As seen, by use of multiple accelerating structures, we can achieve a significantly higher integrated potential (Table 4) than in the single accelerating structure case.

DISCUSSION AND FUTURE STUDIES

We have shown that by proper design we can, by utilizing the beam from our L-band linac, resonantly excite an X-band decelerating structure to meaningful accelerating gradients. In our initial design example we achieved up to 5-MV additional accelerating gradient. Configured properly this implies that we can periodically achieve beam energies near double our original 6 MeV and potentially reach roughly 11 MeV in occasional single pulses without the need for an additional X-band power source after L-band structure. Additionally, after gaining 11 MeV, we can achieve higher potential by using accelerator structures that are designed and configured in a two-beam configuration. However, the amount of the potential that we can get depends on the higher mode of the cavities and the number of structures. Therefore, to optimize our case, we will continue to study the possible higher modes that can give higher integrated potential and check the limits of having more accelerating structures.

ACKNOWLEDGMENT

We wish to thank SLAC National Laboratory Facility for their support and funding and in particular the input from C. Adolphson. Also, we wish to thank the senior management of CSU for their support of the accelerator laboratory and accelerator education.

COMPONENTS OF HEATING AND FUELING OF FUSION PLASMAS*

K. Schrock, M. Gaudreau, J. Kinross-Wright, Diversified Technologies, Inc.,
35 Wiggins Ave., Bedford, MA 01730, USA

Abstract

Diversified Technologies, Inc. (DTI) has bench-tested a table-top scale 'Buck Matrix' modulator with an efficiency of ~96% which uses a single set of IGBT switches for voltage regulation, arc protection, and pulse modulation.

INTRODUCTION

Next generation fusion facilities will require many megawatts of RF power from dozens of gyrotrons. Each gyrotron requires a power system that must deliver high-voltage power, modulate cathode voltage, and protect these expensive gyrotrons from arcing damage. It must be highly efficient to minimize both the power and cooling costs associated with operation and to ensure high facility availability.

Conventional DC power systems, built from WWII era components, have provided the typical approach to powering this class of high-power RF vacuum devices for the last 50 years. These systems, with their variacs, inductrols, spark gaps, ignitrons, and tetrodes, traditionally suffer from reliability and availability problems and are often only 50 – 70% efficient. Scaling conventional RF power electronics technology for next generation high power fusion facilities is not practical in either cost or reliability.

The technology for off-the-shelf, reliable solid-state modulators does exist, but currently requires two layers of solid-state switches – a voltage regulation step followed by a modulator / opening switch for arc protection. These two-step approaches are unnecessarily large and expensive, and an approved approach will be presented.

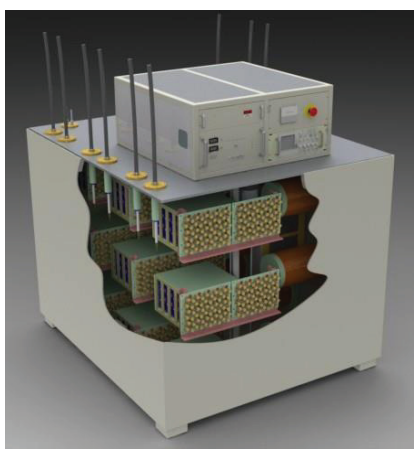

Figure 1: 75 kV, 45 A CW multi-phase buck-matrix regulator with low filter energy – serves dual purpose of regulating power and protecting a 1 - 1.5 MW gyrotron during arcs.

*Work supported by the Department of Energy

TECHNICAL APPROACH

Diversified Technologies, Inc. (DTI), under a DOE SBIR grant, has bench-tested a table-top scale 'Buck Matrix' modulator which uses a single set of IGBT switches for voltage regulation, arc protection, and pulse modulation.

DTI's Buck Matrix modulator (Figs. 1 and 2), with an efficiency of ~96%, cuts the size of the system in half, using a single layer of solid-state switches for both voltage regulation and arc protection/modulation. This cuts the total hardware costs by 30% or more, and eliminates the need for a separate opening switch or crowbar.

Although pulse step modulators also represent a one-step solution, their size and the complexity of their driving transformer make them more expensive than DTI's approach.

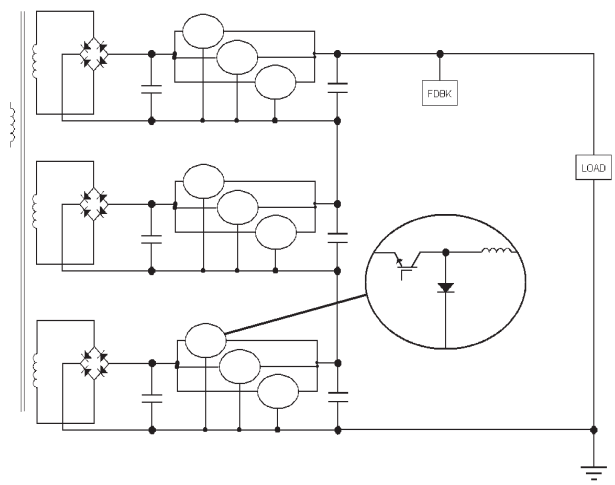

Figure 2: A series/parallel "Buck Matrix" topology combines superb ripple reduction and tube protection for minimum complexity and maximum efficiency. Transformer / Rectifier pairs are shown single-phase for simplicity.

OBJECTIVES

DTI focused on five primary objectives in developing the modulator. The first three focused on demonstrating the technical feasibility of the project: to assess any control system instabilities, to ensure the concept design would meet real gyrotron requirements, and to build and test a low voltage demonstration unit. The latter two tasks focused on the construction of a full-scale prototype. A high voltage electrical design for the full-scale system has been completed, as well as the ground work for the mechanical design, and the auxiliary systems have been

Copyright © 2013 CC-BY-3.0 and by the respective authors

defined, including the custom transformer-rectifier needed to power the Buck Matrix.

Design

Low stored energy is required in the Buck Matrix design to ensure that the tube is not damaged during arcs. This low stored energy is a major constraint of the design of the Buck Matrix; other key parameters are listed in Table 1.

Table 1: Key Specifications of the Prototype

Parameter	Full System	2x2 Demo	Units
Vin	95	2.5	kV
Vk	75	2.0	kV
Ik	45	2	A
Max Stored Energy	30	0.04	J
Max Voltage Ripple	1%	5%	

The principle behind the Buck Matrix converter is that very small output capacitors can be used, since the large out-of-phase ripple voltages will cancel each other out at the converter output. If we consider the case of a 2x2 Buck Matrix, the midpoint of the two sets of output stages sees significant ripple during the switching period.

Any ripple causes the current through each inductor to behave highly non-linearly. For example, a ground-side buck stage inductor will nominally see (Vi/2 - Vo/2) when its switch is turned on. If the ripple voltage at the midpoint swings 50% during a switch period, the voltage seen across the inductor would in reality vary from (Vi/2 - Vo/4) to (Vi/2 - 3Vo/4). The non-linear current waveform no longer has a predictable turn-off time, and the nominally stable operating point becomes marginally stable. Transient load or command changes have a nearly immediate effect on the output capacitor voltages, which can push the converter to a non-ideal operating point.

Simulation of the designed 2x2 Buck Matrix using fixed duty cycle control (open loop) showed a well-behaved circuit, with no output voltage overshoot and symmetric inductor waveforms.

A 3x3 system was later simulated (Figure 4). This system is harder to stabilize because of even smaller output capacitors and more component interactions in a 3x3 Buck Matrix. Simulations are not conclusive on whether fast peak-to-peak current regulation or slower voltage-mode feedback regulation result in a more stable system.

Experimentation

A low voltage 2x2 Buck Matrix was built to confirm the results of the simulation and analysis, and to demonstrate the feasibility of the Buck Matrix concept. Figure 3 shows the test setup.

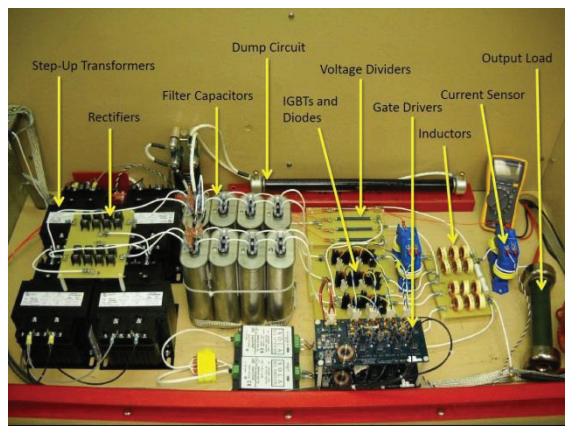

Figure 3: Components of the 2x2 experimental setup.

The 2x2 Buck Matrix performed as expected. Other than the inherent noise from the open hardware setup, the circuit waveforms nearly identically matched those from the simulations. The output ripples appropriately

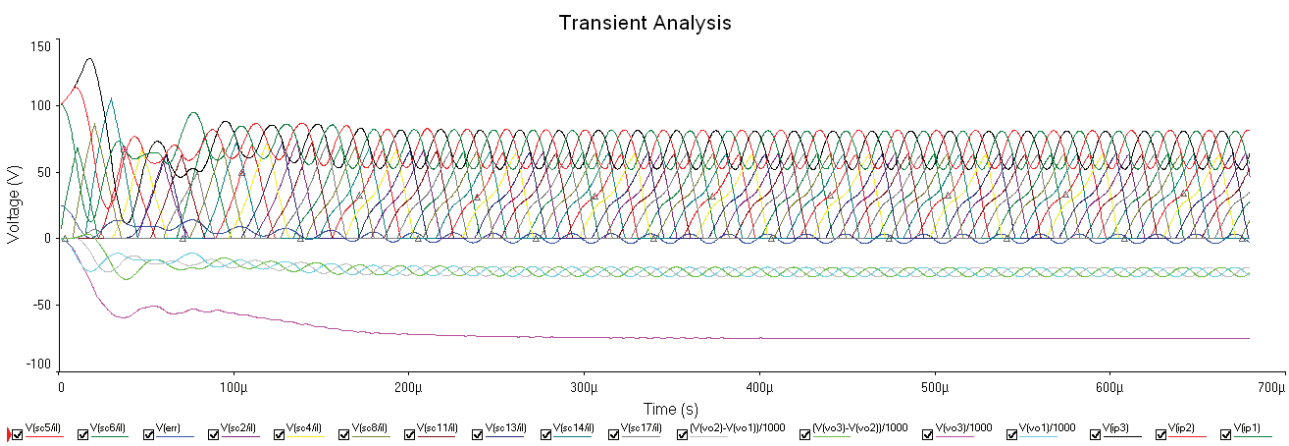

Figure 4: A 3x3 Buck Matrix under peak current mode control, with a fast PI voltage loop compensator. The response is fast, with symmetric inductor currents.

cancelled each other due to phase interleaving. The measured output ripple was approximately 7%; theoretical ripple was 5%. This discrepancy is due to small timing and component value differences. With slightly different inductor and capacitor values, and with slightly different IGBT and diode transition times, the individual component contributions are not perfectly symmetric, thus perfect cancellation is not possible.

Switch Resilience

To verify if standard silicon IGBTs or SiC JFETs could be run at the planned power levels and frequency, two DTI 10 kV switchplates (Figure 5) were manufactured: one with the SiC JFETs, and one with the silicon IGBTs. A test setup was constructed to verify full voltage and full current switching and conduction losses of these different switch plates (Figure 6). The result of this testing allows us to predict with confidence what the expected junction temperature of the transistor will be in the real buck matrix system.

Figure 5: Three DTI 10 kV solid-state switchplates.

Transistor Selection

Silicon Carbide (SiC) transistors have recently become commercially available at reasonable prices. SiC boasts extremely fast commutation, essentially eliminating switching losses in power converters. 85 milliohm and 45 milliohm SiC JFETs [normally-on devices which need to be operated in a cascode circuit and controlled with a low voltage (40 V), extremely low on-resistance and low switching-loss MOSFET] were evaluated.

Two of the tests related to the device physics performed were to examine the JFETs' ability to reverse-conduct (similarly to the internal body diode of many IGBTs), and to determine if the intrinsic over-voltage avalanche characteristics would simplify operation of these devices in series for high voltage applications.

Reverse Conduction

The JFETs do reverse-conduct, but testing revealed that the devices will break if operated with significant current in the reverse direction—similar current levels as the forward conduction current is enough to damage the devices. If reverse conduction is required, blocking and antiparallel diodes should be added

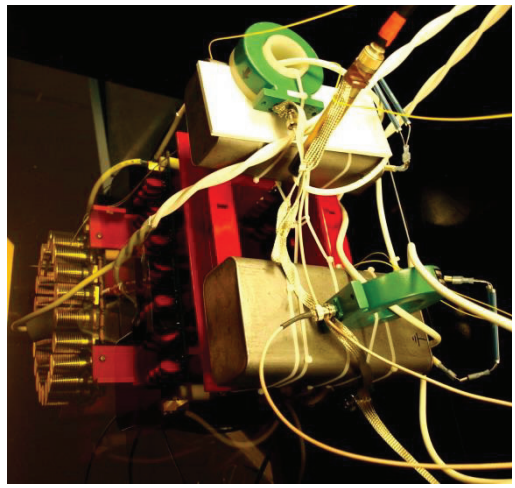

Figure 6: Switchplate test setup in dielectric oil. The assembly is vertically symmetric. A 20-stage switchplate with heatsinks is on the far left, at the bottom of the oil tank; above it is a high voltage diode assembly; on top are the two high voltage capacitors, and current sensors.

Avalanche

To test the avalanche characteristics, the JFETs were pulsed into an inductive load at very low pulsewidths (less than 1 microsecond) and low rep rate. When the JFET was turned off, the inductive voltage spike, which was a function of the input voltage and pulsewidth, would rise to above the device rating, and avalanche into the device. This worked as expected with very low avalanche energies, but damaged the device at higher avalanche energies.

Future Work

The huge reduction in ripple afforded by series/parallel multi-phasing allows the filters to become quite small, and it is precisely this reduction in stored energy in the filter – to below the threshold for arc damage – which enables the elimination of the second switch.

The results of this effort will eliminate half of this hardware, yielding approximately 30% savings, as well as improved system reliability and efficiency. The resulting design will be easily transferable to other voltage and current regimes, and is suitable for any CW or long pulse application – including future RF accelerators, light sources, and synchrotrons, and may also be applicable to other DOE programs, including the International Linear Collider (ILC). Other fusion power systems (e.g. ICRF, LHCD, neutral beam heating) may also make use of this technology with similar performance and cost advantages.

Abstract

Under a U.S. Department of Energy grant, Diversified Technologies, Inc. (DTI) is developing a short pulse, solid-state Marx modulator (Fig. 1). The modulator is designed for high efficiency in the 100 kV to 500 kV range, for currents up to 250 A, pulse lengths of 0.2 to 5.0 μs, and risetimes <300 ns. Key objectives of the development effort are modularity and scalability, combined with low cost and ease of manufacture. For short-pulse modulators, this Marx topology provides a means to achieve fast risetimes and flattop control that are not available with hard switch or transformer-coupled topologies.

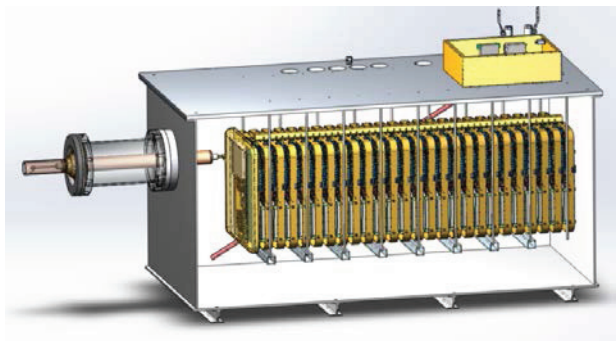

Figure 1 Planned 500 kV Marx modulator with an array of fifty of the plates shown in Figure 3.

INTRODUCTION

Under a DOE SBIR grant and based on research begun under the Next Generation Linear Collider (NLC) program, high energy, short-pulse modulators are being re-examined for the Compact Linear Collider (CLIC) and numerous X-Band accelerator designs. At the very high voltages required for these systems, however, all of the existing designs are based on pulse transformers, which significantly limit their performance and efficiency. There is not a fully optimized, transformerless modulator design capable of meeting the demanding requirements of very high voltage pulses at short pulsewidths.

BACKGROUND

A Marx generator is a system with energy storage capacitors which are charged in parallel at low voltage and discharged in series to provide high voltage output. This is a legacy idea, practiced for decades using resistor charging networks and spark-gaps for discharge. Constrained by the limits of closing switches, such systems required pulse forming networks and crowbars, with their attendant limitations

The Marx topology also enables features which are not common to hard switch modulators. Primary among these is the ability to control each module independently – and thus program the ultimate pulse voltage by choosing the number of modules triggered. The use of a bypass diode rated for full pulse current allows staggering of the modules' turn-on time, and ultimately enables full waveform synthesis in real-time.

TECHNICAL APPROACH

The Marx topology allows a new degree of freedom unavailable to other architectures – DTI can intentionally underdamp the series snubbing within the pulse circuit. This cannot be done conventionally – the reactive overshoot endangers the load. In a Marx, we can compensate for the overshoot by initially firing only a subset of the switches – thus "sling-shotting" the leading edge faster than otherwise possible. We can tune the number and timing of subsequent module firings to counter the reactive ringing, and hold a flattop pulse to the desired voltage and accuracy (Fig. 2).

Similarly, additional modules may be added to fire sequentially later in the pulse to compensate for capacitor droop. This is a critical enabling technology motivating Marx use for long-pulse accelerators (such as ILC), and yields valuable optimization even for very short-pulse systems. The reduction of capacitor size afforded by this flexibility further reduces parasitic capacitance, and thus reduces equipment size and cost while increasing power efficiency.

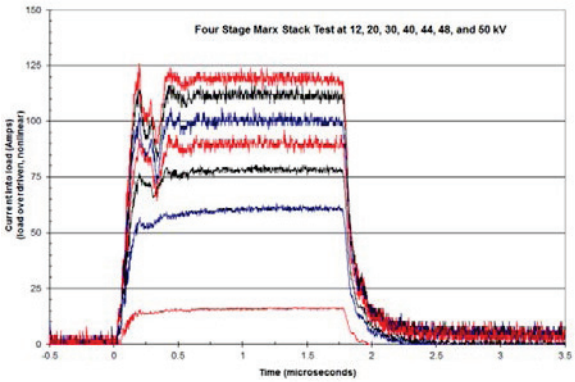

Figure 2 Test pulses of a four-stage Marx bank at 12, 20, 30, 40, 44, 48, and 50 kV. The notch at the beginning of the pulse is the intended result of induced overshoot, which decreases the rise time.

Architecture

The short-pulse modulator under development in this effort is a high peak-power pulse modulator of greater efficiency than presently available, in the 100 kV to 500 kV range, for currents of up to 250 A, pulse lengths of 0.2 to 5.0 us, and risetimes <300 ns (Table 1). A key objective of the development effort is a design which is modular and scalable, yet low cost, and easy to manufacture and maintain. Recently, DTI significantly reworked its original Marx bank architecture to achieve a low-cost, highly modular, and scalable design without compromising pulse performance.

Gate Drives

Table 1 Yale Marx Design Parameters

Pulse Voltage	500 kV
Pulse Current	250 A
Pulse Width	1.8 us
Repetition Rate	20 Hz
Module Voltage	12.5 kV
Module Capacitance	0.6 µF
# Modules for Base Pulse	40
Total # Modules in System	48 – 50
Expected Risetime	300 ns
Heater Voltage	24 VDC
Heater Current	21 A
Insulation	Oil

The relatively high per-module voltage (10-12.5 kV) precludes the use of single IGBTs within each module – thus series switch technology is an enabling feature for this system. For most high voltage modulators, all IGBTs pulse in unison, and a single ground based control system provides both motive power and timing control to all of the "floating" or "high-side" gate drives at the various successive stages. In this solid-state Marx modulator, the topology is such that each module can be independeltly controlled. With this flexibility, the externally supplied "command on" signal must be converted from a single command pulse into distinct ON-OFF commands, one for each module. The central ground-based control for the modulator performs this task, converting the input command into a sequence of ON-OFF commands to the modules to create the optimal pulse. An address – command structure between the controller and driver is used.

For this effort, we took the opportunity to redesign the gate drives with a different topology. Instead of the magnetically coupled gate pulses, we have chosen a more robust gate drive with independent magnetically coupled power and optically coupled gate triggers. This is a far more "brute force" approach, usually reserved for larger high voltage systems, but has the advantage that there is no asynchronous refresh, thus no opportunity for jitter.

Overall Topology

The physical layout of the Marx system has similarly undergone changes compared to our earlier work. In this effort, we revisited the ideal of a flat-pack design, where each module is a thin "pancake". Thus, the system-to-ground capacitance from each module is that of a thin segment of a coaxial capacitor. The large area of each "pancake" is exposed only to modules immediately above and below in the stack. Since the parasitic energy is proportional to V^2, rather than linear in V, we believe the new design will have better than a 10% parasitic capacitance reduction (hence faster risetime) than the prior approach, and far fewer mechanical components.

The co-location of devices inherent in the flat-pack design requires that all the shielding take place either within the multiple layers of the circuit board, or within shielding cans soldered onto the board. A peripheral corona shield minimizes voltage gradients between the Marx bank and the tank walls, as well as directing the parasitic charge into an appropriately stiff driven portion of the system circuitry.

Design Benefits

1) Reduced module costs

Through the use of PC board trace shielding and RF cans in sensitive areas of the circuit, we were able to co-locate controls directly on the board within reasonable proximity to pulsed current sections of the same board. By exposing the IGBTs directly to the oil, we can cool the devices effectively while eliminating machined parts and hardware, further reducing the module parts count, associated materials, and assembly costs. Since the flat-pack design significantly reduces voltage gradients from module to module within the Marx bank, the only significant need for corona and field reduction geometry is at the interface between the Marx bank stack and the walls of the tank. We anticipate more than a four-fold reduction in module mechanical costs, with the potential for additional reductions in manufacturing costs, compared to earlier designs.

Copyright © 2013 CC-BY-3.0 and by the respective authors

2) Simpler Interconnect

Each module in the redesigned Marx bank plugs directly into the two adjacent modules (Fig. 3; Fig. 5). We oriented the connectors and offset the board components and corona shields to allow any individual module to be added or removed from the stack, much like a book on a shelf, without any significant disassembly of support structures or disruption of the rest of the Marx bank. Since all module electrical connections and buswork are integral to the modules, only the fiber-optic control line (and optional fiber-optic monitor) needs to be externally connected. The first module in the stack plugs into a connector supplying charging HV, core bias current, auxiliary housekeeping power, and ground. A connector on the final module is connected to the Marx output coaxial cable, and includes a loopback for the common-mode choke bias current.

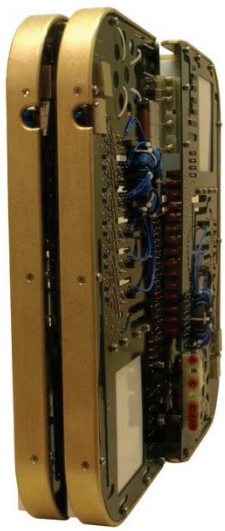

Figure 3 Stack of four connected modules viewed on edge. Fifty of these modules are shown connected in Fig. 1.

3) Scalability

The flat-pack Marx design is inherently modular and scalable, as additional plates may be added for a wide range of voltages. Whether at 100 or 500 kV, a Marx bank can use the same modules. The primary impact of additional plates is an increase in the charging current at the first plate, since it carries the current for all subsequent plates as well. Stray capacitance is also greatest at higher voltages, assuming constant spacing to the tank.

Prototype Testing

During testing of the prototype bank, we ran four modules with all modules simultaneously switched for a 1.5 µs pulse, with a 10 kV pre-charge into the system, resulting in a 40 kV output. The prototype modules performed flawlessly into high voltage, with none of the chatter or jitter that would otherwise be associated with gate drives impacted by noise coupling at high voltage. We then demonstrated the pulse-staggering capability of the Marx design by delaying the successive modules by 0, 0.5, 1.0, and 1.5 µs on a 2.3 µs pulse with a 7.5 kV pre-charge (Fig. 4). The distributed effect of the snubbing RL networks is clearly apparent here, with the fractional overshoot visible as each successive stage turns on into the high impedance load.

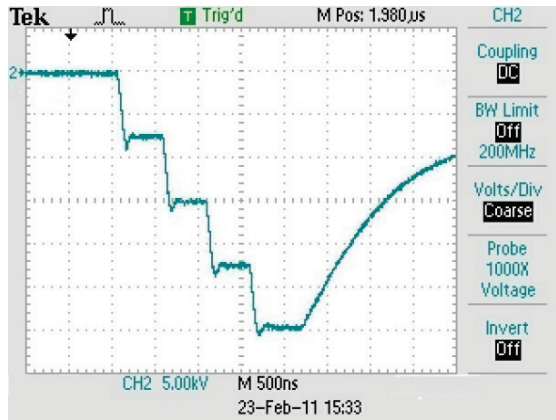

Figure 4 Four modules operated in staggered pulse mode, showing the individual control of each module.

Most recently, DTI has successfully tested a stack of 20 plates with a 12 kV pre-charge into a resistive load. The result was a 2 µs pulse output of approximately 240 kV and 200 amps. DTI will continue carefully constructing and testing modules to ensure the reliability and, above all else, safety of the equipment.

Plans/Conclusion

In Phase III, DTI will extend this design to future short-pulse, high voltage modulators for the next generation of planned accelerators, as well as transition this design to industrial / medical accelerators. We believe that the same combination of modular, low cost elements demonstrated in this Phase II effort will allow solid-state modulators to finally reach a price level that will supplant traditional (but low cost) thyratron / PFN designs currently used in these systems.

TEST OF AN L-BAND ENERGY-EFFICIENT SOLID STATE RF POWER SOURCE*

X. Chang, N. Barov, D.J. Newsham, and R. Wu, FAR-TECH, Inc., San Diego, CA 92121, USA

Abstract

We present the test results of a 1.497 GHz Solid State RF Power Source for the CEBAF linac at Thomas Jefferson National Accelerator Facility. The power amplifier was designed to operate at output power of 6.4 kW, with an overall efficiency greater than 55% at peak power, and is sufficiently compact to fit the existing rack space and cooling requirements at the installation site. Our solid state amplifier is designed for high efficiency, band width of more than ±5MHz at 1.497GHz, and long lifetime. The test results of the whole unit test will be shown.

INTRODUCTION

Thomas Jefferson National Accelerator Facility (TJNAF, JLab) is upgrading their RF system [1] for upgrading their electron beam energy. One of the options is to replace the klystron RF sources with the solid state amplifiers. Compared to a conventional klystron RF source, the solid state amplifier is easier to obtain high efficiency, long lifetime, and is safer due to low operating voltage, with a lower maintenance cost.

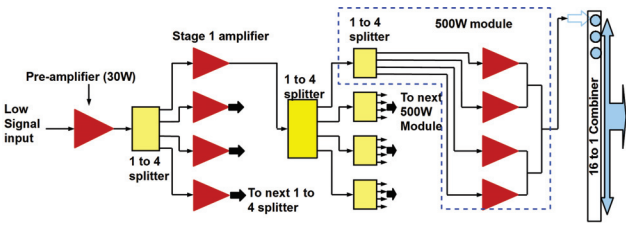

Figure 1: 8 kW Amplifier diagram. There are totally 16 of 500 W module.

Figure 1 is the diagram of an 8 kW solid state amplifier RF source. The low signal is amplified by a commercial 30 W amplifier (pre-amplifier) to drive the 4 transistors in the "stage 1" amplifier, which is contained in a single housing with 16 outputs. Each transistor in stage 1 has a peak output power of greater than 125 W. The output from each stage 1 transistor is split into 16 signals by two 1-to-4 splitters (one contained in the stage 1 amplifier housing and one contained in the 500 W module) and drive the 16 transistors in 4 of the 500 W modules. Isolators are placed between the two levels of splitting. Each transistor in the 500 W module has a circulator with load to prevent cross talking between transistor boards and to isolate the transistors from any reflected power. There are a total of 16 500 W modules and their outputs are combined in a 16-to-1 combiner.

EXPERIMENTS

Transistor Board Development

Our chose RF3934 [2] as our amplifier transistors. It's a wideband transistor which an operate at 120W power. Previous testing to combine the output of 4 transistor boards with a commercial combiner [3] helped improve the performance of the transistor board prior to incorporating the transistors and in-house 4-to-1 combiner into a single module. Figure 2 shows the test set up for testing the 500 W module.

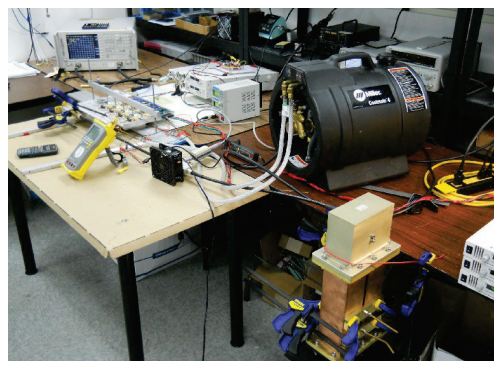

Figure 2: 500 W module test set-up. Output is connected through a 7/8" EIA connector.

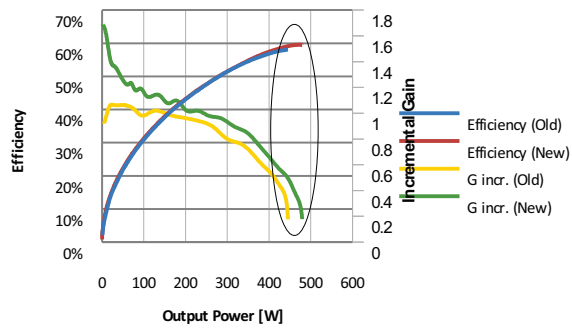

Figure 3: Peak power, efficiency, and incremental gain improvement by board modification.

The improvement of the 500 W module performance is shown in figure 3. With the improvement, the peak power increased from 445 W to 480 W, the peak drain efficiency increased from 58.2% to 59.5%, and incremental gain increased from 0.44 at 425 W to 0.57 at 425 W. The incremental gain here is defined as the change of output power in dB (P_{output}[dB]) divided by the change of input power in dB (P_{input}[dB]).

16-to-1 High Power Combiner

Figure 4: High power 16-to-1 combiner cold test.

The final element of the power amplifier is a high power 16-to-1 combiner shown in Figure 4. It uses coaxial scheme for low insertion loss. The geometries of the inner and outer conductors are optimized to phase and power balance between input ports. HFSS [4] simulation indicates an insertion loss of 0.08 dB, input power imbalance of 0.01dB and phase imbalance of 1° .

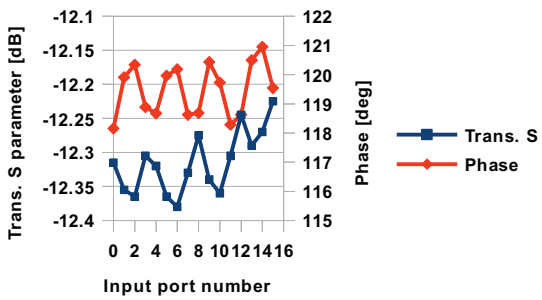

Figure 5: Transmission S-parameter and phase of each input port of the high power combiner.

Cold testing of the 16-to-1 combiner (figure 5) shows an insertion loss of 0.15 dB, an input power imbalance of ±0.03 dB rms, and a phase imbalance of ± 1° rms. The small deviation between the simulation and measurement come from machining and assembling errors.

Cooling System

Proper component cooling is critical to the amplifier performance. Better cooling can not only improve the transistor efficiency and peak power, but also increase the lifetime.

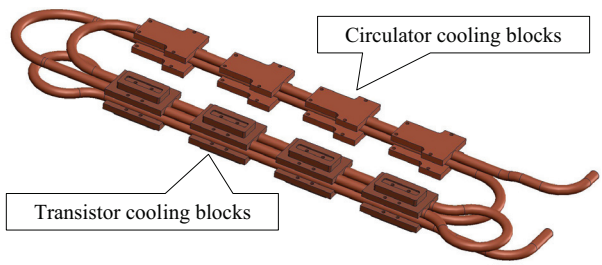

Figure 6: Cooling blocks for transistors and circulators.

Figure 6 shows the cooling scheme for the transistors and circulators (including 50 Ω circulator loads). Each pair of 500 W modules has a single cooling set for the 8 transistors and 8 circulators. The transistors are directly mounted onto the copper cooling blocks with thermal paste. The cooling blocks themselves are soldered onto thick wall (0.065" wall) 5/16" outer diameter copper tubing. The temperature difference between transistor case and cooling water at peak output power is 15 ºC. The temperature of the cooling water in the JLab facility is maintained at 35 ºC, so the peak transistor case temperature is 50 ºC, which provides a large safety margin over the rated transistor case temperature of 85 ºC. For each cooling set, the tubing is bent from a single piece eliminating the need for tubing joints making the system more robust and reliable.

Circulators and circulator loads made an indirect thermal contact to the circulator cooling blocks. The cooling blocks were mounted on outside surface of the 500 W cases. Circulators and their loads were mounted on inside surface of the 500 W case at the same locations of their corresponding cooling blocks. All interfaces were mediated with thermal paste. Each circulator generates about 6 W heating power at operating point. Circulator loads usually has no heating power and the peak power could be about 100 W in the worst case (output power full reflection). As the loads could operate at high temperature (150°C), the 100 W heating power could be easily handled.

Stage 1 Amplifier Test

The Stage 1 amplifier uses transistor boards the are similar to those used in the 500 W modules. The efficiency of these boards are less critical than those used in the 500 W modules because the total efficiency of the amplifier is less sensitive to the efficiency of the earlier stages. To achieve optimal performance, the stage 1 transistors must be more uniform and have higher incremental gain than those in the 500 W module. The boards used for stage 1 were selected and retuned to have well matched gain and incremental gain throughout the operating range.

Compact Design

The whole amplifier was designed sufficiently compact that it fit in the original klystron space. The amplifier is 22" high, 19" wide, and 20" (51 cm) deep, and fits in the original klystron rack.

Full Amplifier Test

The load for the full amplifier test uses a pair of 5 kW water-cooled loads. A high power 1-to-2 coaxial power splitter with an integrated directional coupler was designed and constructed in a 1-5/8" EIA coaxial geometry. The output from the full amplifier was split to into 2 outputs and connected to the loads. The reflection coefficient of the splitter with loads was measured to be better than -24 dB.

Water cooling for both the amplifier and the loads was provided by a circulating water system with a large radiator surface area, and can handle greater than 12 kW total power.

Copyright © 2013 CC-BY-3.0 and by the respective authors

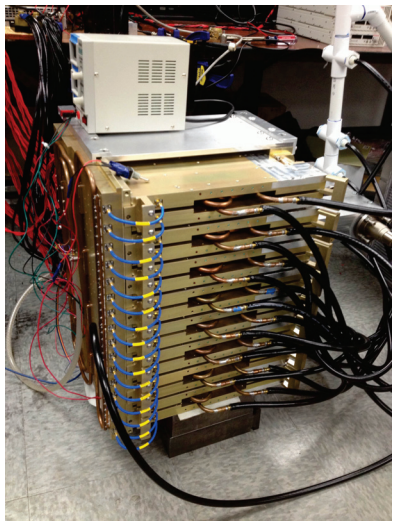

Figure 7: Full amplifier test set-up.

Figure 7 shows our whole unit amplifier and its test set up. The following lists the results near the operating point (6.4 kW) for the full amplifier test:

- Pre-amplifier input power: -7.1 dBm (0.2 mW)
- Pre-amplifier output power: 43.2 dBm (20.7 W)
- Output power: 68.1 dBm (6440 W)
- Pre-amplifier gain: 50.3 dB
- Total gain: 75.2 dB
- Power added efficiency: 54.4%
- Power supply wire loss: ~0.5% of total power
- Cooling water temperature: 37.1 ºC

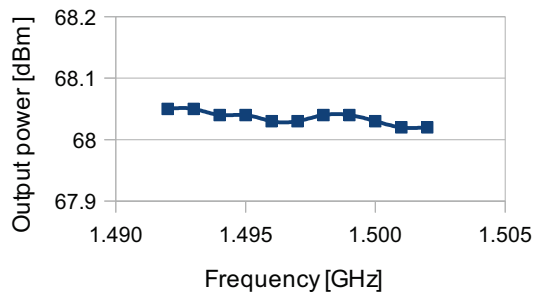

Figure 8: Frequency response of the full amplifier.

The frequency response of the amplifier was measured near the operating point. Figure 8 shows we see that the band width was larger than ± 5 MHz with this limit determined by the range of testing and not the amplifier itself.

CONCLUSION

The transistor boards were improved in peak power, efficiency, and incremental gain. Our high power 16-to-1 combiner has low insertion loss and small input imbalance and can easily handle the power output of the amplifier. The amplifier is compact with a robust and reliable cooling system. The peak power of the amplifier was 7 kW. The power added efficiency of 55% at 6.4 kW output and is expected to be better at higher output power. The band width is greater than 10 MHz.

ACKNOWLEDGEMENT

We would like to express our gratitude to colleagues at TJNAF from whom we received technical support. Special thanks to Dr. Rick Nelson for his helpful discussions.

SYSTEM CONSIDERATIONS FOR 201.25 MHz RF SYSTEM FOR LANSCE*

John Lyles#, Walter Barkley, Jerry Davis, Angela Naranjo, Dan Rees, Gilbert Sandoval,
AOT Division, Los Alamos National Laboratory, Los Alamos, NM
D. Baca, R. Bratton, R. Summers, Compa Industries, Los Alamos, NM

Abstract

Acceleration of long pulses of proton current at high repetition rates (1 mS, 120 pps) at LANSCE have been impacted by reduced capability of the original 201.25 MHz RF system driving the 100 MeV DTL. The present operating point of the existing triode power amplifiers doesn't allow margin for tuning excursions with voltage standing wave effects or for tube manufacturing variations. This has led to the undesirable consequence of operating LANSCE at half of its original duty factor for the past seven years to maintain acceptable beam availability. A recent program has been initiated to restore the accelerator to its original high current operation. Investigated alternatives for high power RF included the development of physically large klystrons, solid-state and new power grid tube (tetrode) amplifiers. The power grid tube was favored as it reused much of the existing infrastructure including water-cooling systems, coaxial transmission lines, high voltage power supplies and capacitor banks. High duty factor tetrodes called Diacrodes®, are capable of supplying the DTL requirements with ample headroom. A LANL-designed power amplifier using the TH628L Diacrode® has produced 3 MW peak and 300 kW of mean power with > 14 dB of power gain and > 60% efficiency. It has been operating for over seven thousand hours generating RF power with a test load. Installation of the first new system begins in January of 2014.

RF SYSTEM SHORTCOMINGS

The LANSCE proton linac uses a DTL powered at 201.25 MHz, to accelerate both H^+ and H^- ions from 0.75 to 100 MeV in four Alvarez cavities, before injection into a coupled-cavity linac. The beam loading is 16.5 mA peak proton current at 120 pps. Nominal 8.7% beam duty factor (DF), with 1 pps of 1225 uS length. DTL cavity 2 has the highest energy gain of ~36 MeV, and requires the highest peak RF power of 3.6 MW, including excitation power. Significant average power (~430 KW) is required for each of three room temperature cavities to accelerate the long beam macro pulses. This is in contrast to the high-peak/low-average power regimes found at 200 MHz proton injector linacs at Fermilab, CERN, and BNL. Over the past 25 years, the manufacture of RF amplifier triodes with consistent lifetime has been challenging, when operating at the high average power needed at LANSCE. These tubes were originally commercialized in 1960, using unique processes such as pressed (non-brazed) seals. In the 1980s the company (RCA) quit the business, which was then bought by individuals. At this time there was concern about the longevity of the 7835 triode as a product.

Studies made in 1987-89 discussed alternatives to the triodes, including new tetrodes, klystrons, or IOTs. Through the last part of that century recurring problems were managed by having a larger supply of tested spare triodes. In 2006, the operating point of the power amplifiers had to be reduced in order to hold operating costs on budget (for all-too-frequent tube replacements) and prevent excess downtime. This led to the decision to operate LANSCE at half of its original duty factor to maintain acceptable beam availability.

A primary goal of the LANSCE Risk Mitigation (LRM) project has been to replace the original 201.25 MHz amplifiers with modern circuits having higher average power capability. Another goal has been to modernize the low level RF controls, to improve operational efficiency and reduce beam losses. In addition, end-of-life klystrons for the CCL are being replaced with forty-five new CPI VA862A1 klystrons.

ALTERNATIVES CONSIDERED

Solid State Amplifier

Broadcast transmitters have led development of solid state PAs. Units with up to 2 MW of modulated power have been installed at low frequencies up to a few MHz. In the VHF/UHF bands, however, power levels are predominantly in the tens of kW. In the past decade, development of CW PAs capable of 180kW was done at 352 MHz [1]. The Soleil group has pioneered using DMOS transistors in large combined circular arrays with 726 individual amplifier pallets for a booster synchrotron. Others have followed with similar designs. Transistors work best with continuous (CW) operation as wire bonds are weakened with pulsed currents, resulting in device derating [2]. The number of particular dies for a pulsed amplifier become similar to a CW rated amplifier, unlike with tubes where significantly higher peak power may be obtained from the same device. Technical problems are known to exist with LDMOS transistors, such as drift in quiescent current over time (aging and radiation-induced). MTBF for transistors are frequently quoted in tens to hundreds of years. In practical high power amplifiers such as at Soleil, the large number of passive and active devices required pushes down the MTBF to about 1 year, despite the inherent redundancies.

In 2009, LANL evaluated a 1600-watt silicon carbide static induction transistor amplifier from Microsemi. It was biased above 100 volts. The device topology (common gate) limited power gain to 9 dB, requiring additional stages for preamplification. It was not pursued for various reasons.

Solid-state devices frequently have short manufacturing life cycles, being marketed for rapidly changing industries such as wireless communications. For this reason, there is a gamble to select the part that will stand out and survive in the market for a decade or more. Transistorized power amplifiers are very useful below 10 kilowatts at LANSCE - as high gain driver stages for tubes. There are no megawatt-level pulsed VHF amplifiers that would fit into the equipment hall, so this avenue was not pursued further.

Klystron or Inductive Output Tube

In the 1980s, LANL investigated high gain conventional klystrons with 40-50 dB gain. The closest commercial device was an ionospheric scatter radar amplifier at 224 MHz (EISCAT), 2.5 MW and 12% DF. Those devices were 5.5 m long and operated at 110 kV. Valvo and Varian both worked on tubes, but Varian preferred to offer multiple 1.5 MW Klystrodes (IOT) to LANL [3]. A multibeam IOT was also proposed using radial stripe beams but the development estimate was too costly and lengthy for LANL to consider at the time. Eimac had previously developed a 267 MHz 250 kW CW IOT for Chalk River Lab. It worked but was plagued with grid contamination from the cathode, which caused loss of control if not corrected. Thompson Tubes Electroniques proposed a 5.7 m long 200 MHz klystron at the time. Valvo eventually left the business. LANL also investigated building in-house, having large hydrogen-braze furnaces from the making of the first coupled-cavity linac. This was not pursued further when we shifted away from in-house klystron remanufacturing.

In 2004, CPI published a concept for a 250 kW coaxial IOT for 200 MHz [4]. Most recently, CPI has proposed a multibeam klystron for 200 MHz for 7 MW peak/52kW average power for Fermilab's DTL. Efficiency is estimated at about 50%. None of these developments has addressed the 3.6 MW peak, 430 kW average power required for the LANSCE DTL, however. In 2010 discussions with CPI led to the concept of a reduced gain (32 dB) high average power klystron with one-less fundamental cavity. In this way the tube length could be less than 4.7 meters. This klystron option was a viable contender for the replacement DTL RF amplifier.

Gridded Tube

The caveat for gridded tubes is that a matching cavity amplifier circuit must be developed around the chosen device. This requires that the tube manufacturer or an independent producer commercialize this complex unit into an amplifier system. An acceptable solution may also have the amplifier development done by the laboratories, although costs must be weighed against industrialization.

Several alternatives were proposed by Eimac in 1987-89 using tubes derived from the 8973, a conventional tetrode. None of these were deemed acceptable for high average or peak power without first testing at 200 MHz, requiring development funding for a circuit. In 1989 Thompson proposed a new tetrode that used the favorable double-ended RF circuit topology of the old triode but with much higher average power due to new grid materials, improved anode cooling, and brazed ceramic seals. This device was eventually developed and tested for resistive heating for fusion research as the TH628 Diacrode® [5]. This tube is a high DF (CW) device with over 3 times the anode dissipation rating of the original triode. The cathode is designed for long life typical of tetrodes, with 2.6 times the emitting area of the RCA triode. Emission current density of 0.95 Amps/cm^2 at the peak cathode current compares very favorably to 3 Amps/cm^2 in the triode for the same RF level. In 1998 LANL started development of a cavity amplifier for this device. The objective was to power combine two of the units for the highest power DTL cavity at 3.6 MW, and using a single amplifier for cavities 3 and 4 for 3 MW [6]. What began as a partial-time effort moved into a fully funded development by the author after the 2006 crisis happened. In 2009 a new test facility was assembled simultaneously with the building of a prototype PA for operation [7].

In 2010, Thales (former Thompson) made a change to the grid material for safety and environmental factors. As a consequence, the modified pyrolytic graphite had increased RF loss at 200 MHz. This lowered the screen grid (g2) RF power dissipation rating. While this didn't affect the intended fusion application below 80 MHz, it required the baseline design for LANSCE to use two amplifiers for all three of the largest DTL cavities. This increased the installed cost but provided ample headroom in the design, allowing the individual Diacrodes® to operate at 55% of their rating. Increased reliability and mean time to replacement for the tubes will result from this pairing of amplifiers.

As the prototype amplifier was being built, the total installed cost was estimated for both dual-Diacrode® and klystron options, based on the recent low gain klystron proposal from CPI. The complexity of the grid tube plant was weighed against the new cost and schedule of development for klystrons plus their new 1.2 MW 110 kV beam power supplies. With the in-house amplifier development about to reach its milestone to produce RF power, a decision was made to install with the Diacrodes® at LANSCE.

Construction of the final configuration of the amplifier was completed in 2010. The common-grid amplifier configuration uses a full wavelength double-ended circuit, and forced air/water cooling. Subsequent power testing

Copyright © 2013 CC-BY-3.0 and by the respective authors

resulted in minor improvements that were implemented in 2011 followed by testing up to 2.5 MW peak power at 12% duty factor. The amplifier has been tested at the 3 MW operating point to demonstrate design margins as well as cathode emission capabilities of the tube. Testing has continued for over 7000 hours with the amplifier using three different Diacrodes®, while also testing the remaining components for the plant. Mechanical and electrical design of the PA, supporting electronics and intermediate power amplifier (IPA) are discussed elsewhere [8][9][10]. The Diacrode® option reuses the same cooling water plant, the HV power supplies, capacitor banks and the 35.5 cm diameter coaxial transmission lines of the old RCA plant.

A tender for manufacturing the LANL-designed PA was issued in 2012 and the work was awarded to Continental Electronics Corporation. One PA has been delivered for testing in October with two more presently in manufacturing. Four more are scheduled to be purchased in the next two years. Two new TH628 Diacrodes® have been tested and accepted and 3 more are in manufacturing, with 3 more to be ordered in the future. Two IPAs have been ordered and delivered from Betatron Electronics, with 2 more expected in the coming years. The lab and the fabricator jointly designed these, based on the LANL prototype. This amplifier uses a Thales TH781 tetrode, and matching TH18781 cavity amplifier. One IPA will drive two combined TH628s at each RF station.

PASSIVE RF COMPONENTS

The 3 1/8 inch diameter coaxial transmission line from the 175 kW IPA is split by a λ/4 hybrid into two paths. One path has a passive phase shifter made like a trombone, with +/- 10 degrees of variability. The other path uses a fixed length delay to compensate for the phase shifter. The outputs from the two final PAs (FPA) are combined in a λ/4 branchline hybrid made from coaxial line. Normally this would shift any reflected power from the DTL into two components 90 degrees apart at the two Diacrodes®, causing difficulty in maintaining power balance with varying reflected power. A separate λ/4 phase delay is placed in the 9 3/16 inch diameter coaxial line on one FPA to make the two tubes operate into the same reflected phase. A similar delay is placed in the input line of the opposite amplifier to place the two amplifiers back in a quadrature relationship for the combiner. Figure 1 shows this configuration with the IPA removed for clarity.

CONCLUSION

The new gridded tube power amplifiers meet the technical requirements for the LANSCE DTL, and also provide a basis for new driver amplifiers for a future RFQ. They are being commercially produced, and installation of the first pair of amplifiers starts in January of 2014. Collaboration with CERN has been ongoing with the Diacrode® option considered for the SPS RF upgrade and for a 6D Muon ionization cooling facility through the TIARA R&D objectives [11].

Abstract

A 650 MHz 50 kW transmitter with a wide-band control in phase and power, based on injection-locked CW magnetrons has been proposed to drive individually Superconducting RF (SRF) cavities for the Project X CW 1 GeV H^- linac. Utilization of the magnetron RF sources for the intensity-frontier project will save a significant capital cost in comparison with traditional RF sources based on klystrons, Inductive Output Tubes (IOTs), solid-state amplifiers. The transmitter setup has been modelled experimentally using 2.45 GHz CW magnetrons with output power up to 1 kW operating in injection-locked mode in pulsed regime with long pulse duration. Measurements with the modelling setups indicated capability of the proposed transmitter to power the SRF cavities suppressing parasitic modulation of the accelerating field caused by mechanical oscillation (the microphonics), beam loading, dynamic tuning errors, and the low-frequency disturbances of the magnetron performance. Results of the experimental tests are analyzed and discussed in this paper.

INTRODUCTION

State of the art the intensity-frontier Project X H^- superconducting 1 GeV linac requires CW, 650 MHz RF sources to power SRF cavities. One of general requirements following from dynamic of non-relativistic or weakly relativistic beam is conservation of a small emittance during the process of acceleration. For this is necessary keeping the accelerating voltage phase and amplitude deviations to be less than 1 degree and 1% of nominal, respectively, [1].

To keep amplitude of accelerating voltage with the required accuracy in spite of microphonics, a dynamic control of the accelerating voltage is required, [2, 3].

The average RF power to feed each SRF cavity, providing an energy gain of ~17 MeV/m for average beam current of 2 mA at the microphonics magnitude, δf=20 Hz, one can determine by the following equation:

$$P_g = \frac{V^2}{4Q_E(r/Q)}\left[\left(1+\frac{I\cos\varphi(r/Q)Q_E}{V}\right)^2+\left(Q_E\frac{2\delta f}{f}\right)^2\right].$$

Here P_g is the RF source power, V is gradient of the accelerating field in the 1 m long SRF cavity for zero synchronous phase, (r/Q) is the cavity impedance, Q_E is the cavity external Q-factor, *f* is the cavity frequency, δ*f* is the microphonics magnitude, φ is the synchronous phase.

For ILC-type 650 MHz SRF cavity with (r/Q)≈ 638 and φ ≈-10 degrees the equation gives P_g≈ 38.5 kW at the necessary range of the power variation of ~ 5 kW. Considering reflections and insertion losses in the RF system one can evaluate the RF source nominal power of ≈ 50 kW necessary for each individual SRF cavity of the CW linac.

To compensate perturbations caused by beam loading, and dynamic tuning errors, a control of phase of the RF field is necessary in each individual SRF cavity.

Traditional RF sources based on klystrons, Inductive Output Tubes (IOTs), solid-state amplifiers are acceptable to provide the required power and the phase control, but the capital cost of the RF system is a significant part of the accelerator project. MW-scale CW klystrons powering groups of the cavities can reduce the costs, but this technique only allows a control of the vector sum of the accelerating voltage in the group. The vector sum control has not been tested in driving SRF cavities for non-relativistic or weakly relativistic particles; it may cause emittance growth because of non-optimized values of phase and amplitude of the field in individual SRF cavities.

The CW injection-locked magnetrons are efficient and less expensive than the aforementioned RF sources, [4].

Analysis of operation of magnetrons injection-locked by a phase-modulated signal, [5-7] demonstrates that the magnetron response on the locking signal is quite linear, has small phase error and quite fast, [8]. The features of the injection-locked magnetrons allow developing the RF source based on the CW magnetrons controlled in phase and power to suppress the perturbations of the magnetron phase performance inherent in magnetrons and moreover to satisfy requirements of the Project X H^- linac as well.

The experiments performed with CW 1 kW injection-locked magnetrons and evaluations presented in this paper indicate that the phase controlled transmitter based on the injection-locked magnetrons with a Low Level RF system including a closed wideband loop will allow eliminating all expected low-frequency perturbations of the accelerating field in SRF cavity including the perturbations caused by the phase performance of the injection-locked magnetron.

Results of the experimental tests are analyzed and discussed in this paper.

THE MAGNETRON TRANSMITTER FOR THE PROJECT X CW H⁻ LINAC

A concept of the 650 MHz, 50 kW magnetron transmitter (with phase and power to be controlled by a LLRF) for the Project X H⁻ CW linac is presented in Figure 1, [9].

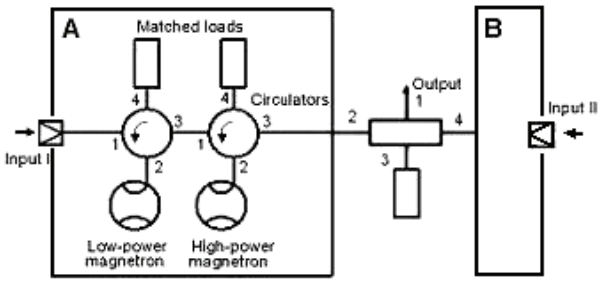

Figure 1: Block-diagram of the magnetron transmitter available for a fast control in phase and power.

The transmitter consists of two identical channels (A and B) of cascaded injection-locked magnetrons, combined in power by a 3-dB hybrid. The phase management is provided by controlled simultaneously and equally the phases at inputs of both 2-cascade magnetrons. The power management is provided at a control by phase difference at the inputs of the 2-cascade magnetrons. The 2-cascade injection-locked magnetron system allows reducing the required locking power.

EXPERIMENTAL FACILITY

The facility was developed for experimental tests of the CW transmitter active components using two CW, 1 kW microwave oven magnetrons. The magnetrons with free run frequencies differing by ≤ 5.7 MHz operated in injection-locked mode at the locking frequency of 2.469 GHz in pulsed regime, at pulse duration of 2.5-15 ms at low repetition rate. Each magnetron was installed in a separate module with necessary RF components, Figure 2. The modules were used to test performance of all active components of the proposed transmitter in various setups.

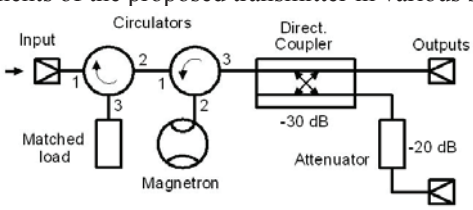

Figure 2: The magnetron experimental module for tests of the transmitter setup.

The experimental apparatus for the tests included a pulsed modulator to power the magnetrons, wide-band CW Travelling-Wave Tube (TWT) amplifiers driven by N5181A Agilent generator, to lock the magnetrons, and measuring equipment.

The modulator with partial discharge of storage capacitor provided simultaneous operation of the both magnetrons, having dissimilar Volt-Amps characteristics; the magnetron with lower anode voltage was fed by a compensated divider. The HV power supply ripple were negligibly low at the modulator output, however the modulator introduced a slope of the output voltage caused by discharge of the storage capacitor. The slope at pulse duration of 5 ms did not exceed 0.4% when 2 magnetrons operated simultaneously.

TESTS OF SINGLE AND 2-CASCADE INJECTION-LOCKED MAGNETRONS

Setup for tests of operation of injection-locked singles and 2-cascade magnetrons is shown in Figure 3, [8].

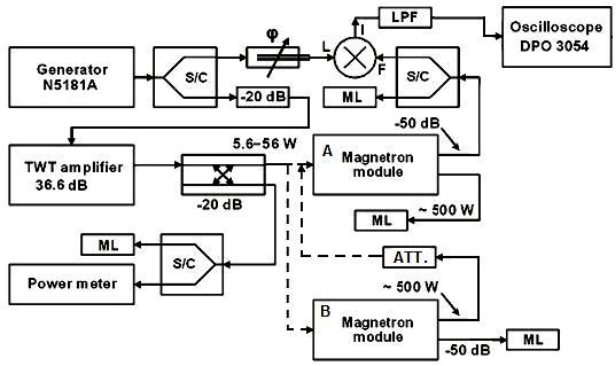

Figure 3: Setup to test operation of single and 2-cascade injection-locked magnetrons. S/C is a splitter/combiner, LPF is a low pass filter, ML is a matched load, and ATT is an attenuator. Powers of the magnetrons are depicted in this figure.

The single injection-locked magnetrons were tested in configuration using module A with the magnetron locked by the TWT amplifier and fed by the modulator, while the module B was disconnected from the amplifier and the modulator. The 2-cascade magnetron was tested in configuration, in which the magnetron module B was locked by the TWT amplifier while the module A magnetron was connected via attenuator to the module B output. In this case the magnetron in the module A was locked by the pulsed signal of magnetron B lowered in the attenuator. The modulator fed both the magnetrons.

Traces of the magnetron intrapulse phase variations are plotted in Figure 4.

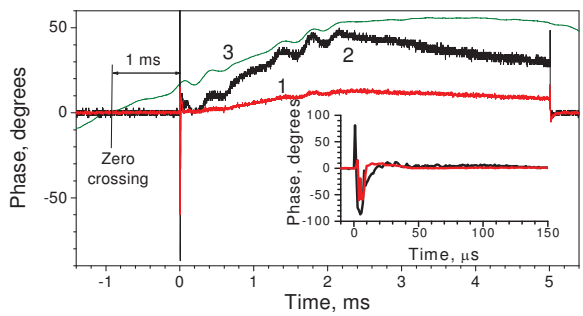

Figure 4: Phase performance of the single, trace 1, and 2-cascade, trace 2, injection-locked magnetrons. Trace 3 shows voltage of the AC line. Trace 1 was measured at the magnetron locking power of -15.6 dB; Trace 2 was measured at the locking power of the magnetron B of -15 dB and the attenuator value of 15 dB. Considering the attenuator value the locking power of the 2-cascade magnetron is -30 dB of the output power.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Shift of the triggering of the modulator vs. zero crossing of the AC line voltage minimized the magnitude (peak-to-peak) of the magnetrons phase perturbations resulted from the magnetic field induced by the filament circuitry, [10].

POWER CONTROL OF INJECTION-LOCKED MAGNETRONS

The fast power control of the injection-locked magnetrons using power combining first was realized in the setup shown in Figure 5, [10].

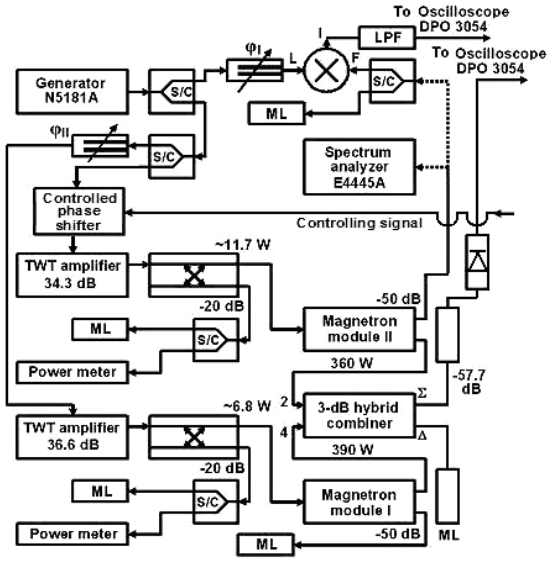

Figure 5: Setup with the injection-locked magnetrons for test of the power control by power combining.

The power control, Figures 1 and 5, is realized by a vector summation of output signals of the injection-locked magnetrons controlled by the phase difference.

Performance of the injection-locked magnetrons at fast power control was demonstrated controlling the analogue phase shifter JSPHS-2484 by a sequence of meander-like pulses with period of ≈30 μs, Figure 6.

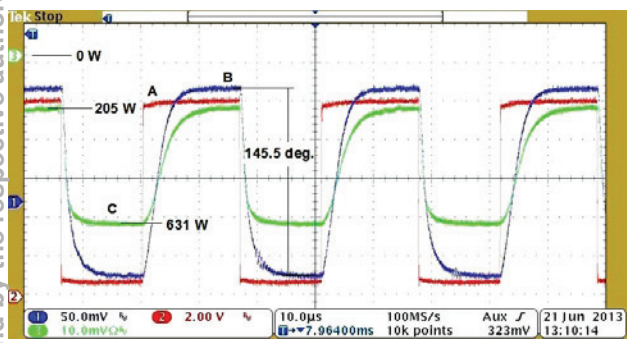

Figure 6: Trace A is shape of the voltage, controlling the phase shifter JSPHS-2484, trace B is the magnetron II phase response on the shifter fast control, trace C shows variation of the power measured by the calibrated detector at the port "Σ" of the 3 dB 180 degrees hybrid.

The high-frequency noise measured for single, 2-cascade injection-locked magnetrons and magnetrons with power combining does not exceed 0.4, 0.7 and 0.5 degrees (rms), respectively.

The bandwidth of the phase control was measured in setups, Figures 3, 5, by a phase modulation in generator N5181A at various modulating frequencies. Measured with Signal Analyzer MXA N9020A in the phase modulation domain the magnitude transfer characteristics of the magnetrons locked by the phase-modulated signal showed that the frequency cut-off at the locking power of ≥-13 dB for single and ≥-27 dB for 2-cascade magnetron setup is ≥1 MHz. It implies that the injection-locked magnetron RF source managed in phase and power by a LLRF controller with a closed feedback loop at the bandwidth of ≈100 kHz will be able to suppress all expected low-frequency perturbations in SRF cavities including the perturbations resulted from the magnetrons.

CONCLUSION

Setups of all active components of the proposed magnetron transmitter rapidly controllable in phase and power by the phase-modulated signal and intended for CW H^- linac of the Project X have been tested using 2.45 GHz 1 kW magnetrons operating in injection-locked mode. The experimental tests verified that the response of all active components of the transmitter based on the injection-locked magnetrons at the control is quite linear, provides small phase error and is quite fast to use a Low Level RF (LLRF) controlling system with a wideband closed loop. The ratio of locking power to output power of -27 dB for 2-cascade magnetron looks feasible at bandwidth of the magnetron phase control of ≥1 MHz. Measured high-frequency phase noise of the transmitter components <1 degree, rms, satisfies requirements of the Project X H^- superconducting linac. The magnetron transmitter with the LLRF controller will be able eliminating all expected low-frequency perturbations of the accelerating field in the SRF cavity including perturbations caused by mechanical oscillations, beam loading, dynamic detuning errors and perturbations resulted from performance of the injection-locked magnetrons, including phase pushing and perturbation caused by induced alternative magnetic field.

AN EFFICIENT RF SOURCE FOR JLAB*

M. Neubauer, A. Dudas, Muons, Inc. Batavia, IL 60510, USA
R. Rimmer, H. Wang, JLAB, Newport News, VA 23606, USA

Abstract

The original CEBAF accelerator at Thomas Jefferson National Accelerator Facility (JLAB) currently uses a system of 340 klystrons with relatively low efficiency, but an MTBF approaching 170,000 hours. Over the lifetime of the project 60% of the tubes have been replaced, giving an MTBF for a single tube of about five to six years. 45% of the klystrons were replaced over the thirteen years of full operation (1995-2007) with an average filament on time of 80% and high voltage on time of 75%, thus a utilization rate of 61% per year or ~4300 high voltage operating hours per year with an overall system efficiency of 35%. This represents 1.6M$ per year of electricity costs and over 20% of the total electricity usage of the high energy mission specific facilities (HEMSF).

We propose the development of a highly reliable high efficiency RF source for JLAB operating at ~80% efficiency yielding system operating costs of only about 0.7M$/year for the 6 GeV machine. A number of RF source designs are being evaluated including the concept of two injection locked magnetrons in a novel combining architecture for amplitude modulation. A cost analysis including efficiency and reliability will be performed to determine the optimum system architecture.

INTRODUCTION

The RF source for the CEBAF machine currently uses 5-8 kW klystrons operating at ~35% efficiency [1]. The annual electricity usage for the HEMSF for the 6 GeV machine is 130,000 MWhrs [2]. As shown in Table 1, the annual savings for the RF source alone would be about 1M$ per year, neglecting various cooling requirements for the power supply and microwave tube. The savings represent a reduction in the HEMSF usage from 130,000 MWhrs to about 113,000 MWhrs for the 6 GeV machine.

Table 1: Example calculations of the impact of a high efficiency RF source on the operating costs and electricity usage per year.

RF output power	5	5	kW
tube efficiency	35%	80%	
DC input power to each station	14.3	6.25	kW
number of stations	340	340	
DC Input power for HPRF sources	4857	2125	kW
Power supply conversion rate	95%	95%	
Total station input power for HPRF	5113	2237	kW
70% utilization rate	6132	6132	hrs/year
Yearly Electrical Useage	29784	13031	Mwh/year
Cost at 61$/Mwh	$1.82	$0.79	($M)
Savings		**$1.02**	**($M) per year**

The MTBF of individual tubes in the CEBAF system can be estimated to be 5-6 years or about 37,000 tube hours with a 75% utilization rate, while the MTBF of the system of 340 tubes is approximately 170,000 system hours (see Figure 1). Magnetrons have a similar MTBF. Varian (now CPII) reported lifetimes of 27,600 MTBF for a 65-80kW X-band coaxial magnetron [3]. In 2006, a study was made at the Naval Post Graduate School in Monterey, of the Total Ownership Cost (TOC) of the Aegis microwave power tubes. In the Aegis system, the MTBF of CFAs was improved from 6000 hours to 45,000 hours from 1983-2002 [4]. Cross-field amplifiers (CFA) are in the same class as magnetrons.

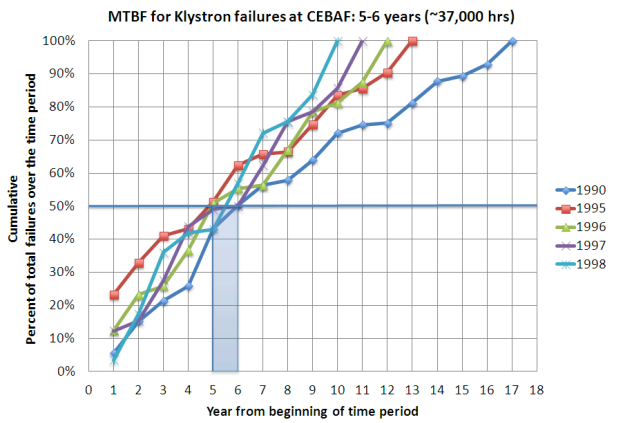

Figure 1: Data Collected from JLAB presentation, "Operating Experience and Reliability Update on the 5 kW CW klystrons at Jefferson Lab," [5].

Another primary use of magnetrons is in medical linear accelerators where they are operated at high peak powers with low utilization rates. The MTBF of the magnetrons in one linac system architecture was doubled from 20 months to 43 months over a four year period [6].

The point to be made is that, the system design and the interface between the tube(s) and power supplies dominates the MTBF of the RF source. It is reasonable to assume that the MTBF of a magnetron based system can be as good if not better, than the klystron MTBF when the system design is optimized at an early stage of development.

APPROACH

We have determined two basic designs which will be further analyzed. The first consists of a single RF source (klystron, magnetron, IOT, etc.), and the second would be a dual magnetron source in which the outputs of two injection locked magnetrons would be phased and combined to produce a required output power level and phase.

An initial power balance spreadsheet analysis has shown that a single magnetron would be more efficient that using either a klystron or IOT device. Thus our focus has narrowed to either a single or dual magnetron system.

*Work supported by DE-SC0009693

Copyright © 2013 CC-BY-3.0 and by the respective authors

Figures 2 & 3 show the system diagrams for each of those two options.

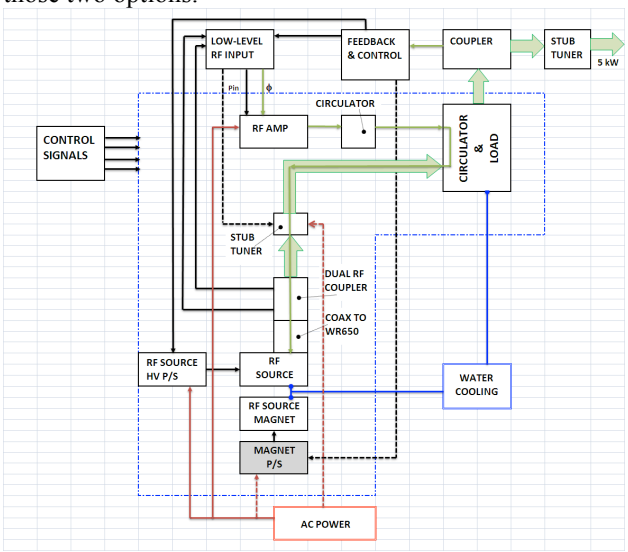

Figure 2: Single RF source system diagram.

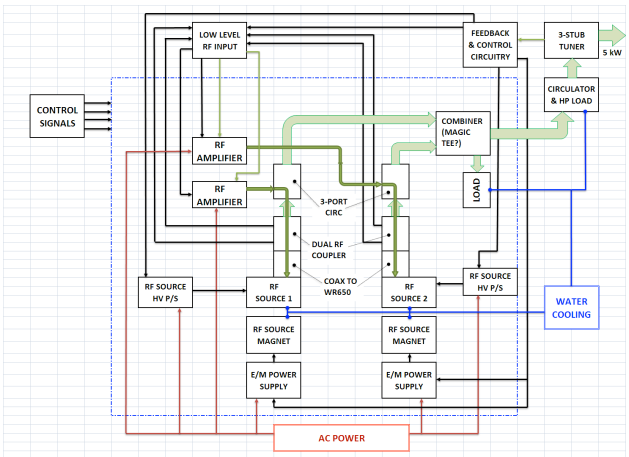

Figure 3: Dual Magnetron source system diagram.

Figure 2 is similar to the current CEBAF system using a single klystron. Figure 3 however shows an injection signal fed through a circulator into a combining network which may be as simple as a magic TEE. Both magnetrons are fed with this signal, injection locked, and deliver their output to combine in the fourth leg of the magic TEE. To adjust the output amplitude, the amplitude and phase of one magnetron is adjusted relative to the other (via the Feedback & Control system). The sum is sent to the output, and the difference is sent back through the circulator to a load. This is a straightforward system, just like the others, but the devil is in the details.

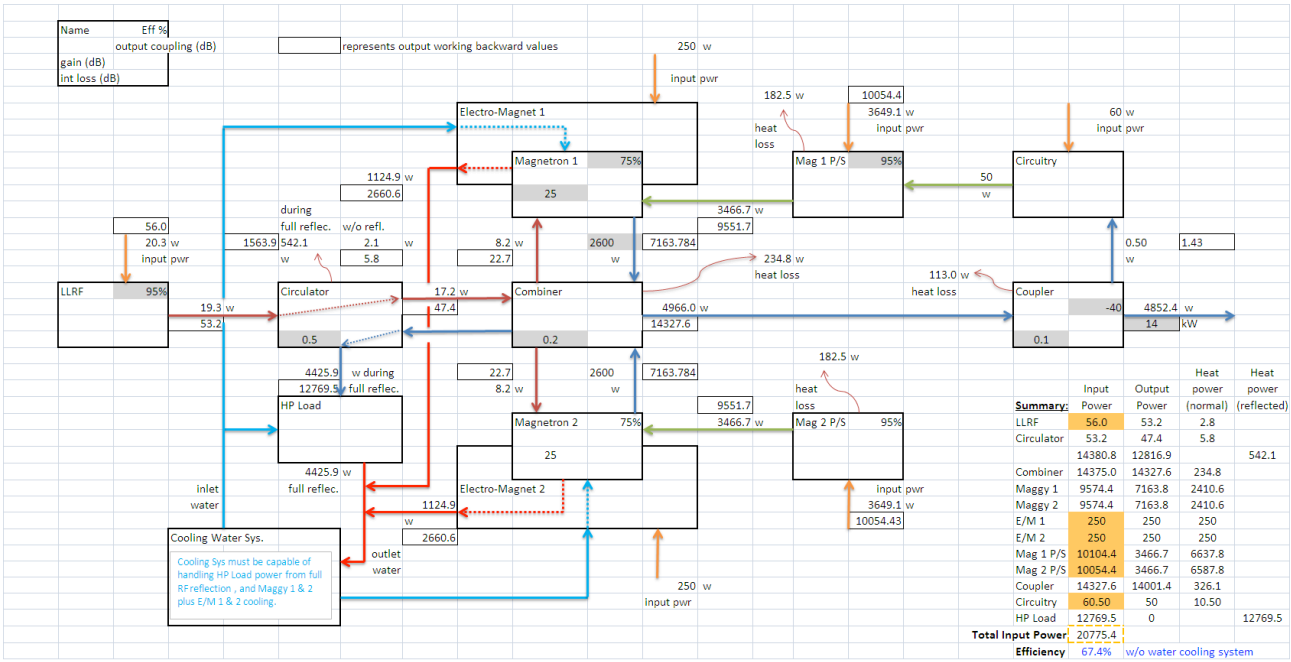
The first of those details is controlling the output phase of one magnetron relative to the other. In the work already done by JLAB, 0.8° phase stability was achieved, limited by noise from the digital power supply used.

Additional details being analyzed and optimized are:

1) What design elements or improvements are required to meet the AM requirements of the combined system?
2) What is the most cost effective combining system?
3) Will an electro magnet be used for the magnetron focusing to optimize efficiency?
4) Will the design of the 1497 MHz magnetron include a side coupling for improved locking?
5) Will phase shifters be required in addition to magnetron pushing by the beam voltage to achieve the required amplitude modulation?
6) What is the overall efficiency of the system under realistic operating conditions? How does it impact TOC?
7) Can a low gain cross-field amplifier (CFA) be used in addition to the phase locked magnetrons to meet the 12 GeV upgrade requirements?

System Efficiency and TOC

The system efficiency of various system architectures is being studied to determine the optimum design. The methodology is shown in Figure 4 (shown on the next page). Each element of the system architecture will be analyzed in terms of input power, efficiency, and heat loss. The TOC is a summation of acquisition cost and operating costs. The payback of the acquisition cost, in terms of cost savings from operating costs, is being determined.



New components will need to be designed, such as the 1497 MHz magnetron, and the methodology to determine the design effort (cost) as well as the TOC without knowing exactly which elements will be involved will utilize a scoring method similar to that shown in Figure 5. In this method, various elements of the designs are "scored" for cost, ease of design, complexity, etc. (1 being easy / low cost, and 3 being difficult / high cost).

	Sum	Total Tube Cost	# of tubes	Eff	Tube Cost (each)	Gun	Interaction Region	Collector	Total System Cost	RF Driver	waveguide system	Feedback System	Power Supply
Klystron	19	15	1	0.4	6	1	3	2	4	1	1	1	1
IOT	14	8.57	1	0.7	6	2	2	2	5	2	1	1	1
2 Magnetrons													
master slave	19	8	2	0.5	2	1	1		11	3	3	3	2
peer to peer	19	8	2	0.5	2	1	1		11	3	3	3	2
2 CFAs	16	8	2	0.5	2	1	1		8	3	2	1	2
1 Magnetron													
Anode V Modulated	12	2.5	1	0.8	2	1	1		9	2	1	3	3
B-Field Modulated	11	2.5	1	0.8	2	1	1		8	2	1	3	2
Gridded	9.8	3.75	1	0.8	3	2	1		6	1	1	1	3

Figure 5: Example of a risk assessment used to determine the optimum architecture for the RF source in this project.

For example, since 340 units are anticipated in the full replacement of the klystrons, there will be learning curve applied to the unit cost of the RF source designed in this Phase I program. This will include a risk assessment and median pricing for the most probable cost of 680 magnetrons. The MTBF of the RF source will be applied to arrive at a total quantity of magnetrons needed, which may exceed 1000 magnetrons over ten years. Cost estimates from various suppliers will also be used where applicable. With this methodology in place, the most cost effective system architecture will be determined.

Figure 4: An example analysis for the system of Figure 3, showing elements of the analysis for total operating efficiency including the cooling system.

1497 MHz Magnetron

The RF source will be based upon a modest scaling of the common water-cooled industrial cooker magnetron: a 3 kW 2450 MHz magnetron [7]. The efficiency of this magnetron is about 70%. The efficiency of the similar 915 MHz water cooled magnetron is over 90%, so it is reasonable to assume a 1497 MHz magnetron can be designed to operate at ~ 80% efficiency. A paper design of a 1497 MHz magnetron is part of our program. Details of the anode structure can be designed in Comsol or CST. The details of the heater package, coupling, cooling, and other mechanical elements of the design will be made in sufficient detail so that bids for a total quantity of 1000 tubes can be obtained.

CONCLUSION

Initial work has shown that design of a more efficient CEBAF RF source system is reasonable, and should save JLAB 1M$+ in electricity costs per year. Technical performance and reliability equivalent to or better than the existing sources needs to be demonstrated. Total cost of ownership and time to recoup the initial investment will be calculated.

HIGH POWER CO-AXIAL COUPLER*

M. Neubauer, A. Dudas, Muons, Inc., Batavia, IL 60510, USA
R. Rimmer, J. Guo, S. Williams, JLAB, Newport News, VA 23606, USA

Abstract

A superconducting RF (SRF) power coupler capable of handling 500 kW CW RF power at 750 MHz is required for present and future storage rings and linacs. There are over 35 coupler designs for SRF cavities ranging in frequency from 325 to 1500 MHz. Coupler windows vary from cylinders to cones to disks and RF power couplers will always be limited by the ability of ceramic windows and their matching systems to withstand the stresses due to non-uniform heating from dielectric and wall losses, multipactor, and mechanical flexure.

We have fabricated and tested a novel robust co-axial SRF coupler (400 MHz, 6 kW CW) design that uses two windows manufactured with compression ring technology and no matching elements in the coax line. This technology allows the use of high thermally conductive materials for cryogenic windows because the braze joint will be in compression. We have also incorporated "explosion bonded" technology into this design to reduce needed parts and simplify fabrication. In this phase, a scaled down version of the 500kW CW double window assembly has been built and tested.

A compressed co-axial window was designed and fabricated using standard ceramics [1]. Low power tests confirmed the broadband match characteristics of a double window design.

Double-window, coaxial input couplers or coaxial pressure barriers have high power CW applications ranging from RF guns for injectors to high power magnetron sputtering systems. Single half-wavelength coaxial windows built with our compression technology will handle significantly more power than standard windows.

INTRODUCTION

Dual-Window Concept

When two coax windows are placed in a length of line, the distance between them can be adjusted to create a perfect match. That distance is approximately a quarter-wavelength. The thickness of the window and its dielectric constant determine the exact distance for the cancellation of reflections. For EIA 3-1/8 50Ω coax line, the ceramic window has the same dimensions as the coax (76.9 mm and 33.4 mm). In our Phase I construction of a compressed window we used a window thickness of 7.6 mm. Using those dimensions the optimum spacing for various frequencies can be determined by various simulation tools. For EIA 3-1/8 coaxial line, Figure 1 shows the window spacing as a function of frequency, which provides a near perfect match.

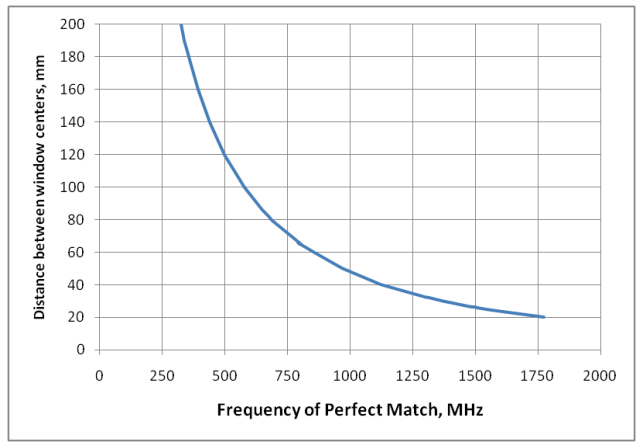

Figure 1: Two alumina windows 7.6 mm thick modeled in EIA 3-1/8 coax for the distance between them which creates a near perfect match.

As the thickness of the window becomes large compared to the wavelength of the match frequency, the actual distance to cancel reflections becomes smaller than the theoretical $\lambda_g/4$. The bandwidth of the match was calculated to be about 2-3% at a VSWR of 1.01:1.

Two windows of different materials can be matched in a similar manner by slightly changing the thickness of one window or the spacing between the two windows.

Explosion Bonding

Our coupler design was discussed previously [2], and illustrates the usefulness of fabricating the outer conductor, vacuum assembly, and window Compression Rings as one piece. A braze joint between the copper outer conductor and stainless vacuum tube, would be very difficult to make due to the large surface areas involved. Explosion Bonding (EB) a thin layer of copper onto the inner surface of a stainless steel tube then machining to size is a good and cost effective solution.

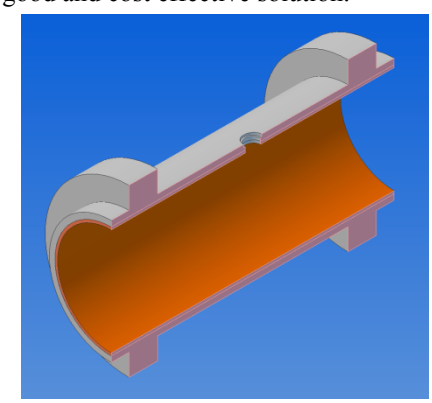

Figure 2: Explosion bonded copper outer conductor, compression rings, and vacuum tube assembly.

One challenge in getting a useable tube lies in the explosion "expanding" the tube in a non-uniform way (bulging), the strength of the explosion, the desired final machined dimensions, and thickness of the copper layer. This is a learning process and depends upon factors such as material, diameter, tube thickness, desired copper thickness, etc. It took two iterations before we determined acceptable initial (pre-explosion) dimensions, and the EB fabricator determined the proper amount of explosive.

Figure 3 is a graphic of the relevant dimensions for the third EB tube. The graphic clearly shows the bulging of the 1" thick stainless steel tube due to the explosive charge. With the earlier trials we, along with the supplier High Energy Metals, Inc., determined that the pre-bonding ID of the stainless steel tube needed to be ~3 inches, after bonding the ID of the Cu sleeve was as shown by the red squares, and the bond line between the Cu and the stainless steel is shown by the green triangles. Thus, the thickness of the Cu layer is approximately 0.300". The ID of the Cu was machined to 3.032" as shown by the dashed line, which leaves the Cu thickness as half the distance between the dashed line and the triangle at that axial location. The gray rectangles indicate the approximate location of the coax windows, and the Cu layer radial thickness is about 0.050" in those locations.

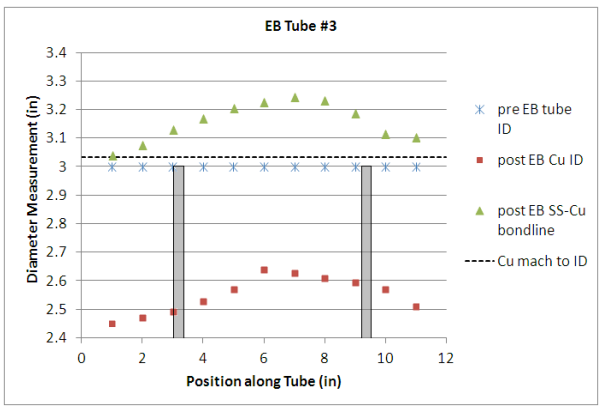

Figure 3: The relevant dimensions for the 3rd Explosion Bonded tube fabrication.

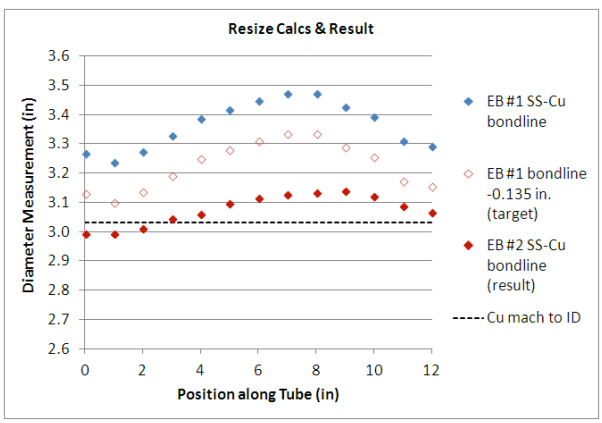

Figure 4: Determination of pre-EB tube ID.

As can be seen from Figure 3 and Figure 4, getting the exact thickness desired is still not exact. Figure 4 shows that there can be a bonding variation (for our size and geometry) of approximately 0.100 to 0.200 inches in diameter. This variation, along with the "bulging" issue requires careful planning and coordination with the EB supplier.

The earlier EB tubes were not wasted as portions of the explosion bonded tube were of suitable dimensions for braze tests to be made. Slices of the tube sufficiently long (~0.8") for two separate window braze tests were machined from the tube, and coaxial windows similar to those discussed in reference 1 were fabricated. In these windows the explosion bonded copper buffer layer surrounding the window ceramic was substantially thicker than in the windows discussed in reference 1, however, the window braze assembly was perfect (Figure 5) and the windows were vacuum tight, and survived a thermal cycle test down to cryogenic temperatures.

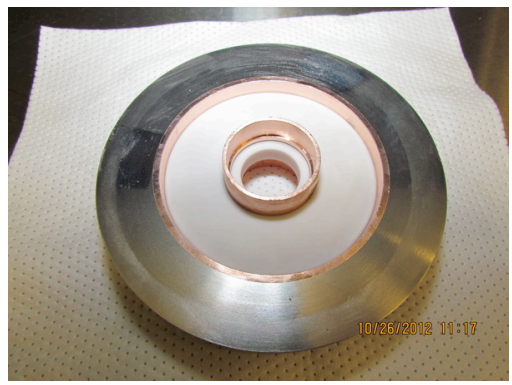

Figure 5: Coaxial window (~3" dia. ceramic) brazed into an Explosion Bonded copper / SS outer Compression Ring.

TECHNICAL APPROACH

Figure 6 shows the hot test assembly as a cut-away concept drawing. The brazed portion of the assembly will be made in two stages. First is the inner window assembly which consists of the inner conductor, the ceramic backing rings, and the two Alumina windows (Figure 7). The second braze bonds the inner conductor assembly to the explosion bonded (EB) assembly, such that the windows are aligned with the thick compression rings of the EB part. EIA adapter flanges and coax are connected for testing purposes.

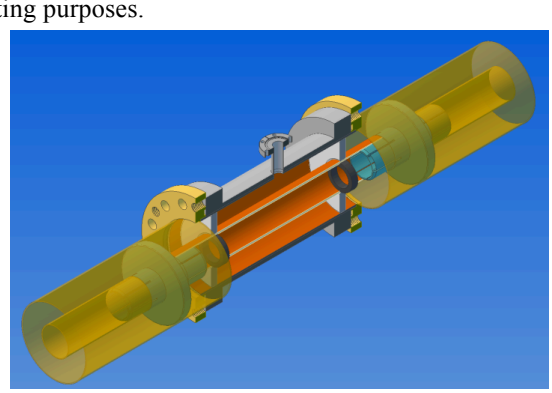

Figure 6: Dual-window Coupler hot test assembly drawing.

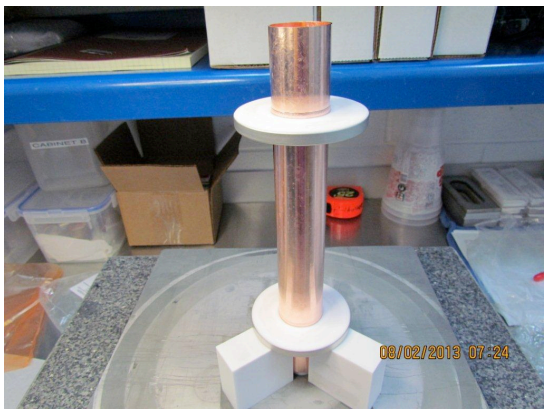
Copyright © 2013 CC-BY-3.0 and by the respective authors



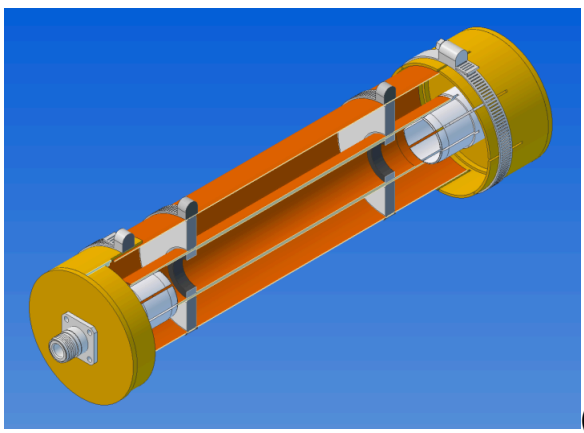


Figure 7: The dual coaxial window inner braze assembly.

Preliminary Testing / Measurements

Prior to the second braze, the inner conductor assembly was tested in a low power RF test (Figure 8). The RF test assembly could be easily made using a thin aluminum sheet rolled and hose-clamped around the metalized OD of the windows. The results are shown in Figure 9. Where the reflection has a -30 dB bandwidth of ~30 MHz, and the S21 transmission loss was measured at <0.01 dB.

Another single brazed window assembly was cycled to 4°K and back in JLab's vertical test dewar, then checked for leak tightness and dimensional changes.

(a)

(b)

Figure 8: Low Power RF test set-up for testing window / inner conductor braze assembly (a – 3D drawing, b – as fabricated).

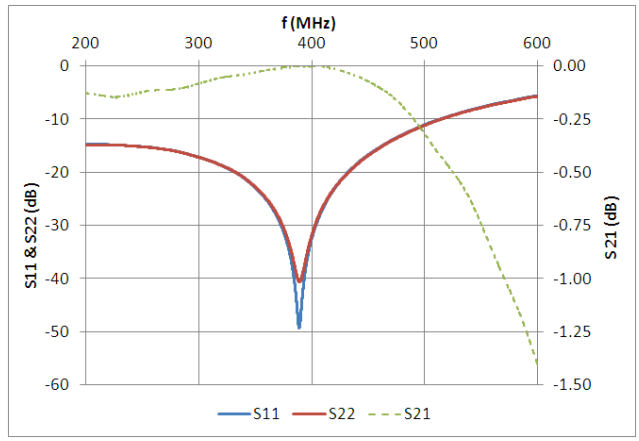

Figure 9: Plot of the S-parameters for the inner conductor low power RF test of Figure 8.

Final Assembly Braze

After measurements of the inner braze assembly, a final braze will be performed between the machined EB tube and the inner braze assembly. Figure 10 below shows the two parts before brazing.

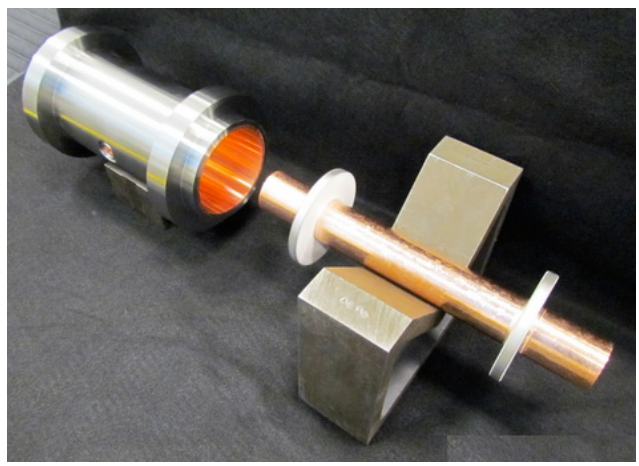

Figure 10: Shown are the inner braze assembly and the machined Explosion Bonded tube.

High Power RF Testing

The Coupler will be thermally cycle tested and vacuum checked to assure a leak tight assembly, then tested at high power using the set-up of Figure 6.

CONCLUSIONS

A dual coaxial window matched coupler has been designed and fabricated using compression ring technology for the windows and explosion bonding to combine the outer conductor to the vacuum wall.

S-BAND LOAD DESIGN FOR SLAC*

M. Neubauer, A. Dudas, Muons, Inc., Batavia, IL 60510, USA
A. Krasnykh, SLAC, Menlo Park, CA 94025, USA

Abstract

S-Band vacuum loads at the SLAC linac are encountering operational problems, now that they have to operate under the stringent requirements of 50 MW peak power, 6 kW average power, and extremely-tight phase stability for the linac. Failure mechanisms have been studied which suggest an RF surface breakdown of the 200 µm Kanthal layer in original RF loads.

Currently there are two approaches for RF load design. The first is based on employing highly resistive materials inside of WR284 waveguide [see SLAC-PUB-15229 or MOPB087 in LINAC12]. An alternative approach is based on using lossy dielectric. This is the approach discussed in this paper.

We have proposed a novel solution which incorporates mode conversion from TE10 in rectangular waveguide to TE01 in round waveguide. Lossy material will be placed in the round waveguide, and the selection of the TE01 mode minimizes the electric field normal to the surface of the lossy material. This lossy material in the TE01 round waveguide will be mechanically confined in compression (without brazing), in order to eliminate tensile stresses in the lossy material. The mode converter will be based upon an X-band mode converter invented at SLAC, and the TE01waveguide load design is based upon HOM load designs developed by Muons, Inc.

We are presently performing additional materials testing, in preparation for fabrication of a full power prototype load. A TE10 to TE01 SLAC converter design will be fabricate for both cold and hot testing.

Operational improvements to the SLAC LCLS linac may require the replacement of all SLAC linac vacuum RF loads. The new design can be scaled for use at other frequencies in a multitude of commercial RF applications.

INTRODUCTION

Recently at SLAC, the increasingly-stringent requirements for phase and amplitude stability of the linac beam have increased the sensitivity to the performance of the present load design. Ten of the current Kanthal loads were inspected, and all ten showed evidence of multipactor. Fifteen spare loads were tested and exhibited multipactor between 1 and 20 MW. An attempt to shift the multipactoring resonance using permanent magnets was not successful.

Dry loads are generally designed using high strength lossy ceramics due to the manufacturing processes used in the construction of such loads. The interface between the lossy ceramic and the support structure is brazed or soldered to make a thermally conductive path between the lossy ceramic, mechanical support, and the cooling circuit. The fact that brazing or soldering is used requires the lossy ceramic to survive large tensile stresses due to the mismatch in thermal expansion between the ceramic and the mechanical support. Efforts to either reduce these thermal stresses, or survive these stresses during thermal cycling, has led to creating strengthened ceramics such as $SiC_{whiskers}$ + Al_2O_3, or using thermally matched materials for the mechanical support such as W_{powder} + Cu in a sintered alloy. Both of these techniques have led to expensive structures due to low manufacturing yields. These low yields are typically due to large manufacturing variables, and narrow process limits, for successful fabrication of dry loads.

In our design, the dry load operates in the TE01 mode to significantly reduce the chance of multipactor, and incorporates mode converters designed by SLAC. The lossy ceramic components are cast into cylinders, from slurries composed of mixtures of SiC and porcelain, and processed to full densification and vitrification. These lossy cylinders are held in mechanical compression rather than being brazed. The microwave characteristics of the lossy ceramic cylinders have been measured, and further measurements will be made to determine the optimum mixture for various loading elements.

TECHNICAL APPROACH

TE01 Mode

The most reliable high peak power load will have no normal electric field components on the lossy material. This should simply eliminate the occurrence of multipactoring and arcing. Since the TE01 mode is a low loss mode, the uniformity of loss within the lossy dielectric is not as critical as it would be if compared to operation using other modes. This fact serves to relax the manufacturing process limits, as compared to those which are required in loads utilizing other modes and designs, such as the TE10 mode in rectangular waveguide utilizing lossy walls.

A SLAC designed TE10 - TE01 mode converter from WR284 rectangular waveguide to 6 inch round waveguide was used for the initial measurements (Figure 1). With two mode converters the insertion loss of lossy cylinders can be measured in the TE01 circular mode. The wrap-around mode converter is primarily scaled from the X-band version that was invented by Sami Tantawi of SLAC [1]. The VSWR of these mode converters back-to-back was 1.13 at 2856 MHz, likely due to out-of-round circular waveguide and non-matching edges at the mating flanges. Some slight tuning on the endplates could improve that number to less than 1.11 at 2856 MHz.

Figure 1: Two wrap-around mode converters for insertion loss measurements of lossy ceramic cylinders. S11 was measured to be less than -23.2 dB at the center frequency.

Novel Lossy Ceramic Cylinders

The lossy material chosen during the program was SiC_{powder} + porcelain. This lossy ceramic material is our new contribution to the design of high power microwave loads. It was chosen because of our system approach to the design and fabrication of a dry load. The fundamental concept that allows for its use is simply that high tensile strength lossy material is not a requirement of our design, as the ceramic material is held in compression.

The comparison of various mechanical properties of alumina and porcelain is shown in Table 1.

Table 1: Comparison of Porcelain and Alumina

	Porcelain	Alumina	
Flexural Strength	130(19)	380(55)	Mpa(ksi)
Tensile Strength	105(15)	170(25)	Mpa(ksi)
Compression	590(86)	2700(391)	Mpa(ksi)
Youngs Modulus	70	370	
Dielectric Strength	25	8.6	MV/m
Fracture Toughness	2	4.5	$MPa\text{-}m^{1/2}$
Thermal Conductivity	5	30	W/m-K

From these values it is clear that porcelain is mechanically inferior to alumina, which explains to a large degree why porcelain has not been used as a lossy ceramic the way that alumina and aluminum nitride have been. This again points to the very important and critical aspect of our systems design approach to this load. *The lossy ceramic is held in compression. It is not brazed and the assembly technique never allows for tensile stress to build up within the material.*

Tests

A number of lossy porcelain ceramics were fabricated with varying amounts of SiC_{powder} incorporated.

Figure 2: Photo of a 6" diameter lossy cylinder.

Their loss was measured using the back-to-back converters configuration of Figure 1 and a Network Analyzer. Using an Agilent 85070E the dielectric constant was measured for similarly made porcelain test disks which incorporated various amounts of SiC_{powder}.

The test disk results indicated that with percentages of SiC_{powder} less than 30% by dry volume, the uniformity of the material was difficult to control. With greater than 30%, the standard deviation was 5-6% of the real part of the dielectric constant, and the standard deviation of the loss tangent was less than 25%. The case where 52% by dry volume of the SiC_{powder} was used produced a lossy ceramic with an average dielectric constant of 7.44-0.37i, yielding a loss tangent of 0.05 as measured by the Agilent probe method.

It should be noted that the Agilent probe is not recommended for materials with loss tangents less than .05, and for materials with ε_r'>5 with loss tangents <0.5[2]. Unfortunately these measured values are exactly in that range, so it is best to assume the error around these values is fairly large. Fortunately, it does suggest the material concentrations that will be best suited for the lossy ceramic cylinders, in terms of tolerances in the manufacturing process, are in the range of 30-50% SiC.

The test assembly of Figure 1 was also modeled on Comsol (Figure 3) to compare measured results with simulated results. Once the model agrees well with the measured results, we will be able to model the loss effects of varying material parameters thus allowing a complete multi-section load model to be simulated with varying amounts of loss per section.

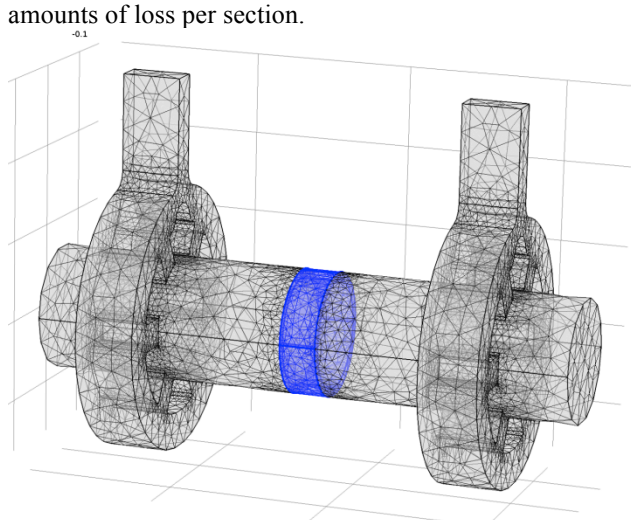

Figure 3: Comsol model of the back-to-back converters and a porcelain test cylinder.

The test cylinders were made by a slip casting process, ground on the outside diameter to 5.990 inches, and placed in the Figure 1 test fixture for S-parameter measurements. As expected, the results show a loss proportional to the percentage of SiC in the cylinder.

The measurements of each test cylinder are considered to be roughly the equivalent of what would comprise a single section of the load, the full load being approximately 10 such sections. Based upon our initial

Copyright © 2013 CC-BY-3.0 and by the respective authors

measurements, Table 2 shows the approximate %SiC needed for the cylinder of each load section, in order to distribute the losses evenly along the length of the load.

Table 2: Typical Loss Requirements for Each Section of the Load and %SiC

Section #	Input	1	2	3	4	5	6	7	8	9	10
Watts	6000	5400	4800	4200	3600	3000	2400	1200	600	300	150
db	67.8	67.3	66.8	66.2	65.6	64.8	63.8	60.8	57.8	54.8	51.8
db/section		0.46	0.51	0.58	0.67	0.79	0.97	3.01	3.01	3.01	3.01
Reflected											51.8
Return Loss	-32.0	35.7	36.2	36.7	37.3	38.0	38.8	39.7	42.7	45.7	48.8
Loss (db/in)*		0.18	0.20	0.23	0.27	0.32	0.39	1.20	1.20	1.20	1.20
% SiC		*25*	*26*	*28*	*29*	*31*	*32*	*43*	*43*	*43*	*43*
*assuming 2.5 inch long cylinders .25 inches thick											

RF Design

The final load design will consist of a number of "identical" (in appearance) sections, with each section designed to be self-matching. That is, for a cylinder length of λ/4 the reflection off the leading edge of the lossy ceramic cylinder is canceled by the reflection off the back edge of the cylinder.

For a cylinder with a dielectric constant of 8 and a loss tangent of 0.04, a 1.1:1 VSWR (26 dB return loss) is achieved over 50 MHz, and the sensitivity to length is ±0.1 inch for a VSWR of less than 1.1:1.

We are currently exploring a manufacturing process that we feel will improve the mixing of the slip and casting of the cylinders, in order to produce a high degree of uniformity throughout the volume of the cylinder.

Mechanical Design

As shown in Table 2, the load is currently planned to be made up of 10 sections with a loss per section of about 600 watts to balance the heat load along the load length. Each section of the load will be constructed to be self-matching as described above, and in a compression assembly similar to what is shown in Figure 4.

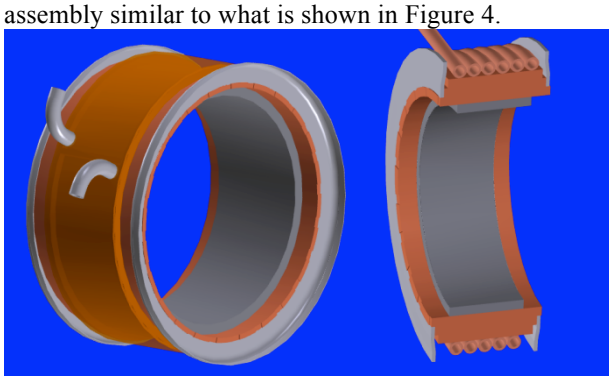

Figure 4: Cross section view of the lossy ceramic cylinder in the compression assembly and different cooling channel options for the prototype assembly.

The compression assembly is designed to be an interference fit at room and operating temperatures. Assembly is accomplished by flowing 100°C water through the cooling channel of the compression ring. The copper expands and easily slips over the lossy ceramic cylinder. This process has been successfully utilized by Muons, Inc. in a number of applications, from HOM load construction techniques to braze assemblies for coaxial RF windows.

The exact details of the construction of the compression ring will be worked out during Phase II.

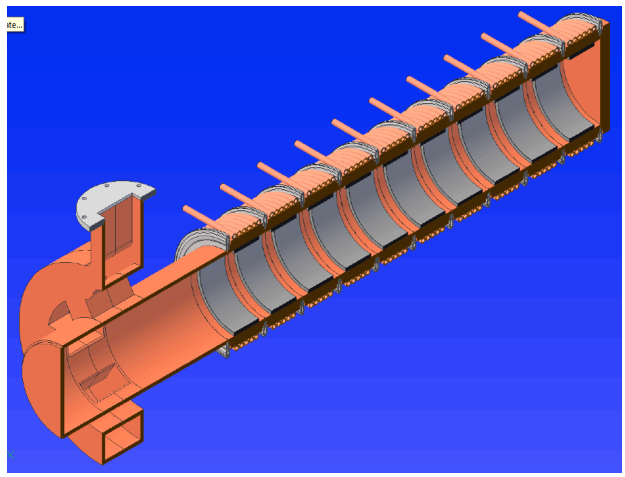

Figure 5: Final prototype configuration of the complete dry vacuum load.

Figure 6 shows ANSYS calculations of the cooling and anticipated operating temperature of the lossy ceramic. It shows that the conservative value of 600 watts of power dissipation raises the maximum temperature of the lossy ceramic by only 2 °C above the cooling water temperature. The reason for this low value is that the surface area of the 6" × 2.5" cylinder is quite large. Thus, we do not expect thermal issues to be significant in this load design.

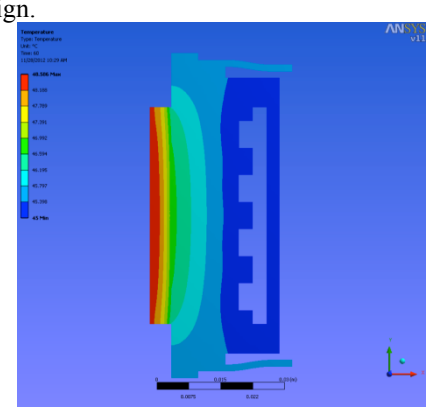

Figure 6: ANSYS results for a single section model.

ACKNOWLEDGEMENTS

HIGH-POWER LOW-VOLTAGE MULTI-BEAM KLYSTRONS FOR ILC AND PROJECT-X*

V. Teryaev[1], S.V. Shchelkunov[1,2], J.L. Hirshfield[1,2], N. Solyak[3], V. Yakovlev[3], S. Yu. Kazakov[3]

[3]Fermilab, Batavia, IL 60510, USA

Abstract

Designs of two multi-beam klystrons with parameters suitable for ILC and for the 8-GeV pulsed stage of Project X (PX) have been developed. The chief distinction of these tubes from other MBKs is their low operating voltage, namely 60 kV for the ILC tube and 30 kV for the PX tube. Advantages of low voltage include no requirement for pulse transformers or oil-tanks for high-voltage components, and simpler modulators. A 6-beamlet quadrant of the ILC tube has been built and is soon to undergo tests; it is designed to produce 2.5 MW at 1.3 GHz in a 1.6 ms wide pulse at a 10 Hz pulse rate; a four-quadrant future version would produce 10 MW. The 6-beamlet PX tube is to produce 520kW, and would operate in one of two regimes, either at a repetition rate of 2 Hz delivering 30 ms pulses, or at 10 Hz delivering 8.5 ms-long pulses. The PX tube is currently undergoing engineering design, with construction scheduled for completion by the end of 2014.

INTRODUCTION

Multi-beam klystrons (MBKs) are the most advanced stage in the evolution of high-power klystron design. The distinct feature of MBKs is their relatively low-voltage beams (beam-lets) as compared to the single beam in traditional tubes. This provides numerous advantages: MBKs can use a simpler (and thus, a cheaper) modulator—or even a switched power supply; no pulse-transformer is required; and there is no need for a high-voltage oil tank to insulate the gun. An MBK can be made significantly shorter (e.g. by a factor at least 2) than a single-beam tube delivering the same power and pulse; in particular the collector length can be greatly reduced. The challenges associated with MBKs are typically to design the cavity chain where all parasitic modes are sufficiently detuned, which is accomplished by using a set of metal shunts inserted in some of the cavities to cause either inductive or capacitive detuning, particularly in the input and/or output cavities where the RF field interacts with all the beam-lets, or by using individual gain and penultimate cavities each serving a sub-group of beam-lets (beam-let cluster) and working at the fundamental mode. To easily match the beam between the gun, the cavities, and collector, the magnetic system is typically divided by iron pole-pieces into regions of independent control. An associated challenge is to have coil and pole-piece configurations where the transverse magnetic field on the axis of each beam-let is less than 0.5% of the longitudinal field, while keeping the magnetic system design relatively simple. In [1] and refs therein, detailed descriptions can be found of tools, methods, approaches and recipes to address the aforementioned challenges; in particular, contemporary state-of-the-art codes such as MAGIC [2], MERMAID [3], and DGUN [4] are invaluable in designing MBKs.

MBK FOR ILC

In [1], the tube's conceptual design was presented. Herein we mention briefly its parameters and main features. Figure 1 presents the layout; the design parameters are shown in Table 1.

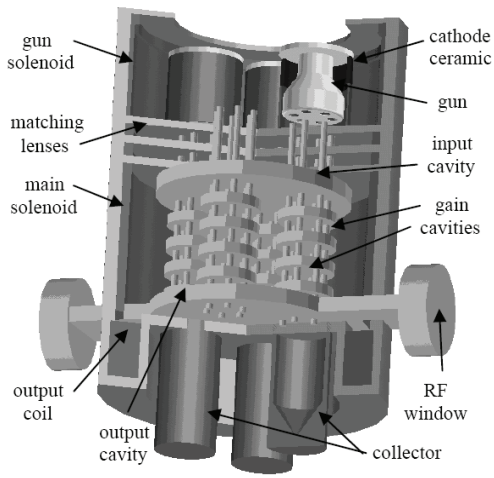

Figure 1: Layout of ILC MBK.

Table 1: Design Parameters of ILC–MBK

Operating frequency, MHz	1,300
Beam voltage, kV	60
Beam-let microperveance	0.85
Number of beam-lets	24
Beam-let current, Amps	12.5

Efficiency, %	65
Output RF power, MW	10
Average output power, kW	150
Pulse width, ms	1.6
Saturated gain, dB	50
Cathode loading, Amps/cm^2	2.7
Gun surface electric field, kV/cm	65
Total tube length, m	1

Copyright © 2013 CC-BY-3.0 and by the respective authors

Note that the electron gun is divided into 4 sectors, each delivering 6 beam-lets. The input and output cavity are common for all beam-lets. The gain cavities are clustered, each serving a group of 6 beam-lets.

At present, to validate the design of the entire tube, and to minimize technical risk, Omega-P is building a single quadrant of the tube that has only 6 beam-lets. The 6-beamlet quadrant is to produce 2.5 MW at a 10 Hz repetition rate; the rest of its parameters are as shown in Table 1.

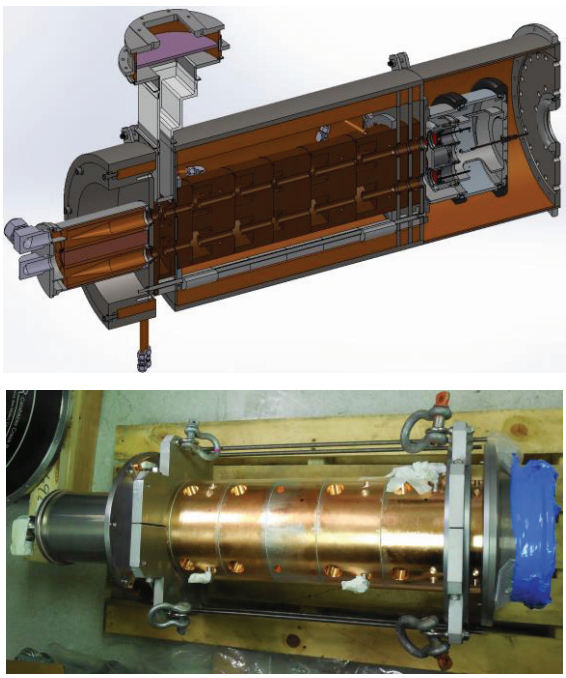

Figure 2: The 6-beamlet quadrant is to produce 2.5 MW at a 10 Hz repetition rate; the tube (at top) is shown inside the solenoid, and the cavity structure with the collector (at bottom) is photographed without the gun.

The 6-beamlet quadrant structure is being built for Omega-P by Calabasas Creek Research Inc. Presently the structure is undergoing final brazing. The magnetic system has been built by Stangenes Industries Inc. and is presently undergoing certification. The expectation is that the 6-beamlet quadrant will be ready for testing in the beginning of 2014.

MBK FOR PROJECT-X

The design parameters of this MBK are shown in Table 2. The tube is to operate at a gun voltage of only 30 kV.

Figure 3 shows a schematic of the tube. Its design incorporates many features found in the 6-beamlet quadrant of the ILC tube. The simulation work has been completed, and presently the engineering designs are nearly complete for the gun, collector, and the chain of gain, second-harmonic and penultimate cavities; the input and output cavities still require some simulation work to optimize the coupling (with a loop-like coupling element for the input cavity, and waveguide for the output cavity) while having the RF field distribution at the location of all 6-beam-lets as identical as possible. Fabrication of the magnetic system will begin soon.

Table 2: Design Parameters of PX–MBK

Operating frequency, MHz	1,300
Beam voltage, kV	30
Beam-let microperveance	0.85
Number of beam-lets	6
Beam-let current, Amps	4.4
Total current, Amps	26.4
Efficiency, %	65
Output RF power, kW	515
Average output power, kW	30/ 42.5
Pulse width, ms	30/ 8.5

Saturated gain, dB	46
Cathode loading, Amps/cm^2	2.1
Total tube length, m	0.85

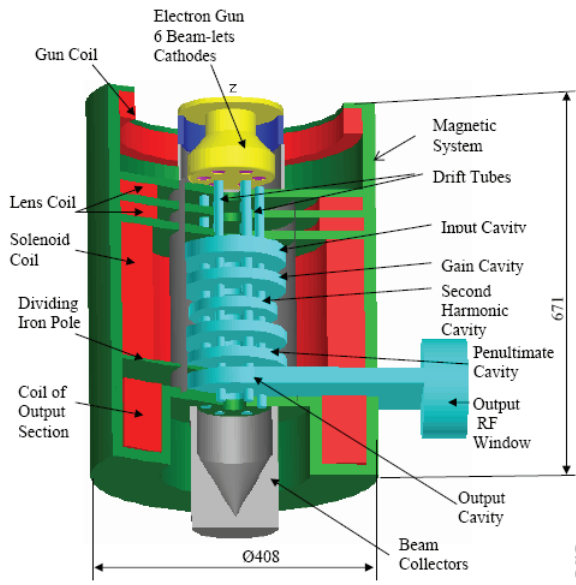

Figure 3: MBK for Project X.

As with the ILC MBK, the PX MBK has its magnetic system divided into several independent regions to allow good beam matching between the gun, cavities and the collector: an example is shown in Fig. 4. In addition, the solenoid around the cavity chain has a special periodic spacing which allows it to have very little transverse magnetic field (0.22 G max.) and only small ripples in longitudinal magnetic field (0.56 G peak-to-peak) at the locations of all 6 beam-lets.

The collector, shown in Fig. 5 is of a cellular design with cells uncoupled from one other; this feature helps to greatly reduce any space charge effects and parasitic mode oscillations.

The cavities operate in the fundamental TM_{010} mode; thus dealing with detuning of parasitic modes which would be required if operation were at higher-order modes is avoided.

OPTIMIZATION OF THE SLED PHASE MODULATION PARAMETERS OF THE FERMI LINAC*

C. Serpico, M. Dal Forno, A. Fabris, Elettra-Sincrotrone Trieste S.C.p.A., Trieste, ITALY

Abstract

FERMI is a single-pass, linac-based, FEL user-facility covering the wavelength range from 80 nm to 4 nm and is located next to the third generation synchrotron radiation facility Elettra in Trieste, Italy. The first FEL line in operation (FEL-1) has been opened to users at the end of 2012, while the second FEL line (FEL-2) covering the shorter wavelength down to 4 nm is in commissioning. The linac is composed of 16 S-band accelerating structures. Seven of them are Backward Traveling Wave (BTW) structures equipped with SLED system. Following the preliminary tests on one plant, in order to increase the operational accelerating gradient, phase modulation of the SLED drive power has been implemented on all BTW structures. The shape of the phase modulation is applied via the LLRF system firmware and can be modified if needed. This paper discusses the optimization of the phase modulation parameters.

INTRODUCTION

FERMI is a single-pass Free Electron Laser (FEL) driven by a normal conducting S-band linac composed of 16 accelerating structures. Seven of them are Backward Traveling Wave structures (BTW), coming from the old Elettra injector, with a filling time of 0.757μs. Each structure is fed by a $45MW$ peak power, 4.5μs pulse width Thales klystron. Taking advantage from the short accelerating structure filling time, the peak power to the structure is increased by shortening the pulse length: each power plant is equipped with PEN (Pulse Enhancement Network) system [1] that stores the energy at the beginning of the pulse and release it near the end of it.

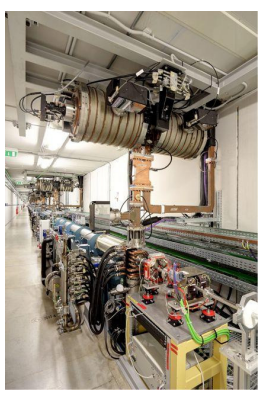

Figure 1: Pulse enhancement network system for a backward traveling wave structure.

* Work supported in part by the Italian Ministry of University and Research under grants FIRB-RBAP045JF2 and FIRB-RBAP06AWK3.

To achieve the Linac target energy of 1.5 GeV, each BTW structure needs to be operated at a gradient of 26 MV/m corresponding to an energy gain of about 155 MeV. Past operation of those structures, showed that breakdown problems inside the sections, associated with the very high peak-field built up during conventional SLED operation, prevented from reaching the desired gradient in a reliable way.

A phase modulation technique was implemented to lower the high peak field inhered with conventional SLED operation: while a preliminary linear phase modulation has allowed to demonstrate the utility of this technique in our application and has allowed to increase the energy gain in the structures, the possibility of an optimization of the phase modulation parameters has been studied to get the optimal trade-off between lowering the peak field, thus improving reliability, and still having an acceptable energy gain.

PRELIMINARY PHASE MODULATION

The phase modulation feature was integrated in the LLRF firmware of FERMI. The preliminary implementation of the phase modulation technique foresees just a linear modulation [2] where two parameters (i.e. the initial phase ϕ_0 and the phase modulation slope m) can be modified to change the shape of the modulation as depicted in Figure2.

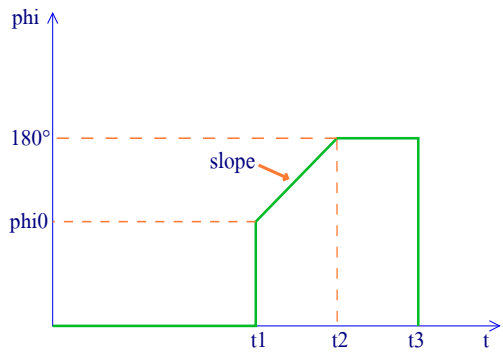

Figure 2: Linear phase modulation.

During a dedicated machine commissioning shift, different sets of parameters were tested: the optimal results (in terms of a trade-off between peak field and gradient loss) were achieved using an initial phase offset ϕ_0 of 95° and a slope m of 149 deg/μs.

A comparison between the pulse shape in case of conventional SLED operation and the one with the optimized linear phase modulation showed that for the same RF pulse

Copyright © 2013 CC-BY-3.0 and by the respective authors

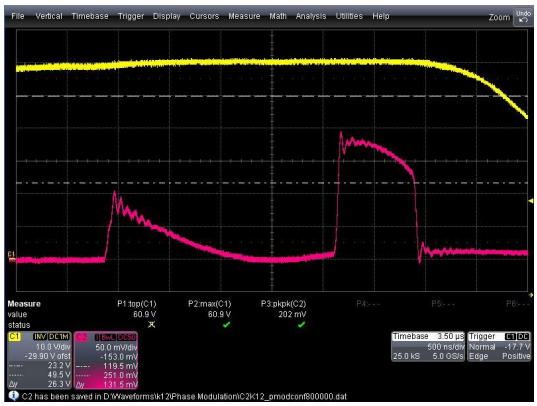

Figure 3: Input cavity field with phase modulation.

length (3000 ns), the peak field is reduced by almost 20%; correspondingly the energy gain loss is about 4%.

It must be noted that by simply using a linear phase modulation it was not possible to achieve a rectangular-like pulse shape. As depicted in Figure3 during the 770 ns pulse duration the normalized field amplitude varies from about 1.8 up to 1.4 (i.e. about 20% variation). Also, it can be pointed out that a huge phase slippage of about 46 degree between the begin and the end of the pulse occurs.

A way to get flatter pulse and smaller phase variations is to implement a continuous non-linear phase modulation.

NUMERICAL EVALUATION FOR A NON-LINEAR PHASE MODULATION

The phase modulation program for rectangular pulse shape has been numerically evaluated by solving the equations 1a and 1b for constant v_0 amplitude during pulse compression [3] [4]:

$$\begin{cases} \tau \dot{v}_c + v_c = -\alpha v_k & \text{(1a)} \\ v_0 = v_c + v_k & \text{(1b)} \end{cases}$$

where v_k and v_c are the generator and the pulse compressor equivalent complex voltages, β is the coupling coefficient between the SLED and the transmission line, $\alpha = 2\beta/(1+\beta)$ and τ is the filling time of the SLED cavities equal to $2Q_0/[(1+\beta)\omega_0]$. In the previous expression Q_0 is the unloaded quality factor of the SLED cavities and ω_0 is the angular frequency of the RF wave.

In our case, β is 10 and Q_0 is 190000. Accordingly, α is about 1.8 and the filling time τ is 1.832μs.

Equation 1a assumes that the resonant frequencies of the SLED cavities and of the RF wave are equal. In case there is a small difference between these two frequencies the equation 1a must be replaced by 2a where $\Delta\omega = \omega_0 - \omega_c$ and ω_c is the angular frequency of SLED cavities [4] [5]. This is necessary to minimize the phase variation during the flat-top of the pulse delivered to the structure.

$$\begin{cases} \tau \dot{v}_c + v_c\left(1 + j\tau\Delta\omega\right) = -\alpha v_k & \text{(2a)} \\ v_0 = v_c + v_k & \text{(2b)} \end{cases}$$

Replacing $v_c = v_0 - v_k$ in equation 2a as derived from equation 2b and discretizing the differential equation 2a we get:

$$\begin{aligned} v_{k_{i+1}} = v_{0_{i+1}} - v_{0_i}\left[1 - (1 + j\tau d\omega)\frac{dt}{\tau}\right] + \\ + v_{k_i}\left[1 - (1 - \alpha + j\tau d\omega)\frac{dt}{\tau}\right] \end{aligned} \quad (3)$$

Let's put:

$$\begin{aligned} w_i = v_{0_i}\left[1 - (1 + j\tau d\omega)\frac{dt}{\tau}\right] + \\ - v_{k_i}\left[1 - (1 - \alpha + j\tau d\omega)\frac{dt}{\tau}\right] \end{aligned} \quad (4)$$

where w_i groups all the term at time instant i. We can write:

$$v_{k_{i+1}} = v_{0_{i+1}} - w_i \quad (5)$$

The goal of a non-linear phase modulation is to get a rectangluar-like pulse shape to the structure during the pulse compression. The amplitude square of the voltage to the structure at time instant $i+1$ can be written into the form:

$$\begin{aligned} \left|v_{0_{i+1}}\right|^2 &= \left|v_{k_{i+1}} + w_i\right|^2 \\ &= \left|v_{k_{i+1}}\right|^2 + \left|w_i\right|^2 + 2Re\left\{v_{k_{i+1}}\bar{w}_i\right\} \end{aligned} \quad (6)$$

So, we have:

$$\begin{aligned} \left|v_{0_{i+1}}\right|^2 = \left|v_{k_{i+1}}\right|^2 + \left|w_i\right|^2 + \\ + 2\left|v_{k_{i+1}}\right|\left|w_i\right| cos\left(\angle v_{k_{i+1}} - \angle w_i\right) \end{aligned} \quad (7)$$

The phase modulation program must set the phase of the generator $\angle v_{k_{i+1}}$ such that the amplitude $v_{0_{i+1}}$ of the compressed pulse is kept as constant as possible.

If we call $v_{0_{PR}}$ the amplitude of the compressed pulse at the phase reversal time t_1, the phase of the generator at time instant $i+1$ for getting a constant amplitude pulse shape (i.e. equal to $v_{0_{PR}}$) could be then calculated with the following equation:

$$\angle v_{k_{i+1}} = arccos\left(\frac{\left|v_{0_{PR}}\right|^2 - \left|v_{k_{i+1}}\right|^2 - \left|w_i\right|^2}{2\left|v_{k_{i+1}}\right|\left|w_i\right|}\right) + \angle w_i \quad (8)$$

SIMULATION RESULTS

Running the simulation code it was possible to find a phase modulation program resulting in a flat amplitude pulse shape. Even if reaching a flat amplitude pulse for a given klystron power and pulse width is at expenses of the energy gain, lowering the peak fields could allow to increase the klystron output power without suffering of heavy breakdown phenomena in the structures' couplers and cells: in the end, this could finally result in a higher energy gain.

To reach a flat-top pulse it is necessary to change the phase by less than 180° at the phase reversal time and then

Copyright © 2013 CC-BY-3.0 and by the respective authors

increase it slowly to keep the pulse flat. As depicted in Figure4 as the phase reaches 180° it cannot further keep the pulse amplitude constant, so it decays exponentially. To get more power to the structure, the phase jump at the phase reversal time should be larger, but then the power cannot be kept constant until the end of the pulse.

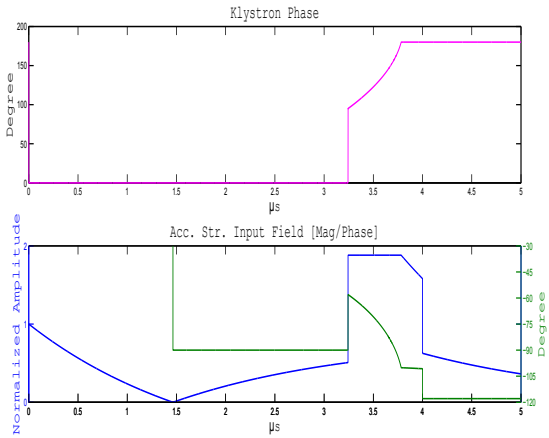

Figure 4: Non-linear phase modulation scheme.

So, for a 4μs pulse width, it was chosen an initial phase jump of 86 degrees: in this condition, the field amplitude at the phase reversal time is limited to about 1.75 (i.e. ≈ 3 in power). A non linear phase modulation than guarantees a constant amplitude field during the 770 ns pulse width. However, with this parameters the phase slippage along the RF pulse is about 50° as showed in Figure5.

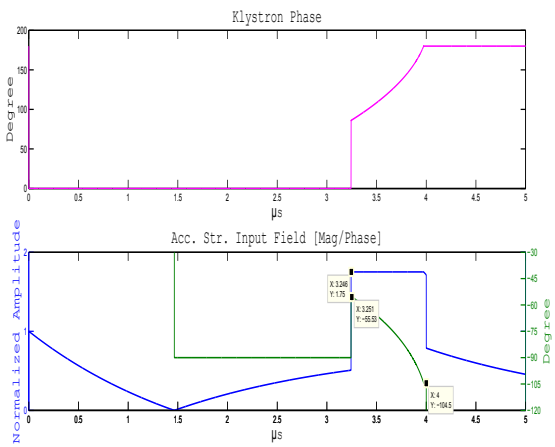

Figure 5: Pulse shape with non-linear phase modulation.

Nonetheless, the phase variation during the flat-top pulse can be minimized by slightly detuning the SLED cavities: this corresponds to choose a suitable $\Delta\omega$ in equation 2a. The frequency shift must be then compensated with a linear ramp of the phase in the first part of the klystron pulse. Figure6 shows the final pulse shape that could achievable with the new phase modulation program.

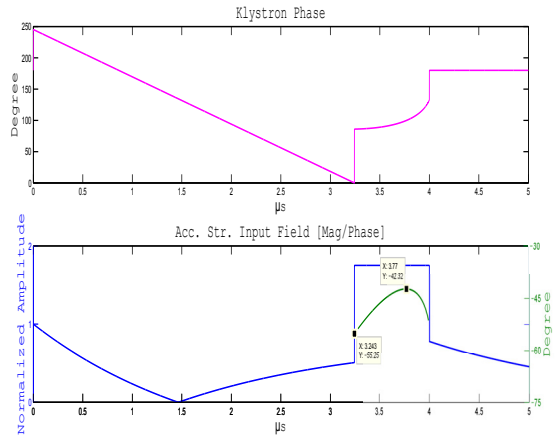

Figure 6: Pulse shape with non-linear phase modulation and SLED cavities detuning.

CONCLUSION

Based on our experience, we can say that our BTW accelerating structures can handle in a reliable way an input peak power of about 97 MW: using the actual linear phase modulation program, to stay below this limit, we operate the klystron at about 32 MW peak power with a 3.5μs pulse width resulting in a accelerating gradient of about 150 MeV.

The new phase modulation program, resulting in a flat amplitude pulse shape, lowers the peak field in the accelerating structure. This could allow to push the power of the klystron up to 36 MW and 4 μs pulse width while still keeping the peak power to the structure under the limit of 97 MW: in this operating conditions, the effective energy gain for each structure should reach about 165 MeV, assuring in this way a reliable margin for the operation of the FERMI Linac at the final target energy of 1.5 GeV.

ENERGY AND REPETITION RATE UPGRADE OF THE S-BAND RF SYSTEM OF THE FERMI LINAC*

A. Fabris#, P. Delgiusto, F. Gelmetti, M. Milloch, A. Milocco, F. Pribaz, C. Serpico, N. Sodomaco, R. Umer, L. Veljak, Elettra - Sincrotrone Trieste, S.S. 14 – km. 163,5, in Area Science Park, 34149 Basovizza, Trieste, Italy

Abstract

FERMI is a single-pass linac-based FEL user facility covering the wavelength range from 80 nm to 4 nm and is located next to the third generation synchrotron radiation facility Elettra in Trieste, Italy. The first FEL line in operation (FEL-1) has been opened to users at the end of 2012, while the second FEL line (FEL-2) covering the shorter wavelength range down to 4 nm is in commissioning. In 2013 the linac energy will be increased following the full RF conditioning of the backward traveling wave accelerating structures and of the SLED cavities. The repetition rate has been also increased to 50 Hz following the installation of the new RF gun and the completion of the upgrade program of the klystron modulators. This paper discusses the strategies adopted for the energy and repetition rate upgrade of the S-band linac and provides a description of the status and of the first results.

INTRODUCTION

FERMI is a FEL facility based on a warm linac followed by a single pass FEL [1]. Two FEL lines are installed: FEL-1 and FEL-2. The accelerator mainly consists of an RF photocathode gun, an S-band linac, an X-band structure, a laser heater, two bunch compressors and the beam transport line to the undulators of the two FEL lines.

The S-band linac is presently composed of sixteen accelerating structures. The first nine structures are forward traveling wave (TW) ones. Two of them are 3 m long and are from the old Elettra injector, while the remaining seven are 4.5 m long and are LIL type coming from CERN. The last seven structures of the machine are 6.2 m long backward traveling wave (BTW) type and are equipped with SLED systems. Also these structures were used in the old Elettra linac injector. The machine layout reserves the space for two more accelerating structures that will be added in the future [2].

Fifteen S-band 45 MW, 4.5 μs. pulsed klystrons are installed, powering the structures, the gun and the three RF diagnostic deflectors. Typical powering scheme is two structures per klystron for the TW case and one structure per klystron for the BTW one. The system is in operation on a 24h/day basis and the total operating hours/year is higher than 6000.

The commissioning of the facility is rapidly advancing [3]. The first FEL line (FEL-1) has been opened to the external users, while the commissioning of the second one (FEL-2) is advancing. FEL-1 is typically operating at 1.2 GeV beam energy and 10 Hz repetition rate. FEL-2 requires the increase of the beam energy to reach the final specifications in term of shorter wavelength. At the same time the installation of the new gun, capable of operating at 50 Hz, and the upgrade of the modulators, completed at the beginning of 2013, will allow to push the repetition rate of the machine from the present 10 Hz value to the design one, once the conditioning of the structures is completed.

REPETITION RATE UPGRADE

All the modulators installed in the machine are pulse forming network (pfn) type (see Fig.1). The first six modulators installed in the machine were assembled using the hardware of the plants of the old Elettra injector to allow the start of the commissioning studies. For this reason they were limited to 10 Hz by the hardware. The pulse forming network, the pulse transformer and the klystron tank were replaced to allow higher dissipation due to the augmented duty factor. The pfn is now water-cooled and has a better pulse flatness, while the pulse transformer has a reduced core dissipation and pulse droop. The klystron tank is water-cooled and additional lead shielding was added to the tube. The high voltage power supply was also replaced with a new one that has a higher range of current and voltage and better stability.

Figure 1: One of the RF power plants.

In addition to the replacement of some of the major components, a revision of the modulators was carried on in order to optimize the operation at 50 Hz and the stability of the klystron anodic voltage. The resonant charging scheme has been replaced by direct charging of the pfn. This allows to avoid the use of big storage capacitors and inductors, which means a reduction in stored energy, in space and in the dielectric oil. Other

advantages of the solution adopted are the improvements in the end of charge voltage repeatability and the reduction of the parasitic capacitance and inductance in the high current path.

Minor upgrades were also performed in the remaining modulators, already designed and assembled for the 50 Hz case. The upgrade activities of all the modulators were organized in order not to affect the commissioning calendar and were completed in time in January 2013.

ENERGY UPGRADE

The energy of the electron beam should be increased to 1.5 GeV for FEL-2 to reach the shorter value of the design wavelength range. Table 1 reports the parameters of the energy gain and power from the klystrons for FEL-1 used until May 2013.

Table 1: Energy Gain (on crest) for FEL-1 (May 2013)

Section type	Energy gain	Klystron power
TW - 3m	~ 47 MeV	32 MW @ 2 μs
TW - 4.5 m	~ 55 MeV	32 MW @ 2 μs
BTW - 6.2 m	~ 120 MeV	22 MW @ 3 μs

Although the energy target should be achievable with the present set of structures, it must be remembered that the machine foresees the installation of two more structures, both in terms of space and available power from the not used output ports of the already installed klystrons. These two structures will contribute with additional 100 MeV to the electron beam energy budget.

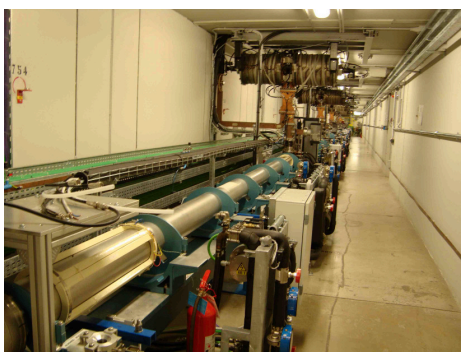

Figure 2: One of the SLED equipped BTW structures.

The increase of energy is obtained by raising the accelerating gradient in the BTW structures (Fig.2) so that their energy gain is in the 150 MeV/structure range. For these structures, equipped with SLED, there is RF power available still maintaining a reasonable safety margin, since operating peak power will be around 32 MW. However, it should be considered that in the past operation in the former injector of Elettra these structures suffered of heavy breakdown phenomena when pushed to high gradient. For this reason till the beginning, a phase modulation of the SLED phase reversal was introduced to lower the peak electric field. Following the preliminary test that showed the advantages of this technique [4], this procedure was routinely applied on all the plants.

For the TW structures, which are powered in pairs, the possible increase in energy is limited by the available power with the present set-up. Since the target energy could be reached only with the improved gain in the BTW structures and considering also that increasing the energy gain in the TW structures would require a re-optimization of the present working parameters at the first bunch compressor, it was decided to leave them untouched.

CONDTIONING RESULTS AND OPERATION

For the commissioning of the plants at 50 Hz and for the conditioning to 1.5 GeV, two periods were allocated so far in the present year: four weeks in May and one week in August. During the first period, both 50 Hz and RF conditioning was performed, while in the second only further 10 Hz RF conditioning was done.

At the end of the first period 1.5 GeV (on crest) at 50 Hz were reached. However, due to the fact that the breakdown rate was still too high, there was no possibility to extend the conditioning period and since the machine was required to operate at 10 Hz in the following runs, it was decided to set the maximum working energy of the machine at 1.46 GeV (on crest) at 10 Hz. In August further conditioning was performed at 10 Hz and the peak energy achieved was increased to 1.54 GeV. It must be noted that the result was only limited by the allocated time.

Table 2: Energy Budget after the Conditioning Periods

Section	50 Hz -May'13	10 Hz -Aug'13
TW – 3m	~ 47 MeV	~ 47 MeV
TW- 4.5 m	~ 55 MeV	~ 55 MeV
BTW -6.2 m	~139 MeV	~149 MeV
Linac energy (on crest)	1.46 GeV	1.54 GeV

The increase to 50 Hz of the power plants was achieved without any issue. In particular there was no change in the plant fault rate and in the frequency of the klystron arcs, which account for the major number of trips of the system. The TW structures, where only frequency rate upgrade was performed and no increase in gradient was required, reached the target value in few days.

The BTW structures operation at the gradient for 1.5 GeV at 50 Hz showed a still too high breakdown rate and therefore they need further conditioning to assess their ultimate performance. During the RF conditioning most of the vacuum spikes were detected by the ion pumps near to the structure input, which seems to suggest that breakdown events took place in the structure input coupler and cells. This is in-line with the observation

Copyright © 2013 CC-BY-3.0 and by the respective authors

performed on these structures in the past and with the simulation performed [5]. The main hardware issue was the failure of the ceramics of the reflected power port of the directional couplers between the SLED output and the accelerating structures input, which occurred three times.

Following the conditioning period, the structure are normally set to the maximum gradient reached that allows both sufficient reliability for the machine operation and consolidation of the results. The experience shows a nice decrease of the total number of vacuum trips with time (Fig. 3).

As for the next conditioning phases, since most of the time, for example when working for FEL-1, the beam energy required is lower than the maximum available, one or two sections are set off-line. On these structures, conditioning can continue without the need of dedicated time. The target is to establish the operation at 50 Hz in view of the experiments with internal users that are scheduled for Fall 2014.

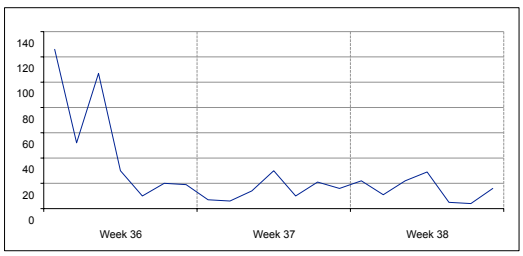

Figure 3: Trend of vacuum faults/week after conditioning.

OUTLOOK AND NEXT ACTIVITIES

The experience has shown that the performance of the directional couplers installed between SLED and structures input must be improved. Numerical simulations have been carried on to revise the design with the support of the components supplier. According to the simulations, the simple reduction of the coupling hole diameter, to reduce the coupling from the present 50 to 65 dB, should allow a reduction of the maximum electric field to an expected safe value. This should allow to operate in a safer condition without the need to revise the waveguide circuit layout. The amplitude of the RF samples from the coupler is still sufficient for the needs of monitoring and measurements with the LLRF. Other alternatives are also under investigation, but these should be seen in conjunction with the boundary conditions of the space available between SLED output and structure input. Other interlocks will be added on the reverse power from the structure, as the one that already protects the klystron, to preventively stop the operation of the plant.

On all the SLEDs a simple linear phase modulation has been applied up to now. A study on the optimization of the parameters of the phase modulation is in course with the target of obtaining a flatter pulse and a lower peak field in the accelerating structure while keeping the energy gain [6].

Although the target energy of FEL-2 should be achieved with the present layout of the machine, the energy budget will be further increased with the installation of the two remaining structures. The procedure for their acquisition is in course and it is expected to install them in 2015. This installation will provide additional 100 MeV.

Another possibility to increase the energy could be to install SLED cavities for the CERN type structures, as also suggested by the MAC committee. Although the filling time of these structures will not allow a maximum efficiency of the SLED process, from a preliminary calculation this could allow to obtain an additional margin of 100 MeV at a relatively moderate cost. Of course this possibility should also be verified with the operating range of other parts of the machine, such as the bunch compressors, and with eventual interferences with the present layout of the machine.

CONCLUSIONS

The S-band RF system of the FERMI linac is in routine operation, accumulating more 6000 operating hours per year. The upgrade of all the plants to 50 Hz has been completed.

The increase of the linac energy is in course, up to now 1.54 GeV at 10 Hz were reached on crest. Further conditioning is required to further slightly increase of some tens of MeV this value, as required for the lower wavelength range, taking into account the margin needed for the X-band and the need to operate some structures off-crest, and to extend these results at 50 Hz.

Further increase in the maximum energy could be reached with the installation of the two accelerating structures foreseen in the machine layout and with the possible upgrade with SLED of some of the TW structures.

TUNER SYSTEM ASSEMBLY AND TESTS FOR THE 201-MHZ MICE CAVITY

Abstract

The MICE cavities include a mechanical tuning system consisting of stainless steel flexure forks attached to the cavity body and driven by pneumatic actuators. The first of these systems was assembled and tested at Fermilab for use at the MuCool Test Area. The actuators were calibrated on a test hoop. The cavity body was measured and the fork contact pads machined to fit. Actuators are going to be mounted on the vacuum vessel housing the cavity. The transfer function of the tuning system and the quality factor of the cavity will be measured with the recently implemented frequency control software.

MICE CAVITY AND TUNER

Each acceleration module (RFCC) of the MICE experiment [1] is composed of four normal-conducting cavities made of copper with a nominal resonant frequency of 201.25 MHz (fig. 1) [2]. The four cavities will be mounted into a vacuum vessel in order to have the same pressure on both sides and avoid deformation of the cavity when pulling vacuum. The cavities will have to work in a high magnetic field that can reach 3T on some points of the cavities surface [3]: a tuning system able to work in such an environment had to be designed. Each cavity will be equipped with a pneumatic system of 6 tuners composed of an actuator and a fork. Each fork, made of stainless steel, will be inside the vacuum vessel and it will stretch and squeeze the cavity when operated by the respective actuator. The actuators will be located outside of the vacuum vessel and will share vacuum with the vessel by means of bellows. All 6 actuators will be connected in parallel and will be controlled by two electronic valves, one responsible for pushing the actuator shaft and the other one for pulling the shaft. The main aim of the tuner will be to compensate for thermal drift of the cavity and for structural differences between the 4 of them, keeping all the cavities at the same resonant frequency.

A test module with only one cavity has been built and is about to be tested in the MuCool Test Area (MTA) at FNAL [4].

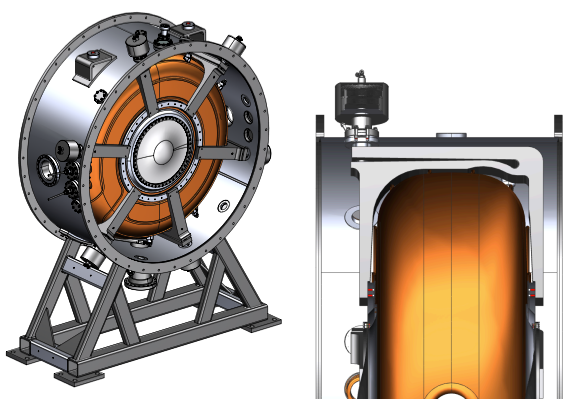

Figure 1: The MTA cavity module and the tuning system.

TEST STAND

Equipment

The six actuators, since working in parallel, had to be tested for possible gas leaks and for uniform response. To do that, a test stand was built at LBNL (fig. 2): a tuning fork was mounted on an aluminum hoop with a spring constant equal to 1/6 of the spring constant of the cavity. The test hoop was placed on an aluminum plate embedding a conflat flange necessary to screw the vacuum bellows of the actuators under test.

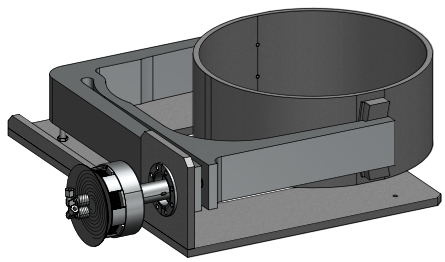

Figure 2: Tuning fork and actuator.

The actuators were controlled by two QPV proportional valves by ProportionAir. Those were connected to a computer running a LabView program. During the test, the pressure applied to each actuator was recorded from proportional valve readout and checked against an analog pressure gauge. The deflection on the test hoop diameter was measured with a dial gauge with a precision of 0.0005 inches, while a linear potentiometer was placed on the fork and aligned with the actuator shaft. The linear potentiometer used is by Novotechnik and it offers a 5 kΩ resistance over a mechanical range of 10 cm. It is powered with a stable 10V signal provided by a voltage regulator. The output voltage is directly proportional to the position of the shaft and consequently the voltage variation is proportional to the actuator shaft movement and to the variation in the fork gap (fig. 3). The voltage was read with a National Instrument ADC and recorded with a LabView code.

Copyright © 2013 CC-BY-3.0 and by the respective authors

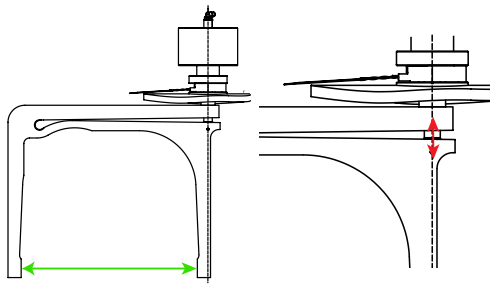

Figure 3: Deflection (left) and fork gap variation (right).

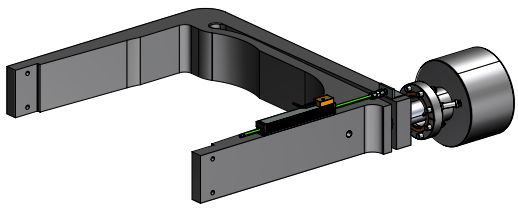

Figure 4: Linear potentiometer on the fork.

Test

In the following, +/- pressures refer to squeeze/stretch mode. For each actuator, the test started at 0 PSI and then the pressure was raised directly to 80 PSI. From this value it was lowered to -80 PSI in steps of 10 PSI and then raised again to 80 PSI with the same step size. The plot of hoop deflection as a function of pressure (fig. 5) shows a clear hysteresis cycle and also a small difference between the slope at positive and negative pressures. The same features appear also in the plot of fork gap variation as a function of pressure. However, when the deflection was plotted as a function of the fork gap variation, the hysteresis almost disappeared and the slopes at positive and negative pressures were much more similar. The tuning fork can be viewed as a mechanical system whose transfer function connects the actuator shaft position (input) and hoop deflection (output). Since its transfer function is linear, the nonlinearity is due to something external and cannot depend on friction between the hoop and the aluminum plate, as initially suspected. The small nonlinearity is likely caused by the actuators and in order to confirm this thesis, the mean of the two points at the same pressure in the hysteresis cycle was computed. The plots of deflection as a function of pressure and deflection as a function of fork gap variation showed a 13% difference between the squeeze and stretch slopes, as expected. On the other hand, the plot of deflection as a function of fork gap variation showed the same slopes (0.13% difference), confirming the actuators as the main source of nonlinearity (fig. 6).

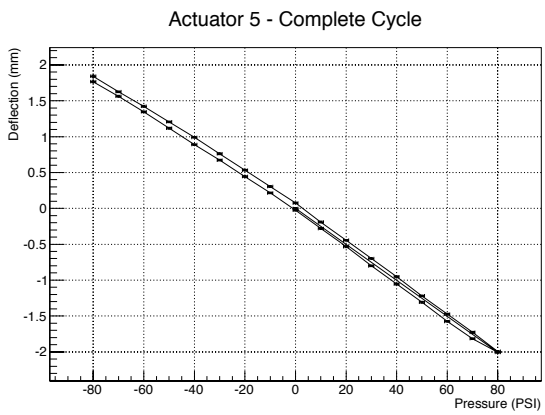

Figure 5: Plot of Deflection vs Pressure for actuator 5.

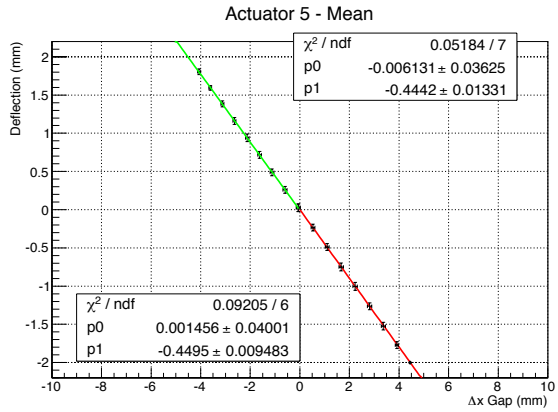

Figure 6: Slopes for stretch (green) and squeeze (red) mode.

Figure 7 shows the slopes for all 6 actuators. In the squeeze mode, all the actuators responded similarly and the results were compatible within the errors. In the stretch mode, the behavior was not as uniform as expected (tab. 1). The maximum slope difference between two actuators was 0.0011 mm/PSI which translates into a difference of 0.11mm or 12% at the maximum tuning pressure of 100 PSI. All 6 actuators will operate simultaneously and the resulting behavior will be the sum of the responses, so this small spread in slope will have no significant operational effect.

Table 1: Actuator Slopes

Actuator	Stretch (mm/PSI)	Squeeze (mm/PSI)
1	0.0224	0.0252
2	0.0225	0.0255
3	0.0233	0.0255
4	0.0227	0.0255
5	0.0222	0.0253
6	0.0229	0.0256

ASSEMBLY

Upgrade

After the measurements on the test stand were completed, the equipment was moved to Lab 6 where a clean room is located. The cavity and the vacuum vessel were surveyed using a laser scanner. The fork contact pads were shaved to match the ring on the cavity that they will be bolted onto and to achieve precise alignment with

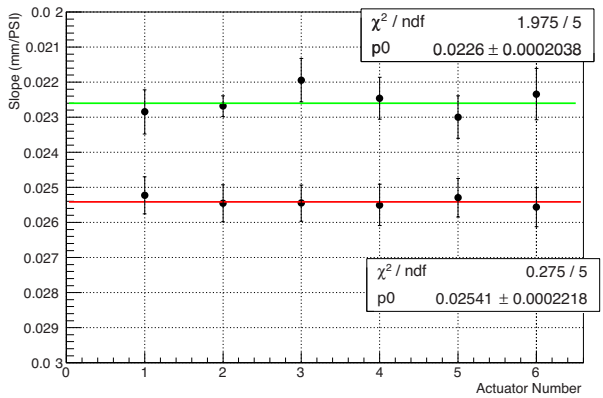

Figure 7: Actuators group behavior.

the vacuum vessel ports. Stainless steel shims will be used as needed between fork contact pads and the mounting rings for fine alignment.

The actuator control system was upgraded. The analog pressure gauges were replaced by electronic units by Omega with 4-20 mA current output. All plastic lines and fittings were replaced with copper tubing and brass fittings. Teflon tape used for thread sealing was replaced with radiation compatible Hercules real-tuff sealant. A valve panel was designed and assembled to allow for manual isolation of each of the 6 actuators and will be mounted directly on the vessel.

Since the cleanroom ceiling is low, the vacuum vessel was placed on a lower stand during assembly. However there isn't enough clearance at the bottom for mounting one of the actuators in this configuration. The test actuator was slightly modified to fit under the shorter stand. It has the same internal components and the same response but it has no vacuum bellows or housing.

A programmable logic controller (PLC) was added to the electronic chain. This is now responsible for the communication with the proportional valves and the electronic pressure gauges. Valve control and pressure readout are currently performed by the PLC at a rate of 1 Hz. The LabView control software is now interfaced with the PLC and not directly with the valves.

Preliminary RF measurements on the cavity were performed while it was positioned on a vertical stand and aluminum windows were installed. The measurements were completed with two B field couplers, a small loop and a bigger one as the input port to obtain critical coupling. The loaded Q measured in transmission mode was 19700 and the unloaded Q, measured in reflection mode, was 40300. The resonant frequency was 200.801 MHz with a drift of about 5 kHz depending on the room temperature.

Future Tests

For tuning tests on the cavity, both the cavity and the vacuum vessel will be moved into a clean room. The tuning forks will be installed on the cavity while it will be mounted horizontally on a fixture. Another custom fixture will be used to install the cavity in the vacuum vessel. The actuators will be screwed onto the forks and low level RF tests will begin in order to measure the transfer function of the tuning system. The vacuum vessel will have no side covers and there will be no vacuum inside or outside the cavity. Linear potentiometers will be mounted on the forks with C-clamps to measure the fork gap variation. Because of mechanical interference, it is not easy to measure cavity ring deflection and we will rely on the gap readout from the potentiometers. During the test, we will measure not only the applied pressure and the fork gap variation, but also the resonant frequency and the loaded and unloaded Q.

The RF measurements have been automated using LabView code and a network analyzer with GPIB interface.

Besides testing the tuning system with all the actuators working as expected, we will also simulate the failure of one or more actuators by isolating their air lines. This will provide knowledge of the limit of the tuning system in case of actuator failure.

SUMMARY AND PERSPECTIVES

The actuators have been tested intensively and their performances have been validated. A control system based on a LabView code and a PLC has been assembled and it's ready for the test with the cavity. The variation in fork gaps will be measured using linear potentiometers.

Changes in the resonant frequency of the cavity as a function of the applied pressure will be measured. The loaded and unloaded Q will be recorded by an automated program and a network analyzer.

RF DESIGN OPTIMIZATION OF A 176 MHZ CW RFQ*

B. Mustapha#, S.V. Kutsaev and P.N. Ostroumov
Physics Division, ANL, Argonne, IL 60439, USA

Abstract

We have recently designed a 176 MHz CW RFQ for the SARAF upgrade project. A full 3D model of the structure including vane modulation was developed. The design was heavily optimized using large scale electromagnetic simulations. Following the choice of the vane type and geometry, the shape and dimensions of the undercuts were optimized to produce a flat field along the structure. Simulations of the same structure with different lengths were performed to verify that the design length produced the best separation of the operating mode from neighboring modes. If built as designed, the RFQ should not need dipole rods for mode separation, but their effect were studied in the case of manufacturing errors. Finally, the tuners were designed and optimized to tune the main mode without affecting the field flatness. The design optimization was mainly performed using CST Micro-Wave Studio and the results were verified using both HFSS and ANSYS. The results of these studies will be presented and discussed.

INTRODUCTION

Soreq NRC, Israel's national laboratory, is exploring the possibilities of upgrading the existing SARAF linac [1]. One of the potential projects is an RFQ upgrade in collaboration with Argonne. In this paper, we present the rf design optimization for a 176 MHz cw RFQ. The proposed design is based on the successful ATLAS upgrade RFQ design [2].

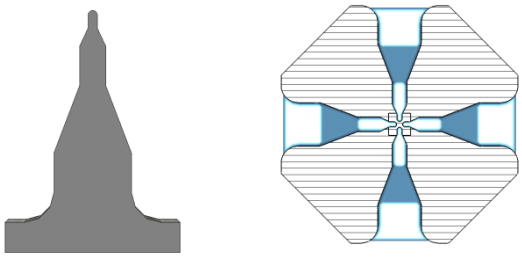

Figure 1: Vane profile (left) and RFQ cross section (right) with an inner diameter of ~ 36 cm.

RFQ STRUCTURE AND PARAMETERS

The selected structure for this RFQ is a 4-vane. The vane profile is based on the ATLAS upgrade RFQ except that this design is a full-vane, not a split-coaxial. At this frequency the transverse size of the RFQ is manageable. Both the vane profile and the RFQ cross section are shown in Figure 1. The structure is about 4 m long divided into 4 segments. The RFQ design parameters are summarized in Table 1. The output energy could be increased by applying trapezoidal modulation while keeping the same vane voltage and power.

Table 1: RFQ Design Parameters

Parameter	Value
q/A	½
Input energy, keV/u	20
Output energy, keV/u	1300
Frequency, MHz	176
Voltage, kV	75
Design current, mA	5
Power, kW	125
Average radius, mm	4.4
Max. modulation	2
Min. transverse phase advance, deg	33
Norm. trans. acceptance, π mm·mrad	2.2
Peak surface field, Kilpatrick units	1.6
Number of cells	250

RF MODELING AND OPTIMIZATION

The electromagnetic design and optimization were mainly performed using the CST Micro-Wave Studio (MWS) [3] and the final results were verified using HFSS and ANSYS. A full 3D model of the RFQ was developed in MWS. Detailed views of the geometry including the undercuts and the modulations are shown in figure 2. This model has pure sinusoidal modulations along the whole RFQ.

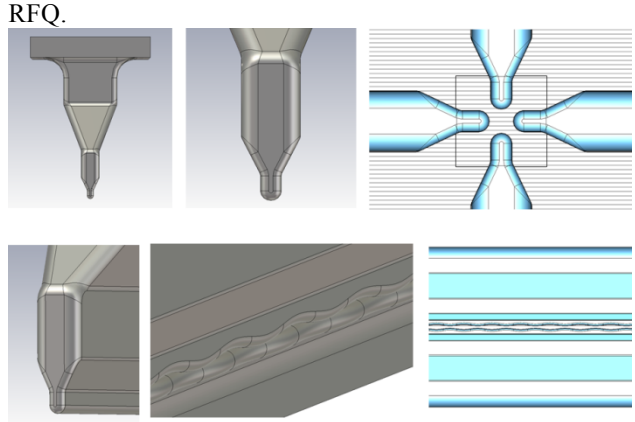

Figure 2: 3D modelling of the RFQ in MWS.

Optimization of Vane Undercuts

In full-vane RFQ structures, vane undercuts are often used to flatten the inter-vane field along the RFQ. These undercuts are applied at both ends of the RFQ and could in principle be of any geometry. We have studied two types of vane undercuts, the first is trapezoidal while the second is square as shown on Figure 3. By optimizing the

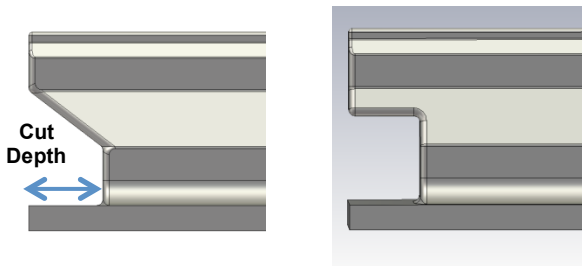

Figure 3: Trapezoidal (left) and square (right) vane undercuts.

cut depth, we were able to obtain a flat inter-vane voltage for both options as shown on Figure 4. However when checking the peak surface magnetic field on the cut planes we realized that it is about 10% lower for the trapezoidal cut shape which should lead to a lower power dissipation.

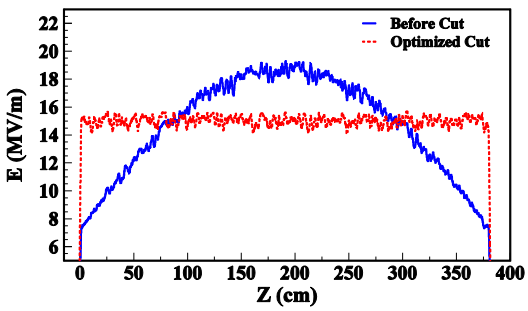

Figure 4: Inter-vane field along the RFQ before and after applying the appropriate vane undercuts.

Therefore we selected the trapezoidal undercut geometry for this RFQ. It is worth noting that these optimizations were done including vane modulations, which has led to non-symmetric entrance and exit undercut depths while before modulations the cuts were symmetric.

RFQ Modes as Function of Length

In order to study the RFQ mode separation as function of length, we have simulated several RFQs with the same cross section and undercuts but with different lengths. The results are shown on figure 5 for mode frequencies as function of length. The modes are identified as Q for quadrupole and D for dipole. The dipole modes marked by (2) are degenerates, their separation shows up for longer structures due only to memory limit in the simulations. The cut-off frequency for this structure is about 170 MHz. At a length of about 1.63 segments, the lowest quadrupole and dipole modes have the same frequency which corresponds to about 0.9×λ. This length is to be avoided because it would be hard to tune the structure for the operating quadrupole mode. The mode separation is best for a length of 4 segments where it is about 3 MHz wide and symmetric around the design frequency. At a length of about 5.5 segments the second dipole mode crosses the main quadrupole mode frequency which will also lead to tuning problems and superposition of quadrupole and dipole fields. The current RFQ design is 4 segments long and has the best mode separation.

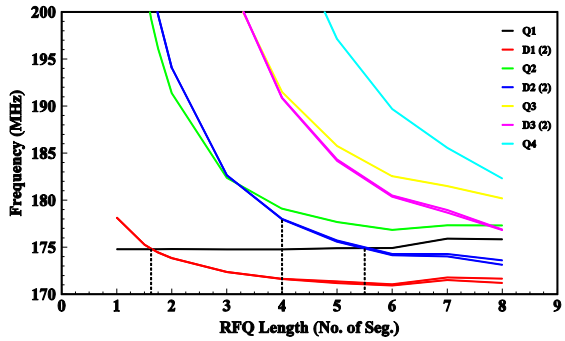

Figure 5: RFQ modes frequencies as function of length in segments (~ 1m).

DIPOLE RODS DESIGN AND OPTIMIZATION

Dipole rods are movable finger-shaped rods attached to the RFQ end plates which could be inserted into the RF volume as needed. Their main purpose is to produce additional separation of the main mode from the neighbouring dipole modes if needed. They are inserted into the quadrupole symmetry planes so they do not affect the quadrupole modes but they are capable of changing the frequency and fields of dipole modes. Based on the actual mode separation for the 4-segments RFQ, we should not need the dipole rods but in the event of manufacturing errors, they are may be useful for correction. The first study performed on the 4-segment RFQ showed low sensitivity of the mode separation to variations in the parameters of the dipole rods, namely the radius, location and penetration. Based on the previous section's results, their effect should be more significant for the 1.63 segment model where the main mode and the first dipole mode have the same frequency. The corresponding results are shown on Figure 6. We clearly see that the dipole mode frequency is more sensitive to the location of the rods with respect to the beam axis. The closer to the axis, the more effective they are. However, the main mode frequency and field are least affected by the rods when they are at mid distance between the beam axis and the cavity side walls, which is the location of maximal quadrupole symmetry. At this location the rods have to be inserted 15" into the RF volume to see a 0.5 MHz separation between the main mode and the dipole mode. The frequencies are not very sensitive to the rod diameter beyond 0.5" and when checking the field stability, a thicker rod disturbs the field more, so a 0.5" rod diameter is near optimal.

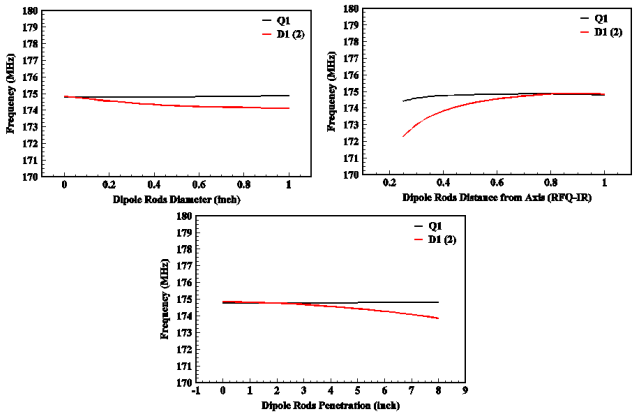

Figure 6: Effect of dipole rods geometric parameters on mode separation for a 1.63 segments RFQ.

TUNERS DESIGN AND STUDIES

A four-vane RFQ is usually built for a frequency just below the operating frequency to make sure it is tunable to that frequency. For the SARAF RFQ, the design target frequency is 175.4 MHz including all the geometry details. The simulation error is estimated not to exceed 0.2 MHz. So the tuners should have a range of at least 1 MHz. The RFQ will have two tuners per quadrant per segment making a total of 32 tuners as shown in Fig. 7. The tuner diameter is 2.5" and could go in up to 2" deep. Figure 8 shows a comparison of the inter-vane field between a case where the tuners are inserted to the same depth uniformly and a case of non-uniform tuning. The latter shows a slope in the inter-vane field which cannot be corrected. Based on these results we decided that the tuners ports should be separate from coupling and vacuum ports to allow for uniform tuning that preserves the field flatness. The simulated frequency sensitivity to the tuners is 37.5 kHz per tuner per inch, which is a 2.4 MHz tuning range if all tuners were inserted 2 inches deep into the cavity.

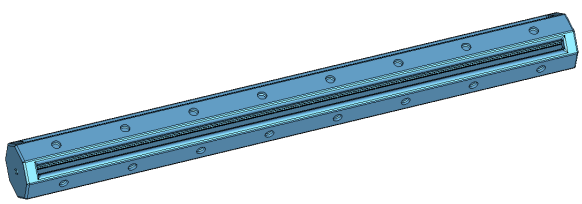

Figure 7: Full RFQ model showing the location of the tuners.

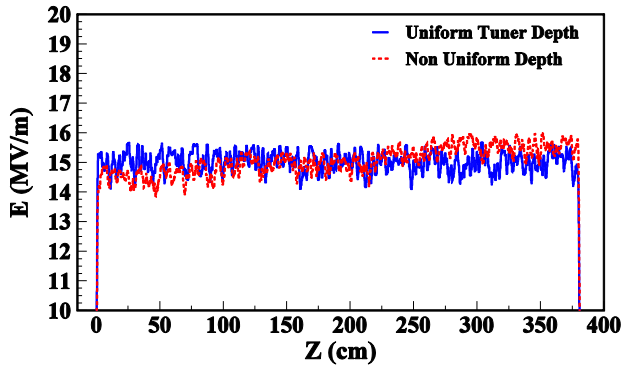

Figure 8: Uniform and non-uniform tuning effect on the inter-vane field along the RFQ.

SUMMARY

We have optimized the RF design for a 176 MHz CW RFQ. The RFQ is a 4-vane structure with optimized trapezoidal vane undercuts for a flat inter-vane field. It is a ~ 4 m long structure made of 4 segments with the best mode separation as function of length. This design should not need dipole rods but we have designed and optimized them to correct eventual manufacturing errors. The RFQ has 2 tuners per quadrant per segment, a total of 32 with a full tuning range of 2.4 MHz. The tuners ports will be separate from the coupling and vacuum ports to allow uniform tuning with minimal effect on field flatness. As successfully implemented in the ATLAS upgrade RFQ, we are planning to design trapezoidal vane modulation which would increase the output energy for the same RFQ length and power.

MODELING VACUUM ARCS IN LINAC STRUCTURES*

J. Norem#, ANL, Argonne, IL 60439, USA
A Moretti, Fermilab, Batavia, IL 60510 USA
Z. Insepov, S. Nurkenov, Nano Synergy Inc, Downers Grove, IL 60516 USA

Abstract

We describe our vacuum arc model, which divides breakdown into four stages: trigger, plasma formation, plasma evolution and surface damage. We have modeled all four stages numerically and find that the properties of surface cracks and unipolar arcs can explain essentially all the experimental data we have seen. In addition to linac breakdown, the model should apply to arcs in a wide variety of applications, such as laser ablation, tokamak edge plasmas and micrometeorite impacts. We also outline differences with other work.

THE MODEL

This effort began as an attempt to understand gradient limits in 805 MHz cavities used for muon cooling. We have described the overall picture of the model and some of the details in a number of papers in the context of accelerator breakdown [1-7].

Recent work has shown that the development of the arc can be explained by two mechanisms: 1) mechanical failure of the solid surface due to Coulomb explosions caused by high surface fields at crack junctions (see ref [5]) and, 2) the development of unipolar arcs that can act as virtual cathodes and produce currents that short the driving potential [3]. Once an arc starts, the surface electric field and field emission increase, increasing ionization of neutrals, increasing in the plasma density [4]. The density increase then reduces the Debye length that increases the surface electric field, thus both the electric field and the density increase approximately exponentially with time. PIC simulations of the unipolar arc model for vacuum arcs relevant to rf cavity breakdown show that the density of plasma formed above the field emitting asperities can be as high as 10^{26} m^{-3} [6]. The temperature of such plasma is low, in the range of 1-10 eV. These high densities can make the Debye screening length, λ_D, become smaller than the mean inter-particle distance or the number of particles in the Debye sphere, to become less that unity. This implies the failure of the ideal plasma approximation, as well as most of the assumptions used in simple calculations. Processes in such a dense plasma can be affected by three body particle collisions so that the Particle In Cell (PIC) method which relies on a simple collisional model, with two body collisions, becomes inappropriate and different methods, such as Molecular Dynamics (MD) must be used

Arrays of cracks are seen in many SEM images of arc damage. We believe these cracks are the result of the cooling of the melted surface that takes place in two stages; first cooling from high temperatures to the solidification point of the metal, followed by cooling from the freezing temperature to room temperature, where the solid contracts by an amount $\Delta x/x = \alpha\,\Delta T \sim 2$ %, where ΔT is the temperature change, x represents the dimension of the damage and α is the coefficient of linear expansion. The model is diagrammed in Fig. 1.

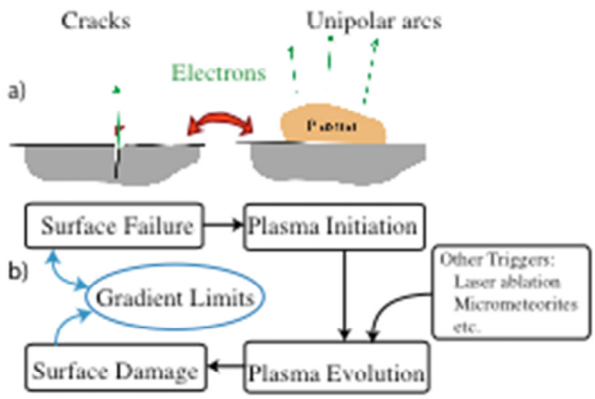

Figure 1: Breakdown proceeds through surface failure, plasma initiation, plasma evolution and surface damage. Part a) shows the physical picture, part b) shows active mechanisms.

The model provides a framework for prediction and experimental study of all aspects of the breakdown process in a variety of environments.

USING THE MODEL

In order to explore the reach of the model we consider the following issues:

Multipactor

We have reported surface damage in coupling cells where the scale of the structure was on the order of 10 nm, rather then the 1 μm commonly seen in 805 MHz Breakdown events. These are consistent with unipolar arcs caused by multipactor, and evidently are not associated with significant shorting currents. These occur at lower gradients and do not seem to be gradient limiting.

Magnetic Field Effects

The geometries of crack junctions can explain magnetic field effects. Data show similar breakdown thresholds with magnetic fields parallel and perpendicular to the surface, arguing for single surface breakdown. With B=0, melted areas are irregularly shaped, and cool so that

*Work supported by Office of High Energy Physics, USDOE
#norem@aps.gov

Copyright © 2013 CC-BY-3.0 and by the respective authors

primary cracks remove strain in one direction and secondary cracks form perpendicular to the primary cracks. Thus, crack junctions occur at right angles. From previous work, this geometry would produce a narrow range of enhancement factors. In a magnetic field, however, symmetric heating from shorting currents pinned to magnetic field lines results in radial strain and circumferential cracking. These cracks occur at variety of acute angles, producing higher enhancements, a wider range of enhancement factors and lower and wider range of breakdown fields [1].

Sheath Parameters

Numerical analysis of plasma sheath properties using MD has produced simple dependence on plasma densities, shown in Figure 2.

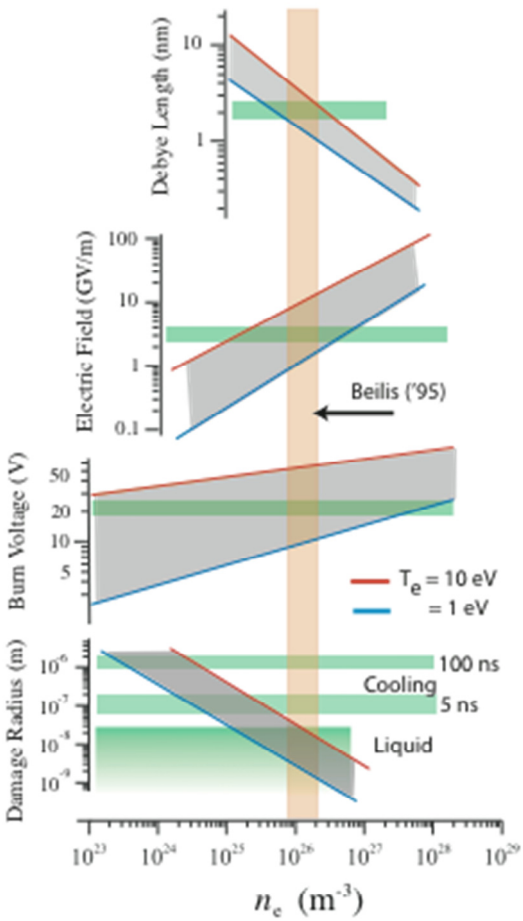

Figure 2: the dependence of experimental parameters on the density of the unipolar arc. More details are presented in Refs. [1] and [2].

If we assume that the plasma density rises until field emission currents short out the sheath, this process 1) sets a limit on the maximum plasma density, 2) determines the dimensions of the unipolar arc, and 3) seems to be compatible with unstable modes (oscillations) in plasma properties. The model can predict plasma dimensions, oscillation frequencies, thermal behavior, burn voltages, shorting currents, time evolution, frequency dependence and the nature of the surface damage produced. All these phenomena are consistent with experimental data [1-2].

Beam Deflection

The immediate results of a breakdown event in an accelerating cavity is a deflection of the beam by the shorting current and the loss of acceleration in the parts of the cavity that are no longer powered. This model assumes that shorting currents, flowing from unipolar arcs functioning as virtual cathodes, on consecutive irises will steer the beam by an angle $\theta = Bl/B\rho$, where θ is the bend angle, B is the magnetic field, l is the cell length and $B\rho$ is the rigidity of the beam. The magnetic field B can be calculated in a straightforward way from the shorting current, however it is unclear if the shorting current is operates on one or both phases of the rf, and how the time structure of the current depends on the electric field, so measurements are useful.

Surface Damage

During the liquid cooling phase, surface tension would smooth the surface, and the relation between the cooling time and the scale of surface irregularities seen in SEM images can be estimated from the dispersion relation,

$$\omega^2 = \sigma |k|^3 / \rho$$

where ω, σ and ρ are the frequency, surface tension constant and density of the liquid metal, and k is the wave number. This smoothing flattens the surface on the scale of microns and eliminates a class of possible field enhancement sites. In accelerator cavities, arcs last for on the order of 100 ns, which is not long enough to heat up the bulk copper, so thin heated surface volumes sit on essentially cold heat sinks and thermal contraction is approximately 2 % of the dimensions of the melted area. We calculate that the typical cooling time constants are in the range of a few hundred ns for accelerator cavities and the structures seen in SEM images of rf cavity damage have radial dimensions on the order of a few microns, see Fig 3. These cooling times are consistent with estimates in Ref [1]. The two stage cooling process seems to result in SEM surfaces that are somewhat smooth at the 1 micron level, but contain cracks with sharp edges at the 1 - 10 nm level that cover 2 % of any large solidified area of copper.

Frequency Scaling, Cooling and βs

Experimental data shows that 805 MHz rf cavities breakdown when the maximum local surface fields reach 10 GV/m, the same breakdown field assumed by Lord Kelvin to explain experimental results in 1904 [7]. We argue that there is minimal frequency scaling if the local field is the primary variable. Different geometries, power sources, frequencies and materials do, however, produce cavities with different maximum surface fields. This can be explained from differences in cooling and field enhancement factors, β. Assuming the plasma properties are similar, size and time history can produce quite different damage. Tiny hot spots cool rapidly and large surface areas will cool more slowly. Above the melting

Copyright © 2013 CC-BY-3.0 and by the respective authors

point surface tension will reduce surface fine structure, and below the melting point, some annealing may also produce significant smoothing,

We have produced estimates of cooling profiles dut to thermal diffusion for a variety of geometries using COMSOL [8], to show how the cooling depends on the nature of the arc parameters. We find three classes of heated surfaces that can be numerically evaluated: 1) tiny (~ micron) melted areas that cool very quickly, 2) large, more or less homogeneous areas with dimensions on the order of a few mm and, 3) intermediate sized regions (10 μm – mm), which are the dimensions seen in 805 MHz cavity damage.

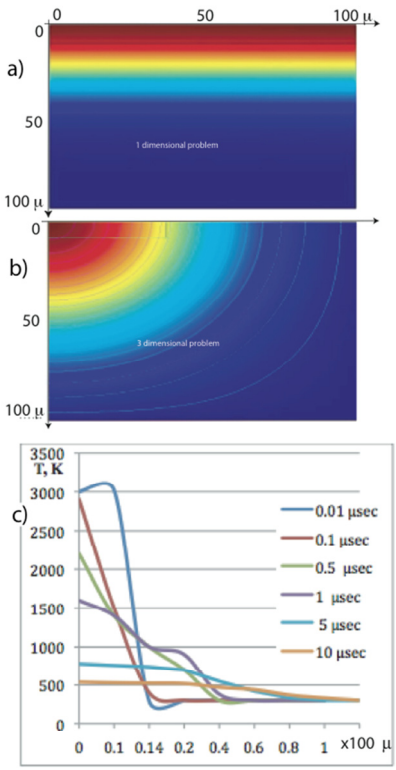

Figure 3: Extreme geometries modeled in COMSOL [8], a) planar, b)point, with c) the cooling profiles produced the case a).

COMPARISON WITH OTHER WORK

The field of vacuum breakdown is quite old, and ideas and methods have been around for a long time. We believe the model we are describing is conceptually simple and the range of applicability is large. We find, however, that this model and the conventional wisdom, do not always agree. We also question models that claim to predict frequency or magnetic field dependence without making any assumptions on the nature of the breakdown process or the damage it produces.

The conventional wisdom of breakdown is that structures producing field enhancements should look like polished fenceposts with hemispherical caps, their properties can be evaluated using a Fowler-Nordheim plot, breakdown is caused by high densities of Joule heating caused by field emission current densities, and these Joule heating events continue during the burn phase of the arc in the form of micro-explosions. While we do not specifically argue against these ideas, we find that more prosaic mechanisms alternatives seem to fit the existing data more easily. Fencepost geometries for field emitters are not seen in SEM images of arc damage, but surfaces are covered with submicron cracks. The efficiency of Joule heating depends very strongly on the geometry and the dimensions of suspected field emitters, and implies that Joule heating must be much less than heat loss to the copper bulk, making significant temperatures very hard to achieve in very small structures. Likewise, if the Debye length of the plasma sheath is on the order of a few nm, it seems hard to understand how localized current densities could produce micro-explosions phenomena due to Joule heating, and, if they could short the sheath, how these current densities could exist at all.

CONCLUSIONS

We have outlined the general principles and some details of our model of breakdown and gradient limits. We feel that this model provides a simpler and yet more general model of breakdown than other alternatives and we are continuing to develop details relevant to other applications. This model seems compatible with a wide variety of experimental data, but disagrees with some conventional wisdom.

ACKNOWLEDGEMENTS

We would like to thank DOE/OHEP, the MAP Program and the staff at Fermilab for support during this work.

TUNING, CONDITIONING, AND DARK CURRENT MEASUREMENTS: 1300 MHZ NCRF CAVITIES AT THE ARGONNE WAKEFIELD ACCELERATOR (AWA) FACILITY*

J.G. Power#, M. E. Conde, S.D. Doran, W. Gai, and E. Wisniewski ANL, Argonne, IL 60439
C. Jing, Euclid Techlabs, 5900 Harper Rd, Solon, OH 44139

Abstract

In this paper, we present data on: (i) tuning and balancing; (ii) high-power rf conditioning; and (iii) dark current measurements; of normal conducting, standing wave, 7 cell, 1300 MHz accelerating cavities. The six cavities were tuned to 1300 MHz and were balanced to >96% in all cells. They are designed to operate with 10 MW of rf input power but are being rf conditioned beyond this operating point to insure low dark current during operation. During rf conditioning, dark current measurements are being recorded to provide a history of the cavity's surface field enhancement factor, *"β"*, throughout the rf conditioning period. Finally, as the final step we plan to record the breakdown rate at 10 MW to add to the breakdown literature for L-band cavities.

INTRODUCTION

Six normal-conducting, L-band rf cavities are currently undergoing commissioning as part of the linac upgrade to the AWA facility [1] to increase the drive beam energy from 15 MeV to 75 MeV. The cavity design (Fig. 1) is a seven-cell, standing-wave, 1300 MHz cavity made with OFE copper and was reported on earlier [2]. As of September 2013, all six cavities have been tuned and balanced but only one of the six cavities has been conditioned. In the first section of this paper we describe the tuning and balancing of all six cavities and in the second half of the paper we describe the rf conditioning of the first of the six cavities including measurements of dark current and the field enhancement factor, β, during the rf conditioning process. The remaining 5 rf accelerating cavities will be rf conditioned during the Fall of 2013.

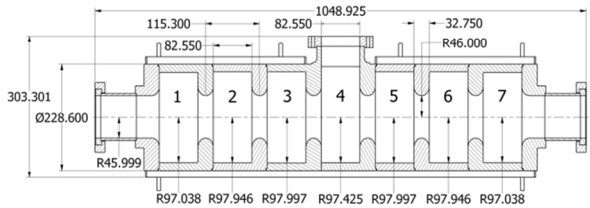

Figure 1: Cross section of the AWA rf cavity.

RF CAVITIES UPON ARRIVAL

Turnkey fabrication of the AWA cavities was enabled by a combination of high fidelity simulations using Omega3p [3], tight machining tolerances, push-pull tuning divots, and the adaptation of a well understood braze joint based on a SLAC design. Using this approach, the cavities were machined to final dimensions (i.e. without iterations), brazed together, and sent immediately to Argonne for tuning and balancing.

Table 1 lists the major figures of merit of the six cavities upon arrival from the vendor. The cavity Q0 was ~98% of ideal and the inter-cell coupling constant, k, was 99.5% of design. While neither of these is subject to adjustments during tuning they were within acceptable limits anyway. The cavities came back from the vendor with resonant frequency, f_0, that were between 290-568 kHz low and all cells had voltage field balance better than 87%. These values, for f_0 and balance, were very nearly acceptable without any tuning and balancing. Moreover, all cavities were within the estimated tuning range based on the combination of the push-pull divots and the temperature adjustment of the cooling water.

Table 1: Designed vs. Achieved Cavity Figures of Merit (upon arrival from vendor)

Parameter	Design	Cavity #1	Cavity #2	Cavity #3	Cavity #4	Cavity #5	Cavity #6

TUNING AND BALANCING

Tuning Divots

Four push-pull tuners (Fig. 2) were used on each of the 7 cells of the rf cavities for a total of 28 divots. The advantage of push-pull tuners over push divots is that they allow for correction of machining errors in either direction. Tuning studs were brazed into holes on the side walls that had I.D. = 1.0" and a floor thickness = 1/8". Based on these dimensions, we estimated that the maximum tuning divot range was equal to half of the floor thickness or 62.5 thousandths. Estimating the volume this would displace, we used SUPERFISH to estimate that the maximum frequency range of the divots would be +/- 80 kHz per cell for a total tuning range of 560 kHz. However, not all of this tuning range can be applied to the frequency shift of the π-mode since the divots must also be used to correct the field imbalance.

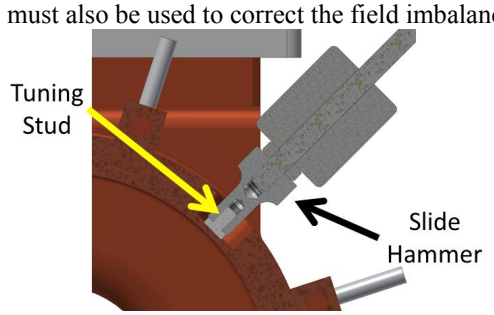

Figure 2: Cross section of a cell with tuning stud brazed in place and slide hammer screwed onto stud.

Beadpull

The beadpull measurement was simulated with SUPERFISH to optimize the size of the bead and the step size to use during the bead pull. The bead used was a metal (Al) needle of length = 0.2", O.D.=0.25", and I.D.=0.008" and was pulled through a horizontal mounted cavity by a 10 pound nylon fishing line with O.D. = 0.007. Beadpull results for all cavities upon arrival from the vendor are shown in Figure 3.

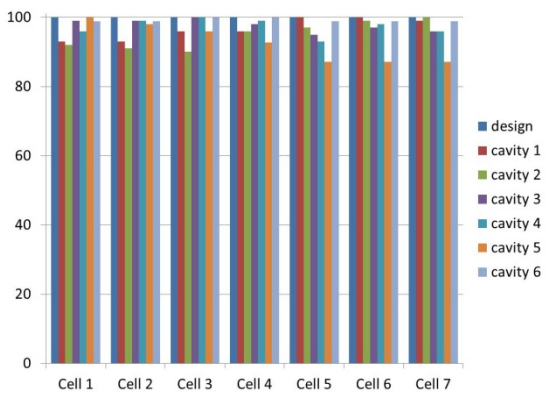

Figure 3: Initial beadpull results before tuning.

Tuning Algorithm

The standard tuning algorithm [4] uses a coupled circuit to model the ideal eigenmodes and eigenvectors while using perturbation theory to model the cavity errors. This algorithm was implemented with an in-house set of matlab codes. The general procedure was to input the frequency shifts due to imbalances from the beadpull measurements into the code to determine the frequency corrections (δf_c) and add that to the overall frequency offset of the π-mode(δf_π). The sum of these ($\delta f_c + \delta f_\pi$) is then applied to the cavity via the tuning divots.

Tuning and Balancing Results

Given that the cavity's frequency tunes were off by 290-568 kHz and that field balance was within 87% of design, then the range of the divots (~560 kHz) is slightly insufficient for a total correction. Several options were considered. We could add 4 more divots per cell but this has the risk of damaging the cavity. We could push divots beyond 62.5 thousandths. In the end, these two ideas were considered too risky and, instead, we decided to lower the operating temperature from 38°C to 20.7°C. Since the tunnel where the linac is installed is air conditioned and the dew point is below 13°C there is no downside to this.

The calculated frequency corrections for the field imbalances were within the range of the tuning divots (80 Hz per cell) in the vast majority of the cases. However, in 3 cases the correction for the largest cell was larger than 80 kHz (Table 2, bold) so the corrections were scaled down. The actual corrections that were applied to each cavity are shown in Table 2.

Table 2: Tuning Applied with the Divots

	Cav 1	Cav 2	Cav 3	Cav 4	Cav 5	Cav 6
Cell 1	0	-28.2	18.9	42.7	-12.4	1.8
Cell 2	0	-15.0	10.991	26.497	4.7	19.6
Cell 3	-10.9	-20.3	-41.6	2	-1.3	-23.2
Cell 4	-37.0	-50.6	-25.0	3.2	-14.5	-29.2
Cell 5	18.6	80.0	**81.2**	**85.656**	**80.9**	40.5
Cell 6	22.1	-22.9	-5.2	38.575	6.8	1.2
Cell 7	12	-11	8.5	25.2	8.8	-10.7

The final frequency of the π-mode was 1300 MHz at an operating temperature of 20.7 °C. The final field balance, obtained after adjusting the divots, (Fig. 4) had a mean value of 99% and was greater than 96% for all the cells in all the cavities.

RF CONDITIONING

The AWA rf accelerating cavities were conservatively designed to operate a peak surface electric field of Ez=33.5 MV/m at an input power of P=10 MW. The cavities are being rf conditioned beyond this operating point to insure low dark current during operation. As of September 2013, only 1 cavity has been conditioned and we present the results here.

Dark Current

During rf conditioning, dark current measurements were recorded at the end of each phase of conditioning. The dark current was not directly measured but the x-rays generated by the dark current (verified to be linear with dark current) was measured instead (Fig. 5) with the light emitted from a phosphor screen and a PMT.

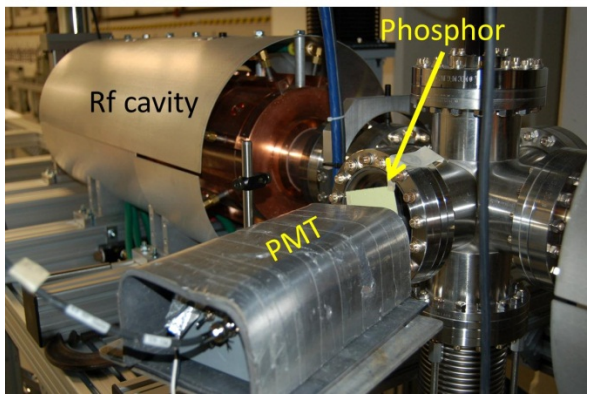

Figure 5: Setup used to measure x-rays from dark current.

Dark current was measured immediately after we had conditioning up to one of the fixed power levels (3, 6, 9, 12, 14 MW) for the first time. This insures that the cavity surface had never seen higher fields than the conditioned level. At that point, the power was lowered back to P=0 MW and the intensity of the phosphor light (proportional to the x-rays which is a proxy for dark current) was recorded as a function of input power (Fig. 6). The data clearly shows that the dark current emitted by the surface is less at the same field after the cavity has been conditioned beyond that point.

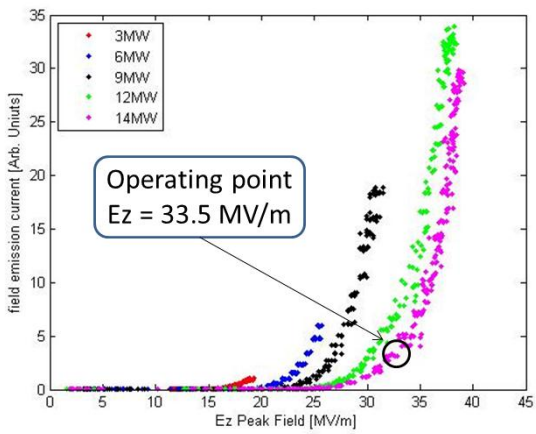

Figure 6: Conditioning History. (dark current vs. field)

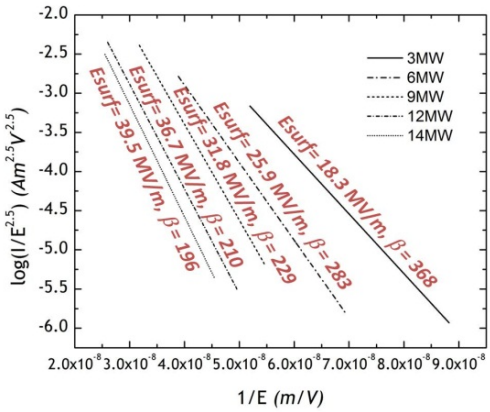

Figure 7: Conditioning History. (β enhancement factor)

The dark current data (Fig. 6) was used to make Fowler-Nordheim (FN) plots (Fig. 7) to get fits of the cavity's surface field enhancement factor, "β", throughout the rf conditioning period. Interestingly, this confirms the not so commonly known rule-of-thumb that the highest field to which the cavity has been conditioned to (E_{SURF}) multiplied by the field enhancement factor (β) is equal to a constant. We can convert the conditioning rf power levels tested to field using the cavity normalization E_{surf}=33.5 MV/m at P=10 MW. Using this, the fields are E_{SURF} = {18.3, 25.9, 31.8, 36.7, 39.5} MV/m. Fitting to the FN data gives β = {368, 283, 229, 210, 196}. Finally, we calculate the product βE_{SURF} = {6.7, 7.3, 7.3, 7.7, 7.7} GV/m and the rule βE_{SURF} = 5-10 GV/m is confirmed.

SUMMARY

Six normal conducting, standing wave, 7 cell, 1300 MHz accelerating cavities for the AWA linac upgrade have all been tuned and balanced. The first of the six cavities has been conditioned to 14 MW and dark current measurements were made. The remaining cavities will undergo rf conditioning soon and we plan to repeat dark current measurements for each cavity. Finally, we will record the breakdown rate at the operating power, P=10 MW, for each cavity.

PPM KLYSTRONS FOR ACCELERATOR SYSTEMS

Patrick Ferguson, Michael Read, R. Lawrence Ives and David Marsden
Calabazas Creek Research, Inc., 690 Port Drive, San Mateo, CA 94404

Abstract

Calabazas Creek Research, Inc. (CCR) is engaged in the development of high power periodic permanent magnetic (PPM) focused klystrons for Accelerator Systems. There are at present 3 ongoing development programs. A 10 kW CW S-band klystron for the Advanced Photon Source at Argonne National Laboratory is nearing completion. An SBIR Phase II grant to develop an S-band 5.5 MW pulsed klystron for the Varian Medical Systems, Inc. CLINAC was funded in April, 2013. An SBIR Phase I grant to develop an S-band 75 MW pulsed klystron for the X-FEL linac at Los Alamos National Laboratory was received in February, 2013. The present development status of these 3 klystrons will be presented.

INTRODUCTION

The impetus to develop high power CW and pulsed PPM focused klystrons is to reduce the cost of producing a large number of klystrons as required by pending high energy linacs. The electron beams for the majority of klystrons for these linacs are focused using electromagnets. These electromagnets require a DC power supply and external fluid cooling. In addition, the electromagnet adds size and weight to the klystron. Employing a PPM structure in lieu of the electromagnet with DC power supply reduces the cost, size and weight substantially with no degradation in operation and life time.

CCR is nearing completion of the fabrication of the 10 kW CW S-band klystron. A 3D pictorial of this klystron is shown in Figure 1 below. The PPM structure consists of as standard geometry with a fixed period where the conventional ring magnets have been replaced by 4 pill box magnets in each half period. This geometry allows ready access to cavity tuners and cooling lines. The four long magnets around the RF output cavity are required to focus the spent electron beam as it loses energy. Initial simulations predicted an efficiency of 70%. However, after determining that the spent electron beam was intercepted just after the output cavity, the PPM structure was redesigned to include the large magnets with the efficiency decreasing to 55%. The electrical parameters for this PPM klystron are listed in Table 1.

Table 1. Electrical Parameters for the APS Klystron

Frequency	2.815 GHz
Beam Voltage	20 kV
Beam Current	1.0 A
Efficiency	55%
RF Output Power	11 MW
Saturated Gain	49 dB
Frequency	>5 MHz

The second PPM program is the development of a 5.5 MW pulsed S-band klystron similar to the solenoid focused klystron presently used in the Varian Medical Systems, Inc. CLINAC. The CLINAC is an X-ray source for treating cancer. The initial SBIR Phase I addressed the L-band RF sources for Project X at Fermi National Laboratory. It was redirected to the 5.5 MW S-band klystron due to the reduction in funding for Project X. The revised program is

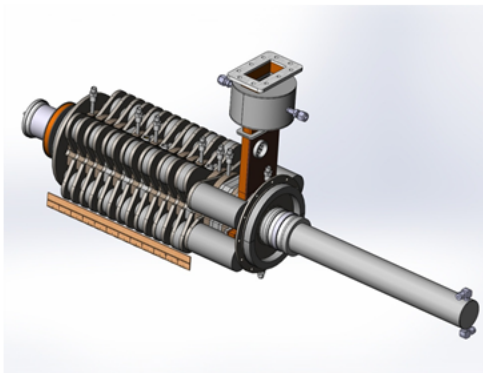

Figure 1: The 10 kW CW S-Band PPM Klystron.

focused on reducing the size, weight and cost of the klystron and associated systems. The techniques established in this Phase II can be directly applied to all DOE klystron programs. The results are listed in Table 2.

Table 2. Electrical Parameters for the CLINAC PPM Klystron

Frequency	2.856 GHz
Beam Voltage	127 kV
Beam Current	90.5 A
Efficiency	48.8%
RF Output Power	5.61 MW
Saturated Gain	48 dB
-1 dB Bandwidth	>10 MHz

One goal is to include using as many existing subassemblies from the present solenoid focused klystron including the electron gun and output waveguide and vacuum window. The cathode will require a slight change in spherical radius with a small change in the focus electrode geometry.

The third PPM klystron development began in February, 2013. The initial specifications stated that a 50 MW klystron operating at 2.8175 GHz was required. At a meeting at LANL after receipt of the grant, the parameters were changed to the higher frequency of 2.856 GHz where there is more knowledge and hardware available and the RF output power was increased to 75 MW with an increase in pulse width from 3 microseconds to 12 microseconds. Further restrictions were imposed on the beam voltage not to exceed 450 kV and the beam current not to exceed 450 A. The resulting electrical parameters are listed in Table 3.

Table 3. Electrical Parameters for the LANL Klystron

Frequency	2.865 GHz
Beam Voltage	450 kV
Beam Current	379 A
Efficiency	48.2%
RF Output Power	82.2 MW
Saturated Gain	51 dB

SUMMARY

Several new klystrons are in development that use PPM focusing to reduce the size, weight and cost of RF systems. The novel approach to PPM focusing provides access to the RF circuit for cavity tuners, and water cooling and eliminates shunting to achieve axially symmetric magnetic fields. PPM focused klystrons can significantly reduce the cost of future accelerator and collider systems.

ACKNOWLEDGEMENT

These programs are funded by US Department of Energy grants DE-SC0004558, DE-SC0007591and DE-SC0009582.

PASSIVELY DRIVEN X-BAND STRUCTURES

T. Sipahi, N. Sipahi, S. G. Biedron, S. V. Milton, CSU, Fort Collins, Colorado, USA

Abstract

Accelerating structures operated at X-band frequencies have been shown to regularly achieve gradients of around 100 MV/m or better. Obviously, use of such technology can lead to more compact particle accelerators. At the Colorado State University Accelerator Laboratory (CSUAL) we would like to adapt this technology to our L-band (1.3 GHz) accelerator system via a 2-beam configuration that capitalizes on the high gradients achievable in X-band accelerating structures in order to increase our overall beam energy in a manner that does not require investment in an expensive, custom, high-power X-band klystron system. Here we provide the design details of the X-band accelerator structures that will allow us to achieve our goal of reaching the maximum practical net potential across the X-band accelerating structure.

GENERAL CONCEPT

The CSUAL linac is an L-band system capable of generating 6-MeV electron bunches [1]. The parameters of L-band linac system are given in Table 1. For many reasons we would like to further increase the electron beam energy without additional significant investment. Our idea is to utilize the electron beam from our linac as a drive source for an otherwise unpowered (passive) X-band linac structure, thus allowing us to increase the beam energy by using the L-band power together with the inherent high shunt impedance of the X-band structure. In our previous study [2] we showed that by using a passive standing wave (SW) X-band cavity driven by our linac we had the potential to increase our 6-MeV electron bunch energy to 11 MeV in 15 cm, but there was a fundamental limit of that configuration. Here we utilize a two-beam configuration based on two traveling wave (TW) X-band structures, one used as an X-band power generator (the decelerator), and one as an accelerator. This configuration is shown in Figure 1. We exploit the TW structure's ability to provide continuous X-band power generated from the passing of the L-band system beam through it and then transfer this power to a second cavity that can be filled in a manner that does not limit as before the achievable integrated potential.

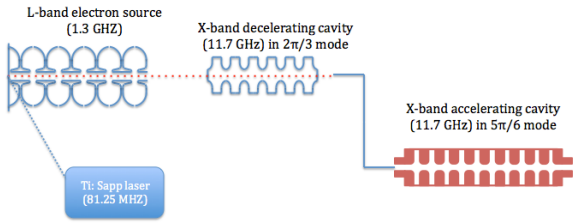

Figure 1: General layout of the two-beam X-band cavity structures [3].

Table 1: Parameters of CSU Accelerator Laboratory

Laser Frequency	81.25 MHz
L-Band RF Gun Frequency	1.3 GHz
L-Band RF Gun Energy	6 MeV
L-Band Macropulse Length	10 μs
X-band Linac Frequency	11.7 GHz
Repetition Rate	10 Hz
RF gun Charge/Bunch	3.5 nC

CAVITY CHOICE

General

We must design two separate cavities, one to be used as a decelerator and optimized to efficiently generate and allow extraction of X-band power without significant disruption to the passing beam, and the other optimized to efficiently accept X-band power and generate the highest practical integrated potential to be used for accelerating electron bunches.

We use a consistent description of cavity geometries as shown in Figure 2 where a is the iris radius, R is the cavity radius, h(=2r_1) is the disc thickness, l is the basic cell length, λ is the wavelength and r_1 is the radius of the iris poles.

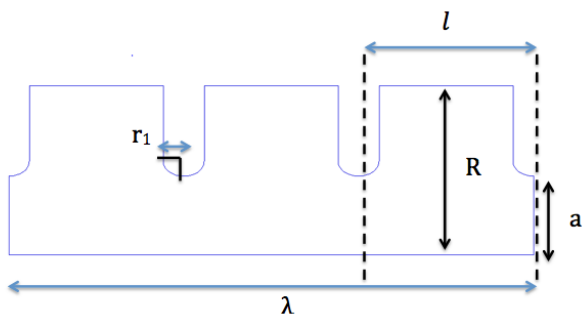

Figure 2: Schematic view of a generic X-band cavity.

In this example we show a configuration for a 2π/3 TW structure.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Decelerating Cavity

Here we choose to use a $2\pi/3$ mode TW X-band structure with parameters given in Table 2 and as computed by the design code SUPERFISH [5].

As we plan on passing through the structure a fairly high current beam we must concern ourselves with HOM effects, thus the optimal tends to larger iris dimensions at the expense of shunt impedance [4]. Figure 3 shows the loss parameter k as a function of the iris radius.

$$k = \frac{\omega R_s}{4Q}$$

where ω is the angular frequency of the RF, Q is the unloaded quality factor of the structure and R_s is the cavity shunt impedance. Clearly a larger iris is desired. This is OK as we found in our earlier paper that even for moderate shunt impedance the structure is relatively short as we are limited by the maximum amount of energy we can remove from the drive beam. Based on our previous study the length of this cavity should be 15.3 cm in order to decelerate the beam from 6 MeV down to 1 MeV. Under such conditions the net X-band rf power that can be generated is 1.4 MW.

Figure 4 shows the power dissipated in the cavity walls as a function of the iris radius. As can be seen this is small compared to the available power generated even for larger values of a/λ and so is not a significant factor.

The resulting X-band power is then coupled out of the cavity and transferred to the accelerating structure.

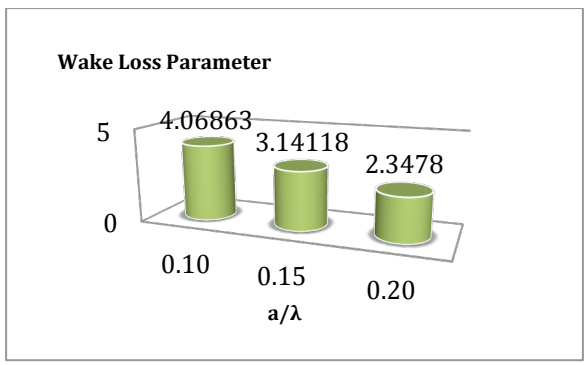

Figure 3: Wake loss parameter vs. a/λ.

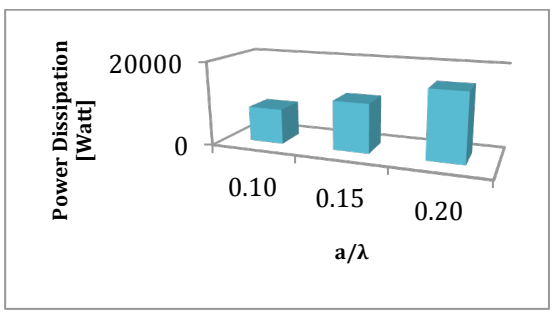

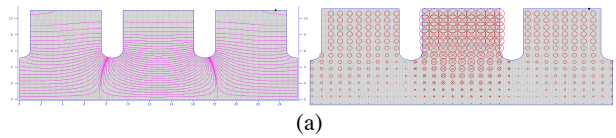

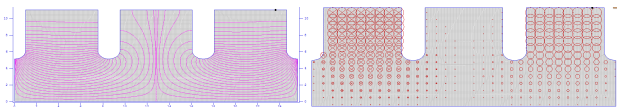

Figure 4: Power dissipation vs. a/λ.

As this structure is powered in a global fashion via the electron beam there is no need to complicate the design with a constant gradient design. Rather we choose a simple constant impedance device.

Figure 5 shows the cavity fields, both electric and magnetic, as computed by SUPERFISH for both Neumann and Dirichlet boundary conditions as specified at the end walls.

(a)

(b)

Figure 5: Electric and magnetic field patterns for $a/\lambda = 0.2$ in (a) Neumann boundary condition at end walls for $2\pi/3$mode (b) Dirichlet boundary condition at end walls for$2\pi/3$mode.

Table 2: Parameters for Decelerating Cavity

a/λ	0.2
Phase Advance per cell (ψ)	$2\pi/3$ radian
Iris radius (a)	0.00512466 m
Cavity Radius (R)	0.0110955 m
Disk Thickness (h= $2r_1$)	0.002 m
Quality factor	6456
Length	0.153 m
Frequency	11.7 GHz
Shunt impedance	79.15 MΩ
Power Dissipation	8360.779

Accelerating Cavity

The optimization for the accelerating cavities follows a different path. This cavity will see a single, relatively low charge pulse, so the aperture requirements are not as severe. Further we wish to maximize the overall integrated voltage seen by the beam during its passage. This clearly argues for high shunt impedance and as long a structure as reasonable.

Our L-band system is also capable of generating beam for over 10 μs, i.e. significantly longer than the fill time of typical X-band structures. We will therefore operate the L-band system with shorter pulses, but pulses long enough to completely fill the X-band structure. This then argues for a structure with a very slow group velocity as it will allow us to fill a longer cavity and capitalize on the long L-band rf pulses.

All structure parameters for the TW accelerator can be deduced from those of the SW structure. In particular, the group velocity can be computed by

$$\vartheta_g = \frac{d\omega}{dk_z} = \frac{2(2.405)c}{3\pi J_1^2(2.405)}\left(\frac{a}{R}\right)^2 \sin\psi e^{-\alpha h}$$

Copyright © 2013 CC-BY-3.0 and by the respective authors

where ψ is the phase advance per cavity traveling wave and α is the attenuation per unit length of the field for the TM_{010} mode through an iris of wall thickness h.

If we wish to decrease the group velocity and we have chosen a minimum a, we are left only with ψ as a variable. This then argues for a large TW mode number defined as n in $2\pi/n$. This is shown in Figure 6 where the relative velocity coming from the sine term is plotted vs. n. A value of n equal to 2 is the SW π-mode. This certainly would argue that the $2\pi/3$–mode is not the best choice and that a mode number of more like 15 or 16 would be better and might still be practical.

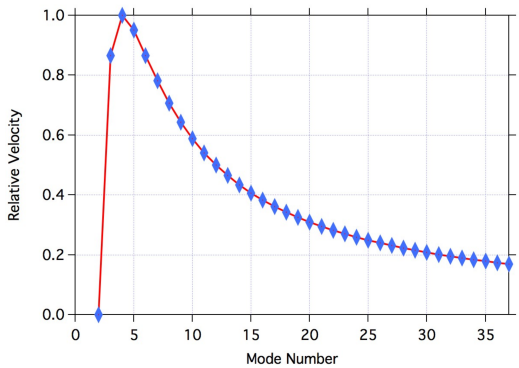

Figure 6: Relative velocity vs. mode number.

For that purpose moving the RF phase advance to $5\pi/6$ (for $a/\lambda = 0.1$) and using a longer cell length compared to that of the $2\pi/3$ (for $a/\lambda = 0.15$) mode in order to preserve synchronous acceleration of the electron bunch slows down the group velocity to 0.95% c and increases α_0 to 1.69 from its $2\pi/3$ value of 0.30 allowing more efficient deposition of the RF power in the accelerating structure [6,7]. Table 3 shows the parameters of this accelerator structure.

Table 3: Parameters for Accelerating Cavity

a/λ	0.15	0.1
Inner radius	0.00512466 m	0.00256233 m
Phase Advance	$2\pi/3$ radians	$5\pi/6$ radians
Cavity Radius	0.0110955 m	0.00999 m
Disk Thickness	0.002 m	0.002 m
Frequency [GHz]	11.7 GHz	11.7 GHz
Quality factor	6456	7474
Shunt impedance	79.15 MΩ	185.67 MΩ
Group Velocity	6.38 %	0.95 %

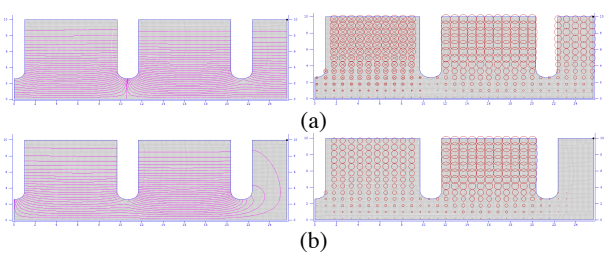

Figure 7: Electric and magnetic field patterns for $a/\lambda = 0.1$ in (a) Neumann boundary condition for $5\pi/6$ mode (b) Dirichlet boundary condition for $5\pi/6$ mode.

Figure 7 shows the cavity fields, both electric and magnetic, as computed by SUPERFISH for both Neumann and Dirichlet boundary conditions as specified at the end walls for the accelerating cavity.

DISCUSSION AND CONCLUSION

In this study we provide designs for two different TW X-band structures that would allow us to achieve higher energies in a compact way. To achieve higher potential one really needs to extract the X-band power from the X-band decelerating cavity and transfer it to a low group velocity traveling wave structure. Optimizing the group velocity by adjusting the inner radius of the constant-impedance structure and using a more relevant mode both improves the power efficiency and overall integrated potential.

ACKNOWLEDGMENT

We wish to thank the SLAC National Laboratory Facility for their support and funding and in particular the input from C. Adolphsen. Finally, we wish to thank the senior management of CSU for their support of the accelerator laboratory and accelerator education.

PROGRESS TOWARD THE DEVELOPMENT OF A RAPIDLY TUNABLE RF CAVITY*

D.J. Newsham, X. Chang, and J.R. Thompson, FAR-TECH, Inc., San Diego, CA 92121, USA

Abstract

A major bottleneck in the development of compact, rapid-cycling particle accelerators is the ability to maintain phase coherence between the short orbit time of the particle bunch and the phase of the accelerating RF field. A ferroelectric loaded RF cavity can achieve the needed phase shift in a significantly shorter time than alternative technologies. The current status of the development of such a cavity including the cold test of a preliminary cartridge and the testing of the bias voltage subsystem will be presented.

INTRODUCTION

FAR-TECH, Inc. is developing a rapidly tunable RF cavity [1][2] that is specifically designed to provide the speed of frequency tuning required for use in modern rapid-cycling accelerator systems (rapid-cycling synchrotron or FFAG). Adjustment of the accelerating frequency between each cavity crossing of the particle bunch will maintain a synchronous phase between the bunch arrival time and the accelerating field on each pass.

The tuning is achieved by applying a bias voltage across a BST(M) [3] ferroelectric based load element placed within the cavity. The speed of frequency tuning is a combination of the fast response time of the BST(M) ($\lesssim$ 10 ns) and the response time of the bias system ($\sim$ 55 ns). Several cooled tuning elements with bias voltages ramped to 40 kV placed near the periphery of pill-box structure can provide a few percent frequency shift on the microsecond time scale.

CARTRIDGE TESTING

The heart of the tunable cavity is the ferroelectric biasing cartridge. This cartridge contains the ferroelectric sample and biasing copper electrodes. This cartridge can be inserted and removed without breaking the vacuum of the main cavity. This separation from the vacuum will also allow a coolant flow of a dielectric fluid to cool the cartridge. Further, using a ferroelectric tube, rather than a solid cylinder will allow both the inner and outer surface to be cooled. To test the performance of the cavity a simplified cartridge and cavity structure was designed, simulated, constructed, and tested. Although an actual cavity would have multiple cartridges place off axis, the test cavity purposefully placed the cartridge on axis to increase the RF field and reduce the power requirement and increase the tuning range for the test. The structure was designed in SolidWorks and simulated with HFSS with several values of the dielectric constant and loss tangent.

Cavity parts and cartridges were constructed as shown in Fig. 1. The cartridge pieces were soldered in two stages using the appropriate alloy for each contact. Soldering was performed in a solder reflow oven with PID temperature control. Frequency and cavity Q-factor were measured at several bias voltages using an Agilent 8720ES network analyzer and a high voltage supply. Because the ferroelectric cylinders are 1 cm long, the conversion from bias voltage to bias electric field is trivial. Full air breakdown occurred at approximately 18 kV bias.

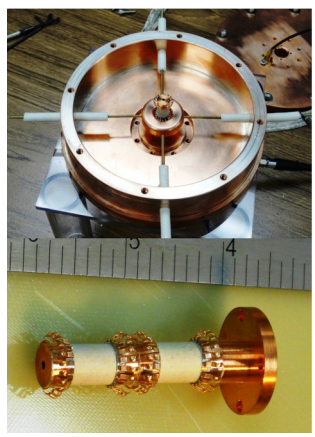

Figure 1: RF cavity used to characterize the biasing cartridge. Test cavity without top plate (*top*). Biasing cartridge (*bottom*).

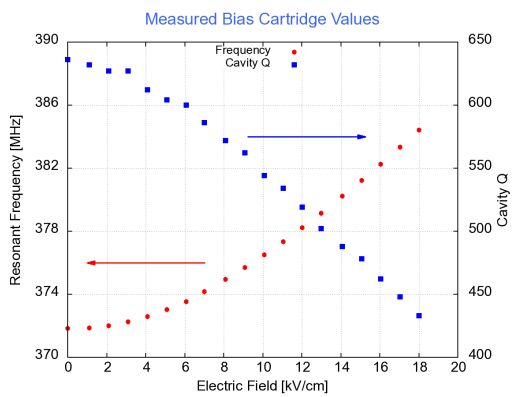

Figure 2: Measured resonant frequency and Q factor for the biasing cartridge in the test cell.

The measured frequency and Q-factor at different voltages are shown in Fig. 2. The HFSS simulation data relating dielectric constant and loss tangent to resonant frequency and Q-factor was inverted to convert the measure values to the values of interest. The result of this inversion are shown in Fig. 3 (dielectric constant) and Fig. 4 (loss tangent). Also included in these figures is

estimated reduction in the loss tangent because the simulated wall losses are less than the real cavity that used bolted end plates resulting in a real wall Q that was 80% of the perfect copper wall Q value. This reduction in the wall Q results in a reduced loss tangent.

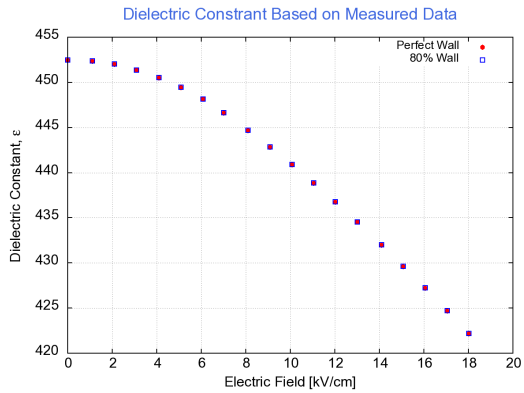

Figure 3: Calculated dielectric constant of the ferroelectric biasing cartridge. The 80% wall value represents a compensation for non-ideal wall losses.

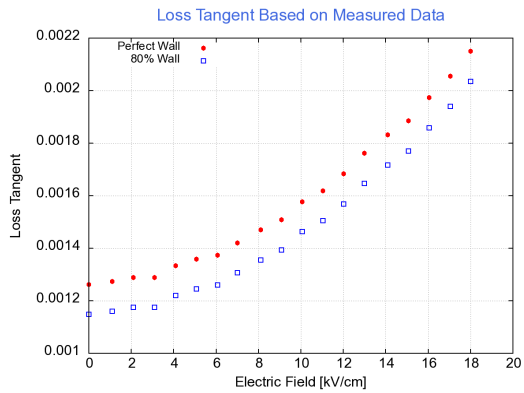

Figure 4: Calculated loss tangent of the ferroelectric biasing cartridge. The 80% wall value represents a compensation for non-ideal wall losses.

With a bias field of ~18 kV/cm there is a greater than 6% decrease in the dielectric constant. The lack of dependance of the dielectric constant on the wall losses indicate that load pulling of the cavity by the ferroelectric was not significant. As the bias voltage increases, the loss tangent becomes greater. When the portion of the total losses that is attributable to the walls is increased, there is the expected decrease in the loss tangent. Although all of the dielectric losses has been attributed to a bulk loss tangent, in reality there is a combination of effects related to the ferroelectric making it an effective loss tangent. In addition to the loss tangent, there is increased RF loss at the joint between the ferroelectric and the copper electrode including: RF electric field enhancement due to micro-irregularities on the ferroelectric surface upon which the metalization is placed; and residual surface charge. These "anomalous" losses can be reduced by specialized dielectric coatings before metalization.

BIAS VOLTAGE DRIVER

The high voltage biasing circuit is critical to the full testing and operation of the rapidly tunable RF cavity. The basic layout for a single stage of the Marx-like bias driver is shown in Fig. 5. For testing, the ferroelectric capacitance is replaced by a fixed load capacitor that is connected to the generator through an external inductor. Each stage consists of 2 storage capacitors and 2 MOSFET transistors for switching each capacitor (4 MOSFETs in total). Switching a storage capacitor in or out requires opening one transistor followed by closing the other transistor in the pair. In order to achieve minimum energy loss, there is a required minimum time (~150 ns) between the opening of one transistor and the closing of the other. When a storage capacitor is switched in, the voltage at the load will begin to oscillate (charge), switching in the second storage capacitor after a half-oscillation (determined by the inductor and load capacitor) will terminate the oscillation at the load (park). The voltage on the load will be nominally constant and twice the voltage on each of the storage capacitors. Reducing the voltage at the cartridge (discharge & park) is performed by sequentially switching out the storage capacitors. By this use of zero current switching, it is possible to recover some of the energy that has be stored in the load. In the process of charging & parking or discharging & parking, the time between the initial firing and the park firing is critical to minimize oscillation in the load.

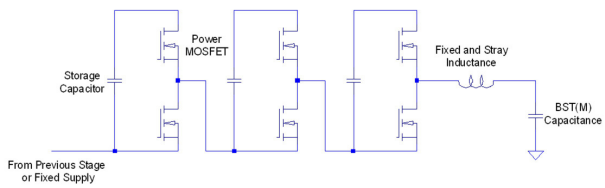

Figure 5: Simplified schematic 1-1/2 stages of the bias voltage generator.

A bias voltage driver board with 2 storage capacitors and a timing control control board capable of driving up to 4 bias voltage driver boards were designed and fabricated. Preliminary testing of a single bias voltage driver board with 1 kV on each of the 2 storage capacitors was started and is currently ongoing.

Voltage Driver Board

Two critical characteristics of the biasing circuit are the switching speed and energy efficiency. The switching speed determines the achievable ramp time, while the energy efficiency determines the bias circuit power requirements.

The choice of MOSFET was between Si based transistors which are faster with lower voltage standoff and SiC based transistors which are slower, have higher voltage standoff, and less mature in the development process. For the demonstration of the ferroelectric biasing cartridge concept, energy efficiency was more important than ramp speed and SiC transistors were chosen. Much

Copyright © 2013 CC-BY-3.0 and by the respective authors

like with Si, as the SiC technology matures, faster SiC devices should become available. Although the SiC transistors are "slower" the anticipated switching time will be faster than the 55 ns currently used. The higher voltage standoff available in SiC transistors allow the stage voltage to increase to 1000 V from the ~600 V initially planned. This reduces the number of stages needed to achieve 40 kV from 68 to 40. Two candidate Cree SiC MOSFET switches, CMF10120D (single die) and CMF20120D (a dual die). Currently, we have only begun testing the single dye transistor. Comparing the performance of these transistors will help determine if the drain to source on-state resistance, or the drain to source capacitance is more important in terms of energy loss, or if they are both minimal compared with the losses associated with the stray capacitance of the stage isolation.

Fig. 6 shows a voltage driver board. Power is delivered from an isolated +24 VDC power buss on the left, running up the edge of the board, which can be common to several. Component and 1 kV power is generated using isolated DC/DC converters from the power buss. Fiber optic coupling was used to provide ground and high voltage isolation between the timing control board and the voltage driver boards, as the voltages at the local ground references ("star points") can vary from ground by as much as the full output voltage. Each transistor is driven by a separate fiber to eliminate the need for digital circuitry on the voltage driver board which can have a high level of noise and because the on/off propagation delays of the transmitter/receiver are significantly different. The storage capacitors are charged with isolated 1 kV DC/DC converters. It is hoped that by using these supplies will have significantly less noise than rectified power from an isolated multi-tap transformer secondary, although there may be a significant loss of efficiency by using multiple DC/DC converters in series.

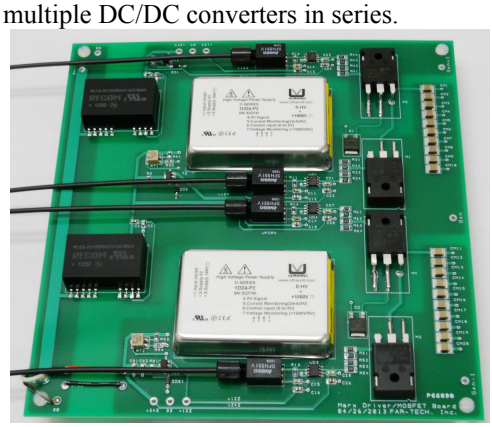

Figure 6: Populated voltage driver board without fiber receiver shields.

Timing Control Board

The timing control board which generates and sequences the appropriate MOSFET gate signals is shown in Fig. 7. As shown, it has only been sufficiently populated to test a single Marx board. The timing and sequencing is provided by an external pulse generator and on board sequencer, with associated individual switch timing delays. The timing delays, which in principle can be programmed in real-time, are hardwired through rocker switches for the prototype. The timing control board will remotely couple to the bias voltage driver board via fiber optics.

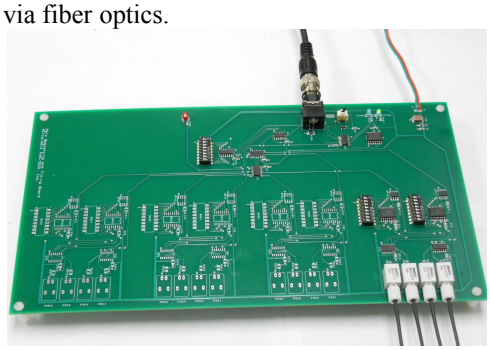

Figure 7: Timing control board with components for a single voltage driver board populated.

Preliminary Testing

The voltage voltage system was initially tested at 100 V per storage capacitor and increased incrementally to the full 1 kV per capacitor. The storage capacitance was reduced to 100 nF (designed for 1 μF) to provide better resolution of the energy loss. At each voltage the charging and discharging delay times were adjusted to achieve a minimum voltage ripple after parking. In general, this ripple could not be reduced below ~4%, possibly because of the voltage droop from switching losses and loss to stray capacitance. At storage capacitor voltages above ~400 V there was a problem of an open transistor suddenly closing and shorting the storage capacitor through the transistor pair. Ultimately, this problem was traced to the fiber receiver which was picking up transient noise and mimicking a "high" output. The problem was solved by adding shielding around the receiver that was electrically connected to the local "star" point. At 1 kV per storage capacitor, the energy loss in each storage capacitor, as measured by the reduction in voltage after the discharge/park was ~2mJ per storage capacitor. This loss is a factor of 3 higher than expected and is currently under investigation. The dual die MOSFET will also be tested; and will help identify the source of the losses.

Abstract

The MuCool Test Area (MTA) at Fermilab is a facility to develop the technology required for ionization cooling for a future Muon Collider and/or Neutrino Factory. As part of this research program, we have tested two 805 MHz vacuum RF cavities in a multi-Tesla magnetic field to study the effects of the static magnetic field on the cavity operation. This study gives useful information on field emitters in the cavity, dark current, surface conditioning, breakdown mechanisms and material properties of the cavity. All these factors determine the maximum accelerating gradient in the cavity. This paper discusses the image processing technique for quantitative estimation of spark damage spot distribution on cavity interior surfaces. The distribution is compared with the electric field distribution predicted by a computer code calculation. The local spark density is proportional to probability of surface breakdown and shows a power law dependence on the maximum electric field (E). This E dependence is consistent with the dark current calculated from the Fowler-Nordheim equation.

INTRODUCTION

High intensity, low emittance muon beams are essential requirements for a future Muon Collider and/or Neutrino Factory. Low emittance muon beams can be produced by ionization cooling. This consists of passing muon beams through low-Z absorber material (liquid H), to reduce all components of the momentum and replacing only longitudinal momentum with accelerating fields using RF cavities. At the same time, to keep the muon beam focused, both the absorbing material and RF cavities are placed inside a strong magnetic field provided by a superconducting solenoid. The ionization cooling process is most efficient if both the accelerating fields and magnetic fields are high. To study the interactions of a static magnetic field with operation at high accelerating fields, two 805 MHz RF cavities e.g. (i) LBNL-Pillbox (ii) All-Season have been tested in a multi-Tesla magnetic field at the Fermilab MuCool Test Area (MTA). During operation with high magnetic field B = 2 - 5 T, the cavity's accelerating field degrades significantly, dark current and X-rays are produced and interior surfaces suffer severe breakdown damage [1-3]. In this paper, we present the spatial distribution of the breakdown damage spots on the interior surface of the RF cavity using ImageJ [4] and Mathematica software [5]. The measured number of breakdown spots per unit area is compared with both the electric field distribution (calculated by computer code) and the dark current calculated from the Fowler-Nordheim equation. Finally a power law dependence on the maximum electric field is discussed.

805 MHZ CAVITIES

LBNL-Pill Box Cavity

A cross sectional view of the 805 MHz cylindrical pillbox cavity of inner diameter 312.4 mm is shown in Fig. 1. Two irises are covered by specially designed copper windows (separately shown). Each window has a radius of 97.9 mm. RF power at 805 MHz is fed in through a kidney shaped coupling slot on the cavity wall using WR975 rectangular waveguide [3] with 20 μs pulse duration and repetition rate of 15 Hz. The cavity is mounted inside a 44 cm bore diameter superconducting solenoid magnet which can generate magnetic fields up to 5 T. The peak electric field was 40 MV/m with RF power 4.2 MW at B=0 field and 16 MV/m with RF power 0.67 MW at B = 3 T.

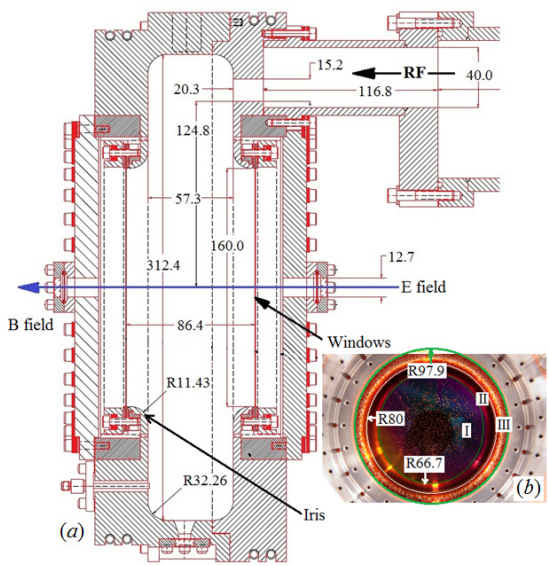

Figure 1: (*a*) Cross sectional view 805 MHz Pillbox RF cavity with copper window [3], (*b*) Copper window of radius 80 mm and iris of outer radius 97.95 mm.

Breakdown damaged spots on vacuum window is shown in Fig. 1(b) and the location of damaged spots are marked by crosshairs using ImageJ software shown in Fig. 2.

Copyright © 2013 CC-BY-3.0 and by the respective authors

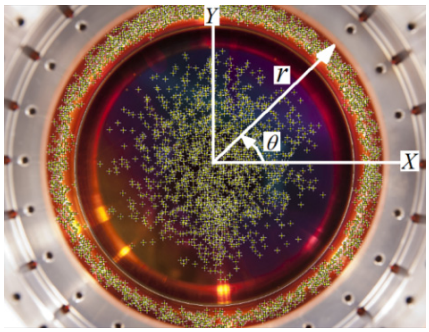

Figure 2: Photograph of copper window and iris with distribution of RF breakdown damage spots, marked with crosshairs using ImageJ software.

All Season Cavity

Another cavity tested at the MTA known as the All Seasons cavity, is shown in Fig.3 [6]. This cavity was designed for both vacuum (3×10^{-8} Torr) and 100 atm compressed hydrogen gas operation. It consists of a SS316 cylindrical body [Fig. 3(b)] of outer diameter 366.9 mm and two end plates. The top [Fig.3(c)] and bottom [Fig. 3(d)] both have a diameter of 290.7 mm.

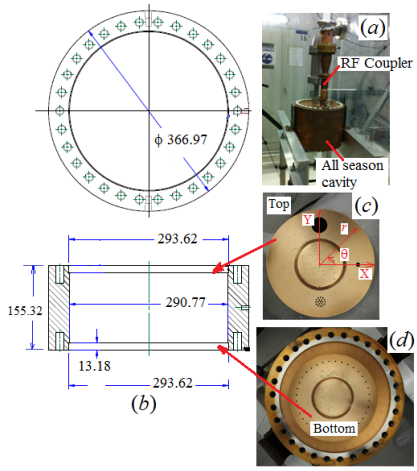

Figure 3: (a) All Seasons cavity (b) cross sectional view (c) top plate (d) bottom plate with cylindrical wall.

RF power was fed to the cavity through a coax coupler [Fig. 3(a)] with 20 μs pulse duration and 15 Hz repetition rate. The cavity was operated at peak electric field of 25 MV/m with RF power 1.2 MW, B=0 T and 22 MV/m with RF power 0.93 MW, B= 3T magnetic field [7].

ANALYSIS AND RESULTS

LBNL-Pillbox Cavity

For the sake of analysis, the surface of the pillbox cavity window was divided into 3 regions as shown in Fig. 1(b). Region I is a circular area of radius 66.7 mm, region II is a ring of inner radius 66.7 mm and outer radius 80 mm. Both region I and region II are part of flat circular window. Region III (iris) is also a ring of inner radius 80 mm and outer radius 97.9 mm. The center of the window is the origin of the coordinate system (X, Y or *r*,θ) shown in Fig.2 where Breakdown Damage (BD) spot locations are identified by crosshairs using the image processing software ImageJ. The BD spot distribution is calculated with the help of Mathematica software. Figure 4(*a*) shows the BD spot distribution in the X-Y plane. The upper half of the iris is close to the RF coupler and has more damage spots than the lower half. The BD spot distribution in r-θ plane is shown in Fig. 4(*b*).

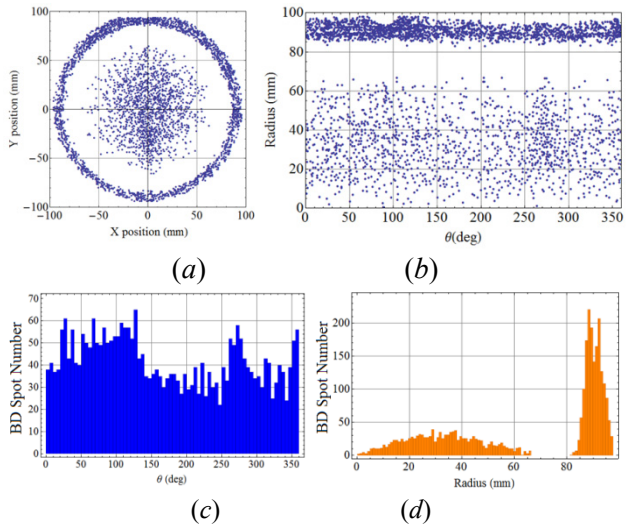

Figure 4: BD spot distribution in X-Y plane (*a*) and r-θ plane (*b*), BD spot no. vs θ plot (*c*) with bin size: 5° and BD spot no. vs *r* plot (*d*) with bin size 0.9 mm.

The number of BD spots at different values of θ and *r* are depicted in Fig. 4(*c*) and Fig. 4(*d*) respectively. The electric field distribution was calculated using computer code [8] and field emission dark current density was calculated from the Fowler-Nordheim equation where we have taken the work function (ϕ) for copper to be 4.65 eV and the field enhancement factor (β) to be 200. Figure 5 illustrates the results of the electric field, dark current density and number of BD spot density. Figure 6 shows the BD spot density vs electric field in the window area. The solid circles represent the data obtained from image processing and the line indicates an electric field (E^n) power fit. This shows the data fit well with $E^{6.28}$.

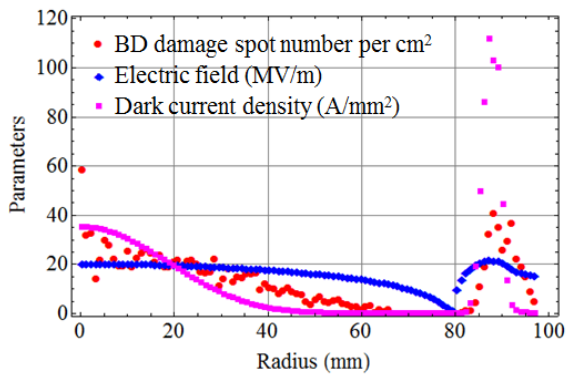

Figure 5: BD spot number per cm^2, RF electric field and dark current density vs radial distance plot.

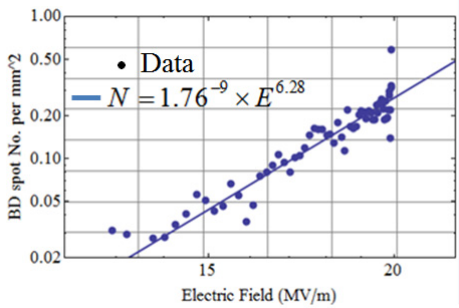

Figure 6: BD spot density vs electric field plot for flat window area.

All Seasons Cavity

Distributions of BD spot are shown in X-Y [Fig. 7(*a*)] and r-θ plane [Fig. 7(*b*)]. The number of BD spots at different values of θ and r are shown in Figs. 7(c) and 7(d) respectively. Fig. 8(a) illustrates the BD spot no. per mm^2 at different radii for the top plate at given θ values and Fig. 8(b) shows the same for the bottom plate. Fig. 9 depicts the computed electric field (with 10 times magnification) distribution and dark current density distribution. This is the same for both plates.

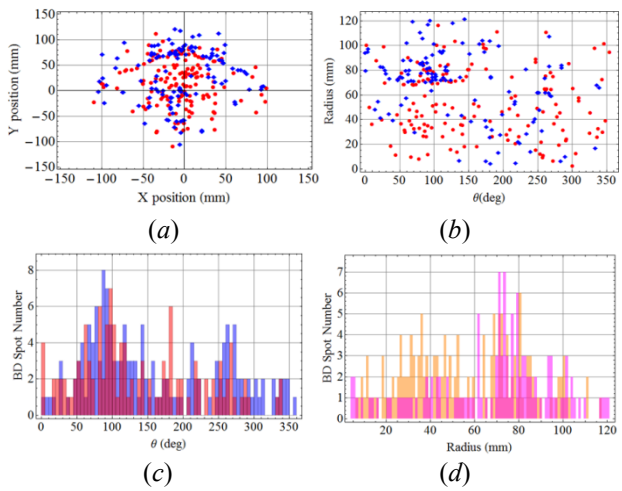

Figure 7: BD spot distribution in X-Y plane (*a*) and r-θ plane (*b*) (in both plots red/blue for top/bottom plate), BD spot no. vs θ plot (c) [blue/brown for top/bottom plate with bin size 5°], BD spot number vs *r* plot (d) [orange/magenta for top/bottom plate with bin size 1.2 mm].

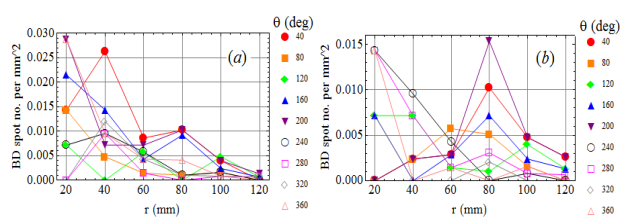

Figure 8: Plot of BD spot number per mm^2 at different radius for given θ (e.g. Red Circle for 40°, Orange Square for 80° and so on) (*a*) for top plate and (*b*) for bottom plate.

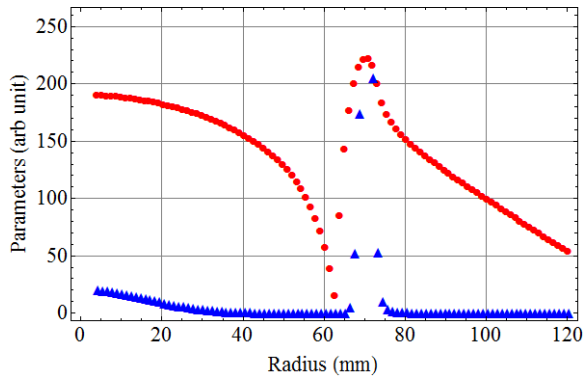

Figure 9: Electric field and dark current density distribution at different radii.

CONCLUSIONS

The BD spot distributions in both cavities are generally consistent with the electric field profiles but there are some differences. In the LBNL-Pillbox cavity, BD spots were distributed more densely over the iris region where the electric field and dark current are high. Note that the iris region includes accumulated damage from more runs than the window. In the flat window region the BD spot density data correlates with 6.28th power of the electric field. In the All Season cavity, fewer damage spots are observed because the surface inspection was carried out at an early stage of the run. In both plates most of the spots are within a radius of 100 mm. Note that in both cavities, data was taken both with and without magnetic field before the surface inspection. In future experiments, inspection will be done separately after runs with and without magnetic field to explore the role of magnetic field in the breakdown process.

DESIGN AND HIGH POWER TESTING OF 52.809 MHZ RF CAVITIES FOR SLIP STACKING IN THE FERMILAB RECYCLER*

R. Madrak#, D. Wildman, FNAL, Batavia, IL 60510, USA

Abstract

For NOvA and future experiments requiring high intensity proton beams, Fermilab is in the process of upgrading the existing accelerator complex for increased proton production. One such improvement is to reduce the Main Injector cycle time, by performing slip stacking, previously done in the Main Injector, in the now repurposed Recycler Ring. Recycler slip stacking requires two new RF cavities operating at slightly different frequencies (df = 1260Hz). These are copper, coaxial, quarter wave cavities with R/Q =13 ohms. They operate at a peak gap voltage of 150 kV with 150 kW peak drive power (60% duty factor), and are resonant at 52.809 MHz with a 10 kHz tuning range. Two have been completed and installed. The design, high power test results, and status of the cavities are presented.

INTRODUCTION

To increase beam power, the Recycler Ring has been converted from an antiproton storage ring to a proton preinjector for proton injection/slip stacking. The increase in power, which is projected to be 80%, is due to a shorter Main Injector cycle time (decreased from 2s to 1.33s), since injection/stacking and acceleration can now be performed in parallel. [1]

Slip stacking is a process in which 6 batches of 8 GeV protons from the Fermilab Booster are 'stacked' on top of an additional 6 batches of beam. It has been performed and studied previously in the Main Injector [2], using an RF system which was designed primarily for the acceleration of beam. The process is as follows: Six Booster batches are injected into the Recycler Ring and captured by one RF system at 52.809 MHz, and then decelerated slightly by changing the frequency of the RF system by 1260 Hz. Then, six more batches are injected and captured by a second RF system operating at 52.809 MHz. Since the two sets of batches have slightly different energies, one set 'slips' azimuthally with respect to the other. When the two sets of batches are aligned, they are injected into the Main Injector, captured, and then accelerated to 120 GeV.

CAVITY DESIGN PARAMETERS

Slip stacking requires two cavities with f_0 = 52.809 MHz, a maximum V_{peak}= 150 kV and approximately 10 kHz of tuning range. The cavities must be tuneable by 1260 Hz for slip stacking itself, and must also have compensation for frequency drift due to heating and variation of cooling water temperature (~ 0.5 kHz/°F). The maximum duty factor will be 60% with a pulse length of 0.8 s.

In the interest of minimizing beam loading, the cavity dimensions were chosen to minimize R/Q while taking into account other practical constraints, such as being able to fit in the allowed area in the tunnel.

The cavity geometry is shown in Figure 1. This is a quarter wave coaxial resonator. The R/Q of 13 Ω is substantially smaller than that in the Main Injector cavities (103 Ω). This is due mainly to the large ratio of diameters of the outer and center conductors. Other key parameters are shown in Table 1.

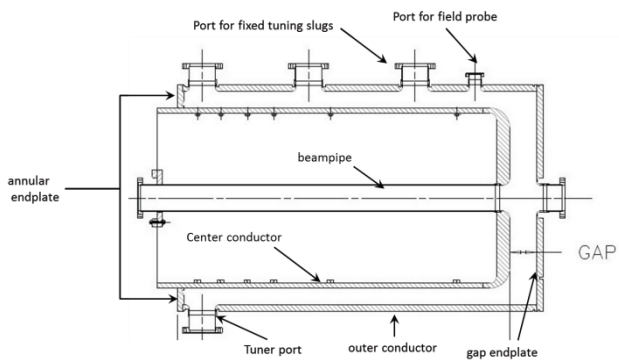

Figure 1: Cavity geometry and features.

Table 1: Cavity Design Parameters

f_0	52.809 MHz
Z_0	10.2 Ω
Vpeak (max)	150 kV
Maximum power	150 kW
Rshunt	75 kΩ
Q	5800
R/Q	13 Ω
Outer conductor ID	32 in
Inner conductor OD	27 in
nominal gap width*	2.9 in
Inner conductor length**	49.75 in
Step up ratio	6

*Based on pre-weld dimensions. Varied between cavities.
**Nominal length from cavity short to gap end

The initial design parameters and calculations were checked by constructing a model cavity from copper sheet metal [3]. Obviously this did not allow for vacuum or any high power tests, however, it was very useful for verifying and/or measuring key quantities at low power. These include factors such as resonant frequency

dependence on various dimensions, higher order modes, and fast tuner development.

Input Coupler

The cavity input coupler is a loop type coupler which connects to a 9-3/16″ , 50 ohm transmission line through a copper and stainless steel bellows. The vacuum window is constructed from a conical 94% alumina ceramic brazed to copper rings. The rings are welded to additional copper sections to form the coupler outer and inner conductors. The coupler 2″ diameter inner conductor is welded to the cavity inner conductor 7.5″ from the shorted end, and the coupler outer conductor is welded to the cavity outer conductor. This results in a cavity accelerating gap to input coupler voltage step-up ratio of 6.

CAVITY CONSTRUCTION

The cavity center and outer conductors were forged at Scot Forge, Spring Grove, IL from OFHC copper ingots. Following the forging they were machined to final dimensions and ports were added. The circular and annular regions which form the ends of the cavity were also machined from solid blocks of OFHC copper.

The cavity center conductor, outer conductor, annual and circular end sections were electron beam welded at Sciaky Inc., Chicago, IL. Figure 2 shows the outer conductor being placed over the center conductor, after the annular end piece was welded to the center conductor. The cavity frequency was tuned after welding the center conductor to the annular ring by adjusting (by machining) the thickness of the endplate near the gap. This was necessary since the cavity frequency changed from pre- to post-weld, presumably because of changes in the effective dimensions due to the welding. The frequency dependence on gap width was measured to be 1.2±0.2 kHz/mil.

Figure 2: Positioning of outer conductor before electron beam welding.

In order to maintain a uniform temperature at high duty factor, there are 12 cooling lines each on the cavity center and outer conductors. Each set has a flow rate of 60 gal/min of 95 °F cooling water. The outer cooling lines and were brazed to the cavity. The lines on the ID of the center conductor were shrink-fit. At completion, each cavity weighs 4500 lbs. Some additional aspects of the cavity mechanical design are discussed in [4].

Cavity Ports

The cavity outer conductor has eight 3.87″ diameter (“larger”) and four 1.65″ diameter (“smaller”) ports. Furnace brazed copper to stainless steel transitions are used to connect either 6″ or 2-3/4″ Conflat® flanges (depending on the port size) to the copper cavity body. One exception is one of the larger ports used for a fast tuner, which uses a copper flange and not a Conflat.

Three of the larger ports located 35″ (on center) from the cavity shorted end were used for fixed tuning slugs. The slugs are OFHC copper cylinders with a diameter of 3.8″ and a 0.5″ radius on the cavity end. They are attached to water cooled Conflat blanks and protrude nominally 1″ into the cavity. Final machining of the length of the tuning slugs sets the cavity center frequency to 52.809 MHz.

The four smaller ports are all located near the cavity gap end: 44″ from the cavity short. Two of these contain disk shaped capacitively coupled field probes for measurement of cavity gap voltage. These were calibrated by simultaneously measuring the field probe power and the cavity gap voltage with an Agilent 85024A High Frequency Probe and network analyzer. The voltage ratio is nominally 10^5:1.

A third smaller port contains a 1″ diameter copper gap shorting slug which can be used in the case where there is a third inactive cavity installed in the ring. The slug is mounted on a linear vacuum feedthrough, which can be remotely moved into the cavity to contact the center conductor.

In one of the larger ports located 3″ from the cavity shorted end and opposite the input coupling loop, a fast tuner is loop-coupled to the cavity through a 2.5″ diameter coaxial ceramic window. The loop area is adjusted to give a nominal coupling impedance of 50 Ω. The tuner is a half-wavelength 50 ohm transmission line which is partially loaded with Al doped YIG and shorted at one end. The garnet section is immersed in a variable solenoidal magnetic field which provides for fast cavity tuning. The fast tuner, which has a range of 10 kHz, is described in more detail in a separate contribution to these proceedings [5].

RF POWER

The Fermilab Tevatron has been decommissioned and we were thus able to reuse the Tevatron RF Stations; this includes the power amplifiers, modulators, 9-3/16” transmission line, and impedance matching anode resonators. The Tevatron RF systems used essentially the

Copyright © 2013 CC-BY-3.0 and by the respective authors

same power amplifiers as does the Main Injector, and these are described in [6].

Power is provided by a cathode driven Eimac Y567B (4CW150000E) 150kW power tetrode. The tetrode is coupled with a monolithic ceramic blocking capacitor to a cylindrical aluminium quarter wave resonator which is used to match the power amplifier output impedance into a 9-3/16″, 50 ohm transmission line. This tap point is at one half the peak voltage. The transmission line includes a variable length phase shifter and a 3:1 coaxial transformer with 3λ/2 between the transformer voltage maximum and the cavity input. Taking into account the cavity input coupler step-up ratio of 6, the 3:1 transformer, and the half voltage tap point on the anode resonator, the total cavity step up ratio from the plate of the tetrode to the cavity gap is 9.

HIGHER ORDER MODES

Both the measured and calculated lowest frequency higher order modes of the cavity are shown in Table 2. Modes are classified as TEM or TE. The TEM modes are of more concern as they can be easily excited by the beam. All TM modes have frequencies of above ~2 GHz. The 3rd harmonic TEM mode is damped by a ½″ Heliax® quarter wave coaxial line with a capacitive pickup on the 9-3/16" transmission line (near a voltage maximum). For damping, a 5 W, 50 Ω load is connected to the heliax line near the 50 Ω tap point.

For the modes listed in Table 2, the frequencies of the TE modes are calculated analytically for a coaxial waveguide, assuming a line length of 50″, and using $\lambda=\lambda_g/(1+(\lambda_g/\lambda_c)^2)^{1/2}$, where λ_g and λ_c are the guide and cutoff wavelengths of the coaxial line [7]. The TEM modes were calculated using the LANL Superfish program [8].

Table 2: Higher Order Modes

Calculated f (MHz)	Measured f (MHz)	Type	order	Calculated f (MHz)	Measured f (MHz)	Type	order

CAVITY TESTING, INSTALLATION, AND COMMISSIONING

Prior to their installation in the tunnel, two cavities were tested to full power in a cavity test cave. The cavities were first subjected to low power (up to 500 W) CW RF for one week, to condition away multipacting between the outer and inner conductors. In this case the cavity was driven through the fast tuner port (with the tuner disconnected). A photo of the cavities installed in the Main Injector tunnel is shown in Figure 3.

Figure 3: Two complete cavities installed in the Recycler.

ACKNOWLEDGMENTS

We would like to acknowledge the huge efforts of the Accelerator Division Mechanical Support and RF Groups, and everyone involved in this project. We would also like to thank Marty Murphy for the photograph in Figure 3.

PERPENDICULARLY BIASED YIG TUNERS FOR THE FERMILAB RECYCLER 52.809 MHZ RF CAVITIES*

R. Madrak#, V. Kashikhin, A. Makarov, D. Wildman, FNAL, Batavia, IL 60510, USA

Abstract

For NOvA and future experiments requiring high intensity proton beams, Fermilab is in the process of upgrading the existing accelerator complex for increased proton production. One such improvement is to reduce the Main Injector cycle time, by performing slip stacking, previously done in the Main Injector, in the now repurposed Recycler Ring. Recycler slip stacking requires new tuneable RF cavities, discussed separately in these proceedings. These are quarter wave cavities resonant at 52.809 MHz with a 10 kHz tuning range. The 10 kHz range is achieved by use of a tuner which has an electrical length of approximately one half wavelength at 52.809 MHz. The tuner is constructed from 3⅛″ diameter rigid coaxial line, with 5 inches of its length containing perpendicularly biased, Al doped Yttrium Iron Garnet (YIG). The tuner design, measurements, and high power test results are presented.

INTRODUCTION

Two new quarter wave copper cavities have been constructed and installed in the Fermilab Recycler Ring for the purpose of slip stacking protons to increase beam power. These have been described in detail in [1]. They are to operate at 52.809 MHz with a tuning range of 10 kHz. Tuning by 1260 Hz is required for slip stacking itself, and additional tuning is needed to compensate for temperature changes. The cavity maximum peak gap voltage is 150 kV with a shunt impedance of 75 kΩ and Q ~ 6000. The cavities will be pulsed for a maximum of 0.8 s every 1.33 s (the Main Injector cycle time).

The cavities are tuned using perpendicularly biased garnet in a coaxial line. This has been done previously and is described in [2] and [3]. The original concept, though not for cavity tuning in particular, is described in [4].

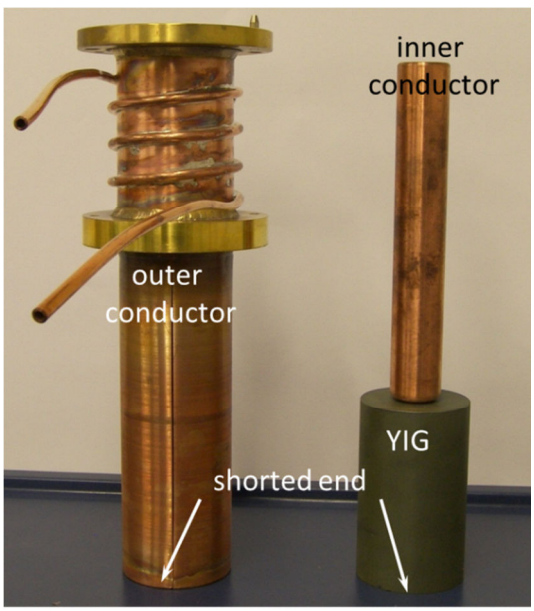

Figure 1: Tuner adjustable section with the inner conductor removed from the outer conductor.

DESIGN

In one of the ports located 3″ (on center) from the cavity shorted end, a fast tuner is loop-coupled to the cavity. The coupling is through a 2.5″ diameter coaxial ceramic window. The tuner loop area of 2.5 in^2 was adjusted to give a nominal coupling impedance of 50 Ω. The tuner is slightly less than a half-wavelength long and is made up of standard EIA 3⅛″ diameter, 50 Ω rigid copper transmission line, in addition to an "adjustable section" which is partially loaded with a 5″ long piece of Al doped Yttrium Iron Garnet (YIG). This section is immersed in a variable solenoidal magnetic field which provides a perpendicular bias for cavity tuning. A photo of the adjustable section, with the center conductor assembly removed from the outer conductor, is shown in Figure 1. The tuner line is shorted at the end opposite the cavity.

The garnet (TCI Ceramics type AL-400) has a saturation magnetization ($4\pi M_s$) of 400 gauss. Its OD and ID are 3.0″ and 0.65″ respectively. The center conductor used in the 15.75″ long adjustable section, which does not have the dimensions of standard 3⅛″ coax line, is shrink fit into the garnet. Over the 9″ length closest to the short, the outer conductor thickness has been reduced from the standard 3⅛″ coax line wall thickness to 0.020″. Both this 9″ section and the bottom copper shorting plate have a 0.0197″ wide slot machined through the copper to reduce eddy current effects.

For heat removal, the outer conductor is water cooled and the adjustable section is filled with a dielectric fluid (Diala AX).

The adjustable section had previously been designed for use as a fast phase shifter in vector modulators operating at 325 MHz [5].

The entire tuner, attached to the cavity and installed in the Recycler, is shown in Figure 2.

Solenoid

The 112 turn solenoid (with TCI Ceramics G4 ferrite flux return) was designed to work at relatively high DC current (80A), but also at high frequency (~2 kHz) AC current. While the AC response is not absolutely required, the ability to tune at ~2 kHz will be an advantage. Obtaining the desired DC and AC response necessitated the use of Litz Cable of sufficient cross section (1/0 AWG) with 270 copper strands of 24 AWG wire insulated from each other. The total strand cross section reduces the losses in the DC regime, and the insulation between strands minimizes the eddy currents in the cable (for the AC regime). A cooling tube was wound on the outer surface of the solenoid as a bifilar coil in order to eliminate the effect of magnetic fields caused by eddy currents induced in it. A DC magnetic field simulation predicted the resulting minimum and maximum magnetic fields in the tuner garnet of 0.058 T and 0.081 T, for 8000 solenoid ampere-turns.

The solenoid current is supplied by a Copley Controls Model 266 amplifier which has a nominal bandwidth of

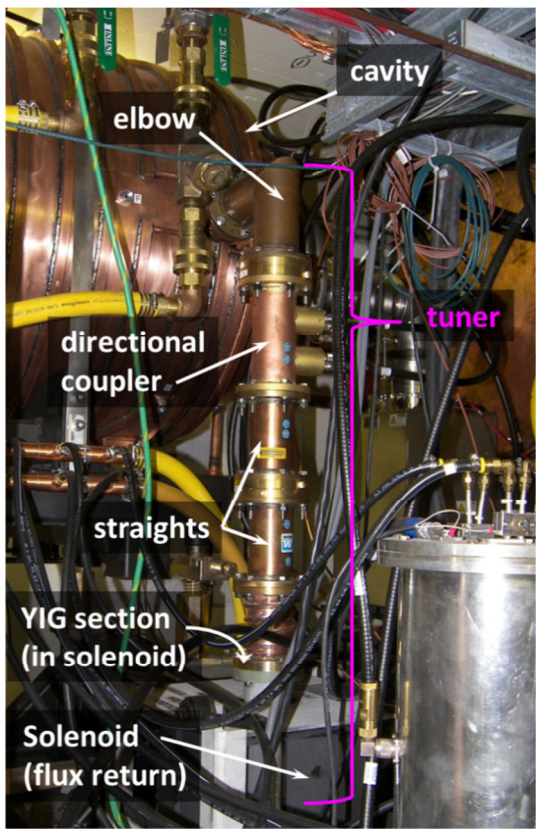

Figure 2: Tuner attached to the cavity, installed in the Recycler. The tuner is made up several 3⅛″ coax sections: an elbow, directional coupler, several straight sections, and finally the YIG loaded adjustable section (here obscured by the solenoid) which is shown in Figure 1.

5 kHz. The tuner response is currently limited by the solenoid inductance of 1.9 mH and the 60V max/80 A max DC supply for the Copley amplifier.

TUNER PERFORMANCE AND MEASUREMENTS

The tuner is characterized apart from the cavity by the measurements plotted in Figure 3. This shows network analyzer S_{11} amplitude and phase measurements as a function of DC solenoid bias. Large phase shifts

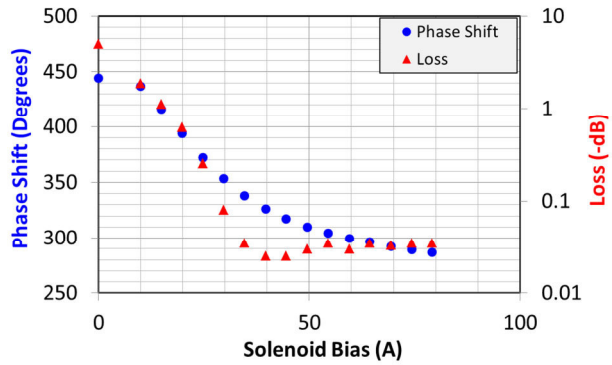

Figure 3: Two-way phase shift in tuner 15.75″ adjustable section at 52.809 MHz (left y-axis) and Loss (right y-axis) as a function of solenoid bias.

correspond to a large frequency change (tuning) in the cavity/tuner system. Operation must be above ~35A, below which the garnet becomes lossy.

The next set of measurements quantifies the operation of the cavity/tuner system as a whole. Figure 4 (wide range) and Figure 5 (operation range) show the frequency (left y-axis) and the Q of the cavity/tuner system (right y-axis) as a function of solenoid bias current. The bias at which we observe a large change in frequency and a minimum in Q corresponds to the case where the tuner is one half wavelength long.

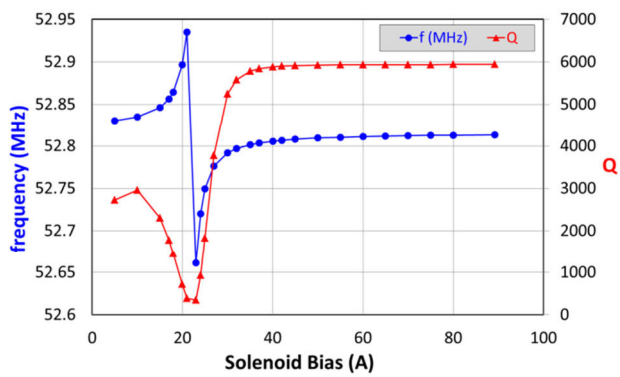

Figure 4: Frequency and Q of the cavity/tuner system as a function of solenoid bias current, for a wide range of tuner biases.

An additional restriction on tuner range is due to the peak voltage that can be sustained in the tuner without sparking. Figure 6 shows low level

Copyright © 2013 CC-BY-3.0 and by the respective authors

measurements of frequency and the corresponding tuner voltage. In this case, the cavity was powered with a relatively small signal. Cavity peak accelerating gap voltage and tuner peak voltage were measured simultaneously. The values were then scaled to cavity gap

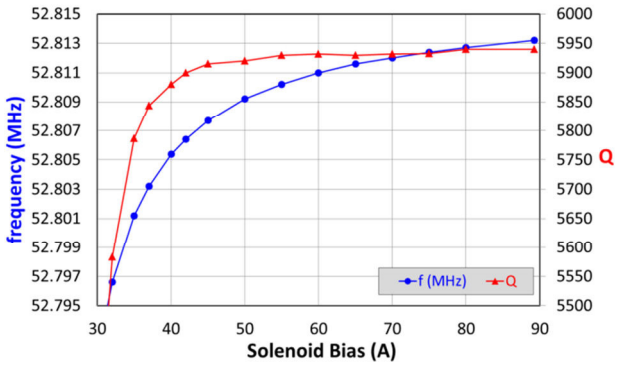

Figure 5: Frequency and Q of the cavity/tuner system as a function of solenoid bias current, for solenoid biases in the range that the tuner is operated (> 35 A).

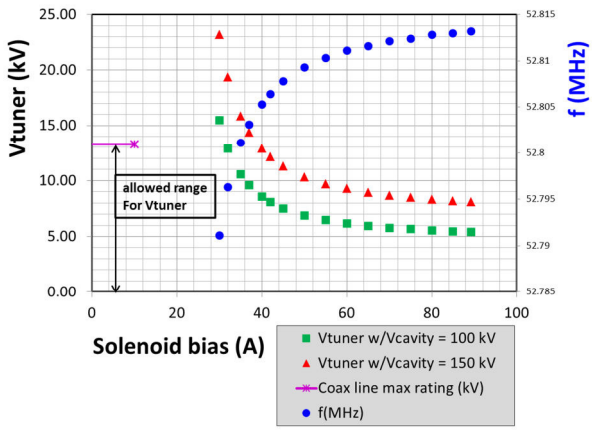

Figure 6: Tuner voltage and frequency of cavity/tuner system as a function of tuner bias. The maximum peak voltage for the tuner 3⅛″ line is also shown. (These measurements were taken from the cavity field probe and the directional coupler which is part of the tuner.)

voltages of 100 and 150 kV. Operating with a tuner voltage above the peak voltage limit for 3⅛″ coaxial line of 13.3 kV will cause arcing and must be avoided. Not only is arcing in the coax line undesirable, but this can also lead to high voltages near the garnet which could be destructive.

Measurements shown indicate I ≥ 32 A and I ≥ 40 A to respect the 13.3 kV limit, for cavity voltages of 100 kV and 150 kV. With no other adjustments, and taking into account the 35 A limit imposed due to losses in the garnet, the tuning ranges are 11.7 kHz and 7.5 kHz for cavity peak voltages of 100 kV and 150 kV.

TUNER SPARK PROTECTION

To avoid destruction of the garnet, several methods of protection are in place to shut off RF power to the cavity in the event of a tuner spark.

The tuner line contains a 60 dB directional coupler with both forward and reverse power taps. The first tuner protection system shuts off the RF drive if a change of more than 3dB/μs is detected in the reverse power.

In the second protection system, a phase detector monitors the phase difference between forward and reverse power. If the phase changes more quickly than that due to normal tuning, the RF drive is again shut off. This is accomplished using a capacitive differentiator and a comparator.

STATUS AND HIGH POWER TESTING

Before being installed in the Recycler, both cavities were high power tested in a shielded "cavity test cave". The cavity and tuner systems have been operated successfully at high power in the Recycler.

ACKNOWLEDGMENTS

We would like to acknowledge the huge efforts of the Accelerator Division Mechanical Support and RF Groups, and everyone involved in this project. In addition, we would like to thank all of those in Technical Division involved in the design and construction of the solenoids.

Abstract

The International Muon Ionization Cooling Experiment (MICE) [1] includes two linear accelerator sections with four RF cavities each within a shared vacuum vessel. Ten cavity bodies have been fabricated for MICE including two spares and one was electropolished at LBNL. A special vacuum vessel was built to house this cavity and form the 201-MHz Single-Cavity Module (SCM). The module and its instrumentation are being assembled and tested at Fermilab for installation and operation in the MuCool Test Area.

MICE RF SYSTEM

MICE is a demonstration of ionization cooling using a full cooling cell surrounded by tracking and particle identification detectors to measure each muon before and after it traverses the cooling cell [2]. It is under construction at Rutherford Appleton Laboratory (RAL). Figure 1 shows the RFCC (RF cavity and coupling coil) module [3, 4] which includes a large-diameter coil around a linac section. Each pair of cavities will be driven by a 2-MW amplifier system for a gradient of 8 MV/m per cavity. Parts of the power distribution network and LLRF system are being procured, developed, built and tested by teams from LBNL, University of Mississippi, Illinois Institute of Technology and Fermilab in the US and Strathclyde University, Daresbury Laboratory, Imperial College and RAL in the UK.

SINGLE CAVITY MODULE

In order to develop the assembly procedure for the RFCC modules and test cavity operation early on at the Fermilab MuCool Test Area (MTA), a special vacuum vessel was designed at LBNL to house a single MICE cavity. The single-cavity vacuum vessel has mostly the same mechanical interfaces as the RFCC module. Figure 2 shows the single-cavity module assembly. Ten RF cavity bodies have been manufactured in industry using techniques developed at LBNL. Cavity half shells were spun from 6mm-thick Cu sheet e-beam welded at the equator. Four ports were pulled around the equator on each cavity for couplers, vacuum pumping and instrumentation. Copper cooling tubes were brazed onto the cavity bodies. Each cavity has a pair of 0.35mm-thick curved beryllium windows for a pillbox-like geometry. Power is brought in through a pair of coaxial loop couplers. The first set of couplers is under fabrication at LBNL. The tuning system comprises stainless steel flexure arms driven by pneumatic actuators [5]. Figure 3 shows the basic design. The actuator body includes two concentric shafts screwed onto threaded holes in the tuner arm. As the shafts are pulled together or pushed apart by pneumatic action, the forces are transmitted to the cavity stiffener rings to elastically deform the cavity body. The actuator cover is attached to a vacuum vessel port with vacuum bellows while the body is thermally isolated from the

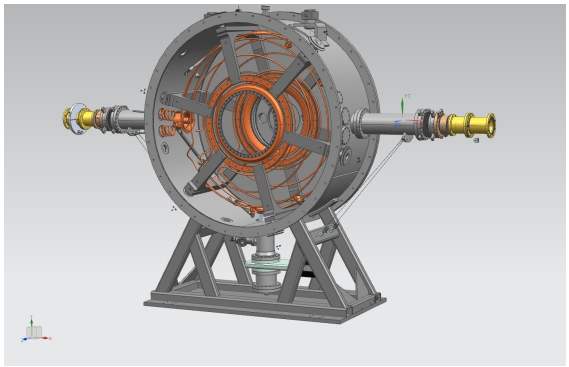

Figure 2: Single Cavity Module assembly view showing parts of the vacuum vessel body, couplers, tuning forks, actuators and cooling tubes. Stiffener and window clamp rings and cavity mounting struts are also visible while the cavity body and Be windows are suppressed for clarity.

vessel. One of the cavities was electropolished at LBNL [6] and sent to Fermilab for installation and testing in this vessel. A prototype tuner arm was mounted on an aluminum test hoop with one sixth the spring constant of the cavity body for initial tests at LBNL. The first set of six production tuner forks and actuators were built at Fermilab and LBNL respectively. The test setup was used at Fermilab to qualify the actuators.

ASSEMBLY STATUS AND PLANS

Clean Room

A class 100 (ISO 5) assembly environment is needed to minimize contamination of the vacuum vessel and cavity interior. The clean room chosen in Lab 6 at Fermilab had been unused for many years but after interior cleaning and curtain repair, it was down to class 10 (ISO 4). Air quality is monitored using a particle counter, all cavity ports are capped during mechanical work and full clean room garb is used by personnel during assembly. Cavity and vessel exterior surfaces were cleaned before and after being moved into the clean room. Flat aluminum cover plates were installed on the cavity in place of the Be windows to keep the interior clean during initial assembly work without risking damage to the thin windows. Covers for the vacuum vessel have to be removed to reduce the size during transport. Transparent plastic plates were used to keep the vessel interior clean during storage and transport.

Figure 3: Tuner model (left), actuator prototype (center) and test setup (right).

Mechanical Setup

The initial hardware configuration is shown in Fig. 4. Due to limited height in the clean room during assembly and in the hallway leading to the MTA experimental hall during transport, a shorter stand was built and the vacuum vessel moved onto this temporary stand. A portable gantry crane was cleaned and placed in the clean room to lift the cavity which weighed in at 227 kg and should be about 400 kg with the tuners installed. Initial measurement of cavity parameters was performed with the cavity mounted on a vertical measurement stand. A rotation fixture was built to hold the cavity locked in a horizontal orientation for tuning fork installation as well as rotate it to a vertical orientation for handling by the crane. The cavity will be mounted in the vacuum vessel using struts forming a six-axis (Stewart) platform. An attachment was designed for use with a portable lift to insert the cavity into the vacuum vessel and hold it while the struts are connected.

Tuner System

In order for the tuning system to work correctly, all the forks should be in a plane parallel to the cavity plane of symmetry and the actuator shafts aligned with vessel ports. Extra material was included on the contact pads in the drawings for the flexure tuning forks. The ports on the vacuum vessel, the stiffener rings on the cavity body (which the forks are attached to) and the forks were surveyed with a laser tracker. Tuner fork contact pads were machined to match the largest gap between stiffener ring surfaces on the cavity and shims were prepared to take up the gaps as needed. The forks have been installed as shown in Fig. 5. A simple alignment tool was designed consisting of a rod with an outside thread on one end so it could be screwed into the tuner fork and a flat surface with a hole at the other end to accept a laser tracker target. These were mounted on

Figure 4: Clean room interior with the cavity (back) mounted on the vertical measurement stand under the portable crane, the vacuum vessel (left) with transparent cover plates on the temporary stand and part of the rotation fixture (front).

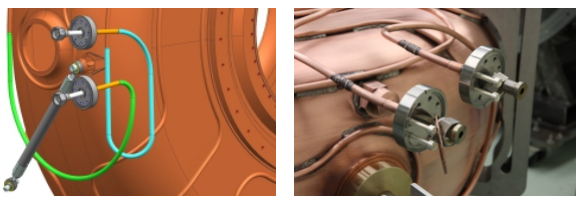

Figure 6: Cooling tube feed-throughs: model (left), installed on cavity (right).

the forks to be used for alignment of the forks on the cavity and alignment of the cavity within the vacuum vessel.

Water Connection

No water fittings are allowed inside vacuum volumes in MICE. The copper cooling water tube on the cavity body goes through a pair of stainless steel two-piece feed-through assemblies on the vacuum vessel (Fig. 6). A section of stainless steel tubing was vacuum brazed to a section of copper tubing. The stainless steel tube was then welded to the feed-through flange and a stainless steel fitting for the water connection on the air side. The copper tubing end was silfos brazed to the copper tube from the cavity body to complete the connection on the vacuum side. The feed-through assemblies were water pressure tested and vacuum leak checked before and after installation.

Diagnostics

The following instrumentation is in preparation for monitoring various aspects of cavity operation:

- On the cavity, couplers and vacuum vessel
  - Two pickup loops inside cavity to monitor the RF field
  - Vacuum gauges for the cavity, vessel and couplers
  - Thermocouples on cavity body
  - Infrared sensors pointed at the thin Be windows for temperature measurement
  - Fiber light guides viewing the cavity interior to detect sparking
  - Piezoelectric sensors on cavity body to detect and localize breakdown through acoustic signals
  - Electron pickups near the coupler ceramic vacuum windows to monitor coupler conditioning
  - Viewports near the vacuum windows to detect light in couplers due to breakdown
- In the experimental hall
  - Water pressure and flow. Note that there are five cooling tubes in the system: one for the cavity body and one for each of the coupler loops and RF windows
  - Gas pressure for tuner actuators
  - Radiation detectors
    - ionization chambers for overall dose rate
    - scintillator+PMT counters for X-ray rates
    - NaI crystal+PMT counter for X-ray spectra
  - Forward and reflected power waveforms from directional couplers near the cavity

Remaining Steps

The cavity will be installed in the vacuum vessel and the transfer function for the tuning system measured shortly. The vessel will be moved to the MTA hall after tuners and instrumentation are fully tested and assembly will be finished in the MTA clean room. The vessel will be initially placed in the fringe field of the MTA solenoid and moved next to the coupling coil prototype for testing in the full magnetic field configuration when that magnet is available. RF power station controls have been upgraded and commissioned with a test load and frequency tuning will be incorporated into the conditioning control software [7].

PROGRESS ON THE FABRICATION OF A CW RADIO-FREQUENCY QUADRUPOLE (RFQ) FOR THE PROJECT X INJECTOR EXPERIMENT (PXIE)*

M. D. Hoff, A. J. DeMello, A. R. Lambert, D. Li, J. W. Staples, and S. P. Virostek
Lawrence Berkeley National Laboratory, Berkeley CA 94720, USA

Abstract

The Project X Injector Experiment (PXIE), a prototype front end of the Project X accelerator [1] proposed by Fermilab, is currently under construction. The complete PXIE beamline [2] is made up of an H^- ion source, a low-energy beam transport (LEBT), a 2.1 MeV, 162.5 MHz radio-frequency quadrupole (RFQ) accelerator, a medium-energy beam transport (MEBT) and a 30 MeV section of superconducting cryomodules. The 4.45 m long CW RFQ consists of four separate modules that are joined by means of specially designed bolted joints. Each module consists of four solid copper vanes that are brazed together to form a 4-quadrant accelerating cavity. The ~100 kW of total wall power heat is removed by means of gun drilled water cooling passages. Mode stabilization is provided by a series of brazed, water cooled pi-mode rods. Tuning is achieved using a total of 80 fixed slug tuners. Fabrication of the PXIE RFQ is now under way at LBNL. Details of the RFQ mechanical design and an update of the fabrication progress are presented in this paper.

MODULES

The 4.45 m long RFQ is assembled from four approximately equal length modules. The modules are sized based on the available copper C101 billet size, available milling machine capacity, general handling considerations and the desire to minimize joints. Each module is fabricated from four tee shaped pieces of copper that weigh approximately 940 kg each before machining (see Fig. 1).

MACHINING

The outer wall features are machined first. The outer wall is machined flat, followed by the pi-mode rod holes, slug tuner ports, sensing loop ports and the vacuum pump port are cut. Then the vane is flipped over and mounted to a 3 inch stainless steel plate for cavity machining. The stainless plate allows easy handling and mounting of the part in the milling machines. The precise cavity contours, pi-mode rod clearance holes and then the four mating braze surfaces are cut with a standard shaped end mill (see Fig. 2 and Fig. 3). The last step is the machining of the vane tip modulations, as described later in this paper.

Figure 1: Raw tee shaped copper for vane fabrication.

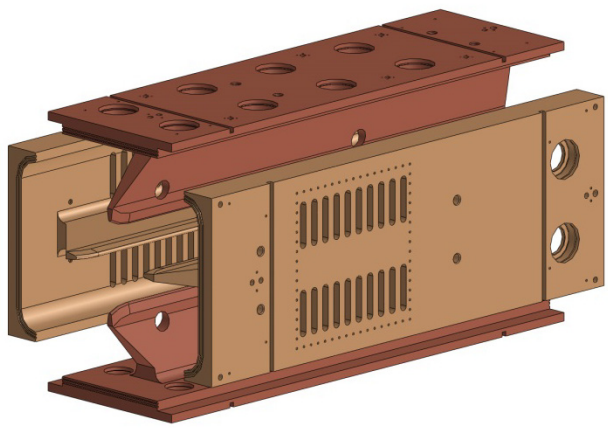

Figure 2: Exploded CAD model of four machined vane.

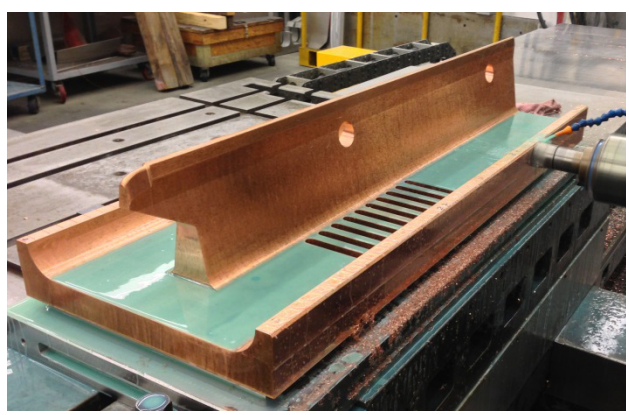

Figure 3: Module 1, horizontal vane being machined.

Copyright © 2013 CC-BY-3.0 and by the respective authors

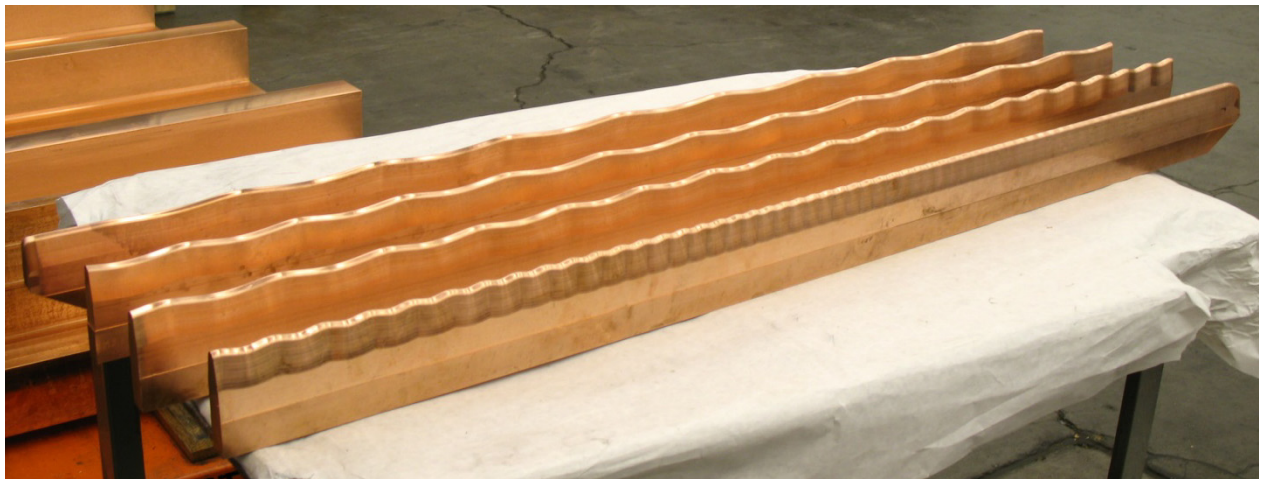

Figure 4: Modulation cut test piece.

PI-MODE RODS

RF mode stabilization between cavity quadrants is accomplished with 8 hollow copper rods per module, 32 total [3]. The rods are approximately 10 mm O.D. by 5 mm I.D. by 425 mm long (see Fig. 5). The rods are hollow to allow coolant to flow inside the rods during operation. The rods are brazed to the cavity walls at the same time the four vanes are brazed together. The rod passes through a clearance hole in the vane that divides the quadrants (see Fig. 6).

Figure 5: Pi-mode rod with two ferrules.

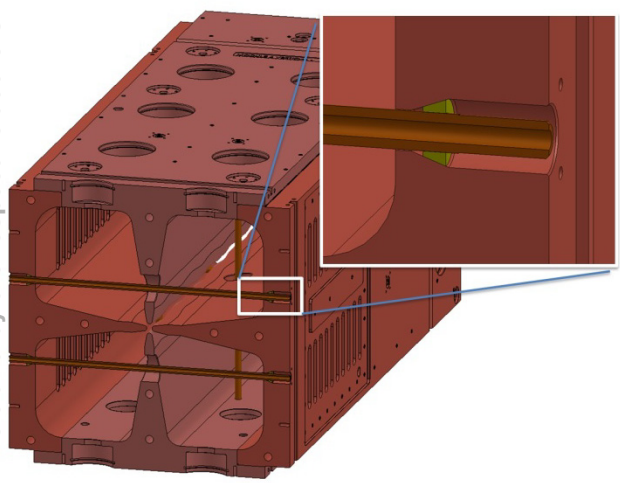

Figure 6: Pi-mode rod with ferrule detail.

VANE TIP MODULATIONS

Vane tip modulations are machined using a specially made carbide cutting tool. Using a profile cutting mill is much faster than a ball end mill (see Fig. 4 and Fig. 7).

Figure 7: Modulation profile cutting tool.

COOLING PASSAGES

Cooling of the RFQ body is accomplished by blind gun drilling ∅12 mm holes most of the long length of the vane. The long gun drilled hole is connected to the outside vane wall by cross-drilled holes at each end. The entry point for the gun drilled hole is then sealed with a tight fitting copper plug that is electron beam welded vacuum tight (see Fig. 8).

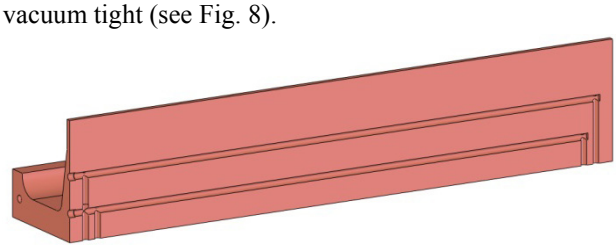

Figure 8: CAD model of gun drilled cooling passages.

BRAZING

When the majority of the machining is complete, the four vanes of a module are gently brought together using

Copyright © 2013 CC-BY-3.0 and by the respective authors

a kinematic, 6 strut fixture to check braze surface fits and measure RF cavity resonance. After the test fit, the vanes are separated, cleaned and CuSiL [4] braze alloy in the form of ∅1 mm wire is loaded into pre-machined grooves. The vanes are then brought back together and clamped into position. Pi-mode rods are then installed and clamped into position too. Brazing is done in a hydrogen furnace in the vertical position. The engineered clamps, using Inconel [5] Belleville washers, allow the copper to expand, yet maintain a firm clamping force during the heat up and cool down cycle (see Fig. 9).

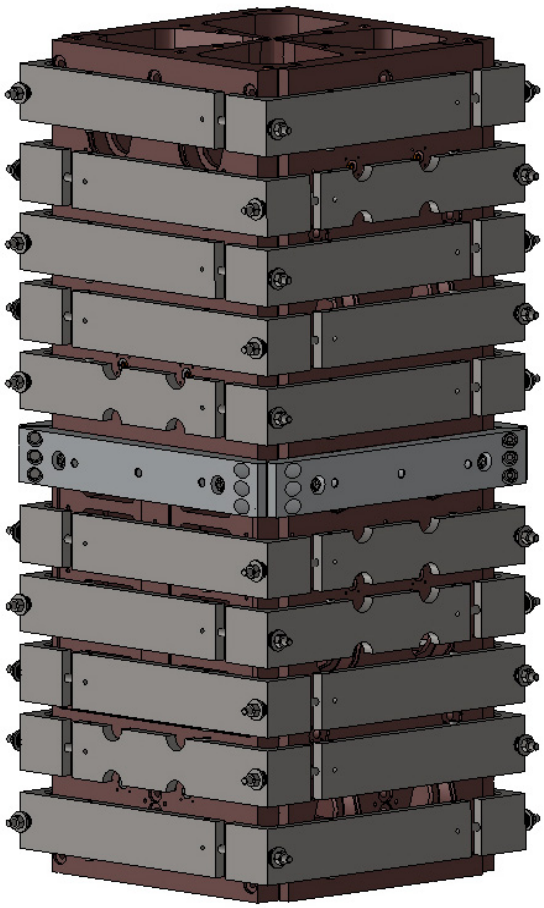

Figure 9: CAD model of vertical module braze with clamps.

POST BRAZE

After brazing the four vanes and 8 pi-mode rods together, the module is machined to its final length with O-ring and RF sealing geometry added to the ends.

Coarse tuning of the RFQ cavity is accomplished with 80 approximately equally spaced slug tuners. First temporary, length adjustable tuners are installed and RF resonance measurement are taken. The temporary tuners are adjusted in length until the desired RF resonance is achieved. The temporary tuners are removed, measured and replaced by non-adjustable, slug tuners. The slug tuners are sealed with an RF joint and O-ring. The slug tuners are held in place with a commercial snap ring.

JOINT PLATES

Modules are joined together using stainless steel plates that form a collar around the soft copper. The collar is tied to the module with a keyed groove and bolts. The collar contains pockets for bolts and nuts to clamp the modules together, squeezing the RF seal and O-rings in place (see Fig. 10).

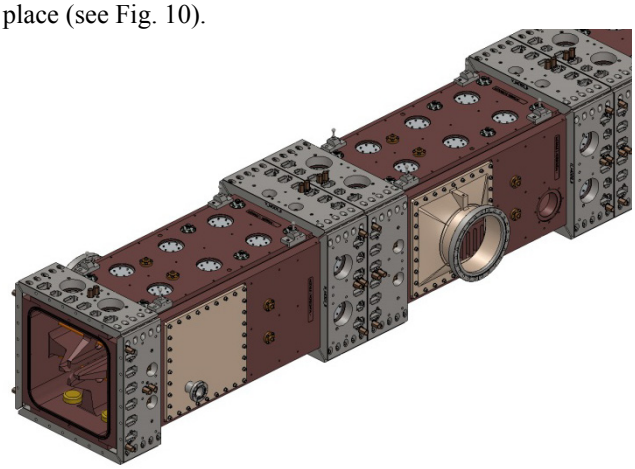

Figure 10: Joint Plates connecting modules.

SUMMARY

LBNL is currently constructing an RFQ for the Project X front end. The RFQ is being fabricated with solid copper vanes that are hydrogen furnace brazed together into four modules 4.45 m long total. Cooling will be accomplished with gun drill passages along the length of individual vanes. 32 Pi-mode rods linking adjacent cavities will provide RF stabilization. Brazed modules are mechanically connected using a special joint plate with bolts. Final tuning is accomplished with 80 static slug tuners. Fabrication is underway at LBNL with expected delivery of the RFQ to FNAL in 2014.

RF, THERMAL, AND STRUCTURAL FINITE ELEMENT ANALYSIS OF THE PROJECT X INJECTOR EXPERIMENT (PXIE)* CW RADIO-FREQUENCY QUADRUPOLE (RFQ)

A.R. Lambert#, M.D. Hoff, D. Li, J.W. Staples, and S.P. Virostek
Lawrence Berkeley National Laboratory, Berkeley, CA 94804

ABSTRACT

PXIE (Project X Injector Experiment) is a prototype front end system for the proposed Project X accelerator complex at Fermilab [1]. An integral component of the front end is a 162.5 MHz normal conducting CW (continuous wave) radio-frequency quadrupole (RFQ) accelerator that has been designed and is being fabricated by LBNL. The RFQ will accelerate H^- ions from 30 keV to 2.1 MeV [2]. The four-vane RFQ consists of four modules with a total length of 4.45 meters. Through application of finite element analysis (FEA), the electromagnetic fields and their resultant effect on the RFQ body temperature and the subsequent deformations due to thermal expansion have been simulated. The analysis methodology developed at LBNL allows for quick evaluation of RFQ temperature, stress, deformation and the resulting effect on frequency without requiring the construction of a prototype. The technique has been applied to the following: RFQ body, RFQ cutbacks, fixed slug tuners, and pi-mode rods. The analysis indicates that the total heat load on the RFQ will be approximately 80 kW, which is removed via water-cooled passages.

INTRODUCTION

The PXIE RFQ is a front end injector for the proposed Project X experiment at FNAL. As this RFQ will operate in continuous-wave (CW) mode, the engineering design and analysis is critical for managing the thermal performance. The aim of this paper is to introduce that analysis method used to determine the heat loads experienced by the RFQ, how these loads affect operating temperature, and how temperature increase affects frequency and the methods by which the cooling water can be used to mitigate the RF heating effects on frequency.

RFQ BODY SIMULATION

The body of the RFQ is simulated using a thin 3D slice of the RFQ cross section. Only one-quarter of the geometry is simulated due to symmetry. The first step of this step in the simulation is to create a vacuum geometry that corresponds to the solid RFQ body. Once created, ANSYS Multiphysics [4] performs RF analysis on the vacuum geometry. Once complete, the RF heat load is calculated and applied to the inner cavity walls of the RFQ body model. Convective water cooling is applied to the gun-drilled cooling channels, as shown in Fig. 1.

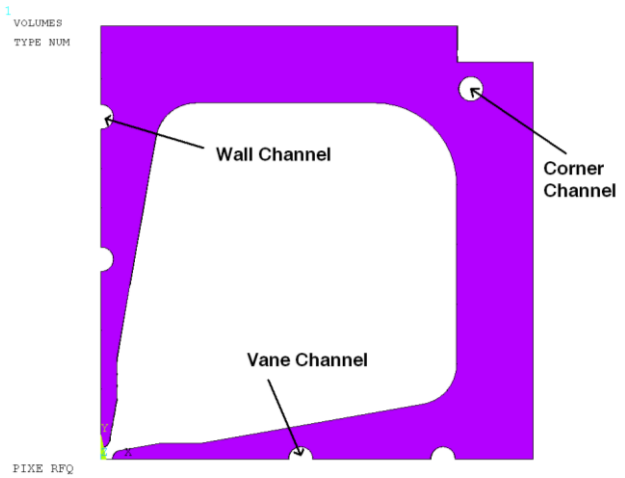

Figure 1: RFQ body cross section with gun-drilled cooling channels.

Assuming that the cooling water is at 30 °C, the resulting temperature profile at steady-state operation is shown in Fig. 2.

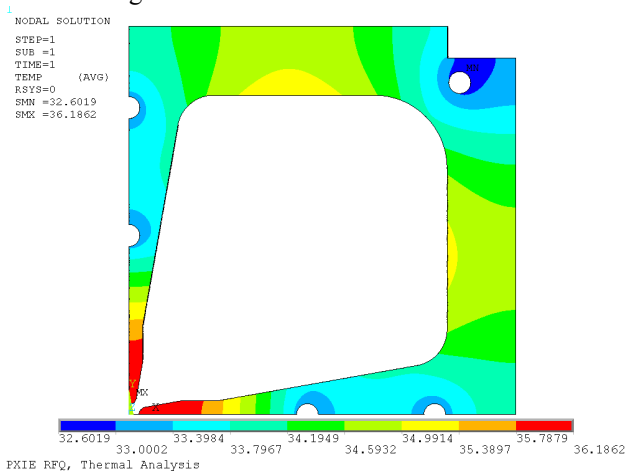

Figure 2: Temperature contours (°C) for steady-state RFQ operation.

The maximum temperature is 36.2 °C and is located at the vanetips. Minimum temperature is approximately 32.6 °C, and is found in the corner cooling passage. Overall, it is evident that with the current cooling scheme, the RFQ body temperature only rises 2.0 – 6.0 °C above nominal water temperature. This temperature rise causes expansion of the cavity walls away from the beam axis, and growth of the vanetips towards the beam axis. Both of these affect the resonant frequency of the cavity. The thermal results are piped into a structural analysis which determines the displacements due to thermal expansion, the results of which are shown in Fig. 3.

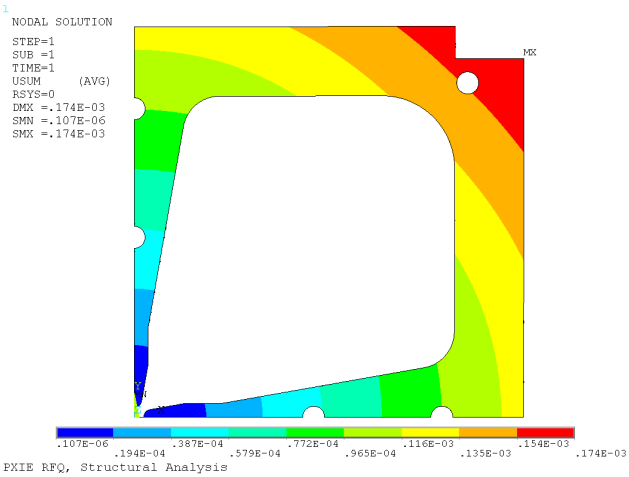

Figure 3: Thermal displacement (m) due to RF heating.

As surface nodes are shared between the vacuum and solid body meshes, the displacements are used to morph the vacuum mesh such that it reflects the deformed geometry. This new cavity geometry, which represents the steady-state operating condition, is used for a final RF analysis to determine the frequency shift due to RF heating and subsequent steady-state frequency. The uncorrected ideal, nominal and steady-state frequencies are shown in Table 1.

Table 1: RFQ Frequencies

Condition	Frequency (MHz)
Ideal	164.36
Nominal	164.28
Steady State	164.27

As Table 1 shows, the frequency drop from initial start up, i.e. nominal frequency, to the final steady state frequency is approximately 10 kHz. This drop is due to RF heating, with thermal equilibrium achieved roughly 10 minutes after RF power turn on. Varying the cooling water temperature in the vanes and walls provides some differential dynamic tuning capabilities that mitigate the frequency shift due to RF heating. The frequency sensitivity to cooling water temperature change is shown in Table 2.

Table 2: Frequency Shift Due to Cooling Water Temperature Change

PXIE Frequency Shift	Average Result
Overall (kHz/ °C)	-2.8
Vane (kHz/ °C)	-16.7
Wall (kHz/ °C)	13.9
Theoretical Shift (kHz/ °C)	-2.9

As the table shows, the theoretical shift closely matches the simulated overall shift, evidencing the accuracy of the FEA model.

RFQ BODY SIMULATION

The RFQ cutbacks are simulated in a similar fashion as the thin slice model. A sub-model of the cutbacks was created and RF analysis in ANSYS was carried out. The result is piped into a thermal simulation, the outcome of which is shown in Fig. 4.

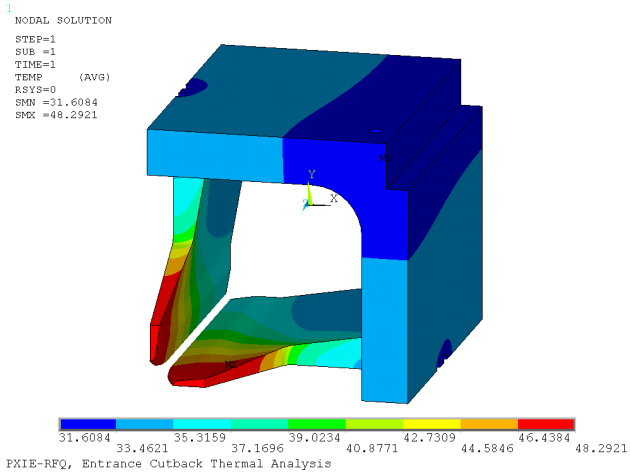

Figure 4: RFQ cutback temperatures (°C) at entrance.

As Fig. 4 shows, the maximum temperature occurs at the tips of the cutbacks, which is the location is the farthest from the cooling channels.

PI-MODE RODS

ANSYS Workbench is used to simulate the heating in the pi-mode rods, which are made from OFHC copper. The pi-rods are brazed into the RFQ structure and cooled via water that is pumped through their inner bore. Heat loads are approximated from ANSYS Multiphysics and CST Microwave Studio. The temperature results are shown in Fig. 5.

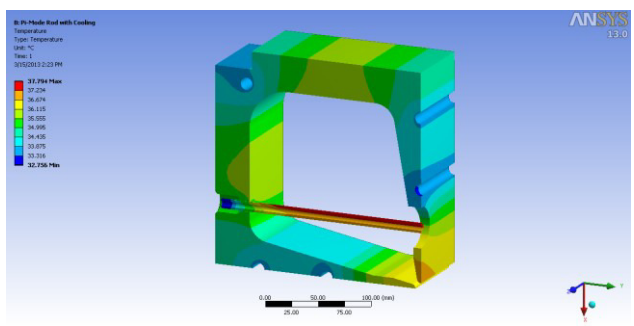

Figure 5: RFQ body and pi-mode rod temperatures (°C).

As Fig. 5 shows, assuming a nominal cooling water temperature of 30.0 °C, the resulting maximum rod temperature is 37.8 °C. As long as cooling water is flowing, the pi-rod temperature is effectively managed. However, in the event of a cooling water failure, failsafe systems will shut down RF power; this is to avoid

Copyright © 2013 CC-BY-3.0 and by the respective authors

excessive heating of the pi-rods, which could cause material yielding due to thermal expansion.

RFQ FIXED SLUG TUNERS

The slug tuners are made from OFHC copper and are installed in their respective ports using a snap ring. An RF spring mitigates any RF leakage at the mating surfaces, and an O-ring is used to seal the vacuum. The slug tuners do not have any active cooling, but instead rely on conductive heat transfer to the RFQ body.

The heat load on a given slug tuner is a function of its penetration depth into the RF cavity; nominal intrusion is 20.0 mm, while min and max intrusion is +/- 20.0 mm from nominal, which gives a tuning bandwidth of +/- 1.4 MHz. The worst-case heating situation corresponds to a slug tuner at maximum intrusion of 40.0 mm, located at the cutbacks. Evaluation of this situation yields a conservative estimate of the conductive cooling capability of the slug tuner to RFQ body interface. The heat flux into a slug tuner for the described condition is shown in Fig. 6.

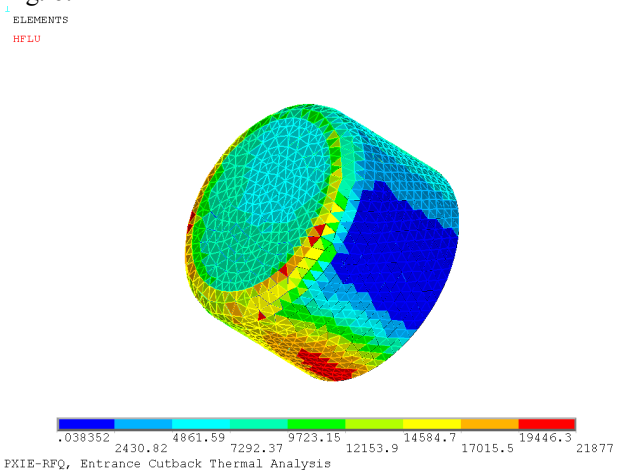

Figure 6: Slug tuner heat flux (W/m^2) at 40.0 mm intrusion.

The heat flux is integrated over the area of the slug tuner to provide the total heat flow into the tuner, which is ~80 W. This heat flow is then used in ANSYS workbench to simulate heat transfer from the slug tuner to the RFQ body. To mimic the effect of contact resistance, the effective area for conductive heat transfer is reduced to less than 10% of its actual area. The resulting temperature profiles are shown in Fig. 7.

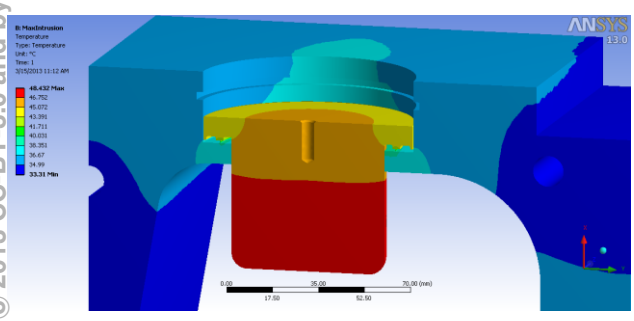

Figure 7: Slug tuner temperatures profiles (^{o}C)

The maximum tuner temperature is 48.4 ^{o}C, which is not problematic. It is unlikely that any of the slug tuners will experience this worst-case scenario; however, in the event that this situation does occur, the conductive heat transfer to the RFQ body is sufficient to cool the slug tuners.

TOTAL RFQ HEAT LOAD

From this analyses, it is possible to calculate the total RFQ heat load, and hence the required cooling that must be supplied to maintain stable operating temperatures. The total heat load of each module is tabulated in Table 3, with the overall total heat load summed at the bottom.

Table 3: Module Heat Loads Due to RF

Component	Heat Load (kW)
Module 1	19.2
Module 2	19.7
Module 3	19.7
Module 4	19.4
Total	**78.0**

As Table 3 shows, the total RFQ heat load is approximately 78.0 kW. This includes the heat of the RFQ body, cutbacks, pi-rods and slug tuners. Assuming a 30% contingency factor, the required cooling system should have a cooling capacity of ~100 kW.

CONCLUSION

This paper illustrates how the use of FEA provides successful prediction of RFQ operating parameters, as well as providing information that helps to size external systems without requiring a prototype module or rigorous experimental testing.

Abstract

The Project X Injector Experiment (PXIE) now under construction at Fermilab is a prototype front end of the proposed Project X accelerator [1]. PXIE will consist of an H^- ion source, a low-energy beam transport (LEBT), a radio-frequency quadrupole (RFQ) accelerator, a medium-energy beam transport (MEBT) and a section of superconducting cryomodules [2]. The PXIE system will accelerate the beam from 30 keV to 30 MeV. The four-vane, brazed, solid copper design is a 4.45 m long CW RF accelerator with a resonant frequency of 162.5 MHz. The RFQ will provide bunching and acceleration of a nominal 5 mA H^- beam to an energy of 2.1 MeV. The average power density on the RFQ cavity walls is <0.7 W/cm^2 such that the total wall power losses are ~80 kW. LBNL has completed the final design of the PXIE RFQ, and fabrication is now under way. The completed PXIE RFQ will be assembled at LBNL and tested with low-level RF prior to shipping to Fermilab. Several aspects of the final RFQ mechanical design along with associated fabrication techniques are presented in this paper.

INTRODUCTION

The PXIE RFQ will operate at a 162.5 MHz resonant frequency and will accelerate a 5 mA H^- beam to 2.1 MeV using a 60 kV vane-to-vane voltage. The 4.45 m long, four-vane CW structure will be comprised of four approximately 1.1 m long longitudinal modules. Only about 12% of the total RF input power goes to beam loading with the rest dissipated on the cavity walls to generate the necessary RF field. The modules will consist of four solid OFHC copper sections that are fully machined with the vane tips modulated prior to being brazed together. Due to the high power CW operation of the PXIE RFQ, a brazed copper structure design has been developed. Final frequency adjustment and local field perturbation correction is accomplished by means of 80 evenly spaced fixed slug tuners. Quadrupole mode stabilization is achieved through a set of 32 water-cooled pi-mode rods. The overall approach for the PXIE RFQ was to combine specific proven fabrication and assembly techniques with other high reliability, low cost features in order to develop a design that poses low risk and is easily manufactured using readily available machinery.

Images from a 3-D CAD model of the completed RFQ design are used in this paper to present detailed descriptions of various design characteristics. A realistic CAD rendering of the full four-module RFQ is shown in Fig. 1 (rendering by Don Mitchell of Fermilab).

RFQ DESIGN DETAILS

Cavity Body

Each module consists of four vanes that are to be machined from a single piece of OFHC copper and will incorporate simple cooling channels produced using a readily available gun drilling technique. Modulations will be machined on the RFQ vane tips with a custom designed fly cutter used in a computer controlled horizontal mill. In order to provide high precision during both machining and assembly, the mating surfaces where the vanes join together also serve as fiducial surfaces. Two different vane geometries will be used in each module (horizontal and vertical) with the opposing vanes being identical. Features located on the outer surface of the vanes such as tuner ports, RF coupling ports, cooling taps, vacuum pumping ports, pi-mode rod penetrations, sensing loop ports and tapped holes for the stainless steel module joining plates will be machined prior to finish machining of the inner cavity surfaces and vane tips. All of the vacuum and RF sealing surfaces for the cavity penetrations are recessed into the outer surface of the RFQ copper body to prevent damage during handling.

The modules will be formed by brazing together the finished vanes along the axially running joints. In order to maintain the tight vane tip-to-vane tip tolerances and ensure that the required field flatness and cavity resonant frequency can be achieved using the slug tuners, a zero-thickness brazing process will be used. Wire braze alloy will be loaded into grooves that are recessed into the joint surfaces. A series of specially designed clamps will hold the vane joints tightly together during the hydrogen oven braze. The alloy spreads throughout the close fitting joint during the braze cycle by means of capillary action. This

Copyright © 2013 CC-BY-3.0 and by the respective authors

technique permits the RFQ modules to be assembled and the cavity frequency and fields measured prior to the braze cycle to allow for dimensional adjustments, if necessary. The braze alloy to be used is Cusil, a copper-silver eutectic that has very low viscosity when liquid. An exploded view showing the four vanes of a single RFQ module is provided in Fig. 2.

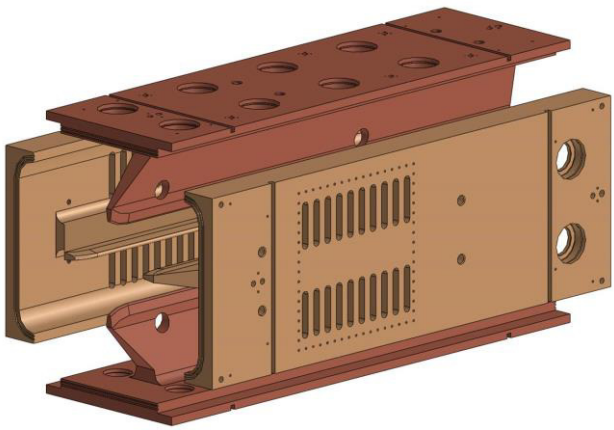

Figure 2: Exploded CAD view of a single module.

The final RFQ cavity is a four vane structure with four identically sized quadrants. A cross sectional view of the RFQ body showing the cavity geometry with cooling passages, tuners and pi-mode rods is shown in Fig. 3. Details of the RFQ features are discussed in the following sections.

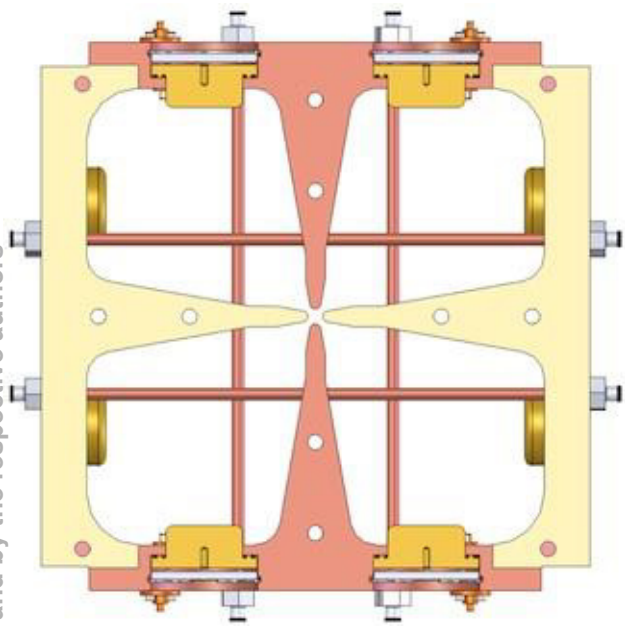

Figure 3: CAD model cross sectional view of the RFQ.

Cavity Cooling

The four cooling channels located in the RFQ vane tips will be supplied and temperature controlled separately from the eight cooling passages in the RFQ cavity walls. During operation, the combined effect of RF generated heat flux on the cavity walls and heat removal through the cooling passages will cause cavity distortion and a shift in the resonant frequency. By holding the wall cooling water constant and adjusting the vane tip water temperature, the structure frequency can be fine-tuned during operation. Due to the fact that the cavity frequency is very sensitive to the vane tip spacing, separate temperature control of the vane tip water provides approximately six times the frequency tuning range of a single cooling circuit.

The passages will be blind gun drilled into the vanes with e-beam plug welds at the end penetrations. Each of the 12 mm diameter passages will carry approximately 4 gallons per minute of cooling water. Vane cutbacks for proper termination of the RF cavity are located at the beginning of the first module and at the end of the fourth module. The cross drilled connection to the vane cooling passages will pass close to the root of the cutbacks to accommodate the higher local heat loads at the ends.

Cavity Tuning

Fixed slug tuners distributed along the length of the RFQ modules will provide cavity tuning. The final design uses 20 tuners per RFQ module (one per quadrant at five approximately evenly spaced locations). The tuners will be machined from solid slugs of OFHC copper.

The lengths of the tuners will be based on automated bead pull field measurements of the fully assembled RFQ modules. Each set of four tuners at a given axial location will be custom machined to the appropriate lengths. RF sealing of the tuners will be accomplished with a canted coil spring that will fit in a groove and be pressed against a recessed lip in the cavity wall. An O-ring outside the RF spring will provide vacuum sealing. A load plate using set screws will be held in place by a snap ring recessed in the RFQ wall and will provide the necessary sealing load on the tuner. The tuner components are shown in Fig. 4.

Figure 4: Fixed slug tuner components.

Pi-mode Rods

In order to minimize the dipole mode and maximize the quadrupole mode, four pairs of pi-mode stabilizer rods per module will be used to provide RF mode stabilization. The rods pass through holes in the vanes and provide a direct connection between opposing cavity walls. The pi-mode rods will be brazed into the cavity walls at the same time that the four vanes are brazed together. The rods are 10 mm diameter hollow OFHC copper tubes that are water-cooled.

RF and Vacuum Seals

A 3 mm wide, 250 μm high raised surface will be machined into the module ends around the periphery of the cavity to provide a primary RF connection between modules. The primary sealing surface will be backed up by a canted coil spring to absorb any RF that leaks past the initial seal. An O-ring outside of the canted spring will provide the vacuum seal. The modules will be joined together using a 'flangeless' joint design in which connecting bolts and nuts are recessed into stainless steel joint plates. The joint plates are connected to the RFQ body by means of a series of bolts and are keyed to a lateral groove in the RFQ outer wall to provide resistance to the axial forces. Fig. 5 shows a CAD view of the module-to-module joint configuration

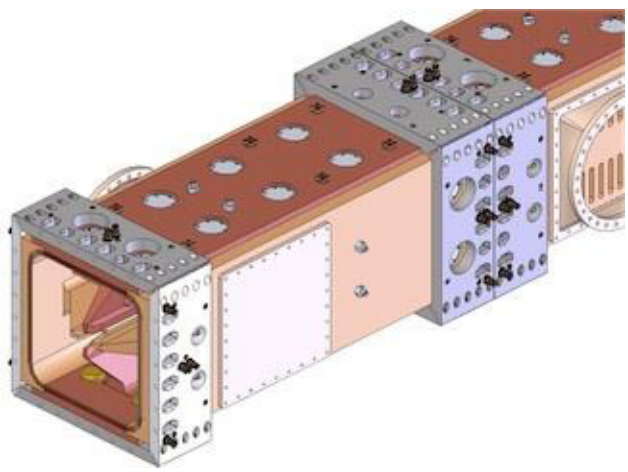

Figure 5: CAD showing a module-to-module joint.

Both RF and vacuum sealing are also required at the numerous penetrations into the RFQ cavities. The RF feed and sensing pick-up ports have sealing schemes that are similar to that previously described for the tuners. The vacuum ports will consist of slotted holes that penetrate the copper cavity walls and that were designed to maximize gas conductance while preventing RF leakage into the pumps. O-rings will provide the vacuum sealing for these ports.

RFQ Assembly

The RFQ modules are easily aligned during assembly as the ends are designed to be self-aligning through the use of dowel pins embedded in the walls at the ends. The bolted end connections are sufficiently strong and stiff such that the fully assembled RFQ can be supported as a single unit. This characteristic allows the RFQ body to be supported using a simple kinematic 6-strut system that cannot impart any direct bending stresses on the assembled RFQ. A CAD image of the full, four module RFQ is shown in Fig. 6.

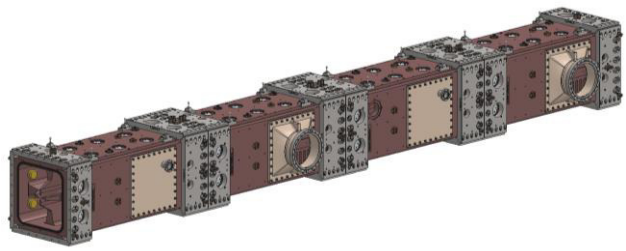

Figure 6: CAD model of the entire RFQ.

THERMAL PERFORMANCE

A series of RF, thermal and structural analyses were performed during the design of the PXIE RFQ. The details of these analyses, which were carried out using ANSYS [3], are provided in [4]. From the RF analysis, the average linear power density was determined to be 137 W/cm with a peak heat flux on the cavity wall of only 0.7 W/cm^2. The peak temperatures in the cavity copper were found to be only 4 to 5°C higher than the cooling water inlet temperature.

The RFQ cooling scheme will use differential water temperature control in the vane and wall passages. This technique provides active tuning of the RFQ by holding the wall water temperature constant and adjusting the vane water temperature up and down. The frequency of the RFQ can be shifted by -16.7 kHz for every 1°C rise in the vane tip cooling water temperature. For uniform water temperature control, the shift would only be -2.8 kHz/°C.

SUMMARY

LBNL has completed the final RFQ design for the Project X Injector Experiment at Fermilab. The overall design scheme was presented in this paper. Construction of the actual RFQ modules is now under way at LBNL and is expected to be completed by the end of 2014. Details of the fabrication progress can be found in [5].

INVESTIGATION ON DOUBLE DIPOLE FOUR-VANE RFQ STRUCTURE

Ki R. Shin[1], Yoon W. Kang, Aly E. Fathy[1], and Mark S. Champion
ORNL, Oak Ridge, TN 37831, [1]University of Tennessee, Knoxville, TN 37996, U. S. A.

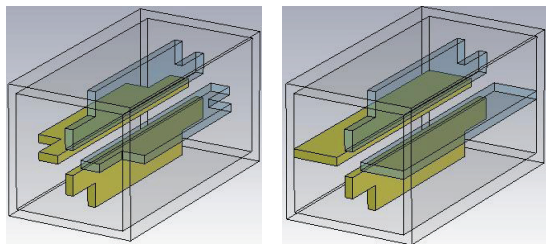
Abstract

Four-vane RFQ is a general choice for the low energy injector of light ion accelerators. In this commonly used four-vane RFQ structure, each vane has undercuts at both ends to create open magnetic field paths that realize uniform electromagnetic fields along longitudinal direction. Meanwhile, there exists another undercut method called as double dipole (DD) that requires undercuts only on 2 vanes [1] that are interleaved with vanes with no undercut. The RFQ with DD cutback can provide a design option besides the traditional 4 vane cutback (4C) method. In this paper, we investigate and discuss some important DD RFQ features in detail: 1) Finite on-axis field at DD RFQ end section, 2) Dipole mode properties, and 3) Mode spectrum with respect to structure length. 3D simulation is utilized for this DD RFQ analysis.

INTRODUCTION

The radio frequency quadrupole (RFQ) has been widely used for focusing, bunching, and acceleration of ion particles [2]. The four-vane RFQ [3] with four vane cut-backs (4C) [2][4] is common design choice for light ion accelerator systems.

The four-vane RFQ is derived from the quadrupole ridge waveguide [3], and requires cut-backs on each vane ends. The cut-back is necessary to avoid perfect electric boundary condition on vane ends, which is essential to provide the required electric field uniformity in whole structure.



Researchers found that two other cut-back methods are possible to maintain the uniform quadrupole mode: double dipole (DD) and folded dipole (FD) [1][5]. These schemes were used in a $< 2.0\ \lambda$ length structure demonstration RFQ model at Chalk River. One drawback of the DD and FD structures is the generation of finite on-axis field at RFQ ends in quadrupole mode. However, these problems may be relieved by adjusting ion source energy level and RFQ radial matching section design [8].

The DD structure is of special interest in this paper because of its unique characteristics on dipole mode that leads to different mode spectrum results. This may provide an alternative design option in some cases where 4C RFQ mode separation is very small.

Therefore in this paper, we investigate some important features of DD RFQ. First, we discuss the on-axis voltage generation in DD RFQ. Next, some interesting dipole mode properties in DD RFQ are covered with qualitative description and discussion. Finally, a DD RFQ mode spectrum result with the Spallation Neutron Source (SNS) RFQ geometry is presented as an example case. The 3D simulation tool CST Microwave Studio [6] is utilized in this study.

ON-AXIS FIELD AT DD RFQ ENDS

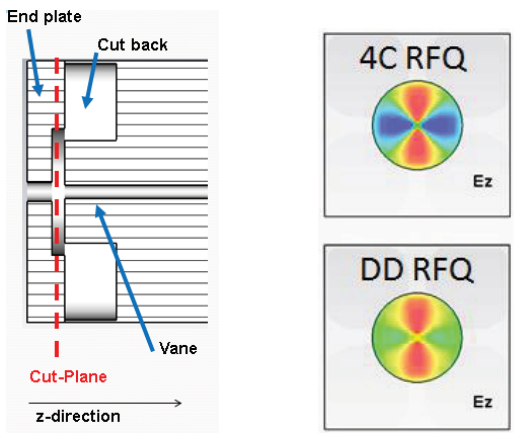


Fig. 1 shows a perspective view of 4C and DD RFQ cut-back geometries. In conventional 4C RFQ, all four vanes are not electrically touching the both end-plates. Meanwhile, only two opposing vanes make contacts to the end-plate in DD RFQ.

(a) (b)

Figure 1: RFQ cut-back - (a) 4C, (b) DD.

Because of this electrical contact of two vanes, DD RFQ generates a finite on-axis voltage. Fig. 2 describes how the on-axis voltage in z-direction is created. In 4C RFQ, the sum of Ez field on beam axis becomes zero. Each RFQ vane induces RF voltage of π phase difference from the adjacent vanes; hence cancellation of on-axis voltage occurs in 4C RFQ [7]. The short circuit condition of two vanes in DD RFQ, however, diminishes this cancellation and finite on-axis potential remains.

(a) (b)

Figure 2: RFQ end region - (a) geometry, (b) Ez field.

The existence of a finite on-axis voltage requires a different end-region design scheme as shown in Fig. 3. The conventional design for 4C RFQ in Fig. 3 (a) is not optimized to reduce the axial voltage. Previous work [1] suggested the design in Fig. 3 (b) which can decrease this axial voltage the most, however it may induce gas flow

Copyright © 2013 CC-BY-3.0 and by the respective authors

issue due to large bore. An intermediate design between these two is the conical one shown in Fig. 3 (c). This design has advantages of small bore with reduced axial voltage.

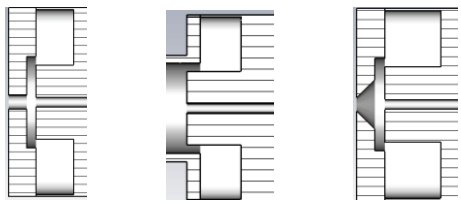

Figure 3: Plate geometry - (a) closed (b) open (c) conical.

The results of simulated axial voltage are summarized in Table 1. The SNS RFQ body geometry with 5λ length is utilized in this simulation study. The 550 kW peak power is assumed to have a similar operating condition in the SNS RFQ. The simulated axial voltage with conical end-plate geometry is 6.38 kV, about 9.8% of SNS RFQ 65kV input beam energy. This axial voltage can be further decreased by introducing a radial matching section (RMS) [8] in RFQ inlet. In this example with SNS RFQ RMS design, 4.77kV axial voltage, about 7.4% of the input beam energy, could be observed.

Table 1: On-Axis Voltage Results by Plate Geometry

	On-axis voltage	*Ratio / 65 kV*
Closed	9.87 kV	15.2 %
Open	3.75 kV	5.8 %
Conical	6.38 kV	9.8 %
Conical + RMS	4.77 kV	7.4 %

DIPOLE MODE CHARACTERISTICS

The DD RFQ provides a unique mode spectrum because of different cavity coupling and dipole mode boundary condition from 4C RFQ.

Figs.4 show how the quadrupole and dipole modes are generated in 4C RFQs. The RFQ magnetic field line path should be closed through circulation in cut-back areas [9]. When the magnetic field in two diagonal quadrants have the same polarity, it becomes the quadrupole mode. Otherwise, it becomes a dipole mode.

In azimuthal plane, the 4C RFQ fundamental quadrupole and dipole modes have π and π/2 phase difference per each quadrant, respectively. For a short RFQ, the magnetic coupling through end-region is stronger than the electric coupling via vane gaps. Hence, the fundamental quadrupole frequency with π phase difference becomes lower than the fundamental dipole frequency with π/2 phase difference [10]. For a long RFQ, however, the electric coupling dominates and the fundamental quadrupole frequency has higher value than the fundamental dipole frequency.

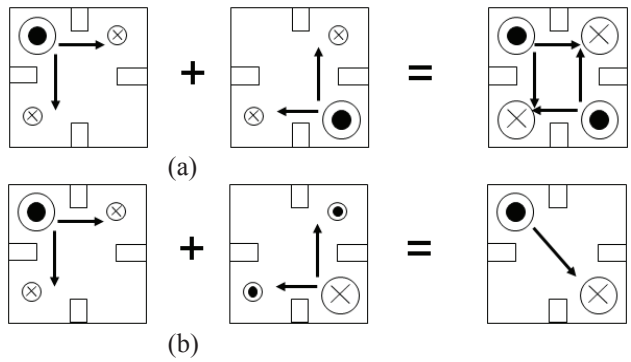

Figure 4: H field circulation at 4C RFQ end-region - (a) quadrupole, (b) dipole mode.

On the other hand, the DD RFQ modes are generated by electrically coupled two dipole cavities. Likewise 4C RFQ, the RF phase difference of each set determines the quadrupole and dipole modes. When two dipoles have 0 or π phase difference, it becomes the dipole or quadrupole mode. Since the two dipoles are connected only through electric coupling, the fundamental quadrupole frequency with π phase difference is always higher than the fundamental dipole frequency with open boundary in Fig. 5 (b). Therefore, the tuning method can be always kept same in DD RFQ independent to the structure length.

The vane pair short circuited to end-plates shown as red box in Fig. 5 causes the DD dipole modes not to degenerate as 4C RFQ dipoles. The DD modes are formed by combination of two dipoles, and the horizontal and vertical dipoles do not have same boundary condition because of the end-plate. H field in one dipole (Fig. 5 (b)) circulates through cut-back area that can be considered as an open boundary. Meanwhile, the other dipole in Fig. 5 (c) experiences the short circuit boundary. The magnetic field path is closed through the small bore openings in this short dipole.

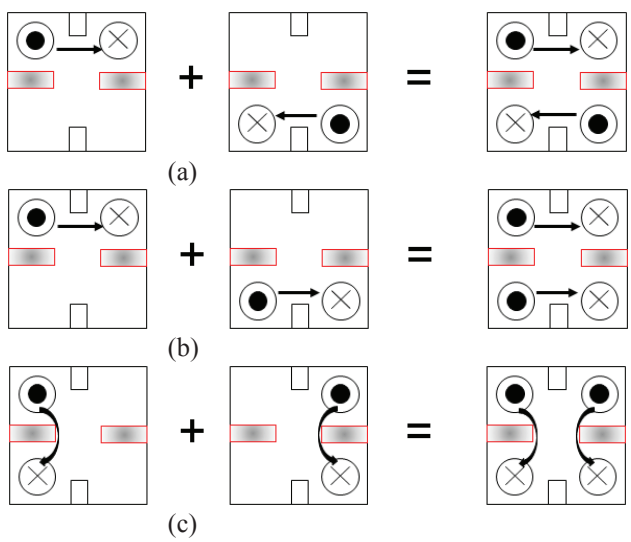

Figure 5: H field circulation at DD RFQ end-region- (a) quadrupole, (b) dipole (open), (c) dipole (short) mode.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Although two dipole modes are not degenerate in DD RFQ, the entire mode spectrum is not complex. Since the open and short circuit boundary dipoles can be approximated as the waveguide and cavity modes, those can be related by cavity length l_v as (1) [11]. The frequency of short fundamental dipole $f_{TE(S)}$ is similar to the first harmonic frequency of the open fundamental dipole $f_{TE(O)}$ and so on. Their harmonic frequencies have similar relations as well.

$$f_{TE(S)} \cong \frac{c}{2\pi}\sqrt{\left(\frac{2\pi}{c}\cdot f_{TE(O)}\right)^2+\left(\frac{\pi}{l_v}\right)^2} \qquad (1)$$

MODE SPECTRUM BY RFQ LENGTH

Figs. 6-7 show the simulation results of 4C and DD RFQ mode spectrum with structure length. The SNS RFQ transverse geometry is used in this simulation. DD dipole frequencies are different from 4C ones, hence DD RFQ could be an alternate design option in some structure lengths. The open boundary dipole in DD RFQ (TE01n+1) has similar frequency with the short dipole (TE10n) by a harmonic order difference. The fundamental open dipole frequency TE010 is always lower than the fundamental quadrupole frequency TE110. With SNS geometry, DD RFQ has good mode separation around 3λ, 5λ, and < 1.5λ lengths.

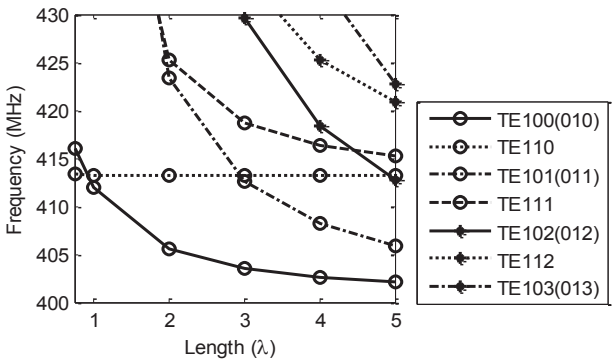

Figure 6: Mode spectrum results of 4C RFQ.

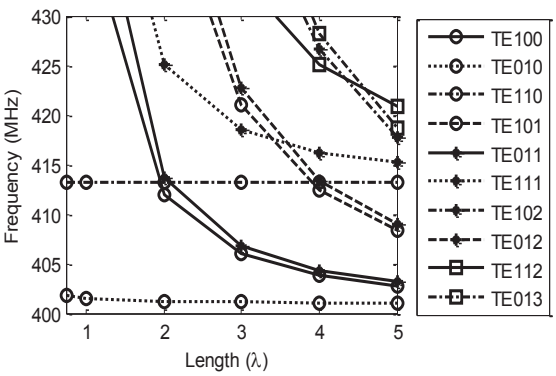

Figure 7: Mode spectrum results of DD RFQ.

CONCLUSIONS

Some results of investigation on the properties of DD RFQ are discussed. The on-axis field generation and end-region design examples are presented. An end gap axial voltage of 4.77 kV is expected with 550 kW peak power. Dipole mode properties of DD RFQ are compared with the 4C RFQ with qualitative discussion. Although dipole modes do not degenerate in DD RFQ, overall mode spectrum is still shows their harmonic relation. The simulation results of mode spectrum are in good agreement with expectation from qualitative approach. The DD RFQ can be an alternative design option in some RFQ lengths where it provides better mode separation than 4C RFQ.

DESIGN AND MEASUREMENT OF DOUBLE GAP BUNCHER CAVITY PROPOSED FOR REDUCTION OF X-RAY RADIATION

Ki R. Shin[1], Yoon W. Kang, Aly E. Fathy[1], and Mark S. Champion
ORNL, Oak Ridge, TN 37831, [1]University of Tennessee, Knoxville, TN 37996, U. S. A.

Abstract

X-ray radiation from accelerating cavities can be serious problem not only in high energy section but also in certain low energy system including beam matching section with buncher cavity. In this paper we propose a double gap buncher cavity design for low energy part of H- ion accelerators which can reduce X-ray radiation. The cavity utilizes Transverse Magnetic (TM) mode at about 400MHz as the operating mode. A drift tube supported by a stem in the cavity can form two gaps that can divide the required gap voltage to a half per each gap. Lower peak field can be realized since this double gap cavity can avoid sharp geometry. 3D simulation is utilized to address the analysis of non-axisymmetric structure. An Aluminum scaled model is built and tested with low power measurement. The measured results are in good agreement with simulations.

INTRODUCTION

For safety, radiation shielding is an important part of a high energy accelerator design [1]. Concrete material surrounds accelerator system in a tunnel to shield any hazardous radiations. Often bunching cavities in low energy section of ion accelerator < 3MeV are placed outside the tunnel only with fundamental radiation shield. X-radiation with non-negligible level can occur, however, if cavities are not under good vacuum condition [2]. Therefore, more conservative design to prevent X-radiation can help to improve system operability.

Assuming a constant vacuum level, X-radiation intensity is related to the cavity gap voltage and discharge current [3][4]. Ref. [3][4] expects that the radiation intensity has quadratic to cubic relation with gap voltage. The radiation wavelength is inversely related to the gap voltage as well [4]. Consequently, lower gap voltage may decrease a radiation dose and hard X-ray generation.

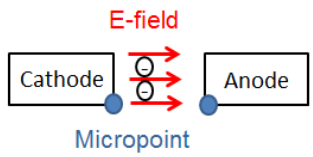
The mechanism of discharge current is rather complex, but in general it is relevant to the field emission and explosive emission mechanism [5]. The electric field in cavity determines the discharge current, and lower electric field is expected. In other words, lower electric peak field with smooth gap geometry may help to minimize discharge current and radiation intensity.

With regarding these voltage and peak field requirements, a double gap buncher cavity design is proposed and its lab type measurement is presented in this paper. This design is aimed to fit the requirement of the cavity 4 with 30mm bore diameter in medium energy beam transport (MEBT) section in the Spallation Neutron Source (SNS) [6]. The cavity length and particle speed are about 13cm and 0.073 v/c, respectively.

X-RADIATION BY VACUUM DISCHARGE

At cavity gap, the X-ray radiation dose D_X is determined by the integration of the radiation intensity J_X over the particle commutation time t_c (1) [3][5].

$$D_X \cong \int_0^{t_c} J_X(t)dt \quad (1)$$



$$J_X \propto i(t)\cdot V^n(t) \quad (2)$$

The radiation intensity J_X is related to the discharge current i(t) at cavity gap and the gap voltage V(t) likewise (2) [3][5]. The variable n commonly has values in range of 1.8~3.0 [3-5]. As a result, V(t) becomes an important parameter to determine J_X. The maximum X-radiation frequency also rises as the gap potential energy increases. This may induce a generation of hard X-ray. Therefore, low cavity gap voltage is desired to decrease X-radiation.

In accelerating cavities with high electric field intensity, the discharge current is generally formed by Fowler-Nordheim field emission mechanism [5]. Fig. 1 describes the field emission process at cavity gap (between cathode and anode), and the current density definition.

In field emission mechanism, some cathode electrons are stripped by strong electric field and collide to the anode. The emission current is a function of electric field; hence smaller electric field is desirable to decrease X-radiation by discharge current.

Most RF cavities are designed to have enough design margins until to reach the field breakdown limit, however, some micropoints on cathode and anode surface (Fig. 1) may lower the barrier of discharging. These micropoints can generate plasma around cathode, and as a result the discharging process starts earlier than as expected. This mechanism is called as explosive electron emission [5]. The anode part can also suffer from extra heating, evaporation, and ionization.

$$j = A\cdot E^2\cdot e^{-\frac{B}{E}}$$

A and B are constants

Figure 1: Field emission at cavity gap and Fowler-Nordheim current density.

The sharp gap shape in low energy ion accelerator section can be more vulnerable to explosive electron

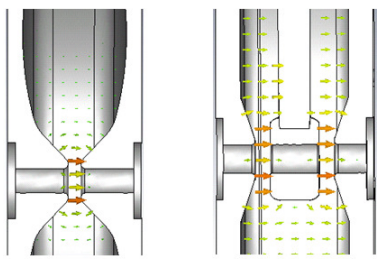
emission mechanism; because the geometry would have more chance to contain micropoints than flat shape.



Regarding all considerations above, we propose a double gap cavity design which can help to relieve X-radiation problem. This design decreases gap voltage and peak electric field that is directly related to X-radiation. The voltage is reduced to a half by using double gap, and the peak electric field can be decreased with flat gap geometry.

DOUBLE-GAP TM MODE CAVITY

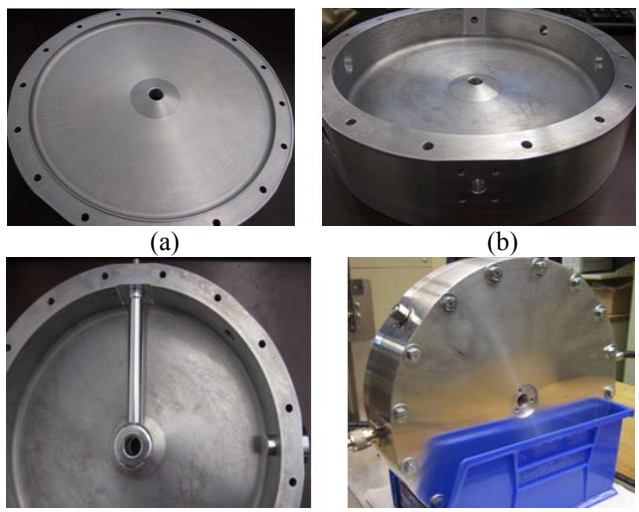
Buncher cavity operates with -90º phase from the RF electric field maximum, as a result the average particle speed does not change. For that reason, the multi gap cavity geometry can be symmetrical. The transverse magnetic (TM) electromagnetic mode can be more reliable from the multipacting issues than transverse electromagnetic (TEM) cavity design [7]. The benefit of higher R/Q in TEM cavity diminishes at higher frequency about 400MHz [8] because of very low Q. The TEM cavity efficiency further decreases for the requirement of SNS MEBT buncher cavity, which has a large bore diameter about 30mm. Therefore, TM mode is adopted as the operating mode.

The design of double gap cavity requires 3D RF analysis because of rotational asymmetry. The CST Microwave Studio [9] is utilized in the cavity design and parameter study.

Fig. 2 shows the electric field formation of the single and double gap cavities. About a half voltage of single gap cavity is formed in each gap of the double gap cavity. Each double gap cavity gap dimension is slightly bigger than the single gap cavity to decrease the electric peak field. Each gap field has the same RF phase in the double gap cavity and matched to the particle velocity.

(a) (b)

Figure 2: Electric field and cavity geometry around on axis- (a) single gap, (b) double gap.



A summary of the cavity parameters are shown in Table 1. The double gap design obviously can decrease peak electric field by 55% and generate half voltage per each gap, which can help to decrease X-radiation intensity. Although this design gives slightly lower power efficiency and may become mechanically slightly bigger due to additional gap spacing. The power efficiency can be improved further by optimizing the cavity gap geometry.

Table 1: Parameter Comparison (3.0cm bore/ 28.2kW rms)

	Single Gap	Double Gap
Frequency (MHz)	401.9	400.1
Gap size (mm)	12.30	14.23 14.23
Q (unloaded, Copper)	21413	20903
r/Q	29.35	27.83
R_s/L (Mohm/m)	5.48	4.47
V_0 (kV)	119.08	57.28 57.28 (Total : 114.45)
T	0.447	0.452
E_0 (MV/m)	2.32	1.93
E_{pk} (MV/m)	29.9	13.26
H_{pk} (A/m)	6565	8644

½ SCALED MODEL FABRICATION

A scaled prototype model of half size is built with Solidworks [10] to verify the design. AL 6061 T6 material with 42% of copper conductivity is used as a cavity material. As shown in Fig. 3, the drift tube assembly is attached on the equator of the cavity main body. Next, the minor piece is mounted to the main piece to complete the assembly. This prototype model is designed for low power measurement; hence does not include the design of cooling channel.

FREQUENCY AND Q MEASUREMENT

Table 2 shows the comparison of the simulated and measured TM010 mode frequency and Q value. S21 parameter is measured with a two port vector network analyser (VNA). The simulation and the measurement showed an excellent agreement in frequency. The 12%

Copyright © 2013 CC-BY-3.0 and by the respective authors

difference in Q measurement comes from extra power loss on the cavity seam plane and coupler ports.

Table 2: Simulation vs. Measurement – Frequency and Q

	Simulation	Measurement
Frequency	800.49	800.56
Q	9286	8179

R/Q MEASUREMENT

One of the cavity figures of merit, shunt impedance, is both RF loss and frequency dependent. Hence R/Q [11], which is independent of the loss and frequency is measured and compared.

Fig. 4 shows a beadpull system setup for R/Q measurement. A spherical metallic bead was used. We try the phase shift measurement to find R/Q since this method is rather simple and accurate [12].

The measured phase shift results in Fig. 5 are all integrated on the cavity beam axis to calculate R/Q. The reference phase outside of the cavity gap is set to zero, and two shifting curves are shown due to the double gap. The same method used in Ref. [13] is utilized to calculate R/Q.

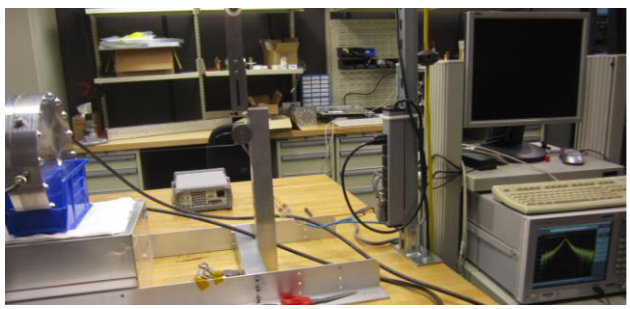

Figure 4: R/Q measurement system.

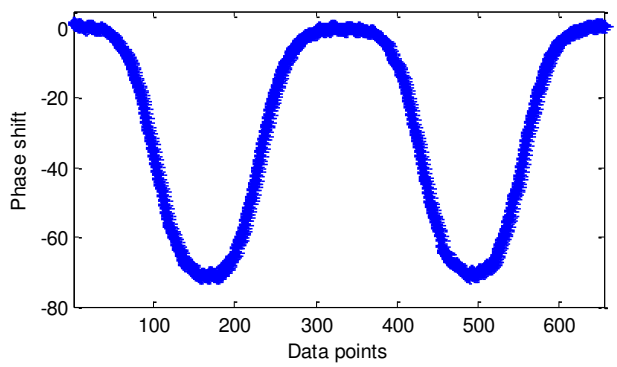

Figure 5: Measured phased shift by perturbation method.

The measured R/Q is in good agreement with the simulation with 94% accuracy as shown in Table 3. The estimated shunt impedance Rs is lower in accuracy with about 83%, because of 12% Q discrepancy already discussed in Table 2. R/Q value will be the same for 400MHz as well.

Table 3: Simulation vs. Measurement – R/Q

	Simulation	Measurement
R/Q	27.83	26.12
Rs (Mohm)	0.258	0.213

CONCLUSIONS

A buncher cavity design to reduce X-ray radiation for better operability is proposed for the low energy ion accelerator section with SNS MEBT cavity example. Gap voltage and peak electric field drastically decreases with this double gap design. Measurement results with scaled model are in good agreement with simulations.

HARMONIC RATCHETING FOR FAST ACCELERATION*

N. Cook†, Stony Brook University, Stony Brook, NY 11790 USA
M. Brennan, S. Peggs, BNL, Upton, NY 11973, USA

Abstract

From medical synchrotrons to accelerator driven systems, there is a need for fast acceleration of protons and light ions. This can be a costly undertaking, requiring specially designed ferrite loaded cavities to be tuned across a wide range of frequencies. Ferromagnetic materials allow for the precise adjustment of cavity resonant frequency, but rapid tuning changes and operation outside material specific frequencies result in significant Q-loss. This leads to a considerable increase in power requirements. We introduce an acceleration scheme known as harmonic ratcheting which reduces the cavity frequency range when accelerating an ion beam in a synchrotron. This scheme addresses the needs of high repetition rate machines for applications in which low beam intensity is needed. We demonstrate with simulations the type of ramps achievable with ratcheting and consider its advantages.

INTRODUCTION

The potential for fast acceleration of low energy ion beams remains rich, with a host of applications proposed to take advantage of rapid cycling synchrotrons or FFAGs. Nonetheless, conventional acceleration of low β charged particles remains expensive and inefficient. The primary challenge of accelerating such particles lies in achieving robust and flexible tuning. Using speciality ferrites, tuning can be obtained at the cost of efficiency. Ferrite materials suffer dramatic loss effects when driven at high bias fields and high magnetic flux [1] [2]. These difficulties have stemmed the advancement of fast and efficient accelerators for low energy ion beams.

The integer harmonic number h relates the RF and revolution frequencies through the relationship $f_{RF} = h\, f_{ref}$. The relative RF frequency range can be significantly reduced below the revolution frequency range by decreasing h in steps as the ions accelerate and f_{rev} increases. This is the motivation and basic method of *harmonic ratcheting*.

HARMONIC RATCHETING

Suppose that two (or more) RF cavities take turns accelerating the beam – one turns on when the other turns off, at different RF frequencies – so that the RF frequency is always constrained to remain in the range

$$f_{min} \;\leq\; f_{RF} \;\leq\; f_{max} \tag{1}$$

where f_{min} and f_{max} are externally determined design parameters. It is possible to make the transition back or forth between harmonic numbers

$$\begin{aligned} h &= n \\ \text{and}\quad h &= n+\Delta \end{aligned} \tag{2}$$

where n and Δ are positive integers, if

$$\frac{f_{max}}{n+\Delta} \;>\; \frac{f_{min}}{n} \tag{3}$$

Equivalently, we have

$$\Delta \;<\; n\,r \tag{4}$$

where

$$r \;\equiv\; \frac{f_{max}}{f_{min}} - 1 \;>\; 0 \tag{5}$$

is the "ratcheting parameter". Equation 4 shows that Δ has a maximum permissible value, which must be greater than 1 if a harmonic transition is to be possible. A ratcheting transition is possible if the following conditions are met.

$$\begin{aligned} n &> 1 \quad &, r &> 1 \\ n &> \frac{1}{r} \quad &, r &< 1 \end{aligned} \tag{6}$$

Several harmonic ratchets can take place during one acceleration ramp. Figure 1 show an example with $r = 0.50$, where the revolution frequency increases from 0.61 MHz to 3.35 MHz, while the RF frequency is constrained to lie between 5.5 MHz and 8.25 MHz.

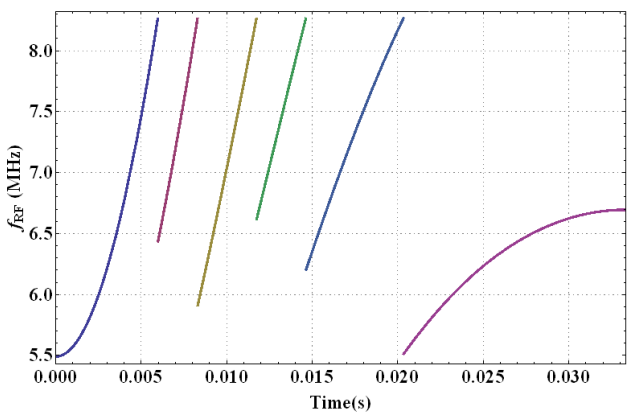

Figure 1: An example of harmonic ratcheting with $r = 0.50$. The plot shows one possible solution – with the harmonic number sequence $h = 9, 7, 5, 4, 3, 2$ – that maximizes RF frequency while minimizing ratcheting number.

Designing a Ratcheting Ramp

The selection of the initial harmonic number in the ratcheting ramp is determined by considering the minimum required bucket length, t_{inj} to accept particles into a single bucket at injection. This length sets a maximum possible initial harmonic. Moreover, the energy acceptance at injection also scales inversely with ${h_{max}}^2$. These requirements can be summarized by

$$\begin{aligned} h_{max} &\leq \frac{1}{t_{inj} f_{rev}(0)} \\ \text{and } {h_{max}}^2 &\leq \frac{2QV_g\beta^2 E_s}{\pi|\eta_s|\Delta {E_0}^2} \end{aligned} \tag{7}$$

Here, Q is particle charge, E_s is synchronous energy, and η_s is the phase slip factor. As the initial harmonic increases, a corresponding increase in voltage is necessary to keep the acceptance the same. Ferrite tuning time poses an additional constraint on the ratcheting permutation. Tuning the inactive cavity from a high frequency down to a low frequency requires circumnavigating the hysteresis curve. This tuning time, τ_t, is on the order of a few ms, which sets a lower limit on the active time for any cavity between ratcheting transitions $\tau_{active} > \tau_t$.

Emittance Growth at Ratcheting Transition

During the harmonic transition, the voltage on the cavity operating near f_{max} at harmonic $h = n + \Delta$ is reduced while a second cavity operating at harmonic $h = n$ has its voltage raised from a feedback level to provide the desired gap voltage at the new harmonic. Assume that this change happens quickly and that both the synchronous phase and total accelerating voltage are smoothly varying when the ratcheting takes place.

The result of the harmonic ratcheting is a relaxation of the bucket potential. As a result, large amplitude particles stray further in phase from the design particle in order to feel the same restoring force, thereby increasing longitudinal emittance S. Similarly, the bucket area A will grow as h is reduced. Both quantities grow as

$$\frac{S_2}{S_1} \propto \frac{A_2}{A_1} \propto \left(\frac{n+\Delta}{n}\right)^{\frac{3}{2}} \tag{8}$$

The emittance growth due to the harmonic number transition matches with the bucket area growth during the ratcheting process. Thus, for small or slow changes in harmonic number, the ratcheting process is inherently stable, as illustrated in figure 4. This transition is calculated non-adiabatically. The transfer of voltage takes place over some time period τ_r. A particle will make $n_t = \beta c \tau_r / C$ turns in that time. If $\tau_r = 100\mu s$, a $\beta = 0.1$ particle makes 50 turns of a 60 m synchrotron.

FERRITE-LOADED CAVITIES

The resonant frequency of a ferrite-loaded cavity is $f = \frac{1}{2\pi} \frac{1}{\sqrt{LC}}$ where L, the inductance of the cavity, is adjustable between minimum and maximum values L_{min} and L_{max}. Consider a cavity with a total ferrite length of l, made of many rings with inner and outer radii r_a and r_b. The inductance is $L = \frac{l}{2\pi} \mu' \ln \frac{r_b}{r_a}$ where the *incremental* complex permeability of the ferrite is written $\mu = \mu' + j\mu''$. The component μ' and the inductance of the cavity are tuned by biasing the ferrite with a pseudo-constant azimuthal magnetic field driven by a tuning current. Ignoring the stray inductance, the required dynamic range of L and of μ' is

$$\frac{L_{min}}{L_{max}} = \frac{\mu'_{min}}{\mu'_{max}} = \frac{1}{(1+r)^2} \tag{9}$$

The voltage across the gap of a cavity is

$$V_{gap} = 2\pi f \, B_{max} \, l \, r_a \ln \frac{r_b}{r_a} \sim f \, l \tag{10}$$

where $B_{max} \approx 0.01$ T is the maximum RF magnetic field that is allowed at the inner radius of the ferrite rings. This shows that for a fixed maximum field B_{max}, the ferrite length l can be reduced if the RF frequency in the cavity is increased. Thus, harmonic ratcheting allows a given acceleration waveform to be achieved with shorter cavities.

The total length of ferrite required with a ratcheting parameter r, relative to a non-ratcheting scheme in which ions are accelerated over the full dynamic range is given approximately by

$$\frac{l_{ratchet}}{l_{non-ratchet}} = \frac{f_{min,non-ratchet}}{f_{min,ratchet}} \approx 2\,\frac{1+r}{D} \tag{11}$$

where $D = \frac{\beta_{max}}{\beta_{min}}$, and the factor of 2 recognizes that only half the cavities are active at any one time. For example, Figure 1 illustrates acceleration over a dynamic range of $D = 5.5$, using a ratcheting parameter of $r = 0.50$. In this case ratcheting makes it possible to decrease the total length of ferrite by a factor of 0.55. Conversely, the gap voltage can be nearly doubled for a fixed cavity length, almost doubling the potential repetition rate of a rapid cycling synchrotron.

EXAMPLE: A RAPID CYCLING MEDICAL SYNCHROTRON

Consider a rapid cycling synchrotron for acceleration of C^{6+} ions for radiation therapy applications. Assume a 15 Hz repetition rate and a circumference $C = \sim 65$ m. Ions must accelerated through a range 8 to 400 MeV/μ.

Once the initial harmonic is determined, the initial RF frequency is set at $f_{RF}(0) = h_0 \beta c / C$. Appropriate selection of a frequency ceiling limits the ferrite to operate within a more efficient permeability range. In this instance, we choose a ratcheting parameter of $r = 0.5$ via a final harmonic transition of $h = 3$ to $h = 2$. Figure 1 shows the RF frequency and figure 2 plots the active harmonic.

When the frequency ceiling is reached at the current harmonic, RF power is transferred to the second cavity system at a lower harmonic number. Each time the harmonic

Copyright © 2013 CC-BY-3.0 and by the respective authors

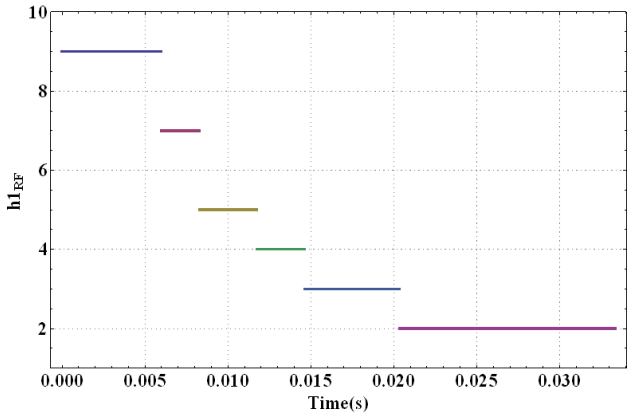

Figure 2: Active cavity harmonic for the ∼65 m Carbon synchrotron harmonic ratcheting ramp.

number is reduced, the RF frequency is reduced by a factor $\frac{h_n}{h_{n-1}}$ where h_n is the new harmonic, and h_{n-1} is the previous value. The maximum frequency swing during the ramp is determined by the maximum value of this ratio, or equivalently the ratcheting parameter r, according to

$$\frac{\Delta f}{f_0} = r \tag{12}$$

For example, if the largest transition in a particular ratcheting scheme is from $h = 3$ to $h = 2$, then the ratcheting parameter is $r = 0.5$, and that particular ramp is limited to a 50% frequency swing.

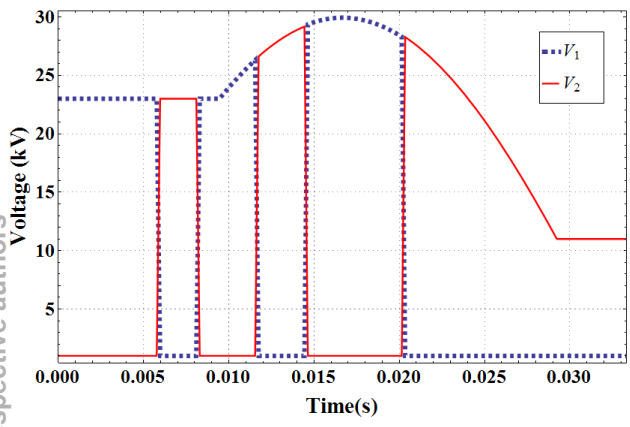

Figure 3: Output voltage for each cavity system. The voltage is calculated to meet the constraint $\phi_s \leq 33°$.

Figure 3 outlines the output voltage needed for each cavity system in our example ramp. The harmonic transition and transfer of power to the inactive cavity cannot be performed instantaneously; the voltage may be raised over $\sim 100\mu s$. Detailed feedforward and diagnostic systems are required in order to maintain the proper voltage. The emittance evolution for our example case is shown in 4.

Ratcheting may also reduce losses due to anomalous effects in ferrite. At sustained high fields, ferrites demonstrate a Q-loss effect (QLE) which can result in a reduction of 20% of maximum field. High bias fields can increase

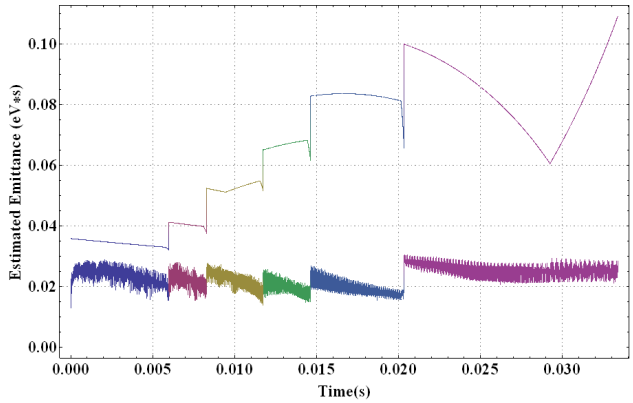

Figure 4: Estimated emittance and bucket area is shown for a simulated ramp with fixed synchronous phase.

this effect by reducing the threshold of Q-loss onset. However, at high bias rates the threshold for this effect is significantly raised [1]. A ratcheting scheme should mitigate QLE by reducing total biasing. Rapid bias field changes may also induce a dynamic loss effect in the ferrite. These losses can lower a cavity's Q value by up to 40%. Unlike the QLE, this effect appears to be more dependent on the temperature and duration of the biasing. By decreasing the time spent biasing at high fields, this effect can be reduced considerably [2].

CONCLUSION

A new scheme for accelerating low energy ions quickly and over a large frequency range is presented. By adjusting the harmonic number during acceleration in a manor specifically tailored to the desired acceleration cycle, a significant reduction in the frequency range is obtained, easing the ferrite's tuning requirement. Moreover, the frequency increase allows potentially several times larger gap voltages to be obtained for the same amount of ferrite, making higher machine repetition rates possible. Alternatively, cavity length could be reduced by an equivalent factor. This approach is particularly suited to low intensity ion beams which do not require filling a ring but necessitate fast acceleration across a range of energies.

MULTIPACTING STUDY FOR THE RF TEST OF THE MICE 201 MHz RF CAVITY AT FERMILAB MTA*

T. Luo†, D. Summers, University of Mississippi, University, Mississippi, USA
A. DeMello, D. Li, H. Pan, S. Virostek, M. Zisman, LBNL, Berkeley, California, USA

Abstract

In this paper, we present a study of multipacting effects for the high power RF test, to be done at Fermilab's Mucool Test Area, of the 201 MHz RF cavity for the Muon Ionization Cooling Experiment. We show how the fringe field of the Lab_G magnet affects the cavity performance due to multipacting and predict the possible multipacting bands in the high power RF test with different magnetic field strengths.

INTRODUCTION

One cavity for the international Muon Ionization Cooling Experiment (MICE) [1], after being manufactured and electro-polished at LBNL, has been shipped to the Fermilab Mucool Test Area (MTA) for the single cavity test. To study the cavity performance in a strong magnetic field, this cavity will be tested in the fringe field of the 5-T Lab_G magnet before the MICE Coupling Coil is ready for operation.

In this paper, we study multipacting (MP) effects for the single cavity with and without the Lab_G magnet fringe field. We show possible MP bands with different magnetic field strengths expected in the high power RF test. The Lab_G magnetic field is calculated by ANSYS, the cavity RF field by S3p [2] and the MP effect by Track3p [3].

MAGNETIC FIELD OF THE LAB_G MAGNET

The magnetic field of the Lab_G magnet has been mapped both experimentally and numerically [4, 5]. However, none of the previous mappings cover the full region where the 201 MHz cavity will be placed. Thus we used ANSYS to recalculate the magnetic field. The field along the central axis is compared with previous mapping and shows good agreement, as shown in Fig. 1. Due to the uniqueness of the solution of Poisson equation, the ANSYS result should also give the correct field everywhere in space, including the fringe field region where the cavity will be placed, which is about 1.0 m away from the Lab_G magnet (center-to-center) if the Single Cavity Vessel is located as closely as possible to the Lab_G magnet.

RF FIELD IN THE 201 MHz CAVITY

The cavity model is built from its CAD drawing, including the curved beryllium windows, the coaxial waveguide and the loop coupler. To build an RF field with power propagating into the cavity and dissipating on the cavity walls, we use S3p with a "waveguide" boundary condition (BC) at the coaxial port and " impedance " BC on the cavity wall. The orientation of the coupler is adjusted to achieve critical coupling ($\beta \approx 1$), with coupling angle at about 17°. The E and B fields in the cavity are shown in Fig. 2.

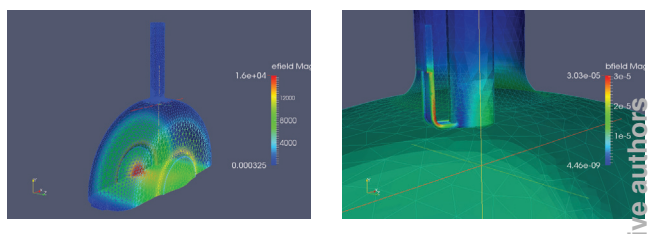

Figure 2: RF field of the cavity. The left figure shows the E field magnitude in the cavity. The right figure shows the maximum B field in the cavity on the coupler loop, where sufficient cooling should be supplied.

MULTIPACTING EFFECT ON 201 MHz CAVITY WITH LAB_G MAGNET

The MP effect is evaluated by the Enhancement Counter (EC) in the Track3P code. The electron is launched from its primary emission surface and tracked for 50 RF cycles, until its energy is too high or too low for MP, or until it hits the absorber surface. Every time it hits the second emission surface, the probability η to generate a secondary electron, which depends on impact energy and surface material, is

Copyright © 2013 CC-BY-3.0 and by the respective authors

recorded. After 50 RF cycles, the enhancement counter:

$$EC = \Pi_{i=1}^{N} \eta_1 \cdot \eta_2 \ldots \eta_N \,,$$

when $EC > 1$, it indicates a possible MP case. The larger the EC, the more likely the MP will happen. The SEY data of copper we used in this paper are for the Argon Glow Discharge (AGD) treated copper [6]. Since Be windows will be TiN coated, we treat these as an absorber surface.

According to its geometry, the cavity is divided into three parts: the coaxial waveguide, the coupler and the cavity body. We study the MP with different magnetic field strengths: $B_{max} = 0$ T, 1.25 T, 2.5 T, 3.75 T and 5 T on the central axis.

The required cavity field gradient for the neutrino factory is 16 MV/m, which corresponds to about 2.8 MW input power per port. Thus we will study the MP from 10 kW up to 3 MW.

MP In the Coaxial Waveguide

Without B field, the MP in the coaxial waveguide can be solved analytically for low-order modes and has been studied thoroughly. With the fringe field of the Lab_G magnet, the MP pattern changes significantly.

- The EC spectrum is shown in Fig. 3. Without B field, there is a narrow MP band at low power from 40 kW to 70 kW. Beyond that, there is no more MP. The Lab_G magnet fringe field induces a resonant pattern at higher power. As the B field increases, more resonant patterns show up at high power but the EC is small compared to the MP at low power.

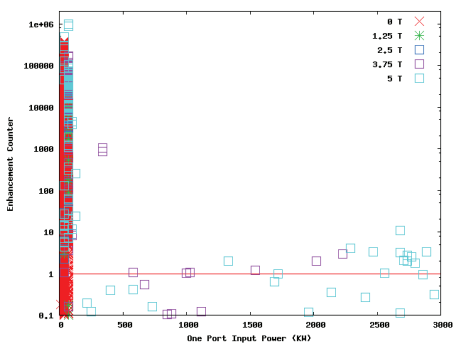

Figure 3: The EC spectrum in the coaxial waveguide.

- The MP impact location is shown in Fig. 4. With Lab_G B field, many resonant patters show up near the RF window with high EC. Most of them happen under 100 kW. Looking into the trajectories of these electrons, they are emitted near the RF window and build the resonance pattern bouncing between the inner and outer conductor of the waveguide. This may explain the copper deposition on the RF window observed in the previous test of the 201 MHz prototype cavity [7].

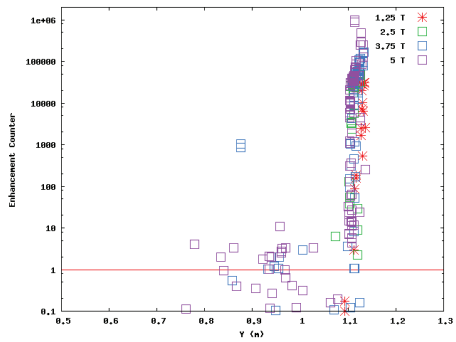

Figure 4: The MP impact location in the coaxial waveguide, where $Y = 1.1$ m is near the RF window.

MP In the Coupler Region

Due to the detailed geometry in the coupler region, the meshing at this area needs to be very dense to achieve an accurate RF field. The computation time would be too long if we carried out the MP calculation in the whole region. Therefore, we choose three typical locations in the upper, the middle and the bottom part of the couple and combine their results.

- The EC spectrum is shown in Fig. 5. Without external B field, MP happens only below 200 kW. As the Lab_G magnet increases its strength, the MP decreases in the low power region but shows up at higher power with smaller EC. No MP is observed above 750 kW.

- The MP impact location is shown in Fig. 6. Without external B field, the electrons emitted at the coupler region migrate up into the coaxial waveguide and build up a resonance there. When the external magnetic field is present, some electrons start to migrate into the cavity body and build up resonance along the curved torus. The stronger the external B field, the more resonance in the cavity.

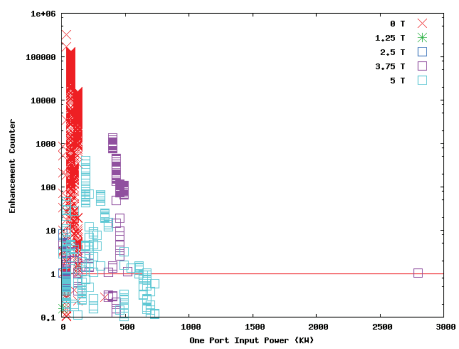

Figure 5: The EC spectrum in the coupler.

MP In the Cavity Body

When studying the MP in the cavity body, for simplicity, we study the cavity without the coaxial waveguide and

Copyright © 2013 CC-BY-3.0 and by the respective authors

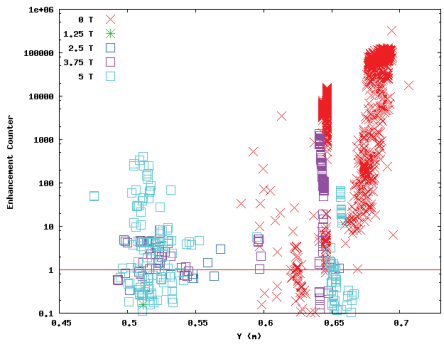

Figure 6: The MP impact location in the coupler. For reference, the extrusion transition between cavity and waveguide is from $Y = 0.601$ m to 0.627 m.

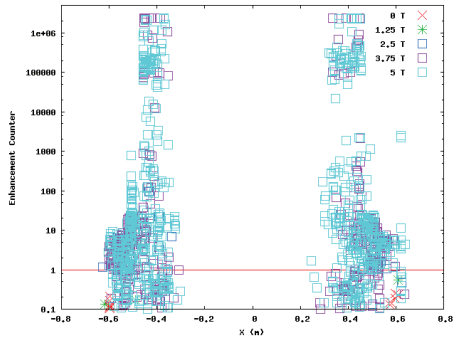

Figure 8: The MP impact location in the cavity body. For reference, the extrusion edge of the vacuum port and instrumentation port are at $X = -0.6$ m and 0.6 m, respectively.

coupler. Without the power input port, we use the E field gradient instead of the input power in the MP EC spectrum.

- The EC spectrum is shown in Fig. 7. When the external B field is zero or small, there is no MP in the cavity. As the B field increases, MP starts to show up in the cavity. The maximum MP happens at around 2 MV/m.

- The MP impact location is shown in Fig. 8. Above 50% of the full field of Lab_G magnet, stong MP starts to show up on the cavity copper side walls around $x \approx \pm 0.4$ m.

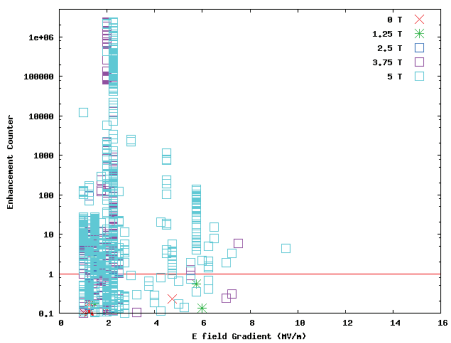

Figure 7: The EC spectrum in the cavity body.

CONCLUSION

In this paper we have studied the MP in the MICE 201 MHz cavity in the Lab_G magnet fringe field for the upcoming single cavity test at Fermilab MTA. Our study has shown that:

1. Without external magnetic field, in the coaxial waveguide, there is a narrow MP band at around 40-70 kW; in the coupler, some electrons migrate into the waveguide and build up MP there; no MP shows up in the cavity body.

2. The Lab_G magnet fringe field will change the MP, and its effects depend on the field strength. With the Lab_G field, simulation shows strong MP near the RF window in the waveguide, which might explain the copper deposition on the RF window seen in the previous test. In the coupler region, the B field guides the electrons into the cavity body and builds up MP along the curved torus. In the cavity body, when the Lab_G magnet operates above 50% of its full field, MP shows up on the copper side walls at low power.

We have applied several approximations in the simulations, such as ignoring other ferrite materials near the cavity, simplifying the loop coupler and RF window structure, using SEY data of AGD copper instead of electropolished copper, tuning the cavity to exact critical coupling, etc. All these factors will affect the MP results. Nonetheless this paper provides a qualitative, or semi-quantitative, description of the MP effect in the MICE 201 MHz cavity in the upcoming single cavity test.

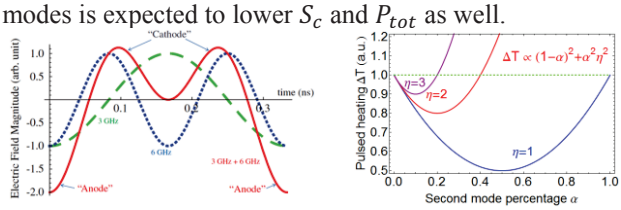
MULTI-HARMONIC ACCELERATING CAVITIES FOR RF BREAKDOWN STUDIES*

Y. Jiang#, J. L. Hirshfield, Yale University, New Haven, CT 06511, USA



Abstract

Multi-harmonic accelerating cavities that are explicitly designed for RF breakdown experiments are described. The fundamental TM_{010} and its higher harmonic TM_{011} or TM_{012} modes of the cavities are to be excited coherently by an external RF source in the expectation of lowering surface pulsed heating and/or surface electric field, so as to reduce breakdown probability and possibly achieve an increase in acceleration gradient.

INTRODUCTION

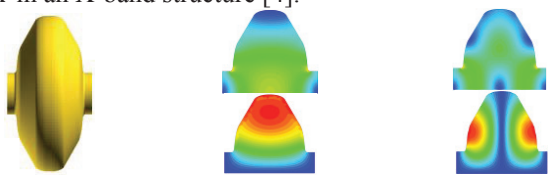
In this paper, microwave cavities that support the superposition of the fundamental TM_{010} mode and at least one more mode whose eigen-frequency is a harmonic of the TM_{010} eigen-frequency are described. These bimodal cavities are explicitly intended to be vehicles that may deepen understanding of RF breakdown and pulsed heating, and as possible candidates for incorporation into multi-cavity high-gradient accelerator structures.

By selectively exciting synchronized multi-harmonic cavity modes driven externally in a precisely-controlled manner from a novel multi-frequency RF source available at Yale [1], unconventional spatiotemporal distributions of electromagnetic fields within a cavity can be realized, with the potential to lower field emission and/or pulsed heating at a given level of acceleration gradient; these effects are believed to be precursors to RF breakdown. In particular, two phenomena provide the main motivation for introduction of a 2nd mode at a harmonic frequency, namely: (a) the so-called anode-cathode effect [2]. In a longitudinally *asymmetric* cavity [2], phase-locked two-frequency operation, with the 2nd mode at a frequency double that of the fundamental, can allow the electric field pointing into one wall (cathode-like) to be significantly smaller than the field pointing out of that wall (anode-like), as shown in Fig. 1. A strong anode field will raise the work function barrier to suppress field and secondary emission; and (b) the suppression of pulsed heating, which is the focus of this paper. To model pulsed heating in a bimodal cavity, we characterize E-field superposition as $E_{total} = (1-\alpha)E_1 + \alpha E_2$, where $E_{1,2}$ is each electric field component with its associated acceleration gradient normalized to the same value, and α is the percentage of the 2nd mode such that E_{total} provides the same acceleration gradient. Similarly, the surface RF H-field is $H_{total} = (1-\alpha)H_1 + \alpha H_2$. Pulsed heating temperature rise ΔT can then be approximately scaled in terms of H_1 and H_2 as $\Delta T \propto (1-\alpha)^2 < H_1^2 > +\alpha^2\sqrt{f_2/f_1} < H_2^2 > =< H_1^2 > [(1-\alpha)^2 + \alpha^2\eta^2]$, where the frequency term $\sqrt{f_2/f_1}$ is related to the ratio of surface resistivities, $\eta = \sqrt{(f_2/f_1)^{1/2} < H_2^2 > / < H_1^2 >}$, and the cross term averages out over one period. Due to the quadratic dependence of ΔT upon α, it is possible to choose an optimal α such that $(1-\alpha)^2 + \alpha^2\eta^2 < 1$. In other words, to have lower temperature rise than for a single mode alone, while maintaining the same acceleration gradient; this is shown quantitatively in Fig. 1(b). The modified Poynting vector S_c [3], and total required RF power P_{tot}, also follow a quadratic dependence on the mode percentage α, so use of two modes is expected to lower S_c and P_{tot} as well.

(a) (b)

Figure 1: (a) Time dependence for a composite field (red line) excited at 3 GHz (green dashed) and 6 GHz (blue dotted), showing a factor-of-two anode-cathode field difference. (b) Dependence of the surface pulsed heating temperature rise ΔT on the 2nd mode percentage α. There is seen to be a range of α within which ΔT can be smaller than for a single mode (the green dashed horizontal line).

TM_{010} +TM_{011} CAVITY



For a simple pillbox designed as a bimodal cavity with a typical iris size of $0.1\lambda - 0.2\lambda$ to support the TM_{010} mode and a 2nd harmonic TM_{011} mode, our analysis shows that $\eta > 3$. This implies that ΔT could not decrease by more than 10% for a simple pillbox cavity. Consequently, a new software package is being developed by us to optimize cavity geometry to support multi-harmonic modes with desired RF properties, such as high shunt impedance and low surface fields, and maximize reduction in temperature rise ΔT. This code integrates *Finite Element Method* and *Generic Algorithm*, so that it can find global optimization of RF parameters. Currently the code package is to include beam-cavity interactions that allow multipactor, wake field, and beam dynamics studies to be carried out in our unconventional structures, so as to provide a single software suite to expedite cavity design and optimization of RF properties and beam dynamics.

Optimization of design for a bimodal cavity supporting the TM_{010} mode and its 2nd harmonic TM_{011} mode can be realized using this code, as shown in Fig. 2. It is a full π-mode accelerating cavity, longitudinally symmetric with iris and beam pipe. Its fundamental frequency is at X-

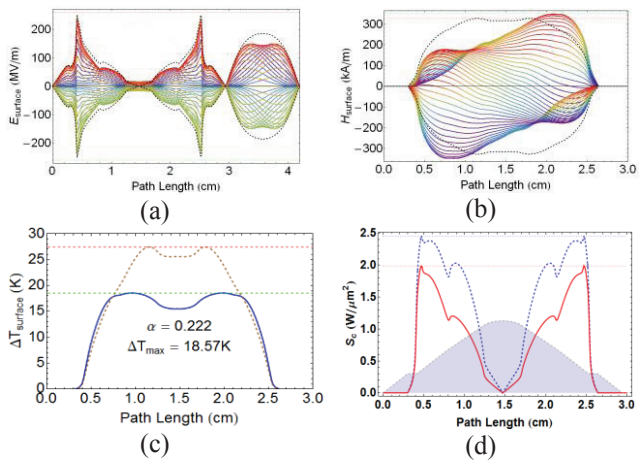
band (12 GHz), to benchmark against the empirical criteria recently proposed within the worldwide High Gradient Collaboration: namely, a surface electric field $E_{sur}^{max} < 260\ MV/m$ and pulsed surface heating $\Delta T^{max} < 56\ K$ in an X-band structure [4].

(a) (b) (c)

Figure 2: Field patterns in an optimized bimodal cavity (a) for the TM_{010} mode (b), and its 2nd harmonic TM_{011} mode (c). Top patterns are *E*-field, bottom are *H*-field.



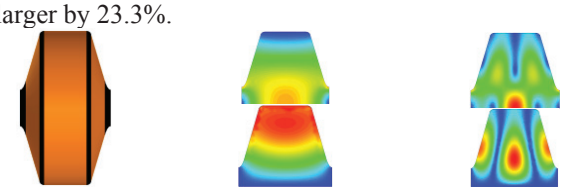


Figure 3: (a) Surface *E*-field and (b) surface *H*-field along the cavity periphery at different times for superposition of TM_{010} and TM_{011} modes, where the dotted line indicates fields of mode TM_{010} alone. *H*-field asymmetry is due to field distribution and chosen phase of the TM_{011} mode. (c) Optimized maximum pulsed heating temperature rise ΔT (blue line) is 18.57 K, compared to that of single mode 27.5 K (brown dotted line), both for a 200 ns pulse width; (d) maximum modified Poynting vector S_c (red line) is $1.95\ W/\mu m^2$ compared to a single mode value (blue dashed line) of $2.45\ W/\mu m^2$. The factor α for the 2nd mode in this example is 0.222. The gray area in (d) indicates the stretched cavity profile.

With this optimized cavity profile, the benefits of reducing surface pulsed heating, modified Poynting vector, and total RF power are demonstrated, as shown in Fig. 3 and Table 1. In Fig. 3, the pulsed heating temperature rise for our 2-mode superposition can be 32% smaller than that for the fundamental mode alone for the same cavity; and the maximum modified Poynting vector S_c can be lower by 20%, with a 22% 2nd harmonic component and a relative phase between the two modes of 90° (both modes are in sychromization should this bimodal cavity be operated in an accelerating structure). The peak surface *E*-field is the same as that of the fundamental mode due to this phase relationship, and no anode-cathode effect is present. Note, that even for a single TM_{010} mode, S_c is small due to the reduced *H*-field around the iris as a result of optimization. In Table 1, RF parameters of this bimodal cavity are listed in comparison with other cavity configurations. Although the instantaneous surface *H*-field is increased, the pulsed heating temperature rise is lowered since the exposure time to the peak *H*-field is shortened, and temperature rise is a time-averaged effect quadratically dependent on the mode percentage α in our 2-mode superposition. The total RF power is reduced, while maintaing the same acceleration gradient, so its effective shunt impedance is significantly increased.

TM_{010}+TM_{012} CAVITY

Because of different magnitudes and profiles of field distributions along the cavity walls for different modes in bimodal cavities, it is possible to have partial electric field cancellation on walls so that the maximum surface *E*-field can be smaller than that of single mode. We have analysed a π-mode accelerating cavity shown in Fig. 4 that supports the TM_{010} mode and its 3rd harmonic TM_{012} mode. When both modes reach the peak axial accelerating fields synchronously, the TM_{012} mode has its surface electric field opposite in direction to that of the fundamental TM_{010} mode on the side walls, and hence lowers the surface electric field significantly, as shown in Fig. 5. Preliminary analyses show that reductions in the maximum pulsed heating temperature rise of up to 21.5%, of the modified Poynting vector by 29.5%, peak surface *E*-field by 19.4%, total RF power by 18.9% are predicted for this bimodal cavity, than those for single mode operation at the same acceleration gradient for the same cavity. Also, its effect shunt impedance of 124.2 $M\Omega$/m is larger by 23.3%.

RF BREAKDOWN STUDY

It is of obvious interest to measure RF breakdown statistics for these bimodal cavity designs, comparing single mode and 2-mode superpostion, and to investigate surface fatigue on cavity surfaces after pulsed heating. An RF breakdown study is to be carried out based on availability in the Yale Beam Physics Lab of a unique 2-frequency phase synchronous RF source at S-band (2.856 GHz) and its higher harmonics, either at C-band (5.712 GHz) or X-band (8.856 GHz). The 2-frequency RF source will provide mutually phase-locked multi-MW ~1 μs pulses at both fundamental and higher harmonic

frequencies with continuously-adjustable amplitudes and relative phase difference. The cavity geometry suitable for RF breakdown tests at Yale using S-band (2.856 GHz) as the fundamental frequency can be directly scaled from the optimized geometries shown above. RF breakdown tests in travelling wave or standing wave single cell structures [5] can be devised to benchmark with the existing RF breakdown data [3]. With better understanding of RF breakdown physics supported by experimental evidence and further development of computational tools, design concepts for accelerator structures comprising multi-harmonic cavities will be developed.

Bimodal cavities with the necessary tight dimensional tolerances require meticulous machining; but should be possible using recently described techniques that maintained dimensions to within 5 μm [6]. Further evidence for precision tuning of a not-dissimilar bimodal cavity has also been reported [1].

CONCLUSION

This paper describes use of multi-harmonic cavities powered by a dual frequency RF source to systematically study mechanisms which seem likely to influence the onset of RF breakdown. It is anticipated that deepened understanding of these mechanisms could lead to improved design of accelerator structures with higher shunt impedance, higher accelerator gradient, and lower breakdown probability than can be built at present.

Abstract

An intense on-axis radiation power from a linear undulator is a serious problem for a VUV/soft-X-ray beamline at medium or high energy light source facility. This problem may be solved by using a specially designed linear undulator such as the Figure-8, Pera, or Knot undulators. However, a permanent magnet undulator of such kind is not capable of changing polarization state. On the other hand, an APPLE undulator is able to generate variable polarization, but is not capable to reduce on-axis power density in linear modes. To solve these problems, we investigated various magnetic structures and found that the combination of Knot and APPLE undulator scheme works to generate low on-axis power density in every polarization mode.

INTRODUCTION

In order to generate the undulator radiation in VUV region at a medium energy storage ring facility, the undulator should have a very long period and a high K-value. In this case, especially for a linear undulator, unwanted high radiation power for higher harmonics concentrates on the radiation beam axis, and hence it give a heave heat load on optical components such as a mirror and a monochromator. To reduce the on-axis heat load, the Figure-8 undulator was proposed [1] and have been used in several synchrotron radiation facilities. Also, similar ides for the same purpose were proposed [2-4]. However, all those ideas except the Figure-8 were not realized may be due to the complicated structure and the advantages are not so significant compared with Figure-8. More importantly, all those exotic devices including the Figure-8 are not capable of varying polarization states. On the other hand, the APPLE-type undulators can generate various polarization states such as the right/left circular polarization, tilted linear polarization, and horizontal/vertical linear polarization. However, in the linear polarization modes, on-axis high power problem form higher harmonics is remaining as a serious problem.

In order to solve all problems described above, we propose a new scheme which is called a Knot-APPLE undulator to reduce on-axis radiation power in every polarization mode.

KNOT UNDULATOR

Figure 1 shows the magnetic structure of Knot undulator. This structure, similar to the Figure-8 undulator, the Halbach structure permanent magnet arrays locate above and below the beam axis, and magnet rows for generating horizontal magnetic field on the beam axis locate at both sides of central magnet rows. As shown in Figure 1, the dimension in the direction of beam axis of each magnet block in the horizontal row is the same with that in the vertical rows except the end structure.

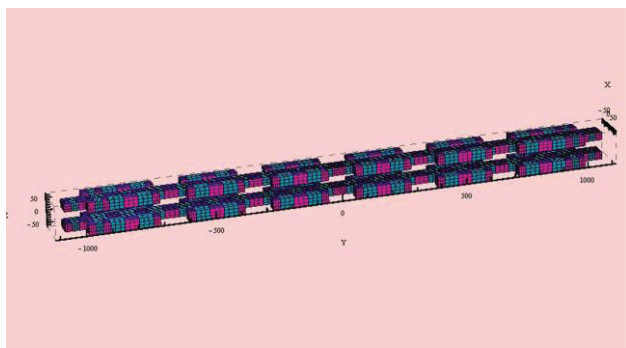

Figure 1: RADIA model of magnet structure for a Knot undulator.

As is seen in Figure 1, there is an empty space between segments in the horizontal structure in order to create the zero-field region. With this structure, the period length of horizontal field is one and a half of vertical field. Figure 2 shows the magnetic field distribution of Knot undulator having the structure of Figure 1.

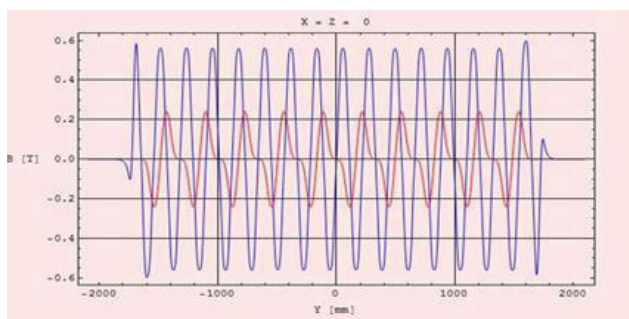

Figure 2: Field distribution of Knot undulator.

In Figure 2, blue line represents the vertical field and red line represents the horizontal field. The period lengths are 220 mm and 330 mm for vertical and horizontal, respectively. The magnet gap to generate the field in this figure is 40 mm.

Figure 3 shows the kick-angle map in an undulator having the field shown in Figure 2 for an electron beam with the energy of 3.5 GeV.

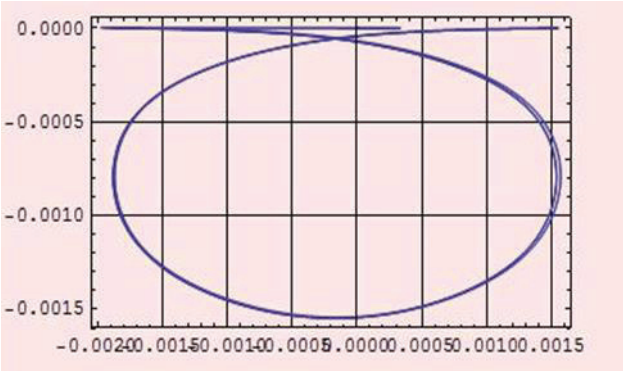

Figure 3: Kick map of Knot undulator.

The on-axis angular flux density spectrum is shown in Figure 4. At 6.2 eV peak position, the horizontal linear polarization with P_L > 99 % is achieved. For the calculation, parameters of the storage ring at Shanghai Synchrotron Radiation Facility (SSRF) are used which are E=3.5 GeV, I=200 mA, and ε_0=11.2 nmrad.

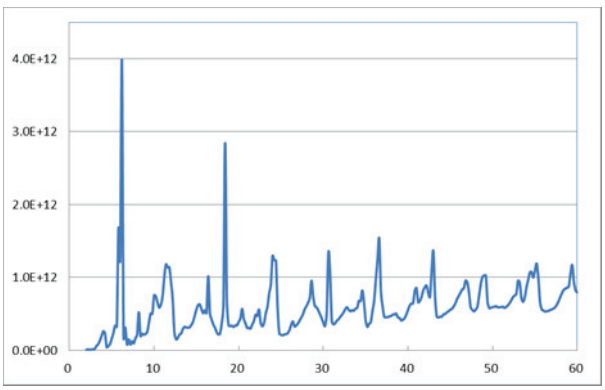

Figure 4: On-axis spatial flux density of the horizontal polarization mode.

KNOT-APPLE UNDULATOR

The Knot-APPLE undulator can be made by dividing central magnet rows into two parts in the same manner for creating the APPLE device. To create a magnet row in one quadrant, one has to combine the vertical row and horizontal row in a fixed position in the same magnet holder. Then, one has to introduce the same motion mechanism with that of APPLE undulator.

Vertical Polarization Mode

To reach to the vertical polarization mode, the magnet row phase has to be moved $\pm\pi$ ($\pm$110 mm) in anti-parallel direction. The antiparallel motion causes tilt of linear polarization which is different form the parallel motion that generates elliptical polarization.

Figure 5 shows the magnet row positions for the vertical polarization mode.

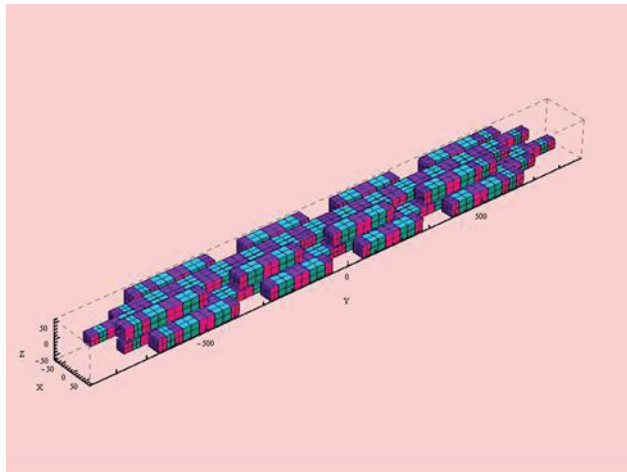

Figure 5: Magnet Structure of Knot-APPLE undulator in the vertical polarization mode.

Figure 6 shows the magnetic field distribution and Figure 7 shows the kick-angle map for vertical polarization mode. As it is obvious by comparing the field distribution for the horizontal polarization mode in Figure 2, the period length of vertical field component is one and a half larger than that of horizontal polarization.

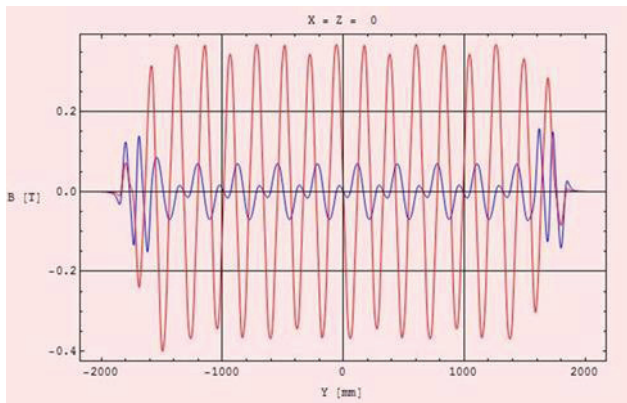

Figure 6: Field distribution of Knot-APPLE undulator in the vertical polarization mode.

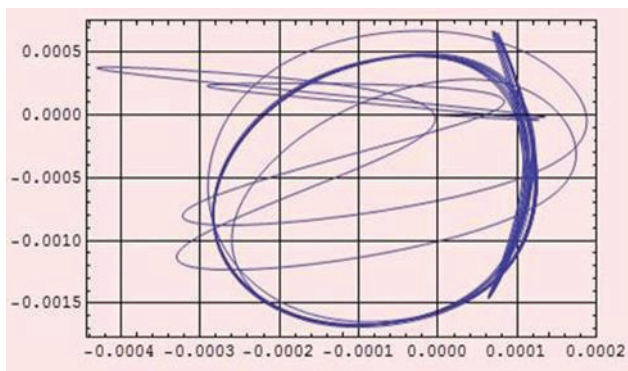

Figure 7: Kick map in the vertical polarization mode.

The on-axis flux density spectrum for the vertical polarization mode is shown in Figure 8. For the calculation, the ring parameters are assumed to be the same with those of horizontal polarization mode. The

degree of vertical linear polarization in this mode is above 97 % at the fundamental (17.4 eV) peak position.

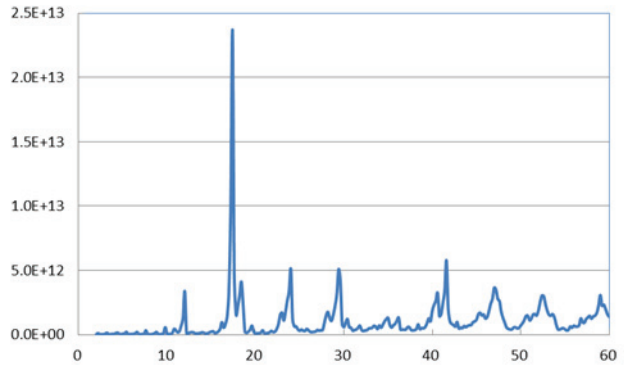

Figure 8: On-axis spatial flux density of the vertical polarization mode.

Elliptical Polarization Mode

To realize the elliptical polarization, different form the antiparallel motion for tilting linear polarization, the parallel motion is required. Figure 9 shows the magnet structure for the elliptical mode.

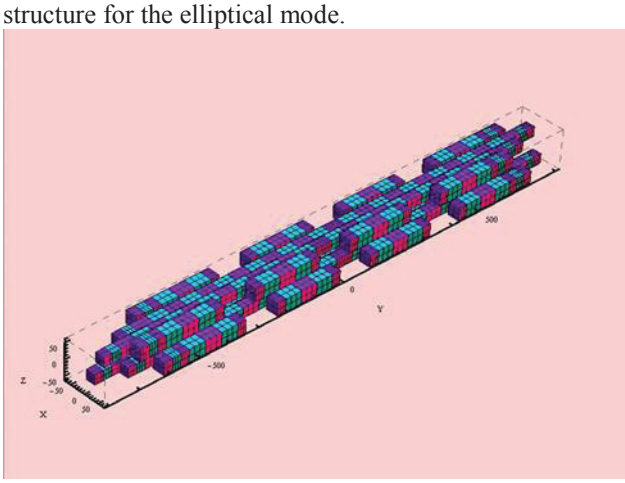

Figure 9: Magnet Structure of Knot-APPLE undulator in the elliptical polarization mode.

Figure 10 shows the magnetic field distribution for the elliptical polarization mode at the magnet row phase of 65 mm, and Figure 11 shows the kick-angle map of this mode.

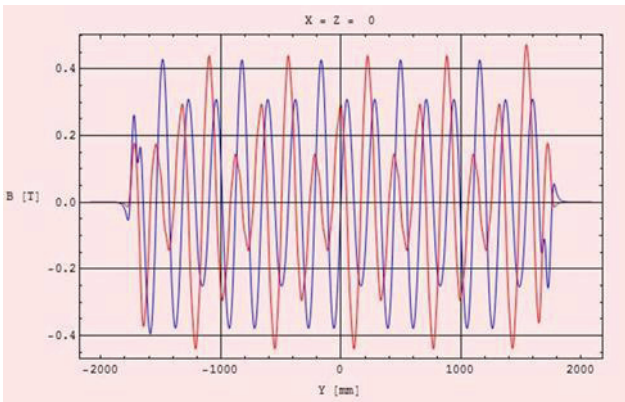

Figure 10: Field distribution of the elliptical mode at magnet row phase D = 65 mm.

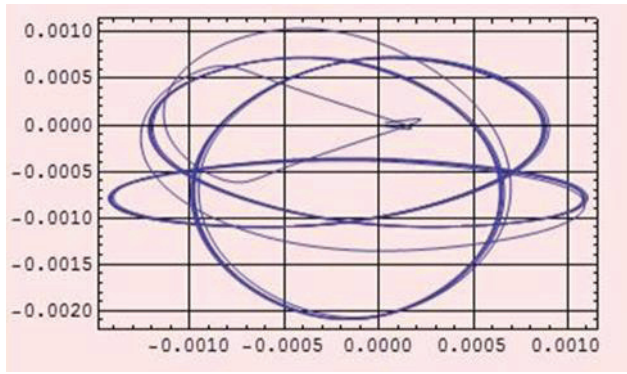

Figure 11: Kick map in the elliptical mode.

The on-axis flux density spectrum of elliptical polarization mode is shown in Figure 12. For the calculation, the ring parameters and the undulator gap were assumed to be the same with previous two cases. The degree of circular polarization in this mode is above 90 % at 9.8 eV peak position.

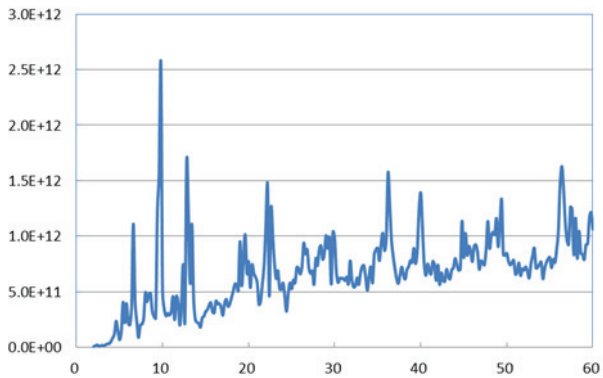

Figure 12: On-axis spatial flux density of elliptical polarization mode.

SUMMARY

In this paper, the Knot-APPLE undulator that is capable to vary polarization states with low on-axis power density at every polarization mode is proposed. This new device can be useful for synchrotron radiation users who use relatively low photon energies at medium/high energy ring facilities.

CONCEPTS FOR SHORT PERIOD RF UNDULATORS

S.V. Kuzikov#, A.V. Savilov, A.A. Vikharev, IAP RAS, Nizhny Novgorod, Russia

Abstract

Two concepts for room-temperature RF undulators, fed by cm- or mm- wavelength radiation and aimed to produce ~1 nm wavelength radiation using relatively low energy electron beams, are considered. In accordance with the first considered concept each undulator segment introduces a high-Q cavity fed by its own multi-megawatt RF source. The 30 GHz pulsed gyroklystron or gyrotrons at 30 - 300 GHz, already elaborated and tested in IAP RAS, are appealing candidates. These sources can provide the effective undulator period of 0.5 - 0.05 cm, the undulator parameter up to 1, and the effective field length of 50 cm for each segment. The second concept implies using high-power short pulse propagating in a long helically corrugated waveguide where the -1st field harmonic is responsible for particle wiggling. High group velocity of this pulse allows providing long interaction of particles with RF fields.

RF UNDULATORS BASED ON HIGH-QUALITY CAVITIES

RF undulator in comparison with traditional undulator, consisting of DC magnets, introduces a strong appeal to use less energetic electron beam, in order to produce the same wavelength of Compton's scattered radiation [1-3]. For example, in order to achieve radiation of nanometer wavelength instead of 1-2 GeV beam in conventional undulator with several centimeters period, one can use several hundreds of MeV beam in RF undulator with period ~1 cm [4]. The inevitable payment for this evident advantage is a necessity to provide high power level of microwaves, in order to have acceptable undulator parameter to be competitive with conventional undulators. In Ka-band the necessary power of the wave (to be counter-propagating to electrons) in waveguide of ~1 cm size reaches GW level. That is why, the modern projects of RF undulators assume cavities of high Q-factors to be powered by existing RF sources (klystrons, gyroklystrons, magnikons) which itself are able to provide tens of megawatts. According to such a concept full RF undulator consists of many relatively short sections to be mutually phased ones. At centimeter wavelength range the bimodal TE_{01}-TE_{02} resonator looks promising [4], at millimeter or sub-millimeter range a multi-mirror Gaussian beam resonator is preferable.

High-Q cavities bring a threat of destroying phenomena like RF breakdown and pulsed heating [5-6]. In order to avoid these undesirable phenomena, a short-pulse RF radiation of GW power level is appealing. In particular, experiments carried out with particle accelerators show that nanosecond RF pulses of GW level can travel through electrodynamic structure without breakdown [7].

There are necessary RF sources of GW power level based on relativistic BWOs [8]. Such sources can deliver more than 1 GW power in X-band and about 1 GW in Ka-band in pulses of 0.1-20 ns duration with repetition rate as high as several kHz. It was proven in experiments that phases of separate sources might be mutually locked [9].

SHORT-PULSE, TRAVELING WAVE RF UNDULATOR BASED ON HELICAL CORRUGATED WAVEGUIDE

A short RF pulse of duration τ, propagating in a smooth waveguide with group velocity closed to light velocity c and directed toward an ultrarelativistic electron bunch, causes wiggling of particles at length $L_{eff}^{count} = c\tau/2$. If one takes 10 ns RF pulse, the interaction length does not exceed 2 m. Interaction distance can be much longer, if RF pulse is co-propagating with electrons. In this case the effective interaction length is:

$$L_{eff}^{co} = \frac{v_{gr}\tau}{1 - v_{gr}/c}, \qquad (1)$$

where v_{gr} – is a group velocity along electron beam.

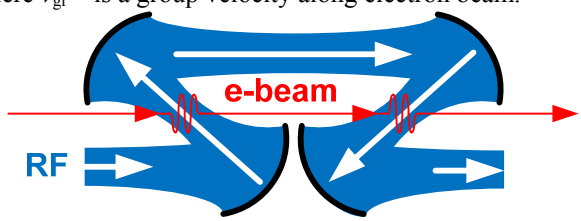

Figure 1: Mirror transfer line employing the "flying" RF undulator.

Of course, the co-propagating RF pulse in a smooth waveguide does not promise considerable Doppler's frequency up-shift. This problem is solved by using a so-called "flying" RF undulator, where a wavebeam spends a part of time moving toward electrons (Fig. 1).

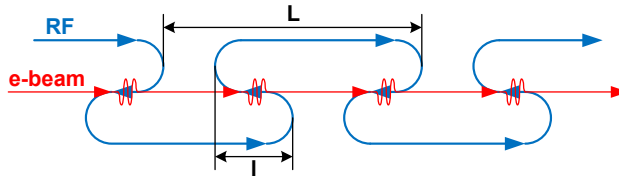

Figure 2: Equivalent scheme of "flying" RF undulator.

The simplified equivalent scheme of the "flying" undulator in Fig. 2 allows writing group velocity along beam in the mirror line:

$$v_{gr} = \frac{c}{1 + 2l/L}. \qquad (2)$$

Copyright © 2013 CC-BY-3.0 and by the respective authors

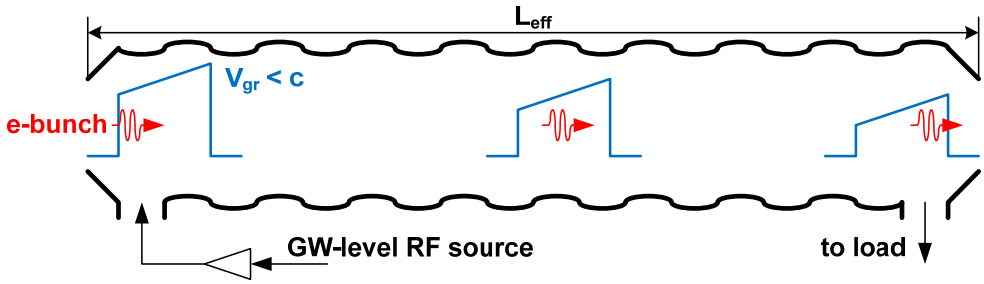

Figure 3: "Flying" RF undulator in form of helical corrugated waveguide section.

Any undulator can be described by dimensionless undulator parameter K, which is proportional to deflecting field amplitude. In an undulator with parameter K the optical radiation (in small signal approach) grows along electron path on z coordinate as $\sim \exp(K^{2/3} z)$ [4]. Let us introduce gain parameter as $\eta = K^{2/3} \cdot L_{eff}$, which can be used, in order to compare the "flying" RF undulator with the undulator, where RF pulse is counter-propagating. Ratio of gain parameters η_F (for the co-propagating 'flying' RF pulse) and η_0 (for the counter propagating RF pulse) is given using equations (1) and (2):

$$\frac{\eta_F}{\eta_0} = \frac{L}{l}. \qquad (3)$$

If the condition l=L is satisfied, then the "flying" RF undulator does not have advantages in comparison with smooth undulator with counter-propagating wave. Maximum of the ratio (4) is achievable, if l goes to zero. In this case the effective interaction length goes to infinity. However, there are big gaps where the interaction is absent at all. Such klystron-type configuration is more sensible to energy spread and beam emittance than configuration with simple counter-propagating wave [10].

In Fig. 3 the improved concept of the "flying" RF undulator, based on helical corrugated waveguide, is shown. Here bunch has continuous interaction with RF fields. In comparison with undulator based on counter-propagating wave in smooth waveguide (with parameter K_0), undulator parameter K in the corrugated waveguide is less, so let us take K=$K_0 \cdot \chi$. Nevertheless, the effective interaction is longer so that normalized gain parameter:

$$\frac{\eta_F}{\eta_0} = 2\chi^{2/3} \frac{v_{gr}/c}{1 - v_{gr}/c}, \qquad (4)$$

is more than unity, if group velocity is high enough:

$$\frac{v_{gr}}{c} > \frac{1}{1 + 2\chi^{2/3}}. \qquad (5)$$

In a corrugated waveguide of the fundamental period D there is an infinite number of the spatial harmonics those phase velocities could be either positive or negative relative to sign of electron velocity. Let us consider the "flying" RF undulator where co-propagating 0-th harmonic has the positive propagation constant h_0 and phase velocity, but -1-st harmonic has the negative propagation constant h_{-1} and negative phase velocity. The group velocity is less than c, positive and constant for all spatial harmonics. Particles oscillate in the transverse fields of the -1-st harmonic with equivalent undulator period:

$$\lambda_u = \frac{2\pi}{|h_{-1}| + k}, . \qquad (6)$$

where $h_{-1} = h_0 - 2\pi / D$, k=ω/c – is a vacuum wavenumber.

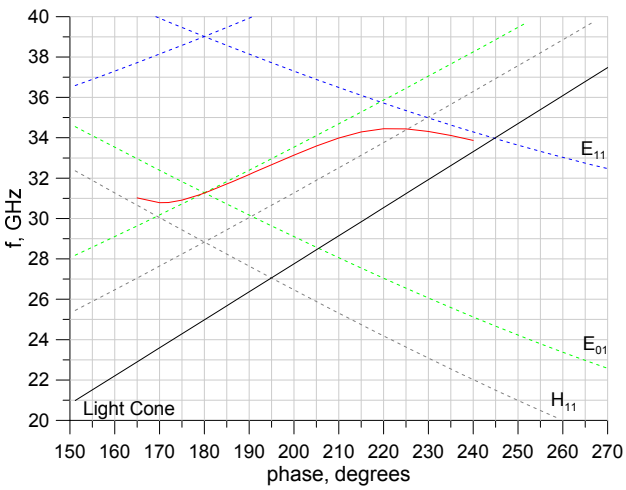

Figure 4: Dispersion characteristic of normal TM_{01}-TM_{11} wave in helical waveguide (red curve).

As it was proven in the paper [3], the co-propagating wave causes large-scale particle motion and dramatically spoils radiation spectra in RF undulator. In the proposed RF undulator the 0-th harmonic always exists and cannot be avoided. Nevertheless, in a helical corrugated waveguide the 0-th and -1-st harmonics can be represented by modes of different transverse structures.

Copyright © 2013 CC-BY-3.0 and by the respective authors

The 0-th harmonic should be chosen so that it does not possess transverse fields in the center where the thin electron beam travels. We suggest RF undulator based on TM_{01} (0^{th} harmonic) – TM_{11} (-1^{st} harmonic) in the one-thread helical waveguide. Dispersion curve of this operating normal wave, i.e. eigen frequency Vs phase h_0D in degrees, is shown in Fig. 4 for parameters: the average radius is R_0=6.1 mm, the period is D=6 mm, and the amplitude of corrugation is a=3 mm. The dashed curves correspond to partial modes in the smooth circular waveguide. The light cone is shown by black solid curve.

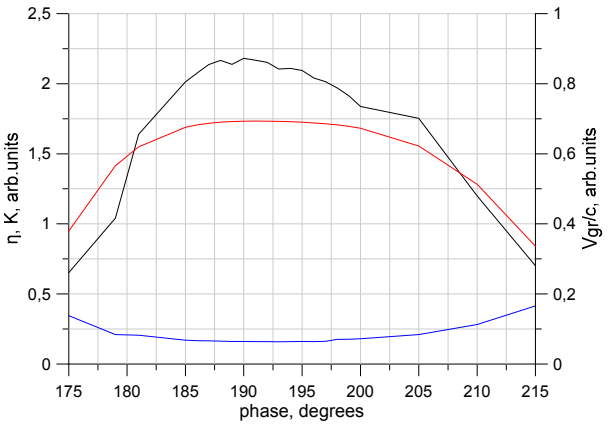

Figure 5: Normalized characteristics of TM_{01}-TM_{11} wave. The blue curve is undulator parameter. The red curve describes group velocity. The black curve is gain factor.

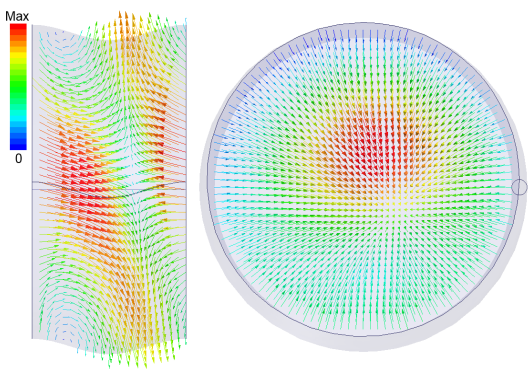

Figure 6: Instantaneous field structure of TM01-TM11 operating wave at phase 190 degrees.

In Fig. 5 K-parameter is plotted for the mentioned waveguide parameters and 1 GW RF power in dependence on the phase. In the same figure one can see group velocity and gain parameter also plotted in dependence on the phase. The highest value of parameter η (near 190 degrees in Fig. 5) corresponds to moderate fields, λ_u=5.4 mm, and group velocity about 0.7c. So we suggest to choose the point 190° as operating one. Such "flying" undulator is the equivalent of 10 m of usual undulator. Field structure of the operating TM_{01}-TM_{11} mode is shown in Fig. 6. Note that at the operating frequency partial TM_{11} mode is evanescent in the smooth circular waveguide.

The surface fields near phase 190° are 2.5 times higher than fields at axis so that Ohmic losses are not negligible. At phase=190° the power loss corresponds to factor $\alpha=6\cdot10^{-2}$ m^{-1} at room temperature. This loss is as high as about 60% of the incident RF power in 10 m helical waveguide. That is why, the pulse shape with the higher amplitude in front in comparison with the rear part of the pulse is desirable (Fig. 3). This pulse shape might provide constant acting fields for the electron bunch at whole undulator.

Schemes TE_{21}-TM_{11} and TM_{01}-TE_{11} are also possible.

CONCLUSION

The proposed concept, based on using GW level, 10-20 ns pulses in Ka-band, makes possible to use alone or a few number of RF sources in long enough "flying" undulator in order to create effective SASE XFEL.

HELICAL SELF FOCUSING AND COOLING ACCELERATING STRUCTURE

S.V. Kuzikov#, S.V. Mishakin, A.A. Vikharev, IAP RAS, Nizhny Novgorod, Russia

Abstract

A new helical RF accelerating structure, which can provide emittance control of the electron beam, is proposed. This structure combines properties of a linear accelerator and a damping ring simultaneously. It makes acceleration of straight on-axis beam as well as beam cooling due to the synchrotron radiation of particles. These properties are provided by specific slow eigen mode which consists of two partial waves, TM_{01} and TM_{11} (near to cut off). The longitudinal field of the first wave is synchronous with electrons, the transverse fields of the second wave are far from synchronous condition and they cause electron wiggling like it occurs in RF undulator. As a result the emittance control might be employed at linear trajectory of the high-energy beam without decrease of the average gradient. Calculations show that surface electric field at level ~0,31 (relative to accelerating field) and shunt impedance ~20 MOhm/m at 30 GHz are achievable. Cooling rate at gradient 100 MV/m corresponds to the equivalent magnetic field ~0,75 T.

INTRODUCTION

High luminosity of colliding particles in meeting point is achievable for compact, well focused bunches. Such bunches are achievable using systems of particle's cooling. At energies up to several GeV dampling rings provides effective cooling [1]. In these rings particles move in spatially-periodic fields of DC magnets. There is cooling effect due to synchrotron radiation of particles [2]. In order to reach TeV level of energy, behind a cooling ring particles are directed in main linac. Unfortunately emittances of bunches propagating in high-gradient accelerator have tendency to increase, because long trains of particles inevitably excite wakefields which spoil beam quality.

At high energies (more than 10 GeV) rings cannot be used, because too high level of energy dissipation caused by radiation, and too big radius of a ring would be necessary. That is why, cooling undulator can be installed at the linear trajectory only. However, DC magnets around the accelerating structure would conflict with feeding, focusing, and diagnostic systems, and inevitably large period does not allow reaching small emittances, because the smallest achievable emittance is proportional to squared wiggler period [3]. Suggested in the paper [3] accelerator with alternating accelerating sections and wigglers would reduce effective gradient.

An accelerating RF structure, which also plays a role of RF undulator, does not reduce gradient. Such structure might be based on helical corrugated waveguide, where the operating normal mode consists of the 0^{th} spatial harmonic (with positive phase velocity), which is actually the accelerating mode, and the -1^{st} harmonic (with negative phase velocity) which is responsible for particle wiggling. The transverse non-synchronous field components can provide emittance control and beam focusing due to ponderomotive force which depends on transverse electric field gradient of the -1^{st} harmonic wave.

The enumerated properties allow to distinguish our new helical self focusing and cooling structure (HSFC) [4] among other helical structures investigated earlier [5, 6]. Nevertheless, there are important properties to be common for all helical structures. For example, like other helical structure a new structure has smooth shape of the constant circular cross-section (no expansions or narrowings) and big aperture (no small irises). A new technology of the mass production, based on a "corkscrew" in a copper mandrel, seems also possible which allows avoiding junctions inside sections.

TM01-TM11 HELICAL ACCELERATING STRUCTURE

Let us consider the accelerating structure based on helical waveguide described in cylindrical system of coordinates (r, z, φ) by equation:

$$r(z,\varphi) = R + a \cdot \sin\left(\frac{2\pi \cdot z}{L} + m\varphi\right). \qquad (1)$$

where R – is a waveguide radius, a and L – are amplitude and period of the corrugation. Period of the corrugation is close to $2\pi/h_{TM01}$, where h_{TM01} – is a propagation constant of the partial TM_{01} mode in smooth circular waveguide of the radius R. If index m equals 1, such helical structure couples partial waves TM_{01} and rotating on azimuth TM_{11}. The TM_{01} does not perturb transverse movement of on-axis electrons, the TM_{11} does not have longitudinal E_z component on axis.

Table 1: Parameters of TM_{01}-TM_{11} HSFC Structure

Radius, R	6.09 mm
Period, L	8 mm
Corrugation amplitude, a	1.25 mm
Azimuth index, m	1
Frequency, f	28.2 GHz
Phase advance, h_0L	4.727
Q-factor (copper)	10800
Norm. accelerating field, E_a / E_s^{max}	0.307
Shunt impedance, R_{sh}/L	18.9 MOhm/m

Parameters of helical structure TM_{01}-TM_{11} was optimized to reach maximum of the accelerating field relative to maximum of the arisen surface field E_a / E_s^{max}, maximum of shunt impedance R_{sh} was also necessary. Results of optimization for geometry at frequency 28GHz are shown in the Table 1. At acceleration gradient 100 MV/m the equivalent magnetic field is as high as 0.75 T. Dispersion relation for the optimized structure in a form of dependence of the eigen frequency f on phase advance h_0L (h_0 – is a Floquet propagation constant) is plotted in Figure 1. The line 1 in Fig. 1 is actually light cone which corresponds to the condition $h_0=k$. The operating mode (curve 2) has low group velocity (several per cents of light velocity). Of course, the operating point is the cross point of the curves 1 and 2.

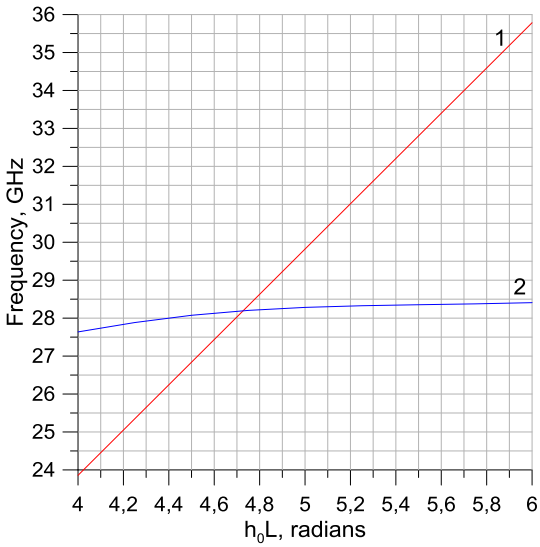

Figure 1: Dispersion characteristics: 1 – light cone line, 2 – dispersion curve of TM_{01}-TM_{11} wave in HSFC structure.

Field structure of the operating mode is shown in Fig. 2 (at middle plane) and in Fig. 3 (at two cross-sections). Accelerating field magnitude is uniform at beam line (Fig. 2).

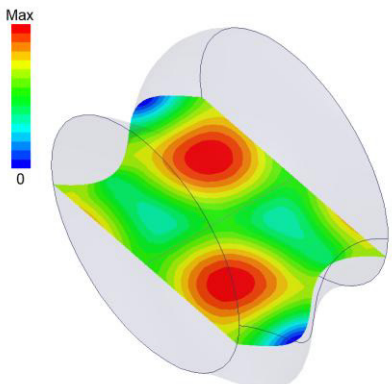

Figure 2: Module of electric field in middle plane.

Transverse field components are also uniform (Fig. 3), but phase velocities of longitudinal component and both transverse components have opposite signs (Fig. 4). Phase velocities of the transverse magnetic components are directed like phase velocities of transverse electric field components.

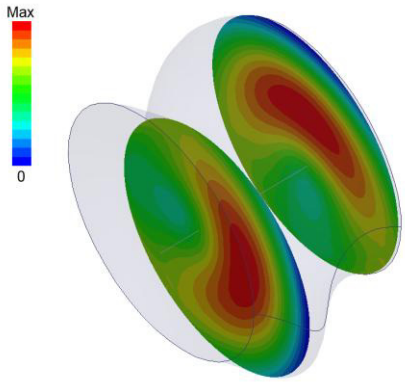

Figure 3: Module of electric field in two sequent cross-sections.

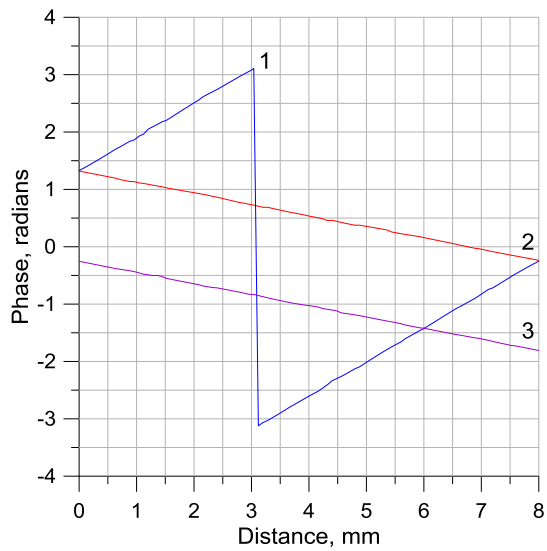

Figure 4: Phases of E_z (longitudinal) field component (curve 1) and phases of E_x (curve 2) and E_y (curve 3) field components.

The helpful feature of TM_{01}-TM_{11} HSFC structure is a flexible focusing of electrons. Physically the reason is that electric field of the -1st spatial harmonic has non-uniform distribution with minimum at axis of the structure. In such system moving electrons "sees" focusing ponderomotive (Miller) force:

$$F_\perp = -\frac{e^2}{4m(\omega + |h_{-1}| v_e)^2 \gamma^2} \nabla_\perp |E|^2 . \qquad (2)$$

where e and m – are charge and mass of an electron respectively, $v_e \approx c$ - is a velocity of electrons, γ - Lorentz's factor, $h_{-1} = h_0 - 2\pi / L$ - is a propagation constant of the -1st spatial harmonic.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Near cut off condition the TM_{11} mode has field maxima determined by E_z components which are far from axis. That is why, there is the focusing force. In the rotating TM_{11} mode E_z component is distributed uniformly on azimuth, but the superposition of TM_{11} and TM_{01} produces field distribution with maxima rotating on azimuth and moving along z coordinate (Fig. 3). The average value of this force does not depend neither on azimuth nor distance.

In order to show focusing effect in TM_{01}-TM_{11} HSFC structure, we calculated by CST Microwave Studio 100 MV/m accelerating section consisted of ten periods. Initial energy of electrons at entrance of the structure was 10 GeV, bunch length was 1 ps, bunch diameter was taken as 3 mm, full charge was as high as 100 nc. In Fig. 5a one can see input transverse bunch population, in Fig. 5b output bunch population is shown. One can see that particles near the centre of the bunch are not perturbed by RF fields, but bunches at bunch periphery are shifted in direction to the origin. This shift is caused by the mentioned action of the ponderomotive force.

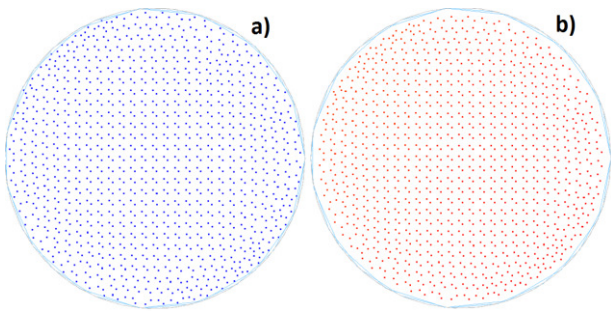

Figure 5: Bunch population at entrance of structure (a) and bunch population at output of structure (b).

Calculations of long HSFC structure, aimed to provide gradient as high as 100 MV/m, show that at distance 3 km energy spread is reduced by factor 40%, transverse emittance becomes less by factor 50%, full energy is less in comparison with classical structure without cooling by factor 17%.

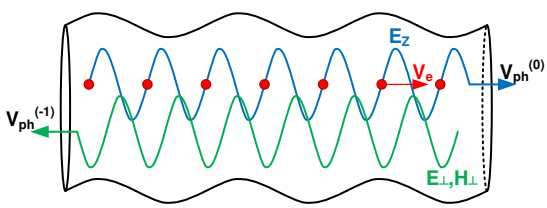

Figure 6: RF undulator excited by bunches itself.

Note that HSFC structure can be used as RF undulator only. In this case there are several appealing features. In particular, the same bunches (if its quality is high enough) could be used, in order to excite the operating mode, and in order to produce undulator radiation. The second reason to use HSFC structure as RF undulator could be important for sources of THz radiation where low-energy (MeV) electrons are used. These bunches experience an influence of Coulomb force, so longitudinal bunch size grows very fast on length. The longitudinal size could be controlled by E_z wave component in the helical structure, if one synchronizes bunches with RF field, like it is shown in the Fig. 6.

OTHER SCHEMES

Schemes, where only properties of RF undulator or only properties of acceleration occur, are also possible.

In particular, helical accelerating structures TM_{01}-TM_{21} or TM_{01}-TE_{21} of elliptic cross-sections do not have on-axis transverse fields. Nevertheless, properties of beam focusing in these structures still exist. The first mentioned structure has $E_a / E_s^{max} \approx 0.3$, but the shunt impedance is less than in the considered TM_{01}-TM_{11} structure.

In the structure $TE_{11} - TM_{01}$, where the 0^{th} harmonic is TE_{11}, and the -1^{st} harmonic is TM_{01}, the shunt impedance is high enough, but the parameter E_a / E_s^{max} is less than in the TM_{01}-TM_{11} structure.

CONCLUSION

Helical waveguides might be used as accelerating structures. These waveguides allows to accelerate electrons (or positrons), to control beam emittances and energy spread due to cooling, to provide self focusing due to transverse ponderomotive force or to combine all the mentioned effects simultaneously.

ACKNOWLEDGMENT

The authors would like to thank Prof. J.Hirshfield for his stimulating interest to this work and for helpful discussions with him.

PROGRESS ON PULSED MULTIPOLE INJECTION FOR THE MAX IV STORAGE RINGS

S.C. Leemann*, MAX IV Laboratory, Lund University, SE-22100 Lund, Sweden
L.O. Dallin, Canadian Light Source, Saskatoon, Saskatchewan, S7N 2V3, Canada

Abstract

Injection into the MAX IV storage rings will not make use of a conventional local injection bump with four dipole kickers. Instead, pulsed multipole injection will be applied. Previously, it was foreseen to use a pulsed sextupole magnet similar to what KEK had originally designed for the PF ring. But after seeing encouraging results with a prototype nonlinear kicker magnet developed for BESSY II, pulsed multipole injection for the MAX IV storage rings was revisited. A nonlinear kicker magnet similar to the BESSY-type can be realized for both MAX IV storage rings. Such a nonlinear kicker offers a broad zero-field region around the center which does not perturb the stored beam, while offering a high-field region around the location of the injected beam making it ideal for top-up injection. This paper summarizes the proposed kicker magnet design and shows beam dynamics results from multi-particle tracking studies. A comparison with the previous PSM design is also included.

INTRODUCTION

Early in the design process of the MAX IV storage rings it was considered that injection into the rings could be performed using a single dipole kicker installed downstream of the DC Lambertson septum. In the meantime, detailed studies have demonstrated feasibility [1] and fabrication of these dipole kickers is well underway. However, a single dipole kicker is not suitable for top-up injection because injection and capture cannot be made transparent to users. Therefore, injection with a pulsed sextupole magnet (PSM) was studied as a means to perform fully transparent top-up injection. This avoids having to balance the four dipole kickers and pulsers required to cleanly open and close a local injection bump over prolonged periods of time. Detailed analysis [2] revealed the great potential of PSM injection and a reference design for the magnet was initiated following the experience gained at KEK in the design of the PSM for the PF ring [3].

The MAX IV storage rings require roughly the same kick from the PSM as the PSM in the KEK PF. However, the position of the injected beam in the MAX IV PSM's is only a third of that in the PF and therefore the required sextupole gradient in the MAX IV PSM is considerably higher. On the other hand, the aperture requirements in the MAX IV storage rings are significantly lower, thus allowing a reduction of magnet aperture and an increase in field strength. An initial reference design for a 300 mm long solid iron magnet (cf. Fig. 1) supplied roughly 1.2 mrad kick (at 3 GeV) at −4.7 mm from the center. The bore is 32 mm leading to a pole-tip field roughly 0.5 T. A single coil per yoke called for 2125 A current. With a stored energy of 20.6 J, the required pulser voltage was 19.3 kV for single-turn injection into the MAX IV 3 GeV storage ring. For the MAX IV 1.5 GeV storage ring a similar magnet was designed which relies on 1527 A current at 400 mm length. Here, however, single-turn injection calls for 640 ns pulse length which increases the required pulser voltage to 92.9 kV. Although two-turn injection is possible and reduces the voltage requirement by 50%, it remains desirable to further reduce this voltage, i.e. lower the inductance of the PSM. However, since the magnet bore already lies within only several mm of the beam-stay-clear area, a significant reduction of the inductance could not be expected for this type of magnet.

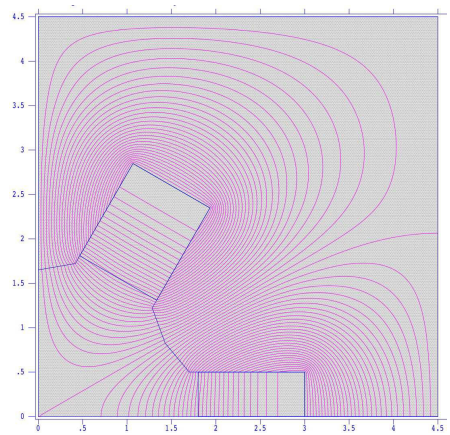

Figure 1: Pulsed sextupole magnet reference design for the MAX IV 3 GeV storage ring. One quarter of the magnet is shown. Scales are in cm. The magnet bore is 32 mm.

NONLINEAR INJECTION KICKER

Around the same time, first reports appeared of a novel nonlinear injection kicker (NLK) developed for BESSY II [4]. This kicker design expands on the original PSM idea to have a high field at the injected beam while keeping the field at the stored beam close to zero. It makes use of a stripline-like design with a geometry intended to create a high-field area strongly localized around the injected beam while suppressing the field at the stored beam through symmetry. Figure 2 shows an initial reference design for the MAX IV 3 GeV storage ring along with the

generated field profile in the midplane compared to that of the PSM and a pure octupole.

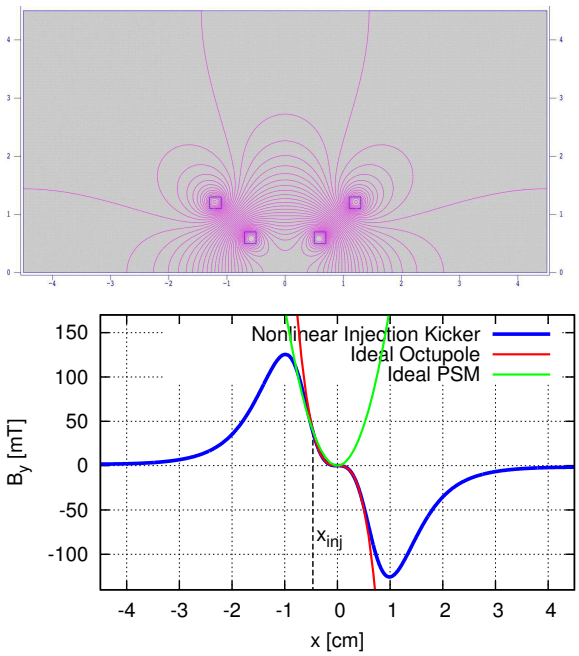

Figure 2: Upper half geometry (top) and resulting field profile in the midplane (bottom) of the reference design for a nonlinear injection kicker for the MAX IV storage rings calculated in POISSON. The design is adapted from the NLK developed for BESSY II.

Such a NLK has several distinct advantages over a PSM. Around the center the field is zero and flat. Between the center and the high-field area the profile is octupole-like (cf. Fig. 2, bottom). This leads to very small perturbations of the stored beam which is crucial given the very tight stability tolerances in MAX IV [2]. While imperfections in the PSM can lead to residual dipole kicks to the stored beam [5, 6], the field in the NLK always has a zero-crossing and therefore offers a field-free area for the stored beam. This area can be found with stored beam via orbit bumps thus enabling beam-based re-alignment of the magnet.

In principle, another advantage of the NLK is the flat area around the field maximum. Ideally the injected beam passes the NLK at this location thus enabling good capture efficiency even for injection of high-emittance bunches. In MAX IV, however, this NLK property cannot be exploited as there is an inherent trade-off between vertical position of the inner rods (in Fig. 2 they are 6 mm from the midplane) and the horizontal position of the field maximum (in Fig. 2 at 10 mm from the center). Since the injected beam in the MAX IV storage rings lies at roughly 5 mm from the stored beam, the inner rods would have to be brought so close to the midplane that the kicker would encroach into the vertical acceptance. On the other hand, as previous studies had demonstrated [2], with the low-emittance beam injected into the MAX IV storage rings[1], capture does not suffer from the gradient sampled in the PSM. Therefore, it was expected that the injected beam can sample the gradient of the NLK field, despite its steeper slope, without suffering significant smearing. This is confirmed by the comparison shown in Fig. 3: although NLK injection increases smearing compared to the PSM, the effective emittance of the injected bunch is still dominated by the large injection amplitudes. The gradient of the NLK at the injected beam does not lead to decreased capture efficiency.

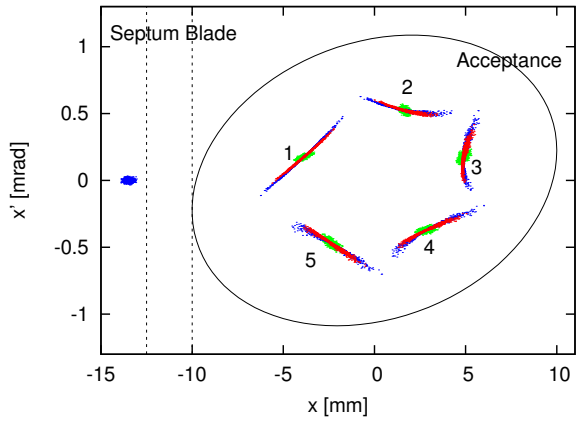

Figure 3: Tracking of the injected bunch with DIMAD during the first five turns in the MAX IV 3 GeV storage ring using single-turn injection. Injection with the NLK (blue) is compared to the PSM (red). For reference, a pure dipole kick (green) has been included. The latter is has no gradient, but it does not allow for transparent top-up injection.

The NLK can therefore be operated in the MAX IV storage rings with the injected beam on the slope. Although such application of the NLK does not exploit the elegant BESSY concept to full extent, it allows using the low-inductance NLK design for pulsed multipole injection (PMI) in MAX IV. The reference design for a NLK adapted to the MAX IV 3 GeV storage ring (cf. Fig. 2) calls for 2855 A and has a stored energy four times lower than the solid iron PSM. The pulser voltage[2] is estimated to be 5.7 kV. In the MAX IV 1.5 GeV storage ring the required current reduces to 1790 A and, with a required pulser voltage of 19.5 kV, single-turn injection becomes feasible. With the NLK two-turn injection is no longer feasible in the MAX IV 3 GeV storage ring as originally designed [2] because the kick of the NLK on the second turn has the wrong sign. However, with the relaxed voltage requirements, this is not considered a problem. For the MAX IV 1.5 GeV storage ring two-turn injection remains feasible as it relies on negligible amplitude of the injected bunch at the kicker during the second passage.

[1] A benefit of using the MAX IV 3 GeV linac as a full-energy injector into both MAX IV storage rings.

[2] This result relies on preliminary assumptions for the inductance of the circuit which is non-negligible compared to the low inductance of the magnet.

DETAILED DESIGN PROGRESS

Because of the minimized perturbation of the stored beam as well as the low magnet inductance, it has been decided to use a BESSY-type NLK for injection into the MAX IV storage rings rather than the originally foreseen PSM. For this purpose MAX IV and SOLEIL have initiated a collaboration with the goal to design and build injection kickers for the SOLEIL storage ring as well as the two MAX IV storage rings based on further development of the BESSY-type NLK. The SOLEIL requirements for PMI are similar to those for MAX IV. While PMI in SOLEIL calls for a stronger kick than in MAX IV, the injected beam is farther away from the magnet center. Vertical beam-stay-clear requirements are comparable. In fact, it has been realized that the same magnet can be used for both MAX IV storage rings if the vertical beam-stay-clear aperture is set to 8 mm as a compromise between bringing the maximum kicker field closer to the injected beam and maintaining sufficient vertical acceptance in the MAX IV 1.5 GeV storage ring. Therefore, the only difference between the injection kickers in the two MAX IV storage rings will be the pulsers.

In comparison to the BESSY NLK, the SOLEIL Multipole Injection Kicker (MIK) design [7] foresees a pulser with a single transducer and all four loops connected in series. The parallel connections in the BESSY NLK were suspected of creating a field imbalance leading to residual kicks to the stored beam [8]. Furthermore, the SOLEIL MIK design does not include metallic walls and uses the ceramic chamber as a vacuum vessel allowing for better cooling and access. A large horizontal aperture (45 mm) prevents synchrotron radiation heating of the chamber without increasing the inductance of the magnet. The minimum ceramic thickness is presently being studied as it limits the vertical separation between the inner rods. Any increase of this separation has to be analyzed carefully as it leads to a significant growth of required current.

The ceramic chamber needs a conductive coating. Different coating thicknesses have been studied in terms of heating from ohmic losses, image currents, and Eddy currents. Furthermore the effect of the coating on the field and therefore on the stored beam have been investigated. Presently 5 μm Ti appears to be a suitable choice for the MAX IV 3 GeV storage ring. With such a coating a minor increase in current compensates for field attenuation, but a small quadrupole gradient at the stored beam remains. If any residual kick, $\phi_{\mathrm{res}}(\mathrm{at}\ 1\sigma_x)$, is to be limited in terms of divergence spread, $10\% \times \sigma_{x'}$, it can be shown that the maximum tolerable residual quadrupole gradient is independent of the stored beam emittance: $(\partial B_y/\partial x)_{\mathrm{res}} < 10\% \times B\rho/(\beta_x L)$. The SOLEIL MIK with 5$\mu$m Ti coating gives a residual gradient of 0.18 T/m, significantly below the 0.36 T/m [0.28 T/m] acceptable in the MAX IV 3 GeV [1.5 GeV] storage ring. This is corroborated by tracking studies where the effect of such a residual quadrupole gradient on the stored beam has been analyzed (cf. Fig. 4) and shown to be negligible. Another study has indicated that the end geometry of the rods and terminals leads to perturbations on an even lower level.

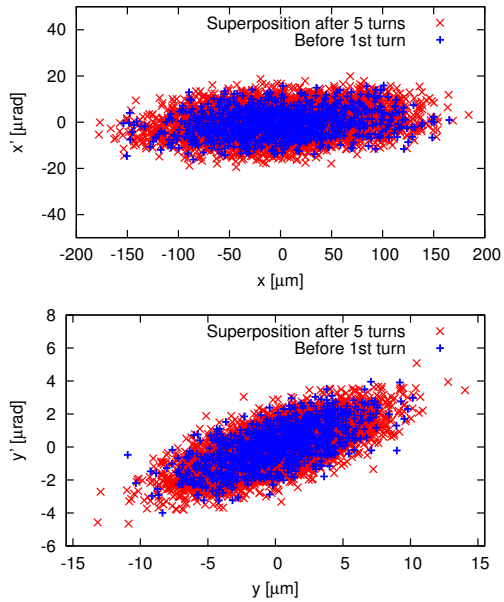

Figure 4: Tracking of the stored beam with DIMAD in the MAX IV 3 GeV storage ring through the SOLEIL MIK in single-turn injection mode. The residual gradient of the MIK leads to negligible perturbation of the stored beam.

ACKNOWLEDGMENTS

The authors would like to thank Peter Kuske and Olaf Dreßler from HZB as well as Pierre Lebasque and his team at SOLEIL for many interesting discussions on pulsed multipole kicker design.

BEAM-INDUCED HEAT LOAD PREDICTIONS AND MEASUREMENTS IN THE APS SUPERCONDUCTING UNDULATOR*

Katherine C. Harkay#, Laura Boon, Michael Borland, Yong-chul Chae, Roger Dejus, Jeffrey Dooling, Charles Doose, Louis Emery, Yury Ivanyushenkov, Mark Jaski, Matthew Kasa, Suk H. Kim, Robert L. Kustom, Vadim Sajaev, Yuko Shiroyanagi, Xiang Sun

Abstract

The first test superconducting undulator (SCU0) was successfully installed and commissioned at the Advanced Photon Source (APS) and is delivering 80- to 100-keV photons for user science. The cryosystem was designed to handle a beam-induced heat load of 40 W. Prior to operations, detailed predictions of this heat load were made, including that produced by resistive wall heating by the image current, geometric wakefields, synchrotron radiation, electron cloud, and beam losses. The dominant continuous wave (cw) source is the resistive wall heat load. The heat load predictions for standard 100-mA user operation were benchmarked using thermal sensors that measure temperatures along the SCU0 beam chamber. Analysis using the predicted heat loads from the electron beam agrees well with the observed measurements.

INTRODUCTION

A test superconducting undulator (SCU0) has been developed at APS [1] and was recently installed in the storage ring. A key design criterion was a vacuum and cooling system that keeps the NbTi coils cooled to 4 K in the presence of heating caused by the electron beam passing through the undulator beam chamber. The SCU0 beam chamber cooling system was designed for 40 W (at 20 K) of cooling capacity based on preliminary calculations of the beam-induced heat load [2]. In this paper, updated predicted heat loads are compared with measurements carried out during SCU0 commissioning [3].

Sources of beam-induced heat load on the SCU0 beam chamber include resistive-wall heating due to beam-induced image currents, synchrotron radiation generated in upstream dipole magnets, wakefield effects, direct beam interception and, potentially, electron cloud-induced multipacting effects. Under nominal operating conditions cw heat loads are present, while specific machine fault conditions may occur that give rise to individual transient heat loads.

Estimates of the various contributions to the heat load due to the beam are shown in Tables 1 and 2 for cw and transient sources, respectively, assuming 24-bunch operation. The central part of the chamber is nominally 20 K and is thermally isolated from the 4-K magnetic structure. The chamber transitions are in the 60- to 300-K cold-to-warm transition region. Where appropriate, the heat loads at 20 K and 60/300 K are given separately.

Table 1: Estimated cw Beam-induced Heat Loads on the SCU0 Chamber, in 100-mA User Operations

Heat Source	Value at 20 K (60/300 K)
Resistive wall	4.7 W (11.3 W)
Wakefields	< 0.5 W (0.8 W)
Injection losses	2 W (non-top-up mode) 0.1 W (top-up mode)
Synchrotron radiation	0.2 W
Beam lifetime losses	<< 1 W
Electron cloud	< 2 W
Total heat load	10 W (12 W)

Table 2: Estimated Max. Transient Beam-induced Heat Loads on the SCU0 Chamber, in 100-mA User Operations

Heat Source	Value
Injected beam loss	13 W
Corrector failure	20 W
Synchrotron radiation with steering errors	25 W
Electron beam steering errors	20 W
Max. transient heat load	25 W

MEASUREMENTS

The beam-induced heating on the SCU0 beam chamber was measured using nine Cernox cryogenic thermal sensors mounted on the beam chamber, shown in Fig. 1 (Temp0-8). Sensors Temp2-6 are mounted on the outboard side of the aluminum section of the chamber, and Temp0,1,7,8 are mounted on the top side of the stainless steel (SS) cold-to-warm transition. The chamber heater is connected to a copper block mounted adjacent to sensor Temp5. A calibrated heat load was applied to the heater using a variable power supply. The chamber heater was used to calibrate the thermal sensors, allowing determination of the heat load from the temperature measurements. This calibration was used to both predict and benchmark the chamber temperatures for storage ring beam operation.

Chamber Heater Calibration

To simulate SCU0 operating conditions, the main coil current was set to 500 A, but there was no stored beam. An external supply current was used to vary the chamber heater power based on the known heater resistance. The chamber temperatures were recorded for P=0, 5, 10, 20, and 30 W, waiting 10-20 min per step. The equilibrium chamber temperatures were determined by fitting the measurements to an exponential function. The zero-power

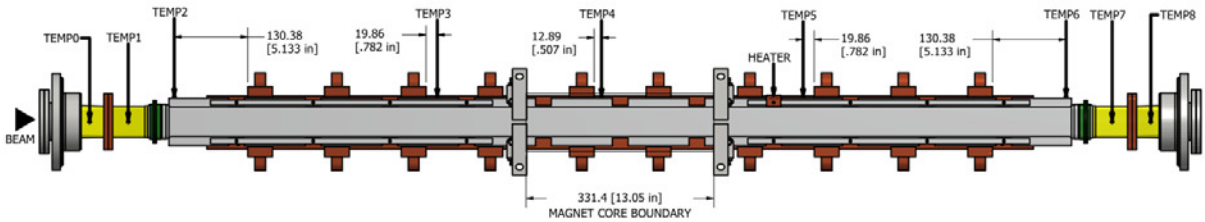

Figure 1: Thermal sensor (TEMP 0-8) locations are noted on a SCU0 beam chamber schematic, top view. The chamber heater is adjacent to TEMP5. Copper thermal links, shown in brown, connect the chamber to the cryocoolers via a common Cu bar. The Al section of the chamber is shown in grey and the stainless steel (SS) section in yellow.

temperature was averaged over 15 min prior to the start of the heater studies.

The temperature gains vs. chamber heater power for sensors 1-7 are shown in Fig. 2 as a function of their positions, s. Sensor 5 shows the largest temperature gain, as expected. The adjacent sensors 4 and 6 show a much smaller temperature gain; heat is extracted between these points by thermal links to the cryocoolers. Ideally, the heater on the Cu bar connecting all the thermal links could have been used, but the heat transfer is not known between the Cu bar and the chamber. The chamber heater calibration is also not exact, but was implemented knowing these limitations.

Because the chamber heater and sensor 5 are collocated between the same thermal links, sensor 5 is used to calibrate the temperature response to a known heat load. A polynomial fit for the temperature gain ΔT as a function of calibrated power P gives:

$$\Delta T = 1.974P - 0.0667P^2 + 0.00119P^3 \qquad (1)$$

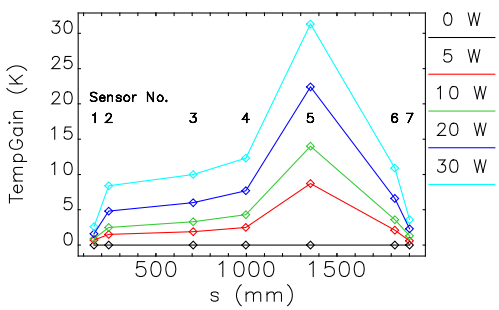

Figure 2: Chamber heater results for sensors 1-7, shown as a function of their positions, s.

Results

The chamber temperatures under stable cw conditions (no beam injection) were predicted using the dominant resistive-wall heat load only. In Table 1, the heat load at 20 K was obtained by multiplying the linear power density over the entire Al chamber length of 1.62 m. The power density varies with the number of bunches; for 24 bunches, it is 2.88 W/m [4,5]. However, the heater calibration should only be valid in the segments within the thermal links, a total length of 1.33 m. Therefore, this shorter length was used to estimate P, and the expected temperature gain was computed using Eq. (1). Also, the calibration was only applied to the central sensors 3-5, since these three sensors are located between thermal links. The baseline, no-beam temperature of the Al chamber central region is 7 K. The predicted power and expected final temperatures (7 K + ΔT) are given in Table 3 for the three standard bunch patterns at 100 mA (nominal user operations), and for 324 bunches at 150 mA (special operations). These predictions were available prior to SCU0 commissioning. The measured temperature (averaged at sensors 3-5) is also shown in the table, and the agreement with the expectations is very good. Finally, the power inferred from the measured temperatures was determined using Eq. (1) and is listed in the table.

Table 3: Comparison of Predicted and Measured SCU0 Chamber Heat Load and Temperatures at Sensors 3-5.

Beam current (mA)	No. bunches	Predicted power (W)	Expected T (K)	Msrd T (K)	Inferred power (W)
100	24	3.8	13.6	12.8	3.3
100	1+56	2.7	11.8	11.9	2.7
100	324	0.5	7.9	8.2	0.6
150	324	1.2	9.3	9.5	1.3

DISCUSSION

The SCU0 cryogenic system performed very well in the presence of the beam, with the magnet temperatures being maintained near 4 K while the beam chamber center temperature reached ~13 K. The 20-K cooling system for the beam chamber, with its 40-W capacity, provides a comfortable margin for normal user operation.

The predicted cw heat load, using only the resistive-wall heating, agrees remarkably well with the measurements using the chamber heater calibration. An independent thermal modeling using finite-element analysis also gives very good agreement with the measured temperatures over the entire length of the chamber [6]. The resistive-wall heating calculation for the Al section includes the anomalous skin effect, where the skin depth is small compared to the electron mean-free path. In this regime, only a fraction of the conduction electrons carry the current, which effectively decreases the wall conductivity [7]. The anomalous skin effect begins to show a difference for a resistivity ratio (RR) > 9 [5]; at 20 K, RR = 11 for 6063-T5 Al. The surface

Copyright © 2013 CC-BY-3.0 and by the respective authors

resistance also increases with surface roughness, and the effect can be computed using an empirical formula. For the SCU0 chamber, a surface roughness of 0.2 μm rms would increase the power loss by as much as 15% [4]. The SCU0 Al chamber was processed using an abrasive-flow polishing technique [8], and the measured surface roughness is on the order of 0.1 μm rms [9]; therefore, the surface roughness effect could be neglected.

All other contributions to the heat load are inferred to be small. The predicted synchrotron radiation heat load of 0.2 W in Table 1 [10-12] is small compared to the resistive-wall heat load for all bunch patterns except for the 324-bunch mode, where the predicted temperatures are underestimated. If the electron beam was mis-steered in the upstream dipole or corrector magnets and/or the chamber was not well-aligned, the synchrotron radiation heat load could be much higher, up to 25 W [13]. The results suggest that both the beam steering and the chamber alignment are within tolerance. The surface roughness of the SCU0 beam chamber has another effect: it can increase the synchrotron radiation absorption in the SCU0 chamber, which can increase the heat load. While this effect has not yet been analyzed, the results in Table 3 suggest that if it exists, the effect is very small.

Wakefields are predominantly in the chamber transitions outside the SCU0 cryostat, and the heat load was predicted to be dissipated primarily in the cooled Cu tapered transition upstream of the SCU0 [14]. The results in Table 3 are consistent with the absence of significant wakefield heating in the center of the chamber. Any potential heat load from beam lifetime losses is also inferred to be negligible, as predicted in Table 1.

So far, there is no evidence of anomalous heat loads on the SCU0 chamber. This is noteworthy, since measured beam-induced heat loads that are 2-10 times greater than what was expected have been reported for in-vacuum superconducting wigglers [15] and in-vacuum cryocooled permanent magnet undulators [16]. In the case of MAX [15], the discrepancy is assumed to depend on the fact that the Cu plating of the inner surfaces of the cold bore has a lower electrical conductivity than foreseen. The SCU0 is an out-of-vacuum device designed with a solid Al chamber wall for which resistive-wall heating is well understood. Calculations predict that high-current closely spaced bunches (such as in the case of 324 bunches) are more likely to drive an electron-cloud-induced multipacting resonance in the APS [2]. In SCU0 so far, there is no evidence of multipacting. Multipacting is believed to be responsible for an anomalous beam heat load and pressure rise at the ANKA in-vacuum superconducting undulator [17].

TRANSIENT HEAT LOADS

Transient heat load predictions in Table 2 assumed that the power is incident on the beam chamber. The maximum transient heat load of 25 W is within the SCU0 cooling capacity. The device was found to quench during unintentional beam dumps that have occurred during user operation due to fault conditions unrelated to SCU0. A beam loss in the magnet coils of ~1 nC (< 0.3% of the full store) could potentially cause a quench [18]. Procedures to mitigate these quenches are under investigation. With the exception of beam dumps, the device has quenched only twice in eight months of user operations, operating above its 500-A design current. The SCU0 magnet current is switched off prior to intentional beam dumps and during machine studies to avoid quenching.

SUMMARY

The cw beam-induced heat load predictions for the SCU0 beam chamber in standard APS user operation were compared with measurements using a simple chamber heater calibration. The expected chamber temperatures were used as a guide during SCU0 commissioning. The agreement between the expected and measured temperatures was very good, within 10%. The resistive-wall heat load is the dominant source, and all other contributions are inferred to be small, as predicted. There were no anomalous heat load sources detected. The SCU0 cryogenic system performed very well in the presence of the beam, as designed.

ACKNOWLEDGMENT

We thank the entire APS SCU0 team for their valuable contributions to the success of this project.

ANL, Argonne, IL 60439, USA

Abstract

The first test superconducting undulator (SCU0) was successfully installed and commissioned at the Advanced Photon Source (APS) and is delivering 80- to 100-keV photons for user science. The magnet cores are mounted on but thermally isolated from the beam vacuum chamber. Protecting the SCU0 from high beam-induced heat loads was an important requirement before operating the SCU0 in the storage ring. Precise alignment of the beam vacuum chamber with respect to both the electron beam orbit as well as the synchrotron radiation generated in the upstream dipole magnet was therefore extremely important. The beam vacuum chamber was instrumented with nine thermal sensors. Using the sensors, the chamber alignment was determined with 100-micron accuracy. This accuracy is 10 times higher than in a standard aperture scan. Other advantages of the thermal sensor-based alignment method include isolating the SCU0 alignment from other components in the orbit bump and providing good longitudinal spatial resolution. The chamber temperatures agreed well with the predicted heat load and dependence on steering. This novel beam-based alignment method and results will be presented.

INTRODUCTION

One of the many challenges of operating a small-gap superconducting undulator in a high-energy synchrotron light source is protection from excessive beam-induced heat loads [1]. For the test superconducting undulator (SCU0) recently installed in the APS [2], this is accomplished through several key features, including an out-of-vacuum design, thermal isolation of the beam chamber from the magnet coils, 40-W cooling capacity on the beam chamber, and a photon absorber to shield the SCU0 from synchrotron radiation from the upstream bending magnet (BM). Precise alignment of the magnet structure and beam vacuum chamber is also essential for proper heat-load protection, as is a well-controlled beam orbit while the device is in operation. Prior to installation in the APS, the SCU0 beam vacuum chamber and magnetic structure were transversely aligned to within ±150 μm relative to fiducials mounted on the vacuum vessel. Correction values were determined for a "cold fiducialization," based on measurements before and after cooldown on the test stand [3]. After installation and cooldown *in situ*, beam-based alignment was used to confirm that the SCU0 chamber position was reproduced and that it remained stable during operation. A standard aperture scan was performed first, followed by beam-based alignment using thermal sensors. The results are described below.

APERTURE SCAN

A standard aperture scan involves steering the electron beam vertically through the chamber until the edge of the beam scrapes the walls and the beam lifetime decays to a small value (typically < 10 min). The extreme values of the vertical beam position monitors (BPMs) are recorded to give a measure of the aperture. With a standard 5-m-long ID chamber, a combination of parallel- and angle-bumps can be used to determine the chamber alignment. However, the SCU0 was installed in sector 6 (ID6) downstream of a half-length ID chamber. Sector 6 thus has two small-aperture chambers and several transitions. Therefore, only parallel orbit bumps were implemented to confirm the overall chamber alignment.

The full vertical aperture of the SCU0 chamber is nominally 7.2 mm and the ID chamber is 7.5 mm. The aperture scan was performed using 2 mA in a single bunch, chosen low to protect the SCU0 but with sufficient BPM response. For comparison, the same measurement was repeated in ID21, a 5-m-long, 7.5-mm, full-height ID chamber known to be well aligned. A model four-corrector parallel bump was used to change the correctors, and a special global orbit configuration closes the bump, with the P1 BPM readings allowed to vary. P0 BPMs are located at the ends of the insertion device (ID) chamber, but they have inaccurate response at large orbit values (> 1 mm). P1 BPMs have a better response at large orbit values but there is a defocusing quadrupole between the P1s and the ID chamber ends. Because a model orbit bump produces a parallel orbit shift in the ID, it can be assumed that the orbit at P1 is nearly the same as P0. The aperture was determined from the P1 readings.

The results are given in Table 1. The ID6 results are very good in terms of symmetry, and the full range is comparable to ID21. The accuracy of this method in determining the chamber center is estimated to be about ±1 mm, given that the full range determined from the scan is ~3 mm smaller than the nominal chamber aperture.

Table 1: Aperture Scan Results for ID6/SCU0 and ID21

Sector	Steer up (mm)	Steer down (mm)	Full range (mm)
ID6	2.2	-2.2	4.4
ID21	2.2	-1.8	4.0

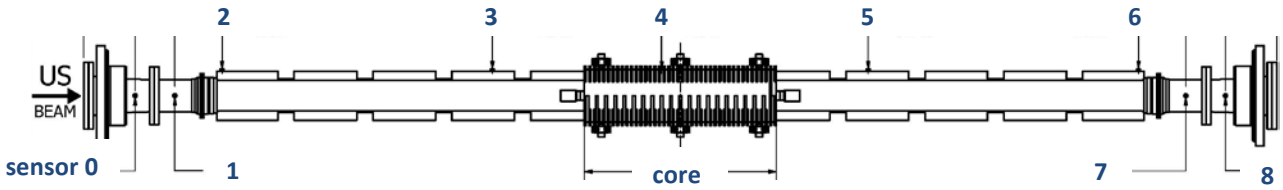

Figure 1: Thermal sensor locations, SCU0 beam chamber (top view). The chamber is stainless steel at sensors 0, 1, 7, and 8 and aluminium at sensors 2-6. The chamber is 2.06 m and the undulator core is 0.34 m in length.

ID STEERING

The SCU0 chamber is instrumented with nine thermal sensors mounted along its length; the locations are shown schematically in Fig. 1. The thermal sensors were used in a novel method of determining the chamber alignment, which is to steer the electron beam in the chamber and observe the temperature response of the thermal sensors. The beam steering was performed by changing the P1 set points and using a global orbit configuration to close the bump, keeping the P1 errors close to zero. The model orbit bump method (as used in the aperture scan) would be preferred since BPMs are not as accurate as correctors. However, the set point method was more straightforward given that it permitted a more complex orbit bump that did not also steer the beam in the BM (see next section). In this case, the image-current resistive-wall heat load dominates. The net resistive-wall heat load increases when the chamber is not centered in the chamber. Therefore, the sensor temperature variation can be used to determine the center of the chamber with respect to the user beam orbit. To maximize the effect, a relatively high image-current heat load is preferred (high bunch current). At the same time, to minimize the risk of accidentally steering high total bending-magnet radiation heat load into the chamber, low current, 25 mA, was used in 24 bunches. Figure 2 shows a typical measurement at sensor 3. The equilibrium temperatures for different vertical orbit offsets were fit to a parabolas to find the minima.

The effect of moving the beam vertically off the median plane was analyzed using the method of images in a planar geometry [4]. The surface current density variation was computed as a function of beam offset. The total power in both walls was then computed and normalized to the total power at zero beam offset. To compare with the data, the measured sensor temperature rise was converted to power using the chamber heater calibration [5]. The agreement is very good (see Fig. 3).

The SCU0 chamber vertical alignment as measured by the chamber thermal sensor minima is shown in Fig. 4. The accuracy is about ±100 μm. The original alignment (black) revealed an offset of 0.3-0.5 mm with respect to the user beam orbit. Partial in-tunnel realignment (red) reduced the offset to < 0.3 mm. Measurements after six months of operation (blue) show that the chamber position remains stable. In addition to the high accuracy, this method isolates the SCU0 alignment from other vacuum components and provides longitudinal spatial resolution limited only by the sensor spacing.

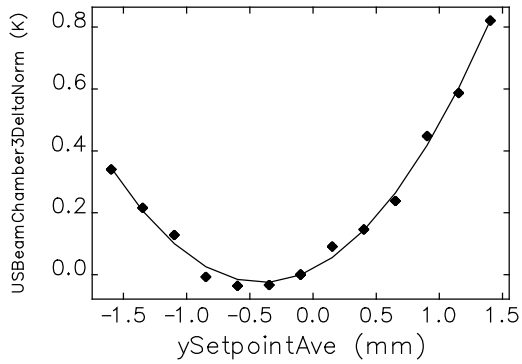

Figure 2: Temperature variation at sensor 3 with vertical beam steering in SCU0.

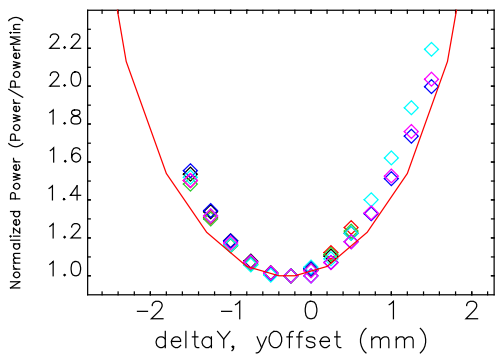

Figure 3: Normalized heat load using calibrated chamber temperatures (sensors 3-5) as a function of the vertical beam offset in the SCU0. The red line shows the theoretical normalized total power (offset by -0.3 mm).

BM STEERING

The availability of thermal sensors on the SCU0 chamber allows a measurement that is rather unique. With perfect alignment and vertical beam steering exactly at the midplane in the main bending magnet (BM), the out-of-plane BM radiation power on the SCU0 chamber is only ~0.2 W. However, vertical ray tracing [6] and photon beam power calculations [7, 8] show that significant synchrotron radiation power (10s of W) can intercept the chamber when the beam is steered in the bending magnet, which steers the photon beam. Studies of BM steering serve two purposes: to measure the relative alignment between the BM and the SCU0, and to establish allowable limits on the photon beam steering.

In order to minimize the image-current heating of the SCU0 chamber by the beam, low bunch current was used (324 bunches). The global orbit configuration was set up to steer the BM exit source point while keeping the ID/SCU0 source point fixed. To limit the maximum BM power to below ~30 W, the beam current was limited to 20 mA. Figure 5 shows a typical measurement at sensor 6. The data show a vertical chamber displacement consistent with ID beam steering (see Fig. 2). The data also show that vertical beam offsets of less than ±1 mm at the BM exit give relatively small temperature increases. Larger steering can potentially steer x-rays in the BM radiation centroid into the SCU0 undulator core, which should be avoided.

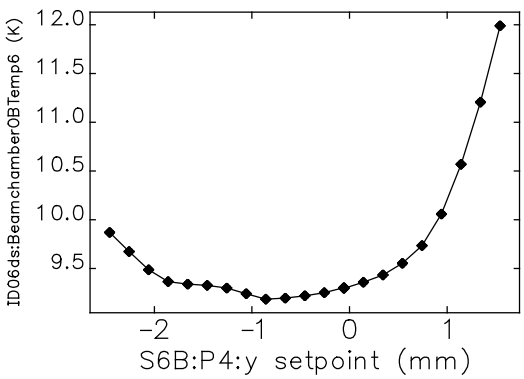

Figure 5: Temperature at sensor 6 with vertical beam steering in the BM.

SUMMARY

The beam was used to measure the alignment of the beam vacuum chamber of the test superconducting undulator (SCU0) at APS using two different methods. A conventional aperture scan confirmed that the overall alignment of ID6/SCU0 was consistent with a well-aligned ID chamber. Beam-based alignment was also carried out using thermal sensors mounted on the SCU0 chamber. The thermal sensor method allowed the vertical chamber alignment to be measured with 100-μm accuracy, which is 10 times higher than the aperture scan. After partial in-tunnel realignment, the SCU0 chamber was confirmed to be aligned to within 0.3 mm, and its position has remained stable over six months of operation. Steering the beam in the BM gives vertical chamber offsets that are consistent with steering in the SCU0, and confirms good relative alignment between the SCU0 chamber and the BM source. Standard beam orbit control and a beam position limiting detector interlock are implemented during SCU0 operation.

ACKNOWLEDGMENT

The authors wish to thank APS staff who contributed to the SCU0 project, especially in the following areas—alignment: J. Penicka, W. Jansma, S. Wesling; installation: J. Gagliano, J. Hoyt, R. Bechtold; wiring: S. Bettenhausen; and design: D. Skiadopoulos, E. Trakhtenberg.

FAST-SWITCHING VARIABLY POLARIZING UNDULATOR*

M. Jaski, R. Dejus, B. Deriy, E. Moog, I. Vasserman, J. Wang, A. Xiao, E. Gluskin
Advanced Photon Source, Argonne National Laboratory, Argonne, Illinois 60439, USA

Abstract

Development of a new fast-switching electromagnetic variably polarizing undulator (EMVPU) is underway at the Advanced Photon Source (APS). The EMVPU can produce x-rays with left- and right-handed circular polarizations and horizontal and vertical linear polarizations in the energy range 400-2000 eV. The undulator will be able to switch between left- and right-handed circular polarizations at 10 Hz, fast enough to allow for magnetic circular dichroism studies that rely on lock-in amplifier techniques. The handedness switch will be accomplished by switching only the vertical component of the field while the horizontal component stays constant. Details of the EMVPU and its initial experimental test models are presented.

INTRODUCTION

The new EMVPU will join other all-electromagnetic undulators that are presently in use at APS—the CPU (circularly polarizing undulator) [1], with Eγ ≥ 500 eV and 1-Hz switching, that has been in operation since 2001; and the recently installed IEX undulator, a quasi-periodic variably polarizing undulator (Eγ ≥ 250 eV) that was designed and built at the APS [2] and commissioned successfully in 2012 [3]. The EMVPU, like those devices, will provide linear polarization (horizontal and vertical) and circular polarization (right- and left-handed) capabilities, but adds the capability of switching the circular polarization handedness at 10 Hz (with an 80% duty cycle), faster than previously available at APS. Fast-switching undulators are also in operation at ESRF [4] and SOLEIL [5] using a combination of electromagnets and permanent magnets.

The requirement for rapid handedness switching of the circular polarization is driven by the users' need to use lock-in detection for their magnetic scattering experiments. They require ample time between handedness switches—time when the photons produced are of the desired energy and polarization and when measurements can be made with a stable photon beam. Not only must the current in the coil stabilize to its new value rapidly, but any eddy currents and associated stray fields induced by the switching must be minimized.

In order to achieve fast switching in the EMVPU, the vertical (By) field coils are single-turn coils machined from a solid piece of copper. This minimizes the coil inductance to allow for the fastest possible switching speed. One-turn coils also provide right/left symmetry near the pole tips, reducing undesirable magnetic multipoles. Transient fields during the switching must also be minimized. Laminated cores minimize eddy currents in the By poles. Eddy currents in the vacuum chamber can significantly slow the switching speed so a vacuum chamber material with low electrical conductivity must be used. Any residual e-beam steering or multipole transients will be compensated during switching using corrector magnets on each end of the device.

PARAMETERS

Table 1 lists selected parameters for the EMVPU.

Table 1: Selected Parameters

Parameter	Value	Unit
Period	12.5	cm
Gap	8.5	mm
Maximum effective field for linear polarization (horizontal or vertical)	3491	Gauss
Maximum effective field for circular polarization	2469	Gauss
Switching speed between right- and left-handed circular polarization	10	Hz

ONE-PERIOD TEST MODEL

General Concept

Figure 1 shows the general layout of the Bx and By coils, poles, and core for the lower jaw of the one-period test model. The upper jaw has similar geometry. The By coils are single-turn coils machined from oxygen-free copper. The By core is made from 0.64-mm-thick M-22 silicon steel laminations with a C5 coating. The laminations are laser-cut and epoxied together. The epoxy-impregnated Bx coils have 46 turns of square copper solid wire [6]. The Bx poles are made of heat-treated vanadium permendur, chosen because it gives 5% higher field than low-carbon steel. The Bx core is low-carbon steel with slots for stainless steel cooling-water tubes. These cooling-water tubes cool the Bx core, which cools the Bx poles; both in turn cool the Bx coils.

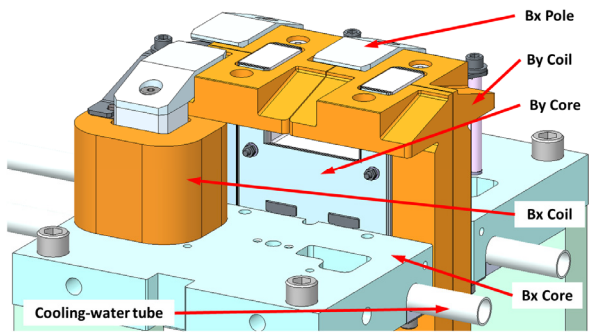

Figure 1: A 3-D CAD model of the one-period test model lower jaw (one Bx coil/pole assembly is hidden to show the By core).

Figure 2 shows a close-up of the one-period test model. The By coils are soldered to bus bars, after being tin plated to ease the soldering. The bus bars are water cooled

with deionized cooling water and in turn cool the By coils.

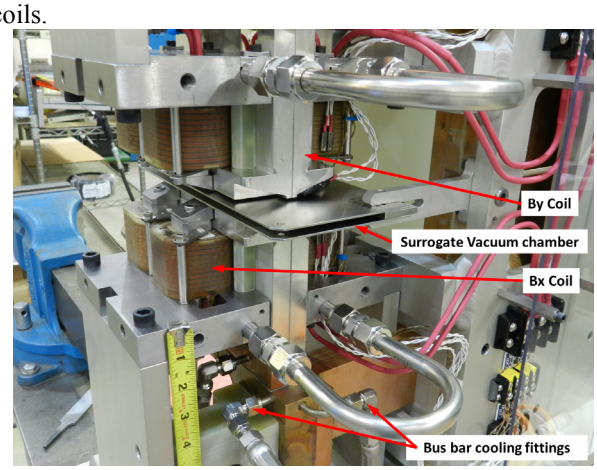

Figure 2: One-period test model.

Thorough testing of the switching speed of the one-period test model requires that the vacuum chamber be present so the eddy currents in the vacuum chamber can be properly taken into account. The final vacuum chamber will be made of stainless steel with a copper coating on the inside. For these tests, a surrogate vacuum chamber was used that would allow side insertion of a Hall probe for magnetic field measurement. The surrogate chamber, seen in Figure 2, is made from two pieces of 1.5-mm-thick 316 stainless separated by a 5-mm gap. The stainless steel pieces are plated with a 75-micron-thick copper strip on the inside.

Measured Field

The final power supply for the EMVPU is not yet available, so the original CPU power supply [7] was used for the testing. Switching rates as high as 10 Hz at 1400 amperes were achieved with the test model, as shown by the measured vertical peak field in Figure 3. The Hall probe was positioned inside the surrogate vacuum chamber. The rise time of the current was 16 ms; the rise time of the field was also 16 ms, showing that the limitation on rise time comes from this power supply rather than the device.

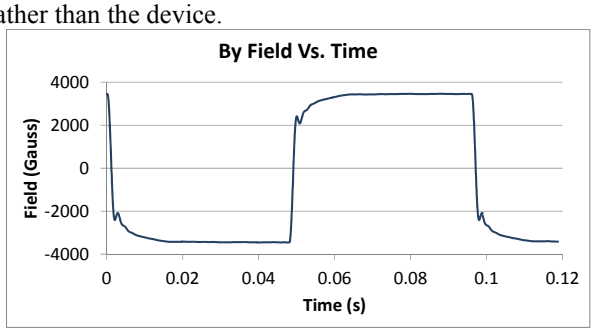

Figure 3: Time-dependence measurement of a one-period test model. The vertical field was ±3500 Gauss, switched at 10 Hz.

Solder Joint

The bus-bar solder joints are produced with a 50-micron-thick Sn60Pb40 (60/40) solder sheet, chosen because it has a melting temperature of 220°C as compared to over 500°C for silver solders. Because soldering needs to be done while the bus bars are assembled on the core, the lower temperature reduces the possibility of the core warping. All solder joints are assembled with a screw and spring washers. The spring washers take up the excess space produced as the solder melts. The joint screws are re-torqued after soldering to provide a full-contact solid joint. Figure 4 shows the solder joints of the By coils to the bus bars. The air gaps are filled with Nema Grade G-10 sheets after soldering.

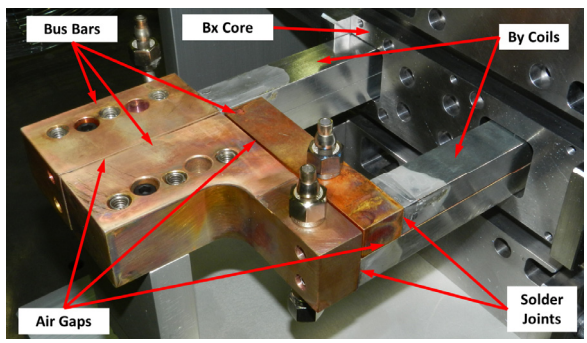

Figure 4: Solder joints of the By coils to the bus bars.

Simulated forces on the By coils and solder joints during switching are less than 1.8-kg force. A stress test was performed on the one-period test model to show how the coil supports and solder joints hold up. A nine-hour run with a current of 1400 amperes at 6 Hz was completed. There appeared to be no effect at all from the test.

FOUR-PERIOD TEST MODEL

A four-period test model is now under development at the APS. Figure 5 shows the model used for magnetic field analysis [8]. A new power supply is also under development at the APS. The new power supply will switch the current from -1400 to 1400 amperes within

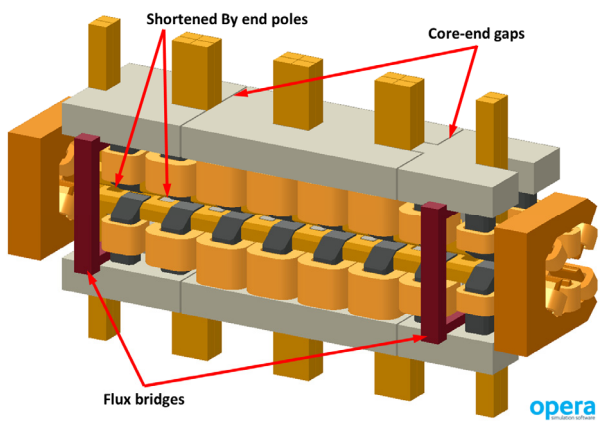

Figure 5: Magnetic field analysis model of the four-period test model.

Copyright © 2013 CC-BY-3.0 and by the respective authors

6 ms. This will allow the field to fully switch within 10 ms (determined from simulations), giving the user 40 ms to take data between each switching event (80% duty cycle).

The two By end poles on each end are shortened vertically to produce the ¼-¾ full-field configuration on each end that minimizes the first and second integrals (i.e., keeps the horizontal beam steering straight and on axis). Simulations guided the addition of flux bridges and 2-mm-wide gaps in the core near the ends to reduce the large horizontal missteering during switching of the By field. An initial missteering of up to 180 micro-radians was reduced to less than 75 micro-radians. Fast end corrector magnets will correct the remaining missteering.

The ¼-¾ full-field configuration is achieved for the Bx field at each end by reducing the number of turns on the end Bx coils and also by shortening the Bx pole tips horizontally. Any further correction will be done with the end corrector magnets.

Figure 6 shows a 3-D CAD model of the four-period test model without the support frames. Corrector magnets with six laminated poles and separate power supplies for each coil are included at the upstream and downstream ends of the device. Table 2 gives the maximum integrated multipoles that each corrector magnet can produce. The horizontal dipole also comes with a skew sextupole component (66 G/cm). This additional skew sextupole component is used to correct the integrated skew sextupole component through the whole device, as was done for the electromagnetic variably polarizing quasi-periodic (IEX) undulator [2, 3].

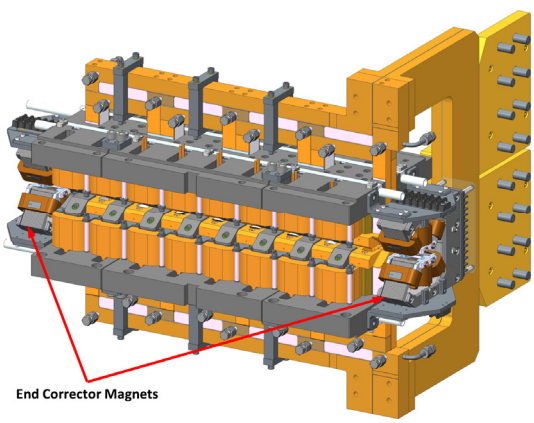

Figure 6: A 3-D CAD model of the four-period test model.

Table 2: Corrector Magnet Maximum Integrated Multipoles

Multipole	Value	Unit
Vertical dipole	958	G-cm
Normal quadrupole	469	G
Normal sextupole	569	G/cm
Horizontal dipole	653	G-cm
Skew quadrupole	69	G
Skew octupole	27	G/cm^2

VACUUM CHAMBER

APS typically uses aluminum insertion device vacuum chambers, but simulations show that the fastest possible switching through an aluminum vacuum chamber is 30 ms, due to the high electrical conductivity and resulting eddy currents in the Al. Figure 7 shows the simulated eddy currents in an aluminum vacuum chamber 130 microseconds after the start of switching.

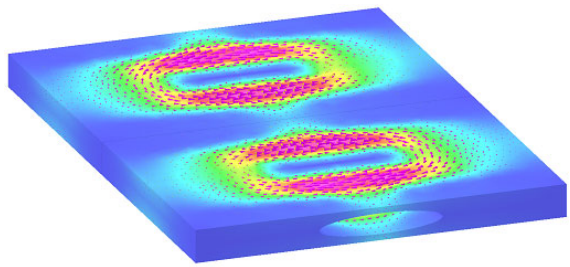

Figure 7: Simulated eddy currents in an aluminum vacuum chamber.

Stainless steel is much less electrically conductive than aluminum, reducing the switching time to 10 ms. The inside wall of the chamber must retain high conductivity, however, to minimize the resistive-wall impedance seen by the electron beam. Therefore, the inside wall will be coated with 75 microns of copper. Simulations show that a 75-micron Cu coating has a negligible effect on the switching speed. Further investigation into a stainless steel copper-coated insertion device vacuum chamber is ongoing at the APS.

Abstract

An electromagnetic variably polarizing quasi-periodic undulator was installed in the Advanced Photon Source (APS) storage ring in April 2012 and has been successfully commissioned with stored beam. This device is identified as the Intermediate Energy X-ray (IEX) undulator. The IEX undulator takes its name from the IEX beamline where it is installed. The IEX undulator is able to produce a variety of polarizations: linear vertical, linear horizontal, and right- or left-handed elliptical or circular. Ten pairs of poles, distributed quasi-periodically along the undulator length, are powered separately, allowing the field strength of the quasi-periodic poles to be adjusted. This adjustability allows the user to seek a balance between the suppression of the higher harmonics and the loss of flux in the fundamental that best suits the measurement being made. The IEX undulator has a 12.5-cm period and can achieve photon energies as low as 250 eV in horizontal polarization and 440 eV in vertical polarization. A description of the IEX undulator will be presented.

INTRODUCTION

The IEX beamline team, consisting of APS staff members along with researchers from the Universities of Illinois at Chicago and at Urbana-Champaign, is commissioning a new dual beamline with one leg dedicated to angle-resolved photoemission spectroscopy (ARPES) measurements and the other dedicated to resonant soft x-ray scattering (RSXS) [1]. The undulator needs to provide photons ranging from 250 to 2500 eV, with horizontal and vertical linear, and left- and right-circular and elliptical polarizations. (Vertical linear polarization only goes as low as 440 eV.) The presence of high harmonics in the spectrum degrades the signal-to-noise ratio in both techniques, so a quasiperiodic undulator is sought for its ability to shift the high harmonics in energy so they are eliminated by the beamline optics.

Several possible variably polarizing undulator designs were considered, including an Apple II (all permanent magnet), an electromagnetic/permanent magnet, and an all-electromagnetic design similar to the circularly polarizing undulator (CPU) [2] presently installed at the APS. The all-electromagnetic design was chosen, largely because of its ability to vary the magnetic strength reduction in the quasiperiodic poles so trade-offs could be made between additional high-harmonic reductions at the expense of a loss in photon beam intensity. Magnetic field simulation and optimization [3] were done, and prototypes were built and tested before building the full-length device. The full-length device was successfully commissioned at the APS in 2012 [4].

PARAMETERS

Table 1 lists selected parameters for the IEX undulator.

Table 1: IEX Undulator Selected Parameters

Title	Description	Value	Unit
General	Period	12.5	cm
	Gap	10.5	mm
	Periods per device (including end poles)	38	periods
Horizontal Linear Polarization	Minimum photon energy	240	eV
	Measured maximum vertical effective field	4614	Gauss
Vertical Linear Polarization	Minimum photon energy	440	eV
	Measured maximum horizontal effective field	3312	Gauss
Circular Polarization	Minimum photon energy	234	eV
	horizontal and vertical effective field	3312	Gauss

DESIGN AND ASSEMBLY

Figure 1 shows the IEX undulator at the magnetic measurement bench. The device is 958 mm wide × 2118 mm tall × 5044 mm long (37.7" × 83.4" × 198.6") and weighs 6350 kg (14,000 lbs). Casters attached to the base allow it to be manually rolled across a flat concrete floor by six people. The undulator is installed onto floor bases that are grouted to the floor. The undulator gap is fixed at 10.5 mm. The jaw assembly is mounted to high-precision linear roller bearings and can manually be moved

Figure 1: The IEX undulator at the magnet measurement bench.

horizontally in and out of operating position, allowing for well-controlled alignment of the fixed gap around the vacuum chamber during installation. There are fine adjustments for longitudinal, vertical, and horizontal positions as well as roll, pitch, and yaw. The undulator is designed with a calculated mechanical fundamental natural frequency of 34 Hz.

Figure 2 shows the coil and pole arrangement for a single jaw. There are a total of 304 B_x (horizontal field) poles and 152 B_y (vertical field) poles. The coils are vacuum impregnated with epoxy [5].

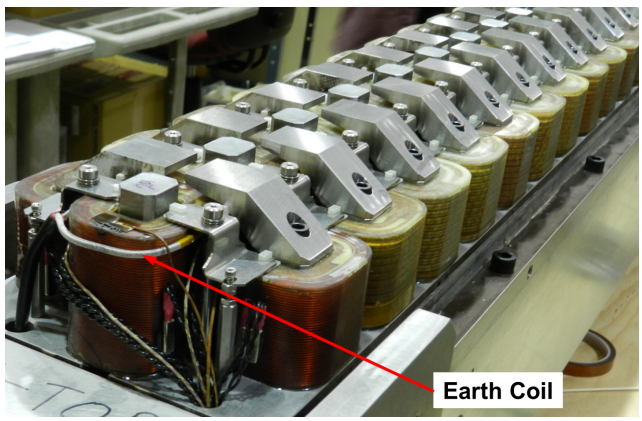

Figure 2: Top jaw coil and pole configuration. The centered vertical field poles alternate with pairs of horizontal poles along the undulator axis. The bottom jaw configuration mirrors this arrangement.

CORRECTOR COILS

End Coils

To minimize the first and second field integrals through the ends of the undulator, fewer turns are used in the endmost coils at both ends. The strength of the last pole is ¼ and the next-to-last pole is ¾ of full field. This leaves room around the end poles to add corrector windings. Six corrector coils are supplied on both the upstream and downstream ends of the undulator to provide a means for electron beam steering and multipole control. Figure 3 shows the configuration of the upstream corrector coils. The coils are labeled top (T), bottom (B), and quadrants Q1, Q2, Q3, and Q4. To minimize the imbalance between the 25% and 75% end poles that causes flux leakage into the full-field poles, a flux bridge is added on each end.

Each corrector coil has its own power supply. Figure 4 shows the coil field directions needed to obtain the various multipole moments. Table 2 lists the maximum achievable integrated multipole corrections, where the limit is imposed by the power supply and by the coil becoming hot. These corrections are more than was needed to meet specifications so the coil currents were limited to 20% of the maximum.

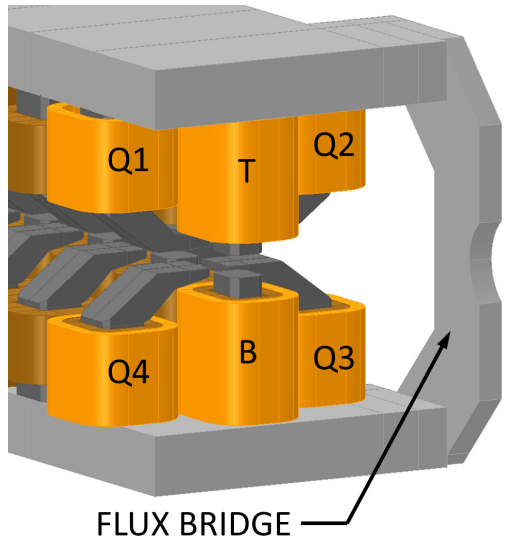

Figure 3: Configuration of the upstream corrector coils.

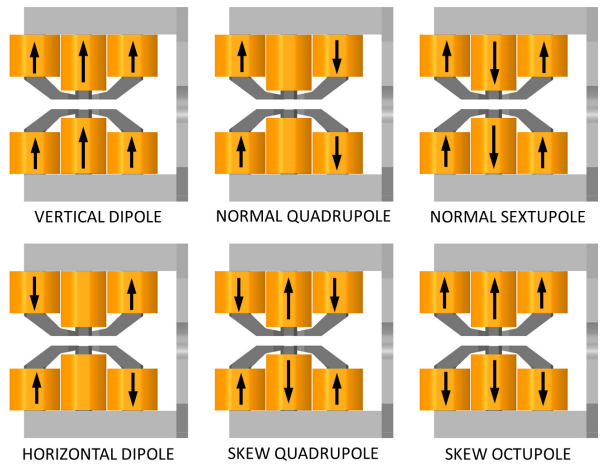

Figure 4: Coil field directions for the various multipole moments.

Table 2: IEX Undulator Maximum Achievable Integrated Multipole Corrections from the Corrector Coils

Multipole	Value	Unit
DS Horizontal Dipole	9021	G-cm
DS Vertical Dipole	13153	G-cm

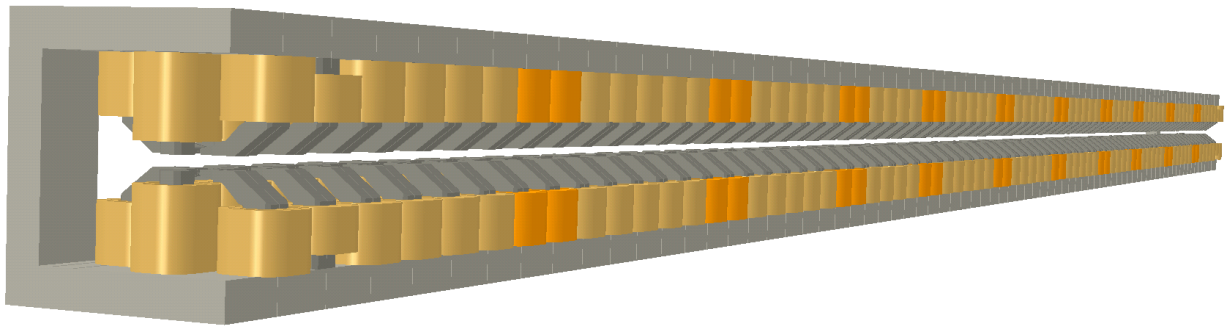

Figure 5: IEX undulator quasi-periodic pole positions.

Skew Sextupole Correction

An integrated skew sextupole component that was out of specification was discovered during magnetic simulations. No combination of end correctors provides a correction that is mainly skew sextupole, but the horizontal dipole corrector also produces a small skew sextupole component. The relative amounts of horizontal dipole and skew sextupole were adjusted by shortening the tips of the downstream horizontal dipole end poles, then increasing the current in those coils. A series of simulations was used to minimize the skew sextupole component.

Earth Coil

An earth coil is provided to compensate for the earth's magnetic field. The earth coil consists of a one-turn coil around the B_y poles on both the top and bottom jaws. The top jaw portion of the earth coil can be seen in Figure 2. The earth coil can supply an integrated B_y field up to 3900 G-cm. This is more than enough to correct the earth's field along with the approximately four-fold enhancement by the steel poles.

THERMAL

The coils are indirectly water cooled. Water lines directly cool the cores. The poles are bolted to the cores, and the coils are epoxied to the poles to ensure good thermal contact. At full power the device operates at 12,000 W; 9,500 W is removed by water cooling. The remaining 2,500 W is removed by air cooling. Blowers and a baffle draw air over the coils and exhaust the warm air (2,500 W) directly into the storage ring tunnel air handling exhaust. This immediately removes the heat from the tunnel so it will not interfere with storage ring tunnel temperature control. The heat loads given above were empirically obtained by building and testing a four-period test model.

QUASI-PERIODICITY

Quasi-periodicity suppresses the higher-order radiation harmonics [6]. The IEX undulator is supplied with quasi-periodic capabilities in both horizontal and vertical polarizations. For a 38-period undulator there are 76 pole sets (two pole sets per period). Coils are numbered 1 to 76. The quasi-periodic coils for the IEX undulator are 7, 8, 14, 15, 20, 21, 27, 28, 34, 35, 40, 41, 47, 48, 54, 55, 61, 62, 67, and 68. Figure 5 shows the configuration of the quasi-periodic coils. The B_x quasi-periodic coils are connected in series and have their own power supply. The remaining B_x coils are connected in series and have their own separate power supply. Similar connections are done for the B_y coils. The quasi-periodic coils can be operated at a reduced current (~85%) that will shift the higher spectral harmonics to a lower energy.

POWER SUPPLIES

Seventeen power supplies are required to operate the IEX undulator: B_x and B_y main power supplies, B_x and B_y quasi-periodic power supplies, twelve end-coil power supplies, and one Earth-coil power supply. Each power supply is bi-polar to allow for degaussing.

DESIGN OF A 17.2-MM-PERIOD PLANAR UNDULATOR FOR THE APS *

E.R. Moog#, M. Abliz, R.J. Dejus, J.H. Grimmer, and M. Jaski, ANL, Argonne, IL 60439, USA

Abstract

The design process for a short-period planar undulator is described. This is a conventional planar design based on Nd-Fe-B magnets and vanadium permendur poles. The period length was driven by the users' request for a high flux of photons at 23.7 keV, with minimal tuning range. A shorter period gives higher flux; 17.2 mm was the shortest value consistent with the gap limitations of the vacuum chamber and with reaching the desired photon energy. Details of the design, especially the various chamfers of edges of the magnet and pole, were examined more closely than has been the standard past practice in order to minimize the period length.

INTRODUCTION

The majority of the insertion devices at the Advanced Photon Source (APS) are of the planar permanent magnet hybrid type, and a variety of period lengths have been installed. This 17.2-mm-period undulator will have the shortest period; it is being designed to meet the specific needs of a group of users who want to maximize their photon flux at 23.7 keV without any need for a significant tuning range. The ideal choice for such a short-period undulator would be to use superconducting technology, but that technology is only now being commissioned at the APS [1]. It will be several years before a customized device can be designed and built for these users. They have opted not to wait.

Keeping the beam impedance from the insertion device vacuum chamber walls low results in a minimum gap for the undulator of 10.4 mm (with a new ID vacuum chamber that is in the design stage; the present typical minimum gap is 11.0 mm). This, combined with the 23.7 keV desired energy, means that the operating point of the undulator is not at the peak in the tuning curve but rather on a slope where a small change in undulator period can have a noticeable effect on the on-axis flux, as shown in Fig. 1 where there is a 15% flux increase between the 17.5 and 17.2-mm period lengths. Shortening the undulator period gives more flux, until the field strength needed to reach the desired energy no longer lies within the achievable gap range. The steepness of the tuning curve for this design project places a high premium on achieving the shortest period possible, and the need for a single specific photon energy means that the magnetic field cannot be lower than expected. To add to the challenge, the required undulator field increases as the undulator period decreases, while a decrease in period generally comes with a decrease in field.

CHOICE OF MAGNET GRADE

The considerations that drive the choice of a magnet grade are the remanent field B_r and the coercivity H_{cJ} of that grade. Recent magnet grades used for APS undulators are Shin-Etsu's N39UH and N42SH. With $B_r \geq 12.7$ kG and $H_{cJ} \geq 21$ kOe, N42SH has been used when the highest field strength was needed. Otherwise, N39UH with $B_r \geq 12.2$ kG and $H_{cJ} \geq 25$ kOe has been chosen for its higher coercivity.

The higher coercivity is desirable for two reasons: 1) for a particular demagnetizing field in the magnet, the higher-coercivity magnet can survive higher temperatures without ill effects, and 2) the higher coercivity correlates with higher resistance to radiation-induced demagnetization. Magnets of either grade, when installed in an undulator whose magnetic design considerations include maintaining a moderate demagnetizing field, will survive a hot day with broken air conditioning. Radiation susceptibility is harder to quantify because of many unknowns, including the spectral sensitivity of the magnets and the spectral distribution of the radiation at the magnets' locations. At the APS, except for two extremely high-dose sectors, the undulators have not been affected by radiation enough to affect users' programs, though small effects have been seen. A common difference between the maximum demagnetizing field and the magnet's H_{cJ} has been ~4 kOe, so a goal is to keep the demagnetizing field at least that far below H_{cJ}. For this short a period, a higher H_{cJ} than N42SH is not necessary.

The magnet grade characteristics given here are from the manufacturer's data sheets and are for 20°C. The temperature of the APS storage ring tunnel, however, is 25°C. Since the on-axis field in the simulations must be met in the real device, the reduction in the manufacturer's B_r due to the higher temperature must be taken into

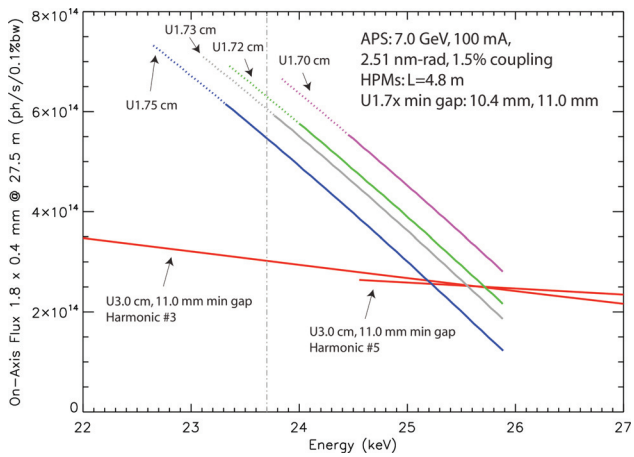

Figure 1: Tuning curves over a narrow photon energy range, for a few period lengths. The solid lines are for a minimum gap of 11 mm; the dotted extensions are for a reduction to 10.4-mm gap.

Copyright © 2013 CC-BY-3.0 and by the respective authors

account. Thus the B_r used in magnetic design calculations is 12.63 kG, after applying the -0.11%/K thermal coefficient correction.

DESIGN PROCESS

In order to finalize the period length, a series of quick calculations was carried out to determine approximately what field strength could be obtained from a variety of period lengths. Both 2-D and 3-D modules from the Vector Fields suite of magnetic design codes [2] were used. The only optimization was to ensure that the relative thicknesses of magnet and pole were close to optimal. From these results, a period length of 17.2 mm was chosen (see Fig. 1). The field requirement would be met with the new ID vacuum chamber; it might be met if a gap smaller than 11 mm could be achieved with the present chamber and if the delivered magnets are stronger than the minimum for the magnet grade.

2-D Design Work

Some initial magnetic design tasks can be carried out using the 2-dimensional codes. The calculations are slightly quicker and the optimization of the chamfering was found to be somewhat quieter than in 3-D. The results were later confirmed in 3-D.

The 2-D magnet model is shown in Fig. 2. The entire non-air part of the model is shown along with an inset showing an enlargement of the gap region. (The entire model includes more air on the non-gap side—enough so the boundary condition there doesn't matter.) Symmetry conditions allow just the quarter-period section shown, with only one jaw, to be calculated. Perpendicular field boundary conditions are applied along the beam axis (i.e., the undulator midplane) and the top boundary, which is the center of the magnet in the beam direction. The lower boundary (the center of the pole) has the magnetic field parallel to the boundary. The pole protrudes into the gap beyond the magnet, leaving a 0.5-mm magnet recess space available for shims to be placed during magnetic tuning of the completed undulator without affecting the minimum undulator gap. This space is needed despite its cost in on-axis field. A small air gap of 0.08 mm is allowed between the magnet and pole, reflecting the tolerance in the magnet and pole dimensions. The chamfers on the corners of the magnet and pole can also be seen.

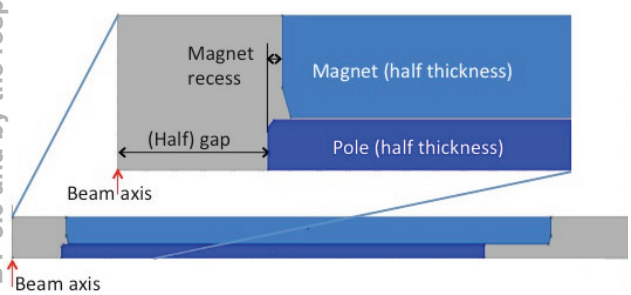

Figure 2: The two-dimensional magnetic model is shown at the bottom, with additional air space at the right omitted. The top section is an enlargement of the gap region, showing the chamfers and the thin air gap between magnet and pole.

The goal of the magnetic design is to maximize the on-axis field of the undulator while not allowing the demagnetizing field in the magnet (the H component parallel to the beam axis, since the magnetization direction of the magnet is parallel to the beam axis) to become too large compared to the magnet grade's H_{cJ}.

The field strength is very sensitive to the thickness (in the beam direction) of the magnet and pole, so it is optimized first. It is also rechecked last, once everything else has been set. Model calculations as a function of magnet thickness find an optimum peak field on axis at a magnet thickness of 5.67 mm. The peak field changes by 1 in 1000 at a thickness change of ±0.047 mm, leading to a tolerance on magnet thickness of ±0.05 mm. (The final recheck of the magnet thickness resulted in an adjustment to 5.63 mm. The pole thickness then becomes 2.81 mm.)

There isn't an optimum magnet height—a taller magnet will always give more field, albeit with diminishing returns, as long as the pole height is sensible. Therefore, the height chosen for the magnet, 52.5 mm, was the tallest that would fit without any redesign of the strongback or gap separation mechanism and without reducing the maximum achievable gap.

The pole height was adjusted to maximize on-axis field, giving a height of 45 mm. This is a broad maximum—it takes a 3-mm change to change the peak by 1 in 1000.

The remaining parameters to set using the 2-D model are the chamfers. There are four parameters to set: the y (vertical) and z (beam direction) dimensions on both the pole and magnet. An attempt to use the Optimizer module from Vector Fields [2] to set all four parameters at once was unsuccessful, but showed that the largest on-axis field was for the least pole material removed by the chamfering. Following the mechanical engineers' advice that the edges should be broken at least slightly, both pole chamfer dimensions are set to 0.15 mm.

Setting the magnet chamfers involves a trade-off between the on-axis field and the demagnetizing field inside the magnet. The surface plots in Fig. 3 show the behavior of both as a function of the magnet chamfer z dimension, Chzz, and the magnet chamfer y dimension, Chzy. (The z in the name is a reminder that this is a chamfer on the edge at the z end of the magnet. The chamfer at the x end will be considered below.) The top panel shows the effective field $B_{y\,eff}$ as a function of the chamfer dimensions. A ridge of higher field can be seen, with a sharper drop-off on the right side in the figure. The lower panel shows the worst value of the demagnetizing field in the magnet block, with the value closest to zero being desirable. It too shows a ridge, but one that runs perpendicular to that in the top panel. Originally the red point was chosen, where the two ridges cross. A slightly higher $B_{y\,eff}$ (by ~1 G) could be reached, but the decision was made to save a few kOe instead. Later, concerns were raised that the zz chamfer was too long to allow shims to be placed stably on the magnet faces, so Chzz was

Copyright © 2013 CC-BY-3.0 and by the respective authors

reduced to 0.5 mm. This change reduced the field by 0.9 G, a negligible amount, and made $H_{z\,max}$ worse by 660 Oe.

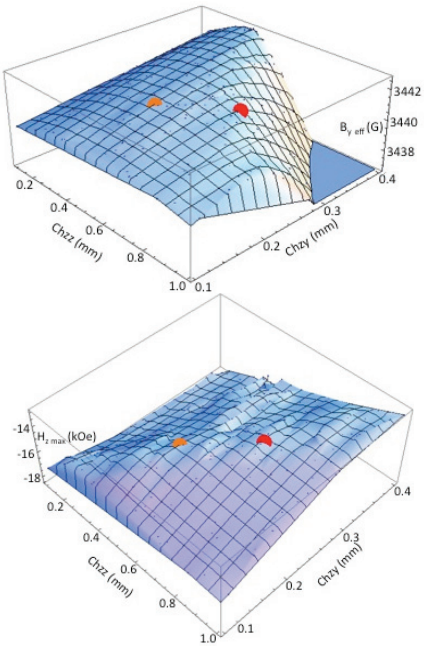

Figure 3: Surface plots showing the dependence of the effective field $B_{y\,eff}$ (top) and the strongest demagnetizing field in the magnet block $H_{z\,max}$ (bottom) on the chamfer dimensions in z, Chzz, and in y, Chzy. The red point, at (Chzz, Chzy) = (0.73, 0.26) mm was initially selected. Undulator tuning considerations prompted a change to the orange point at (Chzz, Chzy) = (0.5, 0.2) mm.

3-D Design Work

The aspects of the design that must be done using 3-D codes are those that involve the roll-off of the on-axis field in the lateral (x) direction, the widths of the magnet and pole in x, and the chamfers at the x end of the magnet and pole.

The 'good-field' region in the undulator is ±5 mm in x to allow for steering of the beam through the undulator and for beam displacements during injection. The roll-off is the peak-to-peak change of field over the range from -5 to +5 mm in the x direction, at the center of the pole in z. The limit on the field roll-off is set by requiring that the photon energies from electrons traveling within the 'good-field' region are the same as far as the user can tell, or specifically, to within 10% of the intrinsic width of the 3rd harmonic. (The roll-off is not used to limit the integrated multipole moments; those are separate requirements.) The full width at half maximum of the 3rd harmonic for a 4.8-m-long undulator is $\Delta E_\gamma/E_\gamma = 5.54*10^{-3}$, and for a 2.4-m-long undulator it is $7.10*10^{-3}$. These translate to $\Delta B/B$ = 0.0019 or 0.0024. For B ~3460 G, the roll-off limit becomes 6.6 to 8.3 G.

The width of the pole is limited by the need to fit around the vacuum chamber, with some allowance for clamping, so 44 mm is chosen, the same as many of the recent APS undulators. As with the magnet height, the on-axis field keeps growing the wider the magnet. The limit on the width then becomes what fits with the existing vacuum chamber. Sixty-seven mm is chosen; at that width any gain from a wider magnet is diminishing anyway. The chamfers at the x edge of the magnet are entirely determined by engineering requirements for the clamping scheme and fitting around the vacuum chamber.

The chamfer on the x edge of the pole remains to be set. The surface plots in Fig. 4 show the effects of the x and y dimensions of the chamfer (Chxx and Chxy, respectively) on the effective undulator field (top) and on the field roll-off (bottom). As the x chamfer dimension becomes larger, the pole is effectively narrowed and the on-axis field grows. As the pole narrows, there is initially no effect on the roll-off, but then the roll-off begins to grow rapidly. The red dot marks the selected pole x chamfer dimensions (Chxx, Chxy) of (7, 4) mm. There is noise on the right side of the roll-off plot, probably due to a meshing issue, but since its level is ~1 G it was not pursued.

The production of the 17.2-mm-period undulator is now underway.

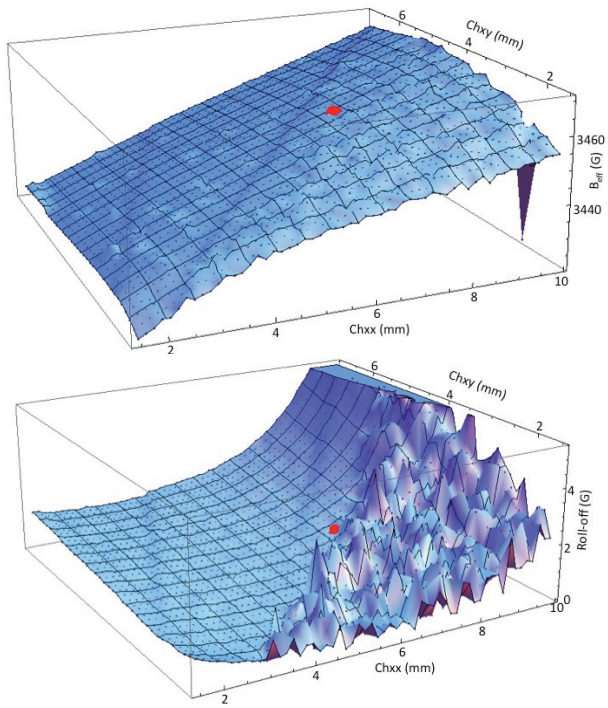

Figure 4: Surface plots showing the dependence of the effective field (top) and the field roll-off (bottom) on the chamfer dimensions in x, Chxx, and in y, Chxy. The red point, at (Chxx, Chxy) = (7, 4) mm is the selected value.

THE INTERMEDIATE-ENERGY X-RAY (IEX) UNDULATOR COMMISSIONING RESULTS *

A. Xiao, M. Abliz, B. Deriy, M. Jaski, M. Smith, I. Vasserman, J. Xu
Argonne National Laboratory, Argonne, IL 60439, USA

Abstract

Strong beam perturbation from the intermediate-energy x-ray (IEX) undulator operation has been expected from the beginning. This paper describes our efforts including the initial magnet design, field measurements and compensation, special considerations of power supplies and the control system, and the final commissioning results with beam. Perturbations are well within the specified limits, and the IEX was made ready for user operation in less than six months.

INTRODUCTION

A 4.8-m electromagnetic undulator was designed, built, and installed at the APS to provide the Intermediate-Energy X-ray (IEX) beamline with variably polarized radiation. Details on the device itself are presented separately [1]. The main parameters of this device are listed in Table 1. Simulation results show that strong nonlinear fields are present in this device. To eliminate beam perturbations, 13 correction coils are included, which correct stray fields, orbit, tune, coupling, and some high-order perturbations. Together with four main coils (By, By-Quasi, Bx, Bx-Quasi), there are 17 power supplies for this single device. Besides the complexity of the device itself, special requirements from user operations are:

Table 1: IEX Main Parameters

Title	Description	Value	Unit
General	Length	4.8	m
	Period length	12.5	cm
Horizontal Linear	Energy	0.25-3	keV
	K Value	5.271-0.694	
Vertical Linear	Energy	0.44-3	keV
	K Value	3.863-0.694	
Circular Mode	Energy	0.44-3	keV
	K Value	3.863-0.694	

- Generates four polarization modes. Horizontal- and vertical-linear modes [H/V], clockwise and counter-clockwise circular modes [CW/CCW].
- In each mode, the quasi-periodic property can be switched on and off [1].
- Precise photon energy reproducibility.
- Polarization refinement at the sample location.

* Work supported by the U.S. Department of Energy, Office of Science, under Contract No. DE-AC02-06CH11357.

To satisfy requirements on energy reproducibility, the device is required to operate on a hysteresis loop. A special magnet degaussing and conditioning procedure also needs to be followed. The device provides radiation to two beamline branches in which, due to different properties of optical elements, different IEX settings are required for different branches to reach $> 99\%$ polarization purity at the sample location.

All facts added up together made IEX commissioning a difficult task. Commissioning started on May 2012 and by November 2012 all operational modes had been successfully commissioned with beam. This paper describes details of the commissioning efforts leading to eventual success.

MAGNET DESIGN AND MEASUREMENT

The magnet design and measurement were done in close coordination with simulation work. Simulation results [2] showed this device would be the strongest nonlinear perturbation source among all IDs that have been installed in the APS storage ring. Special measures were taken during the magnet design phase, including 2×6 correction coils added to each side of the device for making further corrections.

After magnet assembly, the field was measured over the entire excitation curve for each operational mode. Unlike other ID measurements, which measure B_y only in the xz plane (y=0) — i.e., 2D measurement—both B_x and B_y fields were measured in a 3D volume. One assembly fault (a magnet block was inadvertently made from a prototype part) was found through fitting the measured field map to the design model, and corrected. After fixing the fault, the IEX was re-measured and a full set of simulation work was done using the measured field map. For these simulations [3], field data were fitted to the wiggler field expansions while measured field error was represented by a kickmap element; other machine errors were also included. Simulation results showed that the magnet quality met our expections. The simulated dynamic aperture (see Figure 1) was only slightly reduced due to the strong nonlinear field errors. This reduction was expected based on design simulations and can be mitigated using the local correction coils based on later beam test.

POWER SUPPLY

As described in the previous section, the IEX has 17 individual power supplies (PSs) to provide field excitation and local beam perturbation corrections, making it one of the single most complicated powered elements in the ring. To reduce beam perturbations, all PSs are synchronized, and

a smooth linear ramp is made in between for each current change. This feature is built into the PSs local control system. Also, to simplify and standardize the required magnet conditioning and degaussing, these features are also built into the PSs local control system. Results are shown in Figure 2.

(a) Synchronized ramp (b) Synchronized shutdown on interlock event

Figure 2: Waveform of PSs on different events.

CONTROLS

As described in the introduction, the IEX can be operated in many ways. The total operational states comprise 3 (modes, combined CW/CCW to C mode) × 2 (quasi) × 2 (direction) × 2 (beamline) = 24. Each state could generate different beam perturbations and thus needs a separate correction table. We have used a 24-page SDDS file to include all the correction tables, where each page corresponds to one operational state. In each table, there are columns containing photon energies, plus main [H/V] and Earth coil settings. These values are from magnet measurements. There are another 12 columns—6 for upstream (US) and 6 for downstream (DS)—including correctors for horizontal and vertical dipole, normal and skew quad, normal sextupole, and skew octupole. These corrector settings are beam-based and tuned to remove orbit, tune, and coupling variations from IEX operation and restore injection efficiency using higher-order correctors. The IEX local correctors are made from different combinations of the extra windings on the end poles [1]. The correction moments contained in the correction table need to be converted inside the control system before being sent to the PSs.

In summary, besides many general control tasks, the IEX control system needs to accomplish many special requirements. They are contained in the state program code, as illustrated in Figure 3, and include:

- Determine current and future IEX status.
- Choose the proper correction table.
- Convert correction moments to power supply settings and send to power supply.
- Choose the proper way to do mode switch.
- Perform magnet conditioning and degaussing.

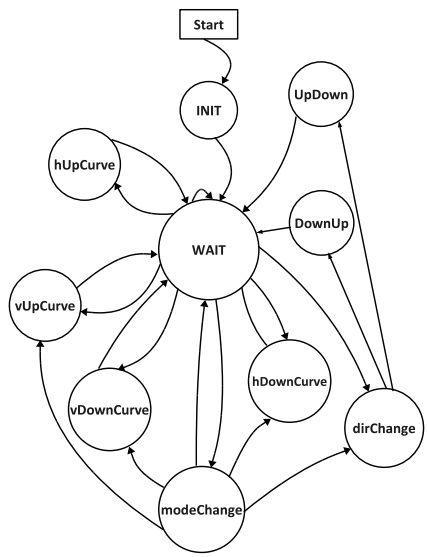

Figure 3: Diagram of IEX control state program.

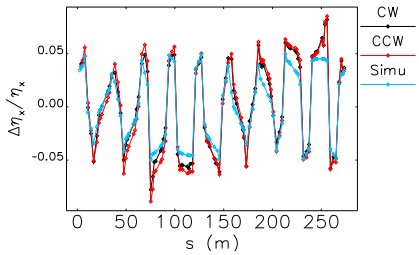
COMMISSIONING WITH BEAM

The IEX was installed in the APS storage ring during the May 2012 shutdown. Thanks to thorough and careful work at every step (some of which is mentioned in the previous sections), in its first test with beam it was turned on and ramped to full strength step by step without beam loss. In this first beam test, there was no local correction—only regular APS orbit correction and feedback systems were employed. This clearly indicated that the device was working properly and that our assumptions and simulations had validity. Then we measured the tune shift and the dispersion perturbations with IEX on, and compared the results to our previous simulations, see Figure 4. We found very good agreement, which shows that the device is very close

Copyright © 2013 CC-BY-3.0 and by the respective authors

to the model and that various field errors were well controlled. After confirming that the device is well within our



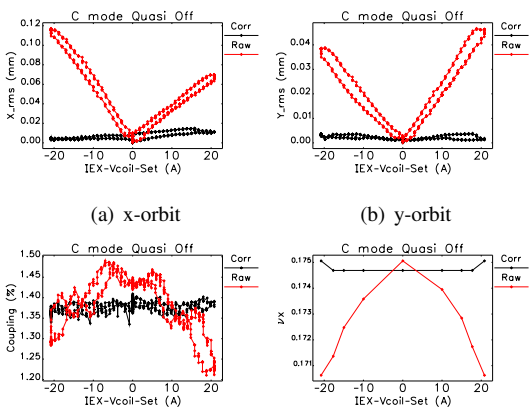


Figure 4: Dispersion error from IEX (quad ring): black/red - measurements made at CW and CCW mode; blue - simulation result.

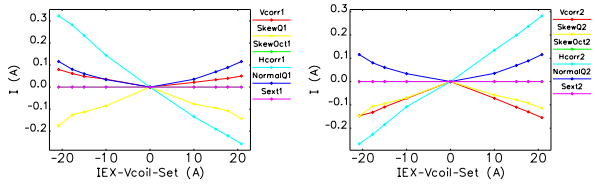
expections and working properly, we started to debug our entire control program, simulate all possible user operation scenarios, and test the protection features with various simulated faults. At the same time, we started to build the local correction table (the 24-page SDDS file) for each operational state.



Techniques used for correction of similar APS devices [4, 5] have been adopted here with some adjustments. First, we measured beam response to the IEX local correction coils individually with IEX off. Then we measured beam perturbations while turning on the IEX. All corrector settings are then determined by multiplying beam perturbations with the inverse of the measured correction coil response. Normally, the tune and coupling variation is less sensitive to beam orbit going through the IEX magnet and had been corrected first, then the orbit perturbations are corrected. After several iterations (generally two is enough), most perturbations have been removed by the local correction coils. Some of the correction coil settings vs. the IEX main coil current and resulting orbit, tune, coupling variation with and without correction are shown in Figure 5 and 6. After about six months commissioning, the IEX was turned over for full user operation.

SUMMARY

IEX is the second circular polarized undulator to be installed in the APS. It has the strongest nonlinear field owing to its complex structure and high field. To eliminate its perturbation to the beam, we took great care in each step to ensure the device properties were within specifications and satisfied all user requirements. The device was able to run at full strength without losing beam immediately upon being turned on. Full correction table generation and debugging/troubleshooting of the control program took about six months (including a one-month shutdown in between). The device is now fully available for user operation with no restrictions.

ACKNOWLEDGMENTS

The successful IEX commissioning is the outcome of flawless work by many physicists, engineers, and technicians. We want to thank all of them sincerely for their great ideas and contributions. Methods developed from previous circular polarizing device commissioning, largely originated by L. Emery, also played a great role in the entire commissioning process. L. Emery's and V. Sajaev's rich experience on commissioning of new devices and their many suggestions helped us to avoid many mistakes.

NON-LINEAR EFFECTS OF INSERTION DEVICES: SIMULATION AND EXPERIMENT RESULTS *

A. Xiao, M. Borland, L. Emery, V. Sajaev
Argonne National Laboratory, Argonne, IL 60439, USA

Abstract

The Advanced Photon Source (APS) Upgrade includes adding more insertion devices (IDs) to the storage ring. Perturbations from IDs have been reviewed, with the most significant sources coming from IDs that generate circular polarized light. To address this, we measured non-linear effects from the existing circular polarized undulator (CPU) and intermediate-energy x-ray (IEX) undulator. Measurement results were compared with simulation results. Proposed correction schemes were tested experimentally.

INTRODUCTION

The ongoing APS Upgrade (APS-U) project includes installing IDs in unused straights and replacing some IDs with devices better-optimized for user requirements. ID perturbations to the beam can be qualitatively expressed by [1]

$$\Delta x'(x) \propto \frac{L_w}{E^2} K^2 \frac{d}{dx} F^2(x), \qquad (1)$$

where L_w is the length of the wiggler, E is the beam energy, K is the wiggler strength, and $F(x) = B_y(x)/B_y(0)$. Non-linear effects come from the roll-off in $F(x)$.

For planar IDs, only one on-axis field (typically B_y) needs to be non-zero. Thus a generally wider ID pole and flatter $F(x)$ is possible, which reduces non-linearities. For IDs that generate elliptical radiation, both B_x and B_y are necessarily non-zero on axis. The required magnet structure is much more complicated, with narrower poles and, as a consequence, larger variation of $F(x)$. Figure 1 illustrates this difference for some of the typical and planned APS IDs. ID parameters are listed in Table 1.

To better understand the beam dynamics effects of ID field non-linearity, several simulation methods have been implemented in `elegant` [2]. Some of the methods require an analytical wiggler field expansion, which can be obtained through fitting a 3D magnetic field map to a model. In this paper, we first describe these simulation tools, fitting methods, and methods to reduce artificial errors from fitting. Then, using IEX as an example, we show simulation results from a measured field map. Finally, we present some experimental results from CPU and IEX operations.

SIMULATION TOOLS AND FITTING METHOD

There are four elements in `elegant` that simulate IDs: CWIGGLER, GFWIGGLER, UKICKMAP, and FTABLE.

# ID is under development, parameters are under consideration.

UKICKMAP uses kick maps [3] obtained from magnet design directly or from tracking results of the other three methods. All other methods use 3D field maps from ID design or field measurement. FTABLE uses the field map directly and is non-canonical, while CWIGGLER and GFWIGGLER require an analytical wiggler field expansion (from the 3D field map fitting) and are canonical. Our typical procedure for simulating nonlinear ID effects is: fit the 3D field map to a field expansion; using CWIGGLER or GFWIGGLER, track a bunch of particles through the element in a "grid" distribution on the $x - y$ plane with $x' = y' = 0$, and determine the kick map at the exit; use the kick map as input to UKICKMAP to perform various

Copyright © 2013 CC-BY-3.0 and by the respective authors

simulations. The key to the entire procedure is fitting a field map to the field expansion. The general field expansion of an elliptical undulator is written as [4]:

$$\begin{aligned} B_x^H &= B_0^H \sum_{m,n} A_{mn}^H \frac{k_{x,mn}^H}{k_{y,mn}^H} \sin(k_{x,mn}^H x) \\ &\quad \cdot \sinh(k_{y,mn}^H y) \cdot \cos(k_{zn} z), \\ B_y^H &= -B_0^H \sum_{m,n} A_{mn}^H \cos(k_{x,mn}^H x) \\ &\quad \cdot \cosh(k_{y,mn}^H y) \cdot \cos(k_{zn} z), \end{aligned} \tag{2}$$

with $(k_{y,mn}^H)^2 = (k_{x,mn}^H)^2 + (k_{zn})^2$ for the field generated from the two middle poles, and

$$\begin{aligned} B_x^V &= B_0^V \sum_{m,n} A_{mn}^V \cos(k_{x,mn}^V x) \\ &\quad \cdot \cosh(k_{y,mn}^V y) \cdot \cos(k_{zn} z + \tfrac{\pi}{2}), \\ B_y^V &= B_0^V \sum_{m,n} A_{mn}^V \frac{k_{y,mn}^V}{k_{x,mn}^V} \sin(k_{x,mn}^V x) \\ &\quad \cdot \sinh(k_{y,mn}^V y) \cdot \cos(k_{zn} z + \tfrac{\pi}{2}), \end{aligned} \tag{3}$$

with $(k_{y,mn}^V)^2 = (k_{x,mn}^V)^2 + (k_{zn})^2$ for the field generated from the four side poles. Here, $k_{zn} = 2\pi n/\lambda_u$, λ_u is the period, and B_0^H and B_0^V are the maximum on-axis horizontal and vertical fields, respectively. The total field is given by

$$\begin{aligned} B_y^C &= B_y^H + B_y^V \\ B_x^C &= B_x^H + B_x^V. \end{aligned} \tag{4}$$

ID field profiles greatly differ from a pure sinusoidal shape and have high harmonic components, making direct fitting very difficult. We thus developed a linear fit method. First, the field data are fit to longitudinal harmonics:

$$\begin{aligned} B_x^C &= \sum_n G_{H,n} \cdot \cos(k_{zn} z) + \sum_n G_{V,n} \cdot \cos(k_{zn} z), \\ B_y^C &= \sum_n F_{H,n} \cdot \cos(k_{zn} z) + \sum_n F_{V,n} \cdot \cos(k_{zn} z), \end{aligned} \tag{5}$$

where $\cos(k_{zn} z)$ are known values at each data point, and $F_{H/V,n}$ and $G_{H/V,n}$ are fit parameters. These F and G parameters are in turn decomposed into transverse harmonics following

$$\begin{aligned} F_{H,n} &= \sum_m \left[-B_0^H A_{mn}^H \cdot \cosh(k_{y,mn}^H y) \right] \cdot \cos(k_{x,mn}^H x) \\ &= \sum_m f_{H,n,m} \cdot \cos(k_{x,mn}^H x). \end{aligned} \tag{6}$$

Note that $k_{y,mn}^H$ and $k_{x,mn}^H$ are still related. Both $k_{x,mn}^H$ and A_{mn}^H are unknown parameters to be fitted. In order to turn this into a linear fit, we give an initial value to $k_{x,mn}^H$, then fit $f_{H,n,m}$. The proper $k_{x,mn}^H$ value is obtained by scanning $k_{x,mn}^H$ over a suitable range and choosing the value that gives the smallest residuals. The same technique is applied to the other F and G parameters.

Depending on the original field data errors and the available field map region, the fit results may be invalid. The F and G coefficients are interrelated via Maxwell's equations, so fitting one will give the other. Usually we fit F_H and G_V as they give the non-zero on-axis field. In the case of large (measured or modeled) field errors, this results in large field errors at the boundary of the available field map. Fitting F and G parameters together will eliminate such errors (see Figure 2). For best results, the field map region

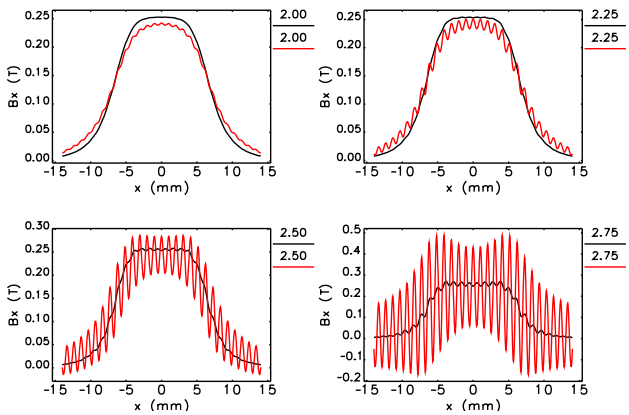

Figure 2: Fitted field profile at different y positions (legend value in mm). Red — fit F_H and G_V only; black — fit all F and G. Large fitting errors appears near the field map boundary.

should extend well beyond the expected dynamic aperture (DA). If an adequate field map region is unavailable, which we encountered in our EMVPU [5] simulation, we must use fewer small transverse harmonics (m) or manually set up boundary conditions that will help constrain the fitting results (see Figure 3).

SIMULATION RESULTS AND BEAM TEST

Figure 1 shows that IEX presents the strongest nonlinearity among all IDs that have been installed in the APS. Thus, detailed simulations were made with both designed and measured field maps. Due to large errors represented in the measured field data, the measured field map was fitted to its design model by adjusting its alignment (x, y, z), peak field (B_0), and roll-off parameter K_x slightly away from the value of the model simulation. Fitting results show that $K_{x,meas} \approx 0.96 K_{x,design}$. A slightly larger magnet field roll-off appears in the real device (see Figure 4). To include field errors, the IEX was sliced into several segments, each segment containing several periods. The error field was represented by a kick map at the end of each segment, calculated using the first field integral of the same

segment. Simulated DA results for various conditions are shown in Figure 5. The simulation results predicted that the APS DA would be reduced slightly by IEX operation. This was confirmed by our beam-based measurements, as seen in Figure 6.

Another device with strong non-linearity is the Circularly Polarizing Undulator (CPU), for which we have a model field map, but no measured one. The non-linearity of the ideal CPU model is weaker than IEX, but the measured beam perturbations, such as orbit, tune, and coupling variations, indicate some larger field errors. The measured DA reduction from the CPU is also more severe than the IEX (see Figure 6). Unfortunately, we cannot simulate these field errors as we have no measured field map.

SUMMARY

Simulation of ID nonlinear effects can be accomplished in several ways. This paper explains how a field map can be fit to a field expansion used by `elegant` and what precautions are required for a valid result. Using the IEX device as an example, we illustrated how a measured field map was used to check the field quality and for DA simulation. Experimental results from both CPU and IEX operation show the importance of such simulation work.

ON-AXIS INJECTION SCHEME FOR ULTRA-LOW-EMITTANCE LIGHT SOURCES *

A. Xiao†, M. Borland, C. Yao, ANL, Argonne, IL 60439, USA

Abstract

Injection design for an ultra-low-emittance light source is mainly limited by two effects. Due to intrabeam scattering and beam instabilities, multiple bunches with tight bunch spacing are injected into the ring to reach high average beam current, which limits the choices of injection technology. Strong non-linear effects due to the significant focusing force applied and the resultant strong sextupoles make the dynamic aperture very small, so that only on-axis "swap-out" beam injection is workable. Using a seven-bend-achromat (7BA) lattice designed for the Advanced Photon Source (APS) storage ring as an example, this paper presents an on-axis injection scheme based on the fast stripline technique together with discussions of the different configuration choices.

INTRODUCTION

When pushing a storage-ring-based light source emittance close to very low emittance, two primary consequences emerge: insufficient dynamic aperture for accumulation-based injection, so that only on-axis "swap-out" injection is workable [1]; and the maximum single-bunch intensity is significantly reduced due to the intrabeam scattering (IBS) and beam instabilities, so a significant fraction of the ring may need to be filled with beam to reach the required average beam current. Both factors put strict restrictions on the choice of injection technology and optics design.

In the scheme envisioned here, a single "swap-out" beam injection only replaces a portion of the stored beam, see Figure 1. The target bunches must be extracted and injected without affecting the emittance and stability of the remaining stored beam. For this to be the case, the kicker field must be negligible at the next upstream or downstream bunches, which requires kicker rise- and fall-times less than the spacing between bunches—usually one to a few rf buckets depending on the specific design, e.g., 10 rf buckets @500 MHz implies 20 ns. Commonly used ferrite kicker magnets cannot meet such requirements, but the stripline kicker technology proposed for the ILC damping ring [2] seems promising and is adopted in this paper.

A series of 40-sector, 6-GeV seven-bend achromat (7BA) lattices [3] have been studied for the future APS Upgrade. The lattice used is shown in Figure 2. In this paper, we will present an injection and extraction design for the 7BA lattice, with discussion of the different injection schemes.

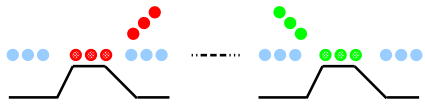

Figure 1: Sketch of on-axis "swap-out" injection (red: extraction bunches; green: injection bunches).

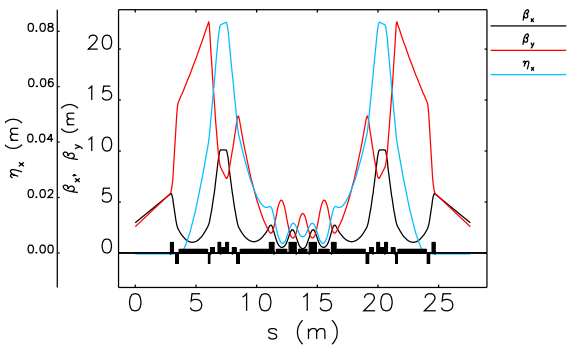

Figure 2: Single-cell optical functions of a 7BA lattice.

MAIN PARAMETERS

The kick angle from a stripline of length L with gap d between the electrodes is given by

$$\Delta\theta = 2g\frac{eV}{E}\frac{L}{d}, \tag{1}$$

where V is the voltage applied to the two electrodes, E is the beam energy, $g \leq 1$ is the geometry factor, and the factor 2 includes the force from both electric and magnetic fields. Using the stripline tested at ATF [4] (60 cm long, 10 mm gap, with $\pm$10 kV pulsers), the kick angle is 0.4 mrad.

The maximum achievable kick angle depends on two major factors: the available pulser strength V and the size of the stripline. Unlike the ILC damping ring, the required injection frequency is much lower, so a pulser with much higher output voltage [5] is available; V is then limited by the detailed design of the stripline (feed through). A smaller gap d increases $\Delta\theta$ for the same gap voltage V, while the maximum achievable V is also reduced due to reduction in the stripline size. As there is yet no detailed stripline design, we assume $V = 30$ kV at $d = 10$-mm gap compared with $V = 20$ kV at the same gap for the ILC damping ring. Larger L will make more efficient use of the limited space, but the maximum L is limited by the required rise/fall time. We choose $L = 0.6$ m, so that the rise/fall time is less than 5 ns. Altogether, the kick strength from a single stripline is 0.6 mrad. To accomplish the injection task, multiple striplines are needed.

Unlike other storage ring designs, an ultra-low-

Copyright © 2013 CC-BY-3.0 and by the respective authors

emittance light source like the 7BA discussed here usually has no more free drift space left inside the arc. The only space available is in the straight sections, which are mainly preserved for insertion devices. Assuming a single straight injection, the separation Δx between injected and stored beam center at the edge of the septum is given by

$$\Delta x \approx N\Delta\theta\frac{NL}{2} = \frac{\Delta\theta}{L}\frac{(NL)^2}{2}, \quad (2)$$

where N is the total number of striplines and $\frac{\Delta\theta}{L}$ is the normalized kick strength in mrad/m.

The minimum separation Δx_{min} is given by

$$\Delta x_{min} = x_{inj} + x_{err} + s_a + s_d, \quad (3)$$

where x_{inj} is the injected beam size, x_{err} is the allowed orbit error from all sources, s_a is the minimum septum aperture determined by other factors (for example, impedance), and s_d is the septum thickness.

Similar to the current APS design, two septums are used. We have set $s_a = 3$ mm and $s_d = 1$ mm for the thin septum in our simulation. The fully coupled injected beam emittance is assumed to be 30 nm. x_{inj} and x_{err} are related to the local beta function at the edge of the thin septum and will be discussed in later sections. All main parameters are listed in Table 1.

Table 1: Main Parameters for Injection

Title	Description	Value	Unit
General	Energy	6	GeV
	Stored Beam Emit.	81	pm
	Inj. Beam Emit.	30	nm
	Beta function at Inj.	≈3	m
	Orbit error (x_{err})	0.4	mm
Stripline	Length	0.6	m
	Gap	10	mm
	Gap Voltage	30	kV
Thin Septum	Length	0.25	m
	Thickness	1	mm
	Field Strength	0.7	T
	Inner Aperture	3	mm
Thick Septum	Length	1.5	m
	Thickness	2	mm
	Field Strength	1	T

BETA FUNCTION AT SEPTUM

A high-beta insertion is often used for the injection section design of a storage ring. Two pairs of kicks with phase advance close to π are located at either side of the septum, while the septum is located at the place of a high-beta function. The advantages of such a design are to minimize the kicker strength and reduce residual betatron oscillation of injected beam.

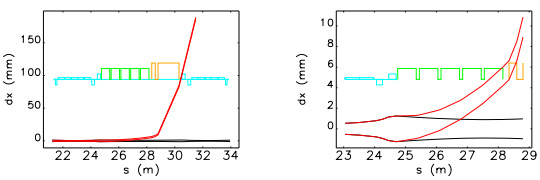
This kind of injection scheme is not applicable to the ultra-low-emittance light source (USR) for the following reasons:

- Phase advance. Since a light source tends to have a very crowded arc cell, there is insufficient space for multiple stripline kickers. Most likely, the stripline kickers will be placed in the same section as the septum.
- Optics perturbation. A specially designed high-beta injection section will break the lattice symmetry, which will typically reduce the dynamic aperture (DA) and momentum aperture (MA) significantly. Having sufficient DA/MA is already a big challenge for a USR lattice design.
- Impedance issues. Injection/extraction regions contribute a large portion to the entire ring's impedance budget. High-beta function makes the problem even more severe.
- Stripline aperture. High-beta function means larger beam size. Accommodation of the injection beam requires larger stripline gap, which reduces the stripline strength.

Due to the above reasons, a high-beta injection scheme was evaluated and abandoned. Those simulation results are not shown here. Note that if striplines and septum need to be put in the same section, then the beam separation is given by Eq. (2). From Eq. (3), a low-beta function at the thin septum, which minimizes x_{inj} and x_{err}, is preferable.

SINGLE STRAIGHT INJECTION AND EXTRACTION

If possible, putting injection and extraction to the same straight section is preferable. The minimum separation for beam extraction $x_{min,ext}$ is also given by Eq. (3) with replacing of x_{inj} to x_{sto} (beam size of stored beam). Using the parameters listed in Table 1, $x_{min,inj} = 5.3$ mm and $x_{min,ext} = 4.5$ mm. From Eq. (2), the minimum total stripline length for injection is 3.25 m, while the minimum total stripline length for extraction is 3 m. To accommodate the thin septum and including space between each element, $\sim$ 1 m of extra space is needed. Thus a minimum 7.5-m-long straight section is required to accommodate both on-axis injection/extraction in one straight section for a 6-GeV ring. Since the straight section length of our design is 5.8 m, injection and extraction require separate straight sections. In our design, sector 38 is used for beam extraction and sector 39 is used for beam injection.



SEPARATED INJECTION AND EXTRACTION

As just discussed, injection and extraction need to be separated into two sectors. The difference between injection and extraction is that the required minimum separation at the thin septum is slightly different. For simulation

Copyright © 2013 CC-BY-3.0 and by the respective authors

convenience, we illustrate here the extraction line using parameters of beam injection as listed in Table 1.

To allow a 3-mm inner aperture for the thin septum, a minimum 5.3-mm beam separation must be provided by the stripline kickers. This number assumes 1-mm septum thickness, 3 sigma of injected beam size ($\sigma = 0.9$ mm at $\beta_x = 3$ m), and 0.4-mm orbit error from various sources. Using a normalized kick strength of 1 mrad/m, the total stripline length is 3.25 m from Eq. (2), requiring five 0.6-m-long striplines. Figure 3 shows the extraction line configuration (injected beam is from right to left), the envelope of injected beam (red line), and the envelope of the first turn of injected beam. This plot also shows why high-beta injection is not preferable, because in that scheme the stripline gap has to be increased to accommodate the entire injected beam envelope, which becomes much wider when using high-beta injection. Since now the minimum aperture limitation around the ring is the thin septum (3 mm), some stripline apertures (for example, 1 and 2) could be reduced to increase the normalized kick strength. The potential benefit from reducing stripline aperture is limited by the feedthrough, so this must be evaluated when we have a detailed stripline design. The separation at the first quadruople is 0.1 m and needs to be considered in the magnet design.

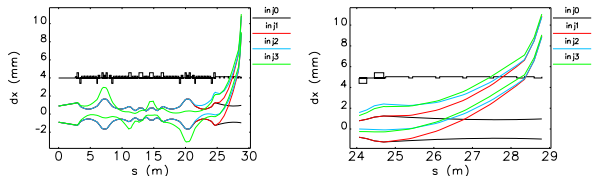
Figure 3: Injection configuration: black - first turn injected beam, red - injected beam, green - stripline, and yellow - septum.



OTHER CHOICES

Besides putting all injection elements into the same straight section, other injection schemes have been studied. For example, we looked at putting striplines in the arc where sufficient drifts are present or using the straight section in the next sector. Results are shown in Figure 4.

The effectiveness of these choices strongly depends on the detailed optical design, i.e., the phase advance between the thin septum and an available space for installing an extra stripline. One could make this a special requirement to the optical design, or modify the existing optical design to make a special section to suit the required phase advance. Other issues make such choices unwelcome, including:

- Broken symmetry. It makes the already challenging nonlinear effects correction even more difficult.
- Less flexibility. A modification of the optical design will require a re-design of the injection line. It becomes more difficult due to the strong nonlinear effects.
- Large orbit oscillation inside arc, see Figure 4. This also causes nonlinear effects and may harm injection efficiency.

These effects can be seen from Figure 4. The additional stripline inside arc (inj2) doesn't increase beam separation at the septum due to the wrong phase advance. The additional stripline installed in other sectors (inj3) does increase beam separation at the septum at the expense of large orbit oscillation inside the arc, which means every change of the chromaticity configuration could result in rematching of the injection line. We have abandoned such options due to unclear benefits and these potential problems.

(a) Overview of different injection schemes (b) Zoom in of different injection schemes

Figure 4: Comparison of different injection schemes: inj0 - first turn injected beam, inj1 - all stripline in one straight, inj2 - one stripline in arc, inj3 - one stripline from the next sector. See how beam orbit varies inside the arc (a) and beam separation at the thin septum (b).

CONCLUSION

Using an APS 7BA lattice design as an example, several on-axis injection schemes have been studied. Results reveal the possible choice of injection technology, the main parameters determining the injection design (injection beam size, minimum septum aperture, etc.), and as a consequence, the requirements on the optics design (drift space, beta function, etc.). Our results show that on-axis injection into the 7BA lattice can be achieved. We attempted to make our discussions here as general as possible, so results can be used for other USR designs.

ADVANCED X-RAY BEAM POSITION MONITOR SYSTEM DESIGN AT THE APS*

B.X. Yang†, G. Decker, J. Downey, Y. Jaski, T. Kruy, S. H. Lee, M. Ramanathan and F. Westferro
Advanced Photon Source, Argonne National Laboratory, Argonne, IL 60439, USA

Abstract

As part of the Advanced Photon Source (APS) Upgrade, new x-ray beamline front ends are planned that include extensive integrated x-ray diagnostic capability. The high-heat-load front-end (HHLFE) design includes a grazing-incidence insertion device x-ray beam position monitor (GRID-XBPM) utilizing Cu K-edge x-ray fluorescence from x-rays striking a pair of copper absorbers. At a 1.0˚ grazing incidence angle, the XBPM assembly is designed to withstand 17 kW power from two inline Undulator A devices at 150-mA stored beam. A second XBPM located outside of the accelerator enclosure monitors fluorescence from the beamline exit mask, which is a critical beamline-defining aperture. In addition, an intensity monitor is used to detect x-ray flux passing through a front-end mask inside the enclosure, while a second intensity monitor is located immediately downstream of the exit mask. Details of these designs and expected performance will be presented.

INTRODUCTION

The ongoing Advanced Photon Source Upgrade (APS-U) requires major improvements in x-ray beam stability. The stability goals are to be achieved on multiple beamlines with two inline Undulators A's delivering beam power up to 17 kW at 150-mA stored current. Since the modern storage ring orbit feedback systems have demonstrated submicron stabilities, the actual x-ray beam stability delivered to the user is determined by the accuracy of the beam position monitors. In the past several years, the APS has made a major effort in developing a hard x-ray BPM. The new device uses the 8-keV Cu K-edge x-ray fluorescence (XRF) from the front-end limiting apertures to infer the undulator beam's core position [1,2]. An experimental test with two inline undulators showed that the XBPM has nearly 70-fold improvement in rejection of bend magnet radiation background and a gap-independent calibration in one of the two dimensions [3]. Based on this successful demonstration, the GRID-XBPM was included as a standard device for the new HHLFEs being developed for the APS-U. In this paper, we report the engineering design of the new XBPM system, including a GRID-XBPM, the second XBPM at the end of the front end, and the two intensity monitors to assist for beam-based alignment of front end apertures. We will also report on the latest design development of a new XBPM based on Compton scattering.

THE FIRST XBPM

Figure 1 shows the first XBPM. It is a GRID-XBPM consisting of two GlidCop absorbers, positioned on the left and right sides of the undulator beam axis. At 1.0˚ grazing incidence angle, they intercept up to 11.5 kW of undulator power during user operations and are able to withstand the full beam in case of mis-steering. The XBPM reads out vertical positions using x-ray pinhole camera optics, with a calibration independent of undulator gaps. It derives horizontal beam position from the difference/sum of the x-ray detector signals from the left and right absorbers. Hence the horizontal position calibration depends on the beam sizes, or undulator gaps. To meet the stringent stability requirements, the pinhole camera and detectors are mechanically isolated from the absorbers, and its height above the floor is monitored in real time by a mechanical motion sensor mounted on an Invar rod. External perturbations to the XBPM include: (1) the annual air pressure variation of 0.6% [4], which distorts the XBPM support plate; and (2) the thermal load of the x-ray beam on the XBPM assembly. Table 1 summarizes the ANSYS analyses for the impacts of these external perturbations. We can see that most distortions are within specifications. The thermal-distortion-induced vertical detector position change will be monitored and corrected in real time with the mechanical motion sensor or treated as gap-dependent XBPM offset.

Table 1: Externally Induced XBPM Position Change

	Angular	Vertical
Barometric Pressure (0.6% rms)	±0.4 µrad	0.04 µm
Beam Load	±0.4 µrad	7 µm
Specifications	2 µrad	3 µm

THE SECOND XBPM

The exit mask of the HHLFE is a critical component of the beamline. It defines the exit aperture of the front end and protects the downstream bremsstrahlung shield from radiation damage. During normal beam operations, it intercepts up to 3.5 kW x-ray power. The fluorescence photons generated by the intercepted beam will be used by the second XBPM to infer the core beam position utilizing yet another set of pinhole camera optics. Figure 2 shows the arrangement of the XBPM2 components. Four silicon photodiodes are used to read out the horizontal and vertical positions of the x-ray footprint on the exit mask. This XBPM will not be linked to the orbit feedback system, but its information will be recorded and logged during user operations.

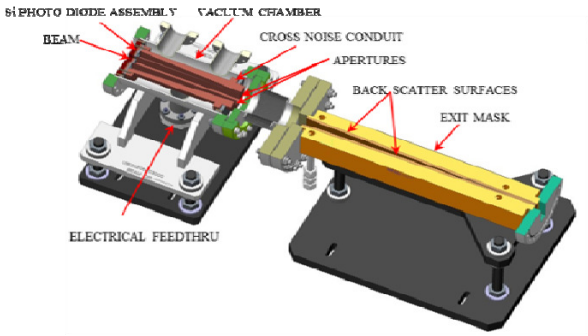

Figure 2: XBPM 2 design. A pair of apertures and four Si PIN diodes form a pinhole camera to read out the position of the x-ray footprint on the exit mask.

THE INTENSITY MONITORS

Two beam intensity monitors, IM1 and IM2, are planned for the new front ends. During normal operations, up to 100-W x-ray photons will be removed from the beam by the front-end beryllium windows, including 30-W x-rays by Rayleigh and Compton scatterings. These scattered photons can be detected using metallic photocathodes or silicon photodiodes, and the signal can be used to center the undulator beam on the exit mask by scanning the electron beam. The symmetry points of the scanning curve serve as the fiducial marks of the XBPM, allowing the operator to put the XBPM back to its standard state after each shutdown, or after the XBPM and its electronics are repaired or serviced. Figure 3 shows the design of the IM2: A large-area gold-coated photocathode is used to capture the scattered radiation from the Be window. The inset shows the estimate photocurrent as a function of undulator K-value, using known x-ray scattering cross sections [5]. For the operating range of Undulator A, the signal current remains in microampere range within a dynamic range of 1:7.

The first intensity monitor (IM1) uses the x-ray fluorescence from the photon shutter to measure the beam intensity passing through the upstream apertures inside the front end. By design, it will be used to fiducialize the GRID-XBPM during machine studies before user operations. Since it is a retrofit to existing photon shutters, the challenging part is to make the signal proportional to the total beam intensity but independent of the beam position on the grazing incidence shutter. Figure 4 shows the arrangement of IM1 components: a combination of an aperture edge and an EDM'd detector mask is used to minimize the signal's beam position dependence.

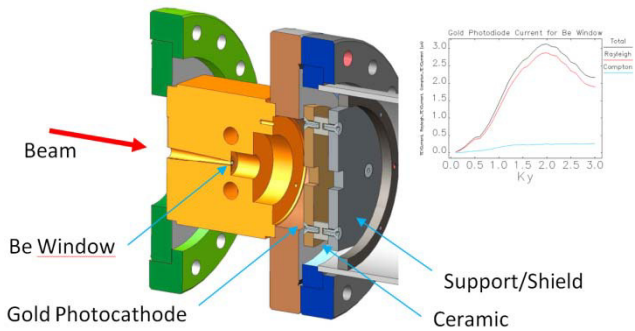

Figure 3: IM2 uses Rayleigh- and Compton-scattered x-rays from the Be window to monitor the x-ray beam intensity. Inset: A photodiode is used to detect x-rays.

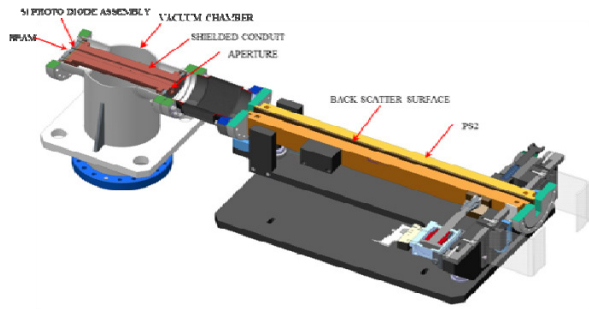

Figure 4: IM1 uses Cu K-edge XRF to measure the x-ray beam intensity when the photon shutter is closed.

SYSTEM DESIGN

Figure 5 shows the schematic of the new XBPM system inside the new orbit feedback system for the APS-U. With a reference from a common hydrostatic leveling system, real-time motion sensors will be used to monitor the positions of the RFBPM and the XBPM to compensate for the thermal expansion/distortion of the vacuum chamber supports. The RFBPM and GRID-XBPM will be used to monitor beam position and angle changes, and to provide information for orbit corrections.

For the x-ray beam exiting the front end, IM2 and XBPM2 will record its intensity and position information in real time and serve as independent validation of the x-ray beam stability achieved by the entire system.

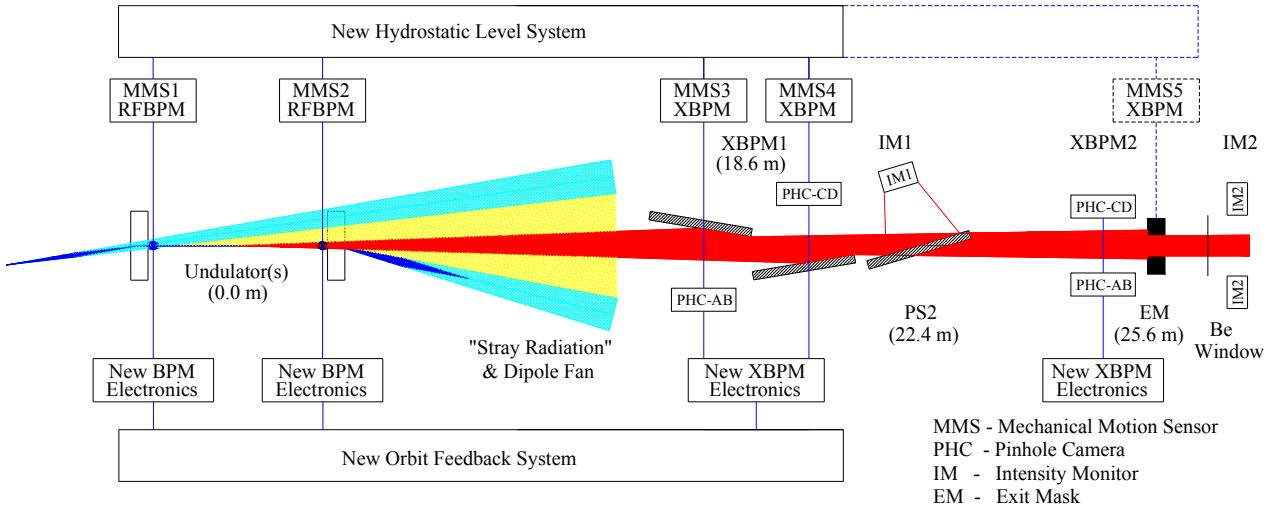

Figure 5: In the APS-U orbit feedback system, the XBPM system is responsible for measuring the x-ray beam angle and monitoring the x-ray beam intensity and position outside of the feedback loop.

SUMMARY AND DEVELOPMENTS

The engineering designs of the x-ray beam position monitor system for the APS high-heat-load front ends are complete. The components are being procured and manufactured. Installation of the first complete set is planned for early 2014.

The grazing-incidence design has demonstrated that a reliable XBPM can be built wherever a beam aperture can survive the beam, and the combination of beam apertures with position measurements simplifies operations of the beam-based alignment and improves its accuracy. However, the design also carries higher cost and requires longer beamline space.

For canted undulator front ends, where two undulator beams are separated by 1 mrad, with each carrying only 8.5-kW power, we are currently developing a different design based on Compton scattering from low-Z materials. Figure 6 shows a prototype: two grazing-incidence diamond blades are inserted from the top and bottom of the beam. At ~ 1.75 mm from the axis, they intercept ~ 500 W from each undulator. A set of pinhole optics and diamond detectors are mounted below and above the diamond blades to read out the horizontal beam position; the vertical beam position is derived from the difference/sum of the signals from the two blades. Initial ANSYS analysis shows that the diamond blades will survive a direct hit by the undulator beam during mis-steering if an appropriate heat spreader material, e.g., Mo-Cu, is used. A preliminary x-ray simulation shows that the signal current will be in the range of tens of μA for closed undulator gap (10.5 mm), and hundreds of nA for open gap (30 mm). This is welcome news for the data acquisition system since the dynamic range requirement is less stringent than that for the HHLFE GRID-XBPM with vertical absorbers. Optimization of the design is still in progress and experimental tests are planned for the near future.

Abstract

For a free-electron laser (FEL) to work effectively the electron beam quality must meet exceptional standards. In the case of an FEL operating at infrared wavelengths the critical phase space tends to be in the longitudinal direction. Achieving high enough longitudinal phase space density directly from the electron injector system in an FEL is difficult due to space charge effects, thus one needs to manipulate the longitudinal phase space once the beam energy reaches a sufficiently high value. However, this is fraught with problems. Longitudinal space charge and coherent synchrotron radiation can both disrupt the overall phase space, furthermore, the phase space disruption is exacerbated by the longitudinal phase space manipulation process required to achieve high peak current. To achieve and maintain good FEL performance one needs to investigate the longitudinal emittance and be able to measure it during operation preferably in a non-invasive manner. Using electro-optical (EO) methods, we plan to measure the bunch longitudinal profile of an energy (~120-MeV), high-power (~10kW or more average FEL output power) beam. Such a diagnostic could be critical in efforts to diagnose and help mitigate deleterious beam effects for high output power FELs.

INTRODUCTION

In order to operate an FEL of high quality, an electron beam with high-peak current, low transverse emittance and low energy spread is required. An operational understanding of electron bunch parameters through diagnostics is needed if one wishes to achieve the optimal desired beam qualities. There are a number of diagnostics of both invasive and non-invasive genres used to determine electron bunch parameters. Invasive diagnostics such as transition radiation (CTR) screens placed directly into the beam of electrons are great if one has a low power beam and does not care if operation is momentarily interrupted. Such diagnostics are not suitable for high power operation as they will be destroyed by the beam, or operational monitoring as they severly disrupt the beam properties upon impact with the diagnostic. As an FEL requires high longitudinal phase space density for optimal output, the required manipulations of the electron bunches can lend to undesirable additional effects which need to be monitored in-situ, and, if possible, avoided. One needs a non-invasive longitudinal phase space diagnostic to allow for the achievement and maintenance of the beam properties.

A method to sample the bunch's electric field without prohibitively disrupting the beam is to utilize a crystal with a birefringent property influenced by an electric field, known as the electro-optical (EO) method. This property is caused by the Pockel's effect and the crystal acts as a Pockel's Cell driven by the electric fields of the electron bunches. The different polarizations of light within a pulse traversing the crystal will have altered path lengths created by the birefringence. The altered pulse becomes elliptically polarized in a manner proportional to the influence of induced birefringence. Equation (1) (derived in Jamison, et al. [1]), gives the resultant Fourier transform of the electron beam's Coulomb field with a probing optical pulse, and the resultant inverse transform in Equation (2). The functions *R(t)* and *R(ω)* are the response of the crystal due its nonlinearity and phase matching.

$$E_{out}^{opt}(\omega) = E_{in}^{opt}(\omega) + i\omega E_{in}^{opt}(\omega) * [E^{Coul}(\omega)R(\omega)], \quad (1)$$

$$E_{out}^{opt}(t) = E_{in}^{opt}(t) + a[E^{Coul}(t) * R(t)]\frac{d}{dt}E_{in}^{opt}(t). \quad (2)$$

The Coulomb field becomes encoded in the optical pulse to later be processed in order to determine the longitudinal bunch profile.

For a relativistic electron, the radial Coulomb field is oriented perpendicular to propagation with an opening angle $\propto 1/\gamma^2$, where γ is the relativistic Lorentz factor. The strength of the field is a function of electron bunch distance, b, from the crystal as found in Eqn (3) below. This field is found to have an effect similar to radiation in the Terahertz region of the electromagnetic spectrum (~100-900μm wavelengths) [2]. Placing the desired (EO) crystal near the longitudinally propagating bunch charge encodes the electric field information in the crystal without directly altering the bunch. The induced birefringence is probed and encoded within an optical pulse incident normally on the crystal.

$$E_{y=b} = \frac{e}{4\pi\varepsilon_0}\frac{\gamma b}{(b^2+\gamma^2 z^2)^{3/2}} \quad (3)$$

The facilities where EO diagnostics have been implemented are in contrast to the CSU and JLab accelerators, typically feature beamline parameters with short bunches, low average power and high electron beam energies. As an example, one facility that has employed an EOS diagnostic is FERMI@Elettra [3], which features a bunch length of ~.54 ps FWHM, operational beam

Copyright © 2013 CC-BY-3.0 and by the respective authors

energy of 1.2 GeV, but at a much lower average power (10s of Watts). These differences in parameters, particularly the electron beam energy and average beam power, lead to modification of previous designs to suit our conditions.

METHODS

There are a variety of EO techniques utilized by different accelerator facilities, chosen based on their intrinsic strengths and weaknesses. It was shown at FELIX [4] that a scanning-delay method employed was capable of sub-picosecond measurements of longitudinal beam profile. In this diagnostic an initially linearly polarized 12-fs, 800-nm Ti:sapphire laser incident upon a ZnTe EO crystal placed near (6 mm from the bunch center) an electron pulse train is induced to elliptical polarization. The signal is further refined via use of a quarter wave plate and subsequent Wollaston prism to separate the polarization affected beam and the reference beam through a balance detector. Because the delay between the laser and the bunch train is scanned, this technique is subject to the natural laser pulse train jitter with respect to the beam and asmearing of the resultant profile limiting the resolution further due to averaging of the signal over many pules.

Another technique, known as spectral decoding, uses a chirped laser pulse to create a time-frequency relationship between the laser spectrum and the traversing electron bunch. This technique has been demonstrated at a number of facilities (FELIX, NSLS and FLASH [5-7]); however, there is a bunch length resolution limit, τ_{lim}, created by temporal distortion of the chirped pulse given by $\tau_{lim} = 2.6\sqrt{T_C T_0}$ [1], where T_C is the duration of the pulse generated by the electron beam and T_0 is that of the optical pulse length. A bunch length shorter than the resolution limit will distort the pulse signal due to Fourier transform artifacts [8]. An advantage of this method is that it is a single shot and so timing jitters and averaging of the signal do not affect resolution.

Similar to the previous method, another technique decodes the temporal profile of the electron bunch electrical field and is aptly known as temporal decoding. Using cross-correlation through second harmonic generation of the probe pulse that has been modified by the beam's electric field within the EO crystal, with a reference pulse (both split from a single pulse prior to probing of the crystal), a spatial mapping of the temporal intensity is created. This measurement is done in a single shot giving rise to individual bunch measurements. The FELIX facility has used this method to measure pulses with sub picosecond resolution [2,9]. A schematic of this method is given in Figure 1.

A fourth EO technique that differs in the manner of EO crystal probing is known as spatial encoding. Rather than probe the crystal with a laser pulse normal to the surface, a pulse broadened by a cylindrical telescope travels at an angle such that an encoding of the temporal profile of the Coulomb field is achieved across the transverse direction of the pulse. The spatial signal is now a measure of the temporal changes of the Coulomb field. As seen in Figure 2, the electron beam still propagates normal to the EO crystal. Because the probe is broadened, any anisotropy of the birefringence may lead to signal errors and quality measurements rely on ideal EO crystals. Employed at SLAC [10,11] and DESY, this single-shot measurement is shown to be capable of <300 fs FWHM bunch length measurements.

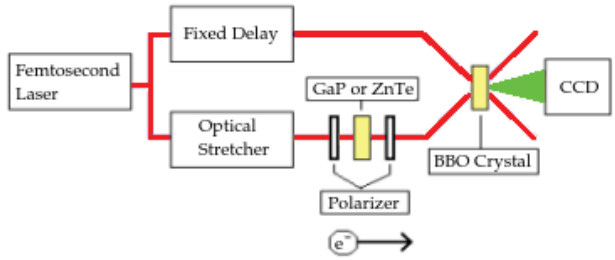

Figure 1: Electro-optical temporal decoding: A pulse is split such that a reference pulse travels through a fixed delay to be later combined the EO probe pulse in a non-linear crystal to create a pulse shape through Second Harmonic Generation (SHG).

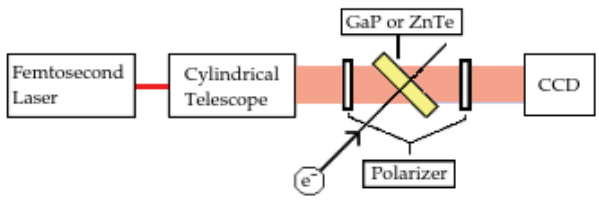

Figure 2: Diagram of electro-optical spatial encoding technique. Electron bunch still passes normal of the crystal, however, the probe pulse is incident obliquely. A cylindrical telescope is used to increase optical pulse transverse dimensions.

When designing the appropriate diagnostic to be implemented at CSU and Jefferson Lab, considerations of accuracy and effective measurement led us to choose the latter two introduced methods: EO temporal decoding and EO spatial encoding. Both of these are carried out in single-shot measurements allowing for single bunch signal probing. The spatial encoding method was found to be a relatively cheap option with a simple design. Where spatial encoding is limited in temporal resolution and noise susceptibility, temporal decoding compensates for these problems by providing excellent temporal resolution and low noise susceptibility due to the more complex cross-correlation design.

The beam energy for application at CSU, as well as the injection energy for the JLab accelerator, are both around 6 MeV. The beam energy for the second desired diagnostic location at Jefferson Lab is over 100 MeV and has a sub-picosecond bunch length. Based on Equation 3, there is a definite Coulomb field signal strength relation to distance from the beamline (b) which will have to be considered for our various applications. Clearly, placing an EO material further from the beamline is acceptable

Copyright © 2013 CC-BY-3.0 and by the respective authors

for higher energies and desirable to mitigate crystal damage, and therefore the crystal holder will be designed accordingly.

Prior to beam line implementation, a THz generation kit from Newport [12] will be used to simulate the desired diagnostic situation. The kit produces a THz wave through AC-biased plasma collapse, which is made to co-propagate with a reference pulse through a ZnTe crystal. Emulation of a real electron beam will be enhanced in the future to more accurately recreate the perpendicularly propagating Coulomb field of an electron bunch passing near the crystal.

ELECTRO-OPTICAL CRYSTAL DEPENDENCE

In order to determine the ideal EO crystal to be used for an actual diagnostic, considerations of crystal damage threshold, resonance and effective radiation birefringence will be made pertinent to our beam conditions. Figures 3 and 4 show the expected electric field intensity and resolution limits for energies around 6 MeV, which is our design beam energy. It is clear that the longitudinal resolution time will be limited to picoseconds measurements, and the low expected intensity may require us to place the crystal in close proximity to the passing bunch(<5mm), possibly subjecting the crystal to heavy radiation and beam halo damage.

DEVELOPMENT AND IMPLEMENTATION

Prior to implementation of an EO system within the CSU and JLab beamlines, several steps must be taken. Initially, we must study how our high average power beams will affect various EO crystals.

After deciding on the optimal crystal, the EO techniques must be developed on a setup that is a physical realization of the apparatus to be installed on the beamline. Currently the THz kit is being assembled. This kit will be bench tested to confirm functionality of the parts and then it will be modified for single shot capability so that a single bunch measurement can be made. Additional modifications will be made to accommodate radiation pulses similar to those generated by the CSU electron beam.

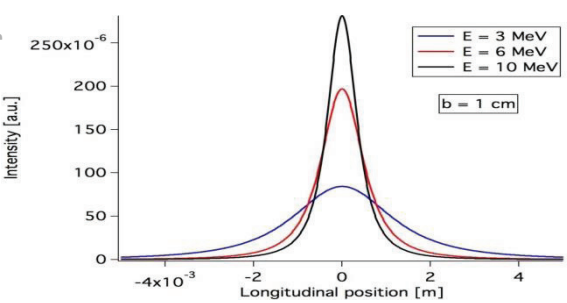

Figure 3: This figure shows the relative intensity of electron bunch electric field as a function of beam energy and position.

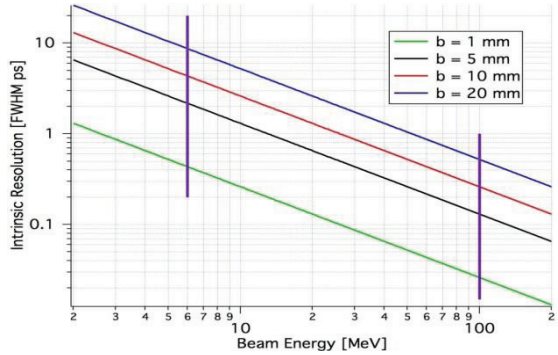

Figure 4: The time resolution of electron bunch EO signal is shown for various crystal distances and beam energies. The vertical bars mark the energies to be explored at CSU and JLab.

INVESTIGATION OF UPSTREAM TRANSIENT WAKEFIELDS DUE TO COHERENT SYNCHROTRON RADIATION IN BUNCH COMPRESSION CHICANES

Chad Mitchell* and Ji Qiang, LBNL, Berkeley, CA 94720, USA

Abstract

The longitudinal wakefield due to coherent synchrotron radiation (CSR) in the bending magnets of bunch compression chicanes can significantly impact the beam quality in high-brightness FEL light-sources. In addition to single-bend CSR effects, transient radiation that is generated within a bend can follow the electron bunch downstream through one or more lattice elements before interacting with the bunch. An analytical 1-D model is used to estimate the size of these upstream wakefields in the absence of vacuum chamber shielding, and an FFT-based, integrated Green function method for computing these wakefields has been implemented in the code IMPACT to investigate their dynamical effects in the second bunch compressor of a Next Generation Light Source.

INTRODUCTION

The bend-induced collective interaction due to CSR in bunch compression chicanes can pose a significant challenge in the design of FEL light sources, producing transverse emittance growth and increased energy spread in the beam delivery system that can result in decreased quality of the resulting FEL radiation. A variety of 1-D wakefield models of CSR have been developed to study these effects [1]-[3], and the primary difference between these models lies in the approximations made regarding the history of the particles over the transit time of the radiation.

The model described in [2] includes transient radiation due to bend entry and exit by assuming that all particles that lie upstream of the nearest dipole at their retarded times lie within an infinitely long drift space. By contrast, the model described in [3] makes use of more detailed information about the upstream lattice. As a result, it also includes radiation that has been emitted within upstream bending elements. This paper investigates the size of these upstream transient effects for chicanes of practical interest.

ANALYTICAL AND NUMERICAL MODELS

For a bunch with a longitudinal density profile λ, the longitudinal CSR wakefield in units of energy loss per unit length takes the form:

$$W(z,s) = \int_{-\infty}^{z} \lambda(z') K_{CSR}(z+s, z'+s) dz', \qquad (1)$$

where K_{CSR} is determined from the Liénard-Wiechert electric field of a point charge and the layout of the lattice [3], z is the longitudinal bunch coordinate, and s is a parameter that specifies the location of the bunch centroid within the lattice. The function K_{CSR} varies on a scale $\sim R/\gamma^3$ that can be many orders of magnitude shorter than the bunch length. One method for evaluating the integral (1) numerically given the density $\lambda(z_j)$ at a collection of longitudinal locations $z_j = z_0 + jh$, $(j = 0, \ldots, n)$ is to represent the density by an interpolating polynomial and to evaluate the integral analytically over each subinterval [4, 5]. For the case of piecewise constant interpolation, the result can be written in the form:

$$W(z_k, s) = \sum_{j=0}^{k} \lambda(z_j) w_{igf}^{k,j}(s), \qquad (2)$$

where for terms with $0 < j < k$,

$$w_{igf}^{k,j}(s) = \qquad (3)$$
$$I_{CSR}\left(z_k + s, z_j - \frac{h}{2} + s\right) - I_{CSR}\left(z_k, z_j + \frac{h}{2} + s\right),$$

and

$$I_{CSR}(s, s') = -\int_{-\infty}^{s'} K_{CSR}(s, s'') ds''. \qquad (4)$$

An explicit expression for I_{CSR} in the case of small bending angles and high energy for an arbitrary lattice consisting of circular arcs (bends) and drifts can be found in [3].

Implementation in IMPACT

The IMPACT code is a parallel particle-in-cell code suite for modeling high intensity, high brightness beams in rf proton linacs, electron linacs and photoinjectors [6]. The model for upstream radiation in equations (2-4) was implemented in IMPACT-Z using an FFT-based, integrated Green function algorithm [4, 5]. This feature provides a fast capability for computing the free-space 1D wakefield due to CSR in an arbitrary lattice consisting of bends and drifts.

To use this feature, an additional input parameter is required for the specification of each dipole and drift element in the IMPACT-Z input file. This parameter specifies the number of upstream elements whose CSR contribution is to be included in the wakefield calculation within that element. In order to provide consistency with the model of [2], it is assumed that the farthest upstream element used in the CSR calculation is an infinitely long drift space.

Upstream Radiation Effects

Consider a 4-bend magnetic chicane whose bends will be denoted as Bend $1, \ldots, 4$, moving downstream from the chicane entry. In this section, we will examine the CSR

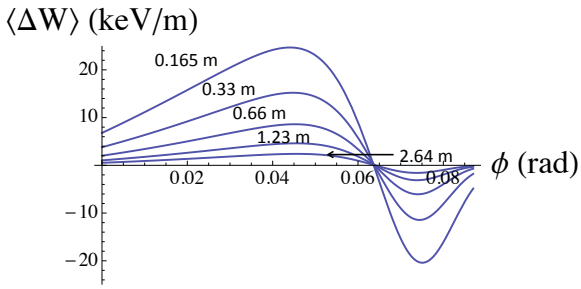

Figure 1: Approximate expression (8) for the difference in mean energy loss with and without the effect of upstream bends for a linearly compressing Gaussian bunch propagating through Bend 3 of the chicane of Table 1. The result is shown for various values of the central drift length.

wakefield when the bunch centroid lies within Bend 3. A portion of the particles within the bunch will lie within Bend 2 at their retarded times. Following a procedure similar to [7], one can use the results of [3] to show that in the limit $\gamma \to \infty$, the contribution of these particles to the total wakefield in Bend 3 takes the approximate form:

$$W_L(z,s) = \kappa F_L \lambda(z - \zeta_L), \tag{5}$$

where

$$\kappa = N r_c mc^2/R \tag{6}$$

and

$$F_L = \frac{4\psi(\phi+\psi+2L)}{\phi\{(\phi+\psi)^2+2L\psi\}}, \qquad \frac{\zeta_L}{R} = \frac{\phi^3}{24}\frac{\phi+4L}{\phi+L}. \tag{7}$$

Here ψ is the total bending angle of Bend 2, L is the ratio of the central drift length to the bending radius, and ϕ is the angle of the bunch centroid from the entry to Bend 3. By contrast, if we suppose that these particles at their retarded times lie within an infinitely long drift, then we recover Case A of [2]. In the limit $\gamma \to \infty$, it follows that (5) holds with $L \to \infty$ [7].

A convenient measure for the size of the upstream effects is the mean and rms value of the difference ΔW between the wakefields predicted from the two models. Making use of (5) in the case of a Gaussian bunch gives:

$$\langle \Delta W \rangle \approx \frac{\kappa}{\sqrt{4\pi}\sigma}\left[F_L e^{-\zeta_L^2/4\sigma^2} - F_\infty e^{-\zeta_\infty^2/4\sigma^2}\right]. \tag{8}$$

Consider a Gaussian bunch undergoing compression in a chicane described by the parameters of Table 1. Figure 1 shows the quantity (8) as a function of the entry angle ϕ into Bend 3 for various values of the central drift length L_c. In computing these curves, the compression of the bunch is modeled by taking $\sigma_z = \sigma_{z0}/[1 + (C-1)\phi/|\theta|]$ where $|\theta| = 87$ mrad and $C \approx 5$ is the compression factor at the chicane exit.

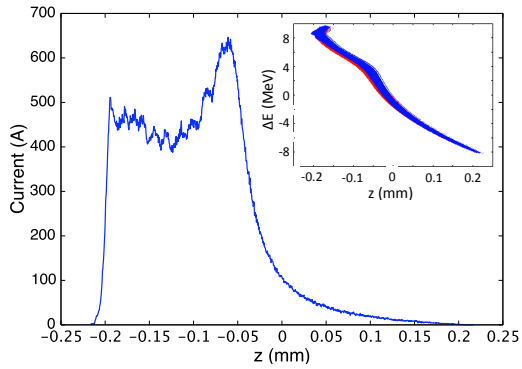

Figure 2: Current profile at the exit of BC2. The head of the bunch appears on the left ($z < 0$). (Inset) Longitudinal phase space at the exit of BC2 with (blue) and without (red) the effects of longitudinal CSR included.

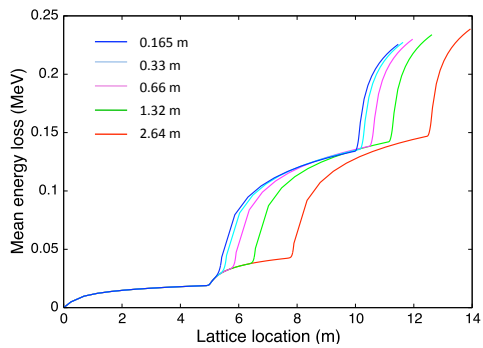

Figure 3: The cumulative loss in the mean energy of the bunch along the length of the chicane is shown for the values $L_c = 2.64$ m, 1.32 m, 0.66 m, 0.33 m, and 0.165 m.

APPLICATION TO A NEXT GENERATION LIGHT SOURCE

This algorithm was used to investigate CSR-induced dynamical effects in the second bunch compressor of a previously proposed Next Generation Light Source X-ray FEL being studied at Lawrence Berkeley National Laboratory [8]. Basic parameters for the chicane are provided in Table 1. Figure 2 shows the compressed current profile at the exit of BC2, together with the longitudinal phase space at the same location, both with and without the effect of the longitudinal CSR wakefield. The CSR interaction throughout the chicane induces a growth in the rms horizontal emittance of 23% relative to the initial value of 0.65 μm.

We study the effect of varying the length of the central drift L_c, leaving the compression factor of the chicane unaffected while controlling the strength of the upstream wakefield within Bend 3. Figure 3 illustrates the CSR-induced loss in the mean energy of the bunch along the length of the chicane for several values of the central drift length L_c. In order to illustrate the contribution of upstream radiation, Fig. 4 illustrates the difference between

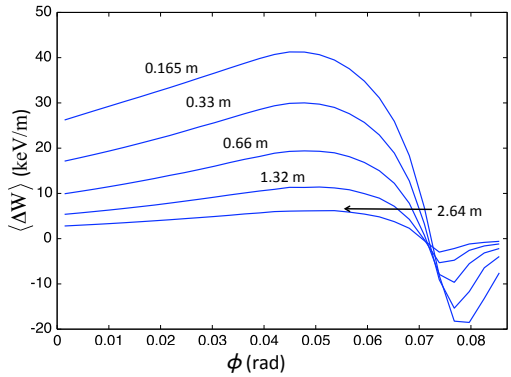

Figure 4: Difference between the longitudinal CSR wakefield in Bend 3 of BC2 as computed using the model of [2] (without upstream transient effects) and [3] (with upstream transient effects) during IMPACT-Z simulation. The average of this quantity over the length of the bunch is shown as a function of bend entry angle. Compare Fig. 1.

the mean CSR-induced energy loss as computed using the two wakefield models [2] and [3] along the length of Bend 3 for the same values of L_c. This difference attains a maximum at 40-50 mrad into the bend and changes sign 10-20 mrad upstream of the bend exit, similar to the curves shown in Fig. 1. The choice of model has a very weak ($\sim 10^{-3}$) relative effect on the final transverse emittance and the second beam moments for all values of L_c considered. The dominant effect of the upstream transient radiation is to introduce a displacement of the bunch centroid in both the horizontal coordinate and momentum, and these quantities are shown in Fig. 5 as a function of the central drift length.

DISCUSSION AND CONCLUSIONS

A one-dimensional free-space wakefield model of CSR including upstream radiation has been implemented in the code IMPACT-Z and used to investigate CSR wakefield effects in the second bunch compressor chicane of a Next Generation Light Source. The difference in mean energy loss due to the coupling with upstream radiation introduces a steering error of 1-3% in the transverse phase plane at the chicane exit. A previous study has investigated upstream radiation effects on the CSR-induced microbunching gain for this system [9], and future work will investigate the effects of vacuum chamber shielding.

HIGH-GRADIENT METALLIC PHOTONIC BAND-GAP (PBG) STRUCTURE BREAKDOWN TESTING AT 17 GHz*

B.J. Munroe†, M.A. Shapiro, R.J. Temkin, MIT PSFC, Cambridge, MA 02139, USA

Abstract

Photonic Band-gap (PBG) structures continue to be a promising area of research for future accelerator structures. Previous experiments at X-Band have demonstrated that PBG structures can operate at high gradient and low breakdown probability, provided that pulsed heating is controlled. A metallic single-cell standing-wave structure has been constructed at MIT to investigate breakdown performance of PBG structures with very high surface temperature rise. The MIT standing-wave structure test stand has an available power of 4 MW for a maximum gradient of 130 MV/m; the actual realized gradient may be lower due to breakdown limitations. The MIT test stand will also utilize novel diagnostics, including fast camera imaging and optical spectroscopy of breakdowns.

INTRODUCTION

Photonic band-gap (PBG) structures, which use a lattice of metallic or dielectric rods to confine an accelerator mode while damping higher-order modes (HOMs), are a topic of ongoing experimental and theoretical work [1, 2, 3, 4]. Previous experimental work has demonstrated successful acceleration using a traveling-wave PBG structure [1] as well as suppression of wakefields [4, 5]. More recent work by MIT and SLAC National Accelerator Lab has shown that metallic PBG structures can operate at high gradient and low breakdown probability, achieving gradients of greater than 100 MV/m with a breakdown probability of less than 10^{-3} per pulse per meter of structure [6]. To expand on this X-band (11.4 GHz) testing a metallic PBG structure has been designed for testing at Ku-band (17.1 GHz). This metallic structure will be used to further investigate the role of pulsed heating on breakdown probability.

STRUCTURE DESIGN

The metallic PBG structure designed for high-gradient testing at MIT is designed as a scaled version of the round-rod PBG structure previously tested at SLAC and reported in [3]. The structure is axially powered via a scaled version of the SLAC $TM_{0,1}$ mode launcher. The PBG lattice has a filling factor, i.e. the ratio between the rod radius to the rod spacing, of $a/b = 0.18$, the same as the X-band structure. The high-field irises on either side of the PBG cell have an aperture of 0.216λ and a thickness of 0.176λ, again in agreement with the X-band structure. The main variation in structure design is that the Ku-band PBG cell has three rows of round rods, as opposed to the X-band structure's two, which is required by the Ku-band structure's open outer wall, as seen in Fig. 1. This open wall allows a direct line of sight to the high-field surface of the inner rods, allowing significantly greater diagnostic access to the structure during testing.

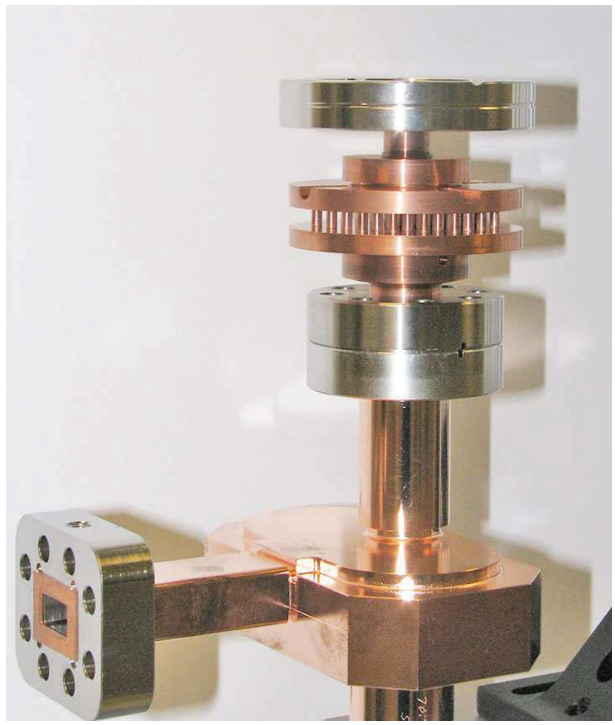

Figure 1: Metallic PBG structure and $TM_{0,1}$ mode launcher at MIT prior to structure brazing. Note the open outer wall of the PBG cell.

This structure will investigate the frequency scaling of breakdown behavior first observed in the testing of the PBG structure at X-band at SLAC, namely the effect of high surface magnetic fields on breakdown probability. To provide an accurate comparison the structure needs to be exposed, as limited by the breakdown probability, to gradients greater than 100 MV/m. The metallic PBG structure is expected to achieve 100 MV/m gradient at 2.4 MW of input rf power, as shown in Table 1. Note that the pulsed heating for this structure is higher than the X-band structure because of the increase in both the surface resistivity of copper and the power density with frequency. This power level is well below the approximately 4 MW of rf power available at the MIT test stand. The advanced optical diagnostics available at MIT combined with testing the structure at very high gradient should provide insight into how the structure fails and criteria for evaluating structure condition during testing.

Table 1: Performance of 17 GHz Round-rod PBG Structure at 100 MV/m

Power	2.4 MW
Peak Surface Electric Field	200 MV/m
Peak Surface Magnetic Field	900 kA/m
Pulsed Heating for 150 ns flat pulse	163 K

This structure has been fabricated using direct machining of the structure into cups which are then brazed together. The structure can be tuned after fabrication by perturbing the coupling cells using stainless steel tuning studs.

STRUCTURE COLD TEST

Prior to hot testing the PBG structures are cold tested using a vector network analyzer (VNA) to confirm that the quality factor, frequency, and coupling match the design values, shown in Table 2. This is necessary to ensure proper operation in hot test, and to properly model the fields in the structure, as described in [6]. By coupling through the input port of the mode launcher single port measurements of the coupling and quality factor can be made. Single port measurement of the field profile can also be measured using the dielectric perturbation technique described in [6]. The results of this field profile measurement can be seen in Fig.2. This PBG structure showed an asymmetric field profile, reduced coupling, and reduced quality factor, as seen in the cold test results. This structure was installed in the test stand, but sufficient coupling could not be obtained, so a new structure was fabricated.

Table 2: Design values of 17 GHz Round-rod PBG Structure

Frequency	17.140 GHz
Q factor	5600
S11	−46 dB

This new structure was fabricated in the same fashion as the first structure. Prior to brazing the performance of the structure was characterized using two coaxial probes situated on-axis in the structure. The transmission between these probes allowed a measurement of the quality factor of the modes independent of coupling through the mode launcher, which suffers when the structure is press-fit instead of brazed. The results of this measurement can be seen in Fig. 3. Note that this measurement shows a lower Q and a shift in frequency relative to the design point; both these values are expected to be closer to the design values after brazing. This structure will undergo both single-port and transmission Q measurements, as well as field profile measurements using a dielectric perturbation, after brazing to confirm that Q, frequency, and coupling are all within acceptable limits of the design values.

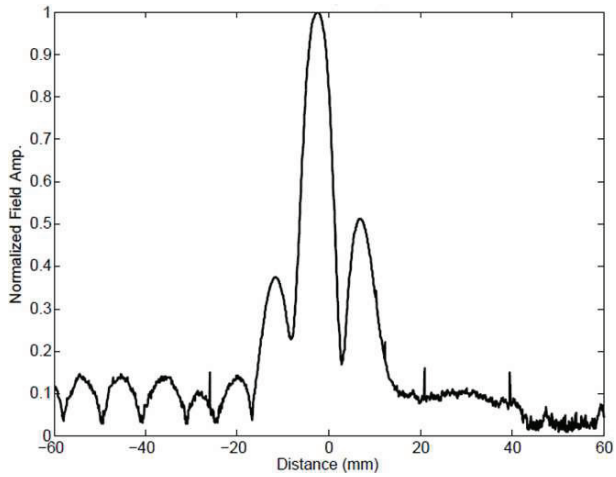

Figure 2: Measured field profile of first 17 GHz metallic PBG structure, obtained via use of a dielectric perturbation technique.

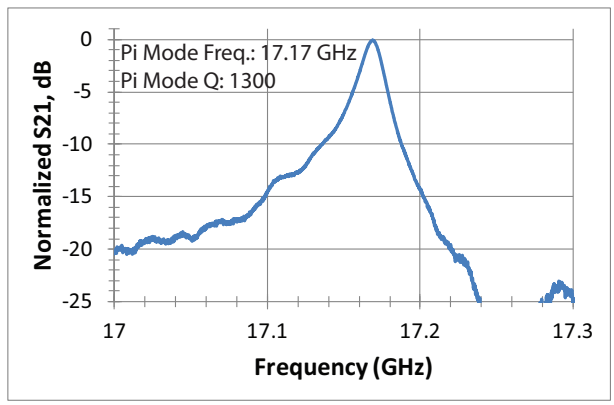

Figure 3: Transmission measurement of the second 17 GHz metallic PBG structure, prior to brazing. The Q of the mode of interest is found to be 1300 at a frequency of 17.169 GHz.

MIT 17 GHz TEST STAND

The standing wave test stand at MIT will be powered by the MIT/Haimson Research Corporation (HRC) relativistic beam klystron operating at 17.1 GHz. The klystron output that can be coupled to the test stand is limited to 12 MW to avoid breakdowns on the microwave window in the transmission line to the test stand. When coupled through a 4.2 dB hybrid (Fig. 4), which is inserted to protect the klystron from reflected power, the power available at the test stand is limited to 4 MW. Because the power density increases with frequency, this amount of available power is more than sufficient to conduct breakdown experiments similar to those at SLAC, as seen in Table 1.

The MIT standing wave test stand will utilize diagnostics. This is made possible through the use of an external vacuum chamber used to contain the device under test. This allows line of sight diagnostic access to the high-field regions of the PBG structure through view ports in the vac-

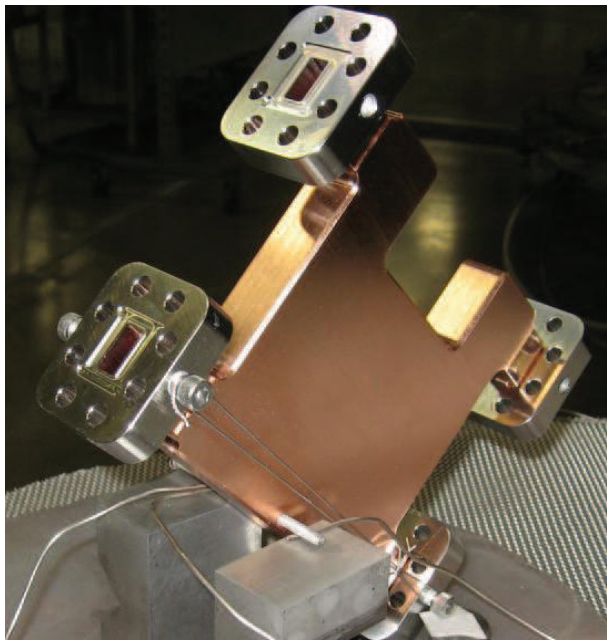

Figure 4: 4.2 dB hybrid from Haimson Research Corporation.

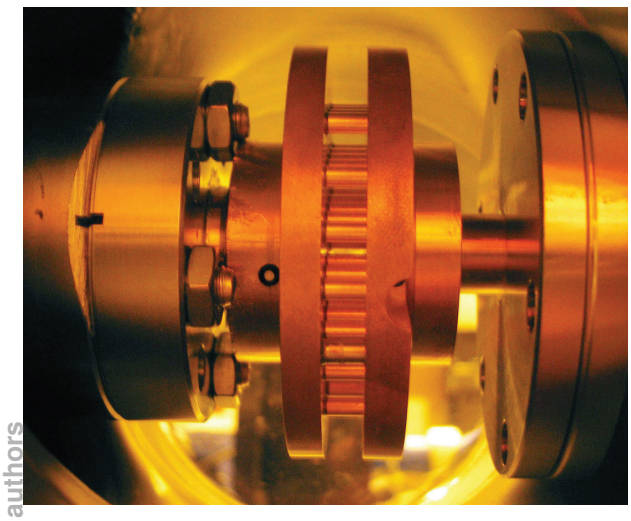

Figure 5: Metallic PBG structure installed in MIT test stand.

uum chamber. A nanosecond-gated ICCD camera will be used to observe and locate breakdown events, and a broadband optical spectrometer will be used to identify breakdown materials. Optical access to the structure can be seen in Fig. 5.

STRUCTURE HOT TEST

The operation of the MIT 17 GHz test stand was validated with the use of the first PBG structure described above. The microwave diagnostics functioned properly, confirming the cold test results that very little power was coupled into the design mode for that structure. Optical diagnostics were not used during this test, but their feasibility was verified as shown in Fig. 5. The second structure should allow proper testing of the high power test stand.

CONCLUSION

A metallic PBG structure has been designed and undergone preliminary tests at MIT. This structure will further investigate the relationship between pulsed heating and breakdown probability in high-gradient accelerator structures. The first iteration of the structure showed reduced coupling and quality factor, likely due to fabrication errors. This structure was used to validate both the cold and hot test procedures at MIT. The Q of the design mode was measured using both single port and transmission techniques, and a dielectric perturbation was used to determine the field profile of the design mode. The structure was briefly placed under hot test. The microwave diagnostics were confirmed to work properly, and optical access to the structure after installation was confirmed. A second iteration of the structure has been constructed and shows improved performance in cold tests of the structure prior to brazing. This structure will undergo further testing after brazing to confirm proper fabrication prior to being installed for hot testing.

FIRST CAVITY RESULTS FROM THE CORNELL SRF GROUP'S Nb_3Sn PROGRAM*

S. Posen† and M. Liepe
Cornell Laboratory for Accelerator-Based Sciences and Education, Ithaca, NY

Abstract

Breakthrough performance levels were achieved for a 1.3 GHz single cell cavity that was fabricated, coated with Nb_3Sn, and tested at Cornell. Unlike previous Nb_3Sn cavities, this cavity showed minimal R_s-increase up to medium fields. This disproves speculation that the R_s-increase in previous cavities was caused by vortex dissipation for $B > B_{c1}$, as surface fields far higher than the measured B_{c1} for this cavity were reached. At 2 K, quench occurred at ∼55 mT, apparently due to a defect, so additional treatment may increase the maximum gradient to even higher fields. At 4.2 K, at ∼12 MV/m, the cavity achieved Q_0∼1×10^{10}, approximately 20 times higher than niobium at this temperature. This makes it the first accelerator cavity made with an alternative superconductor to far outperform niobium at useable gradients.

INTRODUCTION

Superconducting Radio-Frequency (SRF) researchers have been highly effective at finding preparation methods that suppress performance-limiting effects in niobium particle accelerator cavities. Now cavities are regularly produced that operate very close to the fundamental limits of niobium: they have surface resistances R_s close to the ideal BCS value at operating temperatures, and they reach maximum surface magnetic fields close to the superheating field B_{sh}. To keep up with continually increasing demands of future SRF facilities, researchers have begun a significant effort to develop alternative materials to niobium, materials with smaller R_s and/or larger predicted B_{sh}.

Nb_3Sn is one of the most promising alternative SRF materials. Because it has a high critical temperature T_c of ∼18 K, compared to 9.2 K for niobium, its R_{BCS} at a given temperature is much smaller. This makes the material ideal for continuous wave (CW) linacs: benefits include a smaller and simpler cryogenic plant, the possibility of 4.2 K operation (no superfluid; atmospheric operation), and higher cost-optimum accelerating gradients in CW operation. Its predicted B_{sh} is nearly twice that of Nb, up to ∼400 mT depending on the material parameters used for the calculation. This makes the material ideal also for high energy linacs: it would allow Nb_3Sn cavities to operate at higher accelerating gradients than Nb cavities, and therefore fewer cavities would be required.

In the seventies, Siemens AG developed a method to fabricate Nb_3Sn coatings via vapor diffusion, which produced excellent RF results [1]. The University of Wuppertal applied this coating mechanism to particle accelerator cavities, achieving very small R_s at low fields, but their cavities showed a strong increase in surface resistance with increasing field (this effect is called Q-slope, for the shape of the graph of quality factor Q versus accelerating gradient E_{acc}). The Q_0 vs E_{acc} curve of one of the best cavities produced by University of Wuppertal and tested at JLab is shown in Fig. 1 [2].

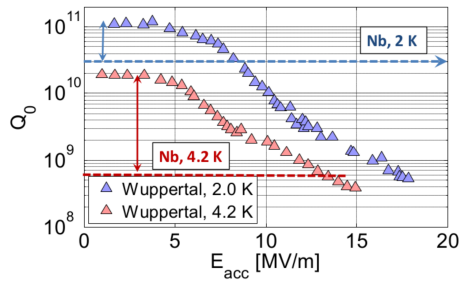

Figure 1: Q vs E curves at 2 K and 4.2 K for one of the best Nb_3Sn cavities produced by U. Wuppertal [2]. The approximate values for a Nb cavity are shown for comparison.

Various causes for the Q-slope were suggested, such as intergrain losses, imperfect stoichiometry [3], and dissipation due to vortex penetration beginning at the lower critical field B_{c1} [4]. As a result, it has been unclear whether or not this Q-slope behavior is fundamental to Nb_3Sn. In a recent historical review, Kneisel called finding the answer to this question and determining the origin of the Q-slope "the next important steps" for Nb_3Sn [5]. More importantly, if vortex penetration at B_{c1} were unavoidable, then bulk alternative SRF materials in general—which tend to have relatively small B_{c1} values—would be severely limited in the fields they could reach without strong dissipation. There is an energy barrier to vortex penetration, which for an ideal surface prevents strong vortex dissipation up to the superheating field B_{sh} [6], but small defects with size on the order of the coherence length ξ can decrease it. Other alternative materials also tend to have relatively small ξ, so the possiblity of vortex penetration above B_{c1} has been a serious concern.

Cornell University is now leading the program for new R&D efforts on Nb_3Sn SRF cavities. In 2009, Nb_3Sn development at Cornell began with the design, fabrication, and commissioning of a small coating chamber for samples. After establishing the capability to repeatably produce Nb_3Sn films of sufficiently high quality for cavity RF surfaces [7], Cornell researchers began work on a large coating chamber for single cell 1.3 GHz cavities, shown in

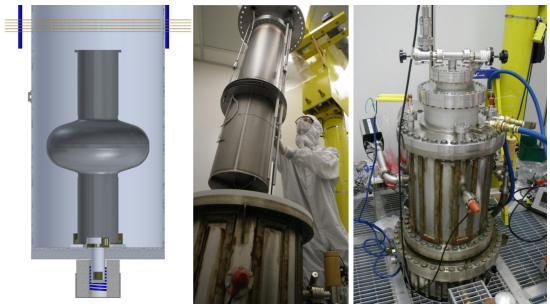

Figure 2: Cross-section of coating chamber (left), coating chamber being lowered into furnace (center), and UHV furnace with chamber inside (right).

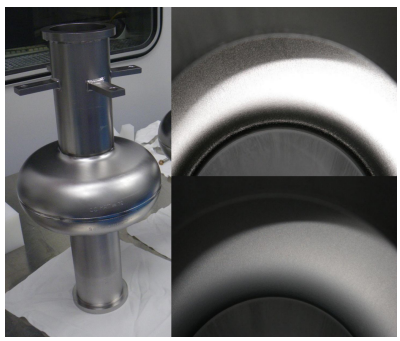

Figure 3: Coated cavity (left); view looking down into cavity before (top right) and after coating (bottom right).

Fig. 2. The first cavity coated showed unusually high R_s in RF testing, which was attributed to problems with the niobium cavity substrate. The performance of the second cavity coated will be presented here.

RF MEASUREMENTS

ERL1-4, a 1.3 GHz Cornell ERL-shaped (similar to TESLA shape) single cell cavity, was coated with Nb_3Sn via thermal vapor diffusion. Visually, the Nb_3Sn surface is a darker gray than niobium, and it is matte rather than shiny, as shown in Fig. 3. After the coating process it was treated with only a high pressure rinse (HPR) before mounting to a vertical test stand for cryogenic performance test. Before insertion to the dewar, the outside cavity surface was covered with an array of temperature sensors (temperature map) to obtain information about the loss distribution. The cavity was cooled at a very slow rate, $\gtrsim$ 6 min/K, as specified by Wuppertal researchers, to reduce trapped flux due to thermocurrents [2].

The Q vs E curve of ERL1-4 is shown in Fig. 4, along with that of the Wuppertal cavity from Fig. 1 for comparison. Overall, the performance is excellent. Unlike the cavities produced by Wuppertal, it does not show a strong reduction in Q_0 above 5 MV/m. At 4.2 K, at medium fields the Q_0 is up to approximately 10 times higher than that of the Wuppertal cavity, and approximately 20 times higher than a niobium cavity. At 2 K, the Q_0 is only slightly higher, indicating that residual resitance dominates over

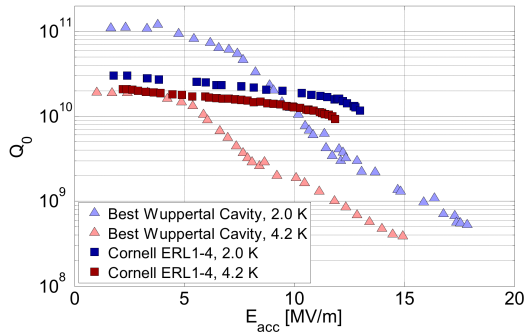

Figure 4: Q vs E curve from the new Cornell Nb_3Sn cavity, showing a small residual resistance at low fields and a large improvement in Q_0 at usable gradients over one of the best U. Wuppertal cavities. Uncertainty in Q and E is approximately 10%.

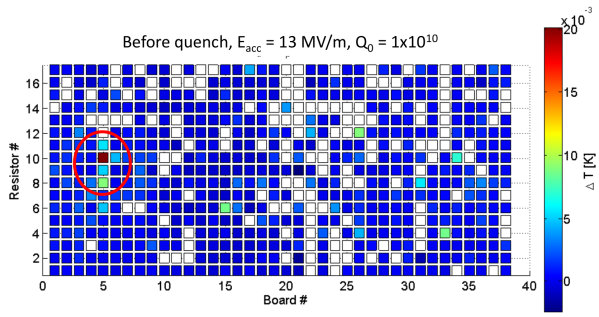

Figure 5: Temperature maps (which show the heating of the outer cavity surface relative to the helium bath) before quench, close to the quench field (top) and after the first quench (bottom). The region of strong localized heating is circled. Notice the difference in scale between the top and bottom.

BCS, with very low R_{res} value of $\sim$9 nΩ, similar to most Wuppertal cavities [2]. Above 9 MV/m, due to its relatively flat Q_0, ERL1-4 has a higher Q_0 than even this exceptional Wuppertal cavity at 2 K.

Quench occurred at approximately 55 mT at 2 K, which was preceeded by a sharp drop in Q_0 on the order of 10%, as well as pre-heating on the temperature map. The pre-heating was highly localized, as shown in Fig. 5. After quench, the same area showed further increased heating, consistent with this being the quench location. Our observations suggest that the limitation is a defect that becomes normal conducting when the Q_0 drop occurs, and triggers breakdown at higher fields. The dominance of this spot on the temperature map shows that this is a local problem—a defect—not a global problem with Nb_3Sn.

Q_0 was measured as a function of temperature, as shown in the left side of Fig. 6. There was no sign of Q_0 change near the T_c of niobium, 9.2 K, indicating excellent Nb_3Sn coverage of the surface. The high-temperature range is highlighted in the inset, from which a T_c of 18.0 ± 0.1 K is measured. Q_0 was converted to an estimated average surface resistance via $R_s = G/Q_0$, where G is the geometry

$B_c(0)$ [T]	0.47 ± 0.6
$B_{c1}(0)$ [T]	0.027 ± 0.005
$B_{sh}(0)$ [T]	0.39 ± 0.05

constant of the cavity. The resulting R_s vs T data was fit using a polymorphic BCS analysis [8]. The fit is shown in the right side of Fig. 6, and the fit parameters and derived values are summarized in Table 1. Δ/k_BT_c and B_c are in good agreement with literature values.

Table 1 lists the material parameters obtained from the $R_s(T)$ fit, together with additional parameters calculated from the fit parameters using Ginzburg-Landau theory (see [9] for derivation of each value). The so obtained B_{c1} value agrees well with a B_{c1} measurement performed with μ-SR by A. Grassellino et al [10] on a Nb_3Sn witness sample produced by Cornell. Figure 7 compares B_{c1} to the Q vs B data, showing that the cavity far exceeds B_{c1} without a significant increase in surface resistance. This is important, as it shows that vortex penetration does not occur at B_{c1} for bulk films of superconductors with small coherence length. The energy barrier keeps Meissner state metastable, even with the small ξ of Nb_3Sn. The Q-slope seen in the Wuppertal cavities therefore does not represent a fundamental problem for alternative SRF materials.

CONCLUSIONS

Exceptional SRF performance was observed in tests of a new Nb_3Sn cavity at Cornell. At 2 K, the surface magnetic field reached 55 ± 6 mT, far exceeding $B_{c1} = 27 \pm 5$ mT without any sign of vortex penetration. This disproves spectulation that the Q-slope observed in previous Nb_3Sn cavities was an inevitable result of exceeding B_{c1}. The gradient was quench limited at a defect, and there is no indication of any fundamental mechanism that would prevent future Nb_3Sn cavities from reaching even higher fields. Future research on preparation methods to achieve better Nb_3Sn surfaces can be expected to overcome non-fundamental limitations as they have in niobium, allowing fields close to $B_{sh} \sim 400$ mT to be reached. Even with the current performance achieved, Nb_3Sn now becomes a promising alternative material for certain future accelerators, as at usable accelerating fields $\sim$12 MV/m, we have shown that at 4.2 K Nb_3Sn cavities can achieve a Q_0 of 10^{10}, $\sim$20 times higher than niobium.

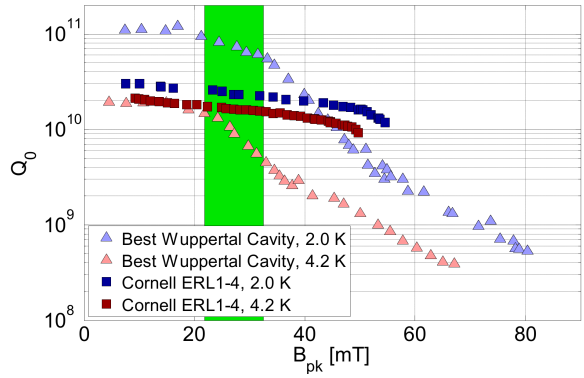

Figure 7: Q vs B curves of the Cornell and Wuppertal cavities. In green is the Cornell cavity's $B_{c1} = 27 \pm 5$ mT, which is exceeded without indication of vortex dissipation.

ACKNOWLEDGEMENTS

The authors would like to express sincere thanks to summer student assistant F. Wohlfarth; A. Grassellino et al. for sample B_{c1} measurement; N. Valles for polymorphic fit program; J. Halbritter, author of the SRIMP program; P. Kneisel for excellent summary of Nb_3Sn SRF history [5]; and H. Padamsee for helpful discussions.

Abstract

Ytterbium (Yb) lasers have good thermal and optical properties. The Yb lasers can be pumped by laser diodes. The oscillation wavelength is near the excitation wavelength. Yb can be highly doped in YAG crystal, so Yb-doped crystal has large gain even if the crystal is thin. These properties are advantages for high power operation. Additionally, because of broad emission spectrum of Yb, the passively mode-locked Yb lasers can easily generate femtosecond pulse at high repetition rate. The Yb lasers have been applied to many fields such as optical frequency comb and X-ray generation. Now, femtosecond pulse of much higher energy at high repetition rate is being required for dielectric laser accelerator (DLA) and lasertron. We have developed high power mode-locked Yb laser, and aim to generate 500 fs pulse of 500 W average power at 50 Hz. In this research, e acheived 20 W mode-locked Yb fiber laser amplification system at 1MHz. We report this achievement and the structure of our Yb laser system to achieve our final goal.

INTRODUCTION

Passively mode-locked lasers can easily generate femtosecond pulse at high repetition rate. The femtosecond pulses have been used in many scientific fields. In the accelerator field, femtosecond pulse of much higher energy at high repetition rate is required for new acceleration technologies such as DLA [1], lasertron [2] and laser wakefield plasma acceleration.

Yb lasers have many advantages for high power operation. Yb can be pumped directly by laser diodes (LD), which can convert electricity into light with as high efficiency as 60 percent. Since the difference between the oscillation wavelength and the excitation wavelength is as low as 90 nm, the quantum efficiency of Yb is very high. Furthermore, Yb can be doped in YAG crystal with high concentration, which enables thin disk lasers. The large surface to volume ratio of the thin disk enables efficient heat removal from the laser material and decreases the wavefront distortion due to the thermal lens effect.

Although the Ti:Sapphire lasers excel at less than 100 fs pulse generation, the Yb lasers have advantages over the Ti:Sapphire lasers when we need several hundreds fs pulse generation for high power operation.

† matsumura@nuclear.jp

In this research, we have developed a high power mode-locked Yb laser, and are aiming to generate 500 fs pulse with 500 W average power at 50 Hz for the new acceleration applications.

CPA SYSTEM OF YB LASER

To achieve the generation of 500 fs pulse of 500 W average power at 50 Hz, CPA was adopted. The schematic layout of the Yb laser is shown in Fig. 1. For amplification, Yb fiber and Yb:YAG lasers were used. The Yb fiber lasers have higher gain than the Yb solid lasers, and fibers can be cooled sufficiently by air. However, LDs for fiber lasers cost more than those for solid lasers, and power scaling cannot be applied for the fiber lasers. Additionally, the fiber lasers can't amplify high intensity pulse because of its damage threshold. For these reasons, the Yb fiber amplifiers were adopted at the first half part, while the Yb:YAG amplifiers were adopted at the second half part.

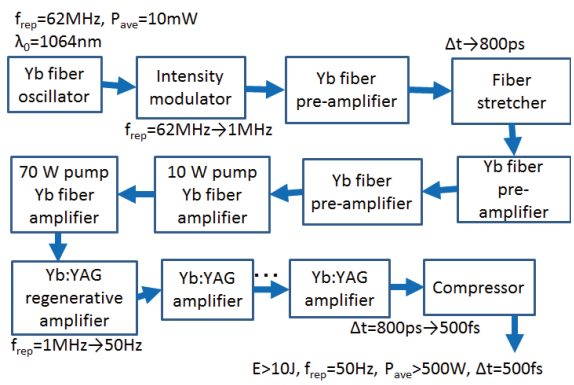

Figure 1: Schematic layout of Yb CPA system.

The ultra-short pulse at 62 MHz was emitted from a Yb fiber oscillator. After that, the pulse was picked up from the pulse train by an electro-optical (EO) module. The repetition rate was reduced from 62 MHz to 1 MHz. Then, the pulse was stretched to 800 ps by a fiber Bragg grating (FBG) stretcher. Through these fiber modules, the power of the pulse decreased. Therefore, three small Yb fiber pre-amplifiers were equipped. These pre-amplifications were needed to suppress amplified spontaneous emission (ASE) at the next amplifiers. After the three pre-amplifiers, the pulse was amplified up to several μJ by two Yb fiber amplifiers pumped by 10 W and 70 W LDs. Next amplifications are done by Yb:YAG lasers. A regenerative amplifier reduces repetition rate from 1 MHz to 50 Hz while amplifying the pulse. Finally, the pulse is amplified up to 10 J by

Copyright © 2013 CC-BY-3.0 and by the respective authors

the sequent Yb:YAG amplifiers. A grating pair and double prism pair are being considered as a compressor candidate. Whether the compressor is the grating pair or double prism pair, the pulse is compressed from 800 ps to 500 fs, and 500 fs pulse of 500 W average power at 50 Hz is generated by this Yb laser system.

PRESENT EXPERIMENTAL RESULTS

In this section, the experimental results and present laser status are described.

Yb Fiber Oscillator

The Yb fiber oscillator was mode-locked by nonlinear polarization rotation (NPR). Its structure was almost same as typical NPR mode-locked Yb fiber lasers [3]. However, the polarization beam splitter was not used as an output component because the output from it includes more ASE than that from other components in principle. In our oscillator, the reflected light from a grating was used for output. The power of it was 10 mW and the repetition rate was 62 MHz. The central wavelength was 1060 nm, and FWHM of the spectrum was 49 nm.

EO Fiber Module, FBG Stretcher and Preamplifiers

A part of the 62 MHz optical pulse was captured by a photodiode. The frequency of photodiode signal was reduced from 62 MHz to 1 MHz. The delay and voltage of 1 MHz signal was adequately adjusted for the EO module. Figure 2 describes the result of intensity modulation. The pulse was picked up from the pulse train as shown in Fig. 2. The SN ratio after the pre-amplifiers was about 100.

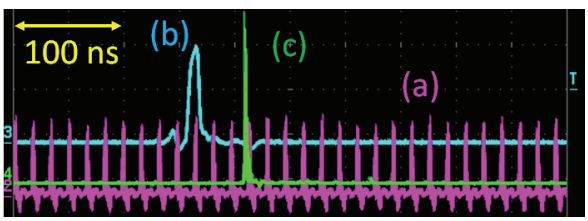

Figure 2: Intensity modulation result. (a) The pulse train from the oscillator, (b) The electric pulse applied on the EO module, (c) The pulse picked up by the EO module

A FBG has periodic refractive index in a fiber, and reflects light at designed wavelength. A FBG stretcher reflected light at different positions according to the wavelength, and gave the pulse positive dispersion. The pulse was stretched to 800 ps here.

The pulse was attenuated through the EO module and at the reflection of the stretcher. In order to suppress ASE at the Yb fiber amplifiers, one Yb fiber pre-amplifier was equipped after the EO module and two were after the stretcher, which were pumped by LDs of 150 mW, 150 mW and 200 mW respectively. By equipping these preamplifiers, the input power to the first Yb fiber amplifier was improved from 0.1 mW to 137 mW.

Yb Fiber Amplifiers

Two Yb fiber amplifiers amplified the pulse after the pre-amplification. The first amplifier consists of 10 W LD and 4 m long 10 μm-core Yb double cladding fiber. The second amplifier consists of 70 W LD and 2 m long 25 μm-core Yb double cladding fiber. The structure of them is described in Fig. 3. The edges of the fibers were cut at the angle of 8 degrees to reduce Fresnel reflection. The 70 W LD was so strong that the fiber chuck had heavy thermal load. For this reason, all-metal chucks were adopted for the both sides of the second amplifier. Additionally, the fiber chuck mounts were large, so they acted as good heat sink and reduced the thermal load of the fiber and fiber chucks.

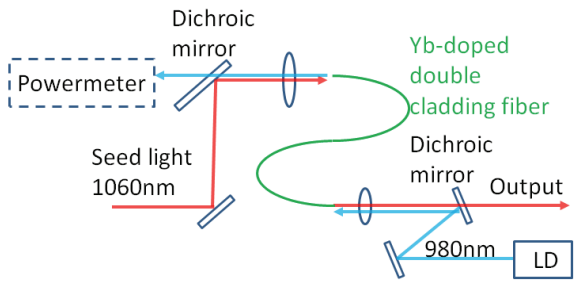

Figure 3: The structure of the Yb fiber laser amplifier.

Figure 4 shows the amplification result from the second amplifier. The 70 W LD was cooled by water, but the water temperature wasn't controled (was controled at room temperature). The maximum output power was 18.0 W then.

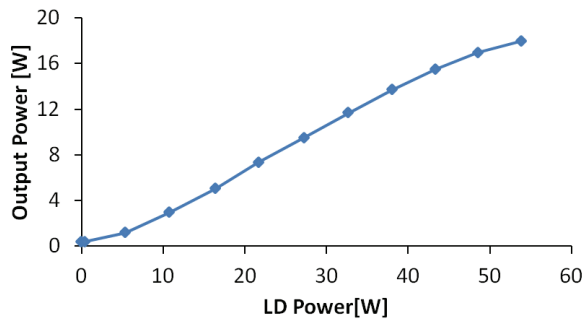

Figure 4: The output power from the second Yb fiber amplifier. The 70 W LD was cooled by water, but the water temperature wasn't controled.

The central wavelength of the LD was around 976 nm, but it depended on its temperature. Considering the narrow FWHM of Yb absobtion cross section around 976 nm, it was important to adjust the wavelength by controlling the cooling temperature. The experiment was done by measuring the LD power from the fiber at the seed laser injection side. The powermeter was set behind the dichroic mirror in Fig. 3. The measured power means the power not used for the amplification. Not all the power could be measured because of small diameter of the lens, but that was enough because the temperature to minimize the measured power was only the parameter we needed. From Fig. 5, Cooling

Copyright © 2013 CC-BY-3.0 and by the respective authors

temperature of 289 K was the best for over 50 W LD operation. The maximum output power was improved to 20.9 W at 289 K. The SN ratio was measured by a photodiode, and it was about 100. Additionally, the observation of this photodiode signal showed ASE was small. Therefore, the pulse energy could be calculated as 13 μJ when ASE was ignored.

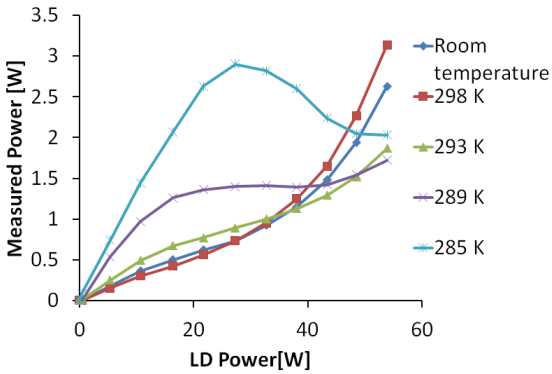

Figure 5: Power measurement experiment by changing cooling temperature.

Yb:YAG Solid Amplifiers

The first Yb:YAG amplifier is a regenerative amplifier. Here, the repetition rate will be reduced from 1 MHz to 50 Hz. The basic experiment was done to check whether a Pockels cell could pick up and dump the pulse. The result of this experiment showed the Pockels cell could pick up and dump it clearly. The SN ratio was over 150.

The final Yb:YAG amplifier is being designed now. Here, 50 pieces of Yb:YAG crystals are arranged symmetrically on the edge of a rotating disk. The seed pulse comes at 50 Hz, but each pulse injects on the different Yb:YAG crystals in 1 second. Therefore, the thermal load per one crystal decreases. The pulse energy will be amplified up to 10 J by 8 modules of 10 kW LD.

Compressor

Two ways to compress the pulse from 800 ps to 500 fs are now being considered. One is transmission grating pair. The other is double prism pair. The grating pair is often used for high intensity lasers. However, its cost is very high and a large vacuum chamber is required. Although the double prism pair cannot give large dispersion, its cost is relatively low and it may not need a vacuum chamber because the prism surface is very plane. To know the required distance for double prism compression, the dispersion was calculated based on Ref. [4]. In this calculation, the laser diameter was considered. The prism material was F2. The wavelength was 515 nm to make the dispersion large. The calculation result are shown in Fig. 6. From this calculation, it was shown that 32 times round trips between 3 m prism pair distance are needed to compress 800 ps pulse when the prism size is 50 mm and the FWHM of spectrum is 10 nm. Therefore, it will be difficult to cmpress the pulse by the double prism pair of 50 mm prisms.

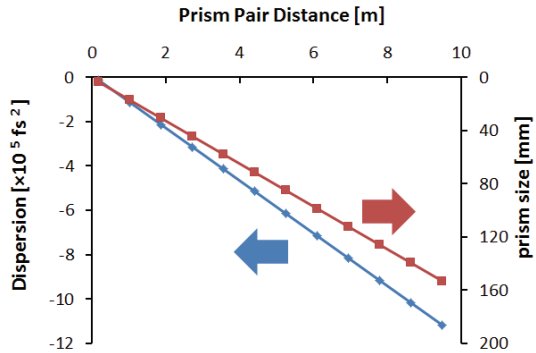

Figure 6: Dispesion and required prism size for the prism pair distance.

CONCLUSION

In this research, we reduced repetition reduction to 1 MHz, amplified the pulse up to 13 W average power without noise pulse, and achieved over 10 μJ pulse energy. The present laser parameters and the goal parameters are compared in Table 1. We will go to the stage of the Yb:YAG amplifiers. In the near future, the generation of 500 fs pulse of 500 W average power at 50 Hz will be achieved.

Table 1: Present Laser Parameters and Goal Parameters

	Present	Goal
Pulse energy	13 μJ	10 J
Repetition rate	1 MHz	50 Hz
Average power	13 W	500 W
Pulse duration	800 ps	500 fs

BELLA LASER AND OPERATIONS*

W.P. Leemans, J. Daniels, A. Deshmukh, A.J. Gonsalves, A. Magana, H.S. Mao, D.E. Mittelberger, K. Nakamura, J.R. Riley, D. Syversrud, C. Toth, N. Ybarrolaza, LBNL, Berkeley, CA 94720, USA

Abstract

The BELLA laser system is the first high repetition rate petawatt class laser in the world. The laser was acquired from THALES to allow laser plasma acceleration (LPA) experiments that aim at exploring the physics of linear and non-linear interactions of intense lasers with plasmas towards the development of a 10 GeV module. Here we present details of the operation of the BELLA laser and beam line systems, including the control and data acquisition system.

INTRODUCTION

Laser plasma accelerators (LPA) [1] have the potential to drastically cut the cost of doing science with accelerators due to their much reduced size compared to conventional accelerators of the same energy. While it could be decades before a laser plasma accelerator can match or exceed the capabilities of something like the proposed International Linear Collider—a 25 miles (40 kilometers) long machine that would produce electrons and positrons at extremely high energies (0.5 TeV center of mass), straw man designs [2] and more detailed physics studies are underway to explore the possibility of LPA technology towards a linear collider [3,4]. In recent years, LPAs have made significant progress towards producing high quality beams with ever higher energy. In 2004, three independent groups showed the first demonstration of relatively narrow energy spread electron beams at the ~ 100 MeV level from mm-scale devices [5-7]. In 2006 the first production was shown of GeV electron beams from a 3 cm long plasma channel guided LPA at LBNL [8] and in 2011 a novel method for controlling injection via longitudinal tailored density profiles was demonstrated [9]. In the 2006 experiments, the laser peak power was of the order of 40 TW and the operating plasma density was a factor of ~10 lower but extended over a ~10 times longer distance than in the 2004 experiments. Motivated by the success of these experiments, designs were developed at LBNL to achieve 10 GeV electron beams from meter-scale accelerator structures using a PW-class laser system, which led to the formal BELLA (BErkeley Lab Laser Accelerator) project proposal to the Department of Energy, Office of High Energy Physics in 2007. BELLA represents an essential step towards investigating how more powerful accelerators of the future might be more compact. The initial experiments with the BELLA laser system and facility are aimed at demonstrating that high quality 10 GeV electron beams can be generated using a laser powered plasma structure that is about 1 meter long. The research supported by BELLA will also investigate fundamental laser-plasma interaction physics that aims at optimizing the coupling efficiency of laser to electron beam energy, controlling both the energy spread and emittance of the electron beams, and staging multiple LPA modules together. The 10 GeV beams could also be used to study beam driven plasma wakefield acceleration, as well as positron production and subsequent acceleration in plasma based accelerators. Although its main purpose is accelerator research, the development of a compact 10 GeV accelerator has several potential applications. BELLA could be used to build a free-electron laser (FEL) operating in the soft x-ray window that produces few femtosecond radiation pulses that are intrinsically synchronized to laser pulses, to THz radiation pulses or directly to the electron beam. Such a device could be an extraordinarily valuable tool for biologists, chemists, materials scientists, and biomedical researchers, allowing them to observe ultrashort, nanoscale phenomena.

We will next discuss the performance of the BELLA laser. As the key physics in the LPA studies are primarily dependent on laser intensity, the key parameters are laser pulse energy, pulse duration, laser beam profile and their stability. From an operational point-of-view, pointing stability is also essential. We also will introduce the BELLA control system, which is used for both control of all experimental subsystems and data acquisition. Details will be presented elsewhere.

BELLA PROJECT

The project phase of BELLA consisted of the construction and commissioning of a PW-class laser that supports the research aimed at the development of 10 GeV LPA modules. The project was formally launched in October 2007 and funded in 2009. The scope of the BELLA project included the design and construction of the conventional facilities required to house and safely operate the BELLA laser, the acquisition of the BELLA laser system itself, design and construction of ancillary systems to support the laser operations, site and system integration, and performance verification of the BELLA laser system.

The BELLA facility has been fully designed to achieve all key performance parameters of the laser system and future experimental systems. This includes clean-room (class 10,000 and 1,000) areas for the laser and experimental areas, with gowning area, assembly area and tightly controlled environmental conditions to minimize temperature and humidity effects as well as low vibration

*Work supported by DOE, Office of High Energy Physics and NSF

levels; a separate utility room that houses all power supplies and other heat producing equipment; a radiation shielded target area for all high power laser-plasma interaction experiments, including a beam dump to stop and absorb 10 GeV class electron beams; a control room equipped with computer hardware to allow remote operation of the laser system, equipment and personnel safety systems as well as experiments. Legacy infrastructure demolition in the BELLA building and subsequently construction of the new facility took place from October 2010 – March 2011 and March 2011-November 2011, respectively.

The BELLA laser was constructed by a commercial vendor (THALES) [10] and first built at the THALES factory from November 2009 through January 2012. Following factory acceptance testing in February 2012, the laser was shipped to Berkeley in April 2012 and installed at LBNL from April 2012 through July 2012. More than 80 crates arrived in April 2012 carrying well over 40 metric ton in equipment. The laser was first operated in July 2012 at which time a new world record was set: > 1 PW peak power at a repetition rate of 1 Hz [11].

Final acceptance testing took place in September 2012.

BELLA LASER PERFORMANCE

The overall layout of the BELLA facility is shown in Fig. 1. The laser system occupies a large optical table located in the BELLA laser bay. The power supplies for the laser are located in a separate utility room, which is located right above the laser bay. Following a sequence of amplifiers that increases the energy of initially stretched pulses from nanoJoules to tens of Joule, a grating based optical compressor generates sub-40 fs pulses with peak power up to 1.3 PW at 1 Hz. The beam transport system delivers and focuses (with an off-axis parabola) the high power laser pulses to a target region where the plasma source is located. An achromatic high power laser diagnostic telescope images the target region onto a dedicated suite of diagnostics system to analyze the laser beam properties at all power levels. The first optic in the telescope has a hole in the middle to allow the electron beam to pass through towards a monitoring phosphor screen, an integrating current transformer, the magnetic spectrometer system and the electron beam dump. The entire system is controlled remotely via a LabVIEW based control system. Details on the laser system, laser beam transport, laser diagnostics and control system are discussed next. Details on the magnetic spectrometer design and operation will be published elsewhere.

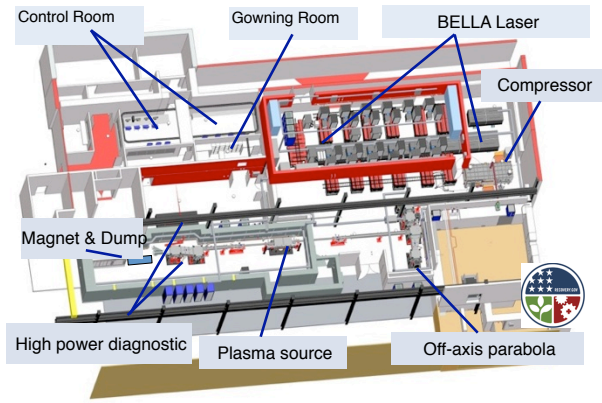

Figure 1: Layout of the BELLA facility. The laser beam is generated in the BELLA laser room. The Compressor is a grating based system for laser pulse compression. An off-axis parabola focuses the beam on the plasma source, which is located in a radiation shielded experimental area. The high power diagnostic is used to image the focused laser beam onto a broad suite of diagnostics. The magnet and beam dump are used to characterize the electron beams and safely stop them. The experiments are run remotely from a control room.

BELLA Laser System

The BELLA laser system is based on Ti:sapphire as gain medium. Pulses from a 75 MHz oscillator are first stretched, amplified in a regenerative amplifier, compressed and contrast improved in a cross-polarized wave (XPW) system. A booster amplifier and pre-amplifier followed by a first high-energy amplifier (AMP1) increase the energy to the 1.2-1.5 J level. A second high-energy amplifier (AMP2) brings the energy to about 20 J and a final amplifier (AMP3) increases this energy to as much as 65 J. The regenerative and booster amplifiers operate at 1 kHz, the preamplifier and AMP1 operate at up to 10 Hz, and AMP2 and AMP3 are operating at 1 Hz. The 1 Hz repetition rate is determined by the repetition rate of the twelve large aperture frequency doubled Nd:YAG pump lasers (GAIAs) that provide 15 J pulse energy each: four of them pump AMP2 and eight pump AMP3. The ultimate laser pulse energy in the main Ti:sapphire laser line can be adjusted with fine control from about 25 mJ to more than 40 J on target. The commissioned laser system is shown in Fig. 2.

Copyright © 2013 CC-BY-3.0 and by the respective authors

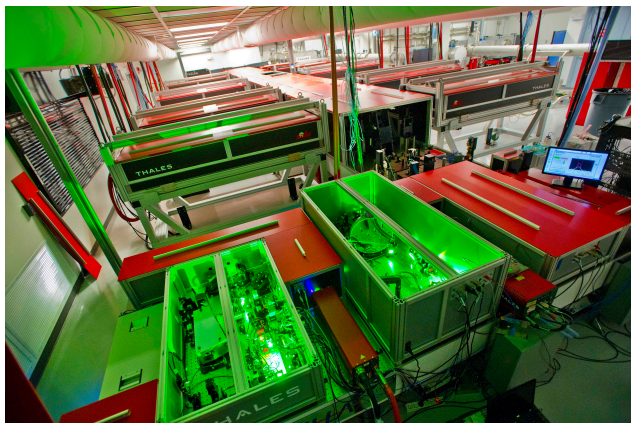

Figure 2: Picture of the BELLA laser system installed at LBNL. The green glow is from scattered light at 532 nm produced by the pump lasers in the front end of the laser. The high energy pump lasers (GAIA) are seen in the center part of the picture.

A plot of energy output vs. time is shown in Fig. 3. The best r.m.s. stability that has been obtained so far is of the order of 0.3%. The stability is affected by both vibrations causing beam motion and the stability of the pump laser systems.

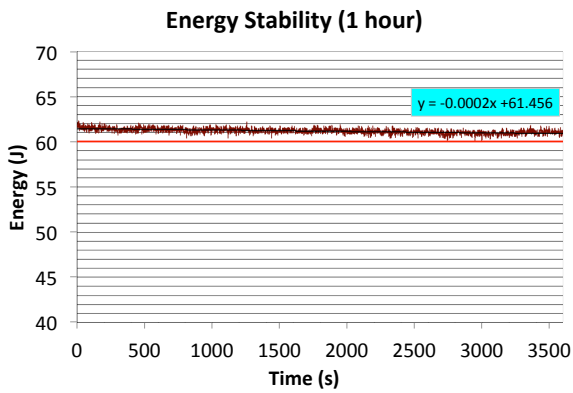

Figure 3: Example of BELLA laser energy stability vs. time.

Following amplification the wavefront of the beam can be adjusted and optimized using a commercial deformable mirror with 52 pistons. The deformable mirror (DM) has allowed focusing of the laser beam at full power onto the targets with a Strehl ratio in excess of 0.9. An example of the achieved mode profile at 32 J is shown in Fig. 5. Note that the mode was measured using an optic with hole in the middle (see below).

Following the DM, an all-reflective telescope magnifies the laser beam to ensure that the fluence is low enough to avoid damage on gratings of a four grating vacuum compressor. Pulse duration can be tuned by control of the separation of the gratings and pulse shape can be tuned using grating angles. To date, pulses as short as 35 fs have been produced at energies in excess of 42 J, i.e., providing >1 PW peak optical power in each pulse at a repetition rate of 1 Hz. The flexibility in pulse duration and energy tuning enable access to a broad range of pulse duration and peak power levels to carry out a large variety of studies of LPAs.

Laser Beam Transport System and Diagnostics

Following compression, the beam is sent to the target area using four routing mirrors, one of which is the final focusing off-axis paraboloid with a focal length of nominally 13.5 m. Each one of the routing mirrors is equipped with a beam pointing monitoring system and motorized controls to ensure correct pointing of the beam throughout the entire laser transport system. Leakage through one of the mirrors in the compressor is sent to a dedicated diagnostic bench where experiment relevant laser performance parameters are monitored. These include laser near- and far-field profiles, laser pulse shapes using a Frequency Resolved Optical Gating system (FROG/GRENOUILLE), laser pulse energy, laser pulse duration and beam wavefront using a Shack-Hartmann sensor. The wavefront sensor enables control of the DM to ensure high Strehl ratio beams at focus in the target chamber. An example of a GRENOUILLE trace and retrieved laser pulse shape are shown in Fig. 4. The shortest pulse duration obtained at the target location to date is about 35 fs (FWHM).

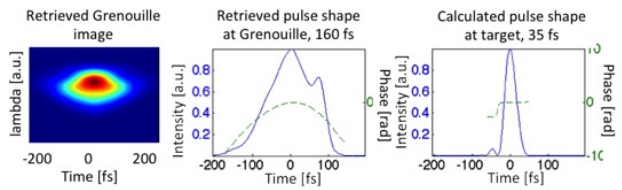

Figure 4: Example of a GRENOUILLE trace and a retrieved laser pulse shape obtained at ~ 40 J on target.

An example of the typical laser mode at medium energy is shown in Fig. 5. Similar or better quality modal shapes have been obtained at all energy levels. The Strehl ratio is typically in the range of 0.85-0.95.

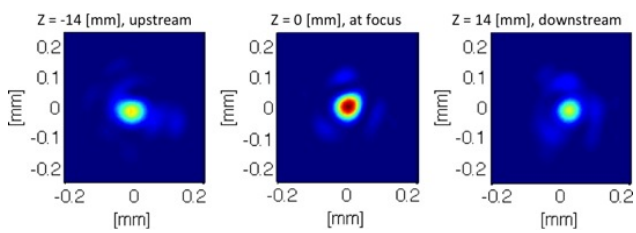

Figure 5: Example of the laser mode at ~32 J on target. The laser beam was imaged onto a 12 bit CCD camera using the high power diagnostic, including a wedge with hole. The hole contributes to the Airy pattern like fringes of the image and the actual focal quality of the beam is better as verified in separate measurements using a wedge without hole. The typical Strehl ratio of the beam at focus is higher than 0.85 and beams with 0.95 Strehl ratio have been obtained following extensive optimization with the deformable mirror.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Significant attention has also been paid in the design and implementation of both the laser system and the beam line components. Due to the long focal length of the focusing system, tight tolerances on pointing stability are essential for experiments involving special capillary discharges. The floor of the BELLA facility was vibration tested and met tight specifications. Mirror mounts and supports were designed, constructed and tested/optimized to minimize vibrations. As a result, beam pointing stability at the focus (i.e., target chamber location) is measured to be better than 1.2 micro-rad. A beam monitoring system has been implemented to ensure also that on a day-to-day basis, the laser beam path is properly aligned.

CONTROL SYSTEM

The BELLA control system was developed in-house and incorporates requirements that had been developed during the BELLA project phase and are based on past and present experience with the development of laser plasma accelerators. The GEECS platform (Generalized Equipment and Experiment Control System) monitors and controls equipment distributed across a network, performs experiments by scanning input variables, and collects and stores various types of data synchronously from devices. Examples of devices include cameras, motors, and pressure gauges. GEECS is based upon LabView graphical object oriented programming (GOOP), allowing for a modular and scalable framework. Data is published for subscription of an arbitrary number of variables over TCP. A secondary framework allows easy development of graphical user interfaces for a combined control of any available devices on the control system without the need of programming knowledge. This allows for rapid integration of GEECS into a wide variety of systems. A database interface provides for device and process configuration while allowing the user to save large quantities of data to local or network drives.

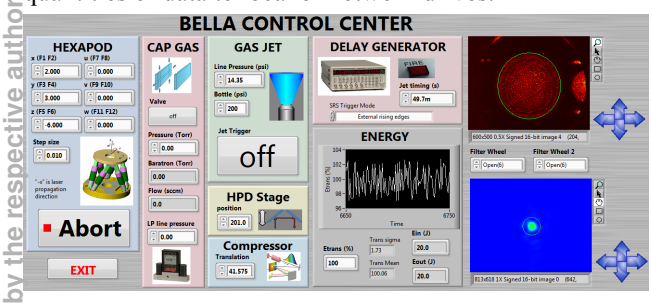

Figure 6: Graphical User Interfaces (GUI) such as this, containing data of different types, can be built in minutes with minimal programming knowledge using the GEECS framework.

ACKNOWLEDGMENT

This work was supported by the DOE, Office of High Energy Physics under contract DE-AC02-05CH11231. The BELLA Project was funded from the American Reinvestment and Recovery Act (ARRA). We would like to thank all present and past LOASIS members and collaborators for their contributions as well as DOE staff from the HEP office and the BSO office. Special thanks go to Ken Barat, Carlo Benedetti, Jeremy Coyne, Rob Duarte, Zak Eisentraut, Eric Esarey, Steve Fournier, Cameron Geddes, Steve Gourlay, Bob Gunnion, Mark Kirkpatrick, Doug Lockhart, Greg Mannino, Nicholas Matlis, George Sanen, Koen Schakenraad, Carl Schroeder, Ohmar Sowle, Suzanne Suskind, Jeroen van Tilborg, Jean-Luc Vay, Sue Walker-Lam, and Sergio Zimmermann for their contributions during the pre-planning and project phase of BELLA. We also want to acknowledge the THALES staff for their contributions.

Abstract

SLAC's new Facility for Advanced Accelerator Experimental Tests (FACET) had its second user run in April–June, 2013. Several new milestones were reached during this run, including the achievement of beam driven plasma wakefield acceleration of a discrete witness bunch for the first time, and energy doubling in a noble gas plasma source. The FACET beam is a 20 GeV electron bunch with a charge of 3.2 nC that can be compressed and focused to a size of $20\,\mu\mathrm{m} \times 20\,\mu\mathrm{m} \times 20\,\mu\mathrm{m}$ rms. To create the two-bunch, drive/witness beam structure, a chirped and over-compressed beam was dispersed horizontally in a chicane and a bite was taken from its middle with a tantalum finger collimator, corresponding to a longitudinal notching of the beam due to the head-tail energy correlation. A new 10 terawatt Ti:Sapphire laser was commissioned and used during this run to pre-ionize the plasma source in order to increase the efficiency of energy transfer from the beam to the wake. Ultimately, a witness beam of hundreds of pC in charge was accelerated by a drive beam of similar charge in a preformed lithium plasma with a density of $5 \times 10^{16}\,\mathrm{cm}^{-3}$, experiencing gradients reaching several GV/m in magnitude.

INTRODUCTION

The field of plasma wakefield acceleration (PWFA) has long been motivated by a need for new technologies that can provide higher accelerating gradients than conventional microwave powered metallic structures in order to make multi-TeV energies and beyond accessible to future generations of linear colliders. A conceptual design was recently developed for a plasma wakefield powered linear collider with a center of mass energy of 1 TeV that is extendible to the multi-TeV regime [1]. The main linac consists of modular plasma accelerator stages into each of which a fresh electron beam is injected to drive a wake over a meter-scale plasma source to provide an energy gain of 25 GeV per stage to the primary collider beam. Besides the high average gradient of such a collider design, the wall-plug efficiency is another very attractive feature, estimated to be well over ten percent. Current research efforts in beam driven plasma wakefield acceleration are largely devoted to creating a single plasma accelerator stage akin to what would be used in a collider, first as a proof-of-concept, and then as a test bed for studying the complex dynamics involved in the beam-plasma interaction.

In order to achieve accelerating gradients on the order of 10 GV/m with a GeV-scale drive beam, plasma densities on the order of $10^{17}\,\mathrm{cm}^{-3}$ are required. This sets the plasma wavelength, and thus the scale of the longitudinal spacing between the drive and witness bunch, to distances on the order of 150 μm (=500 fs temporal spacing). The drive beam must have a density that is > 1.8 times the background plasma density in order to produce a nonlinear blowout [2], which sets the scale for the peak current to the kA scale with a transverse size on the order of a few tens of microns, which is ultimately focused down to several microns by the strong fields generated in the plasma. FACET is the only facility in the world that can meet these demanding beam requirements, as well as produce a witness beam of several hundred pC or more to sample the large magnitude fields.

Previous electron-beam-driven plasma wakefield acceleration experiments that were performed at SLAC's Final Focus Test Beam (FFTB) facility have shown that the PWFA mechanism can produce accelerating gradients in excess of 50 GV/m by observing the energy gain in the low charge tail of the wake-driving electron beam. The tail trailing behind the head of the beam sampled the accelerating phase of the plasma wake, finally doubling the energy of the 42 GeV electrons [3]. What remained to be demonstrated, however, was the acceleration of a coherent beam of electrons, rather than individual particles. FFTB lacked the capability to produce a distinct drive and witness electron beam with the required temporal spacing, on the order of 500 fs from center to center. Several years after the FFTB was decommissioned, FACET was designed and constructed with this goal in mind, leveraging the knowledge gained from the FFTB experiments and the linac infrastructure available at SLAC [4]. Now, FACET has finally been able to fulfill the experimental requirements needed to study the acceleration of actual beams via

beam-driven plasma wakefields, and has also continued to explore new dynamical regimes of plasma wakefield acceleration.

ELECTRON BEAM

The data presented here were taken by the E200 experiment from June 2013 during the second User Run of FACET. The first two kilometers of the main SLAC linac were used to provide a 20.35 GeV electron beam with a charge of up to 3.2 nC. In the final 100 m of the beamline a chicane provided the final compression of the beam, with a minimal bunch length of 20 μm rms, corresponding to a peak current of 20 kA. A final focusing section focused the beam down to the desired transverse dimensions at the entrance to the plasma source, approximately 20 μm $\times$ 20 μm Gaussian rms in x and y. An imaging spectrometer transported the beam from the exit of the plasma source to the final diagnostic area and ultimately to the beam dump. Figure 1 shows a schematic view of the final 100 m of the FACET beamline with a detail of the experimental area where the plasma source is located.

The two-bunch beam structure was generated by bisecting a linearly chirped, horizontally dispersed beam using a tantalum finger collimator. Jaw collimators were also employed to remove the spectral tails at the horizontal extrema, where the energy spread was uncorrelated with longitudinal position. The beam was then over-compressed in the chicane, placing one portion of the remaining beam in front of the other with the desired spacing optimized for PWFA experiments.

Two diagnostics were used to measure the longitudinal

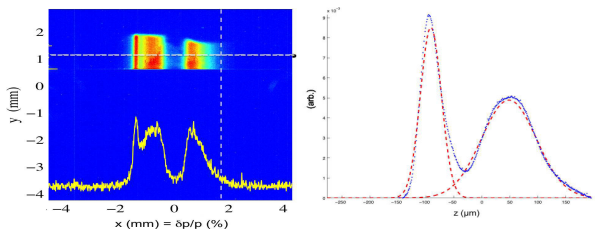

Figure 2: Specral profile of the elecron beam (left) and longidutinal profile of the electron beam (right) after notch collimation and before entering the plasma source.

phase space of the beam after collimation. The first was a wiggler spectrometer that measured the X-ray intensity profile generated by the beam in a low field triplet of wiggler magnets. The wiggler spectrometer is located at a point in the chicane with the same large magnitude of dispersion as the point where the beam is notched by the tantalum collimator further upstream, thus it provided direct feedback on how the beam is being notched in space and in energy on a shot-by-shot basis.

The second diagnostic used to measure the longitudinal phase space of the beam was an X-band transverse deflecting structure. This device streaked the beam itself onto an optical transition radiation screen located near the plasma source, roughly 25 m downstream. The streaking process precludes the beam from having an optimal profile for PWFA, however, so this method of measuring the longitudinal profile is limited to statistical studies of the beam profile used in the experiment. Figure 2 shows a typ-

ical spectral and longitudinal measurement for a two-bunch beam prior to entering the plasma source for PWFA experiments.

PLASMA SOURCE

The plasma was generated by ionizing a lithium vapor, which was generated inside a heat pipe oven roughly 40 cm in length. A room temperature buffer gas of argon was used to contain the lithium vapor and also completely filled a parallel bypass line, which was able to be inserted into the beamline in lieu of the lithium oven for control measurements. The density and length of the lithium vapor can be controlled by adjusting the heat applied to the oven and the pressure of the buffer gas. The choice of a noble gas for the buffer is motivated by its high ionization threshold, which drastically reduces the likelihood of generating plasma outside of the lithium region.

A new 10 TW, 800 nm Ti:Sapphire laser system was installed and commissioned for the 2013 FACET User Run. The primary purpose of the laser system was to ionize the lithium vapor in the heat pipe oven, generating a wide column of plasma before the arrival of the electron beam. Though it has been shown that if the electron beam is dense enough, it can itself tunnel-ionize the outer shell electrons of a metal vapor and still subsequently drive a non-linear wake [5], using the laser to generate the plasma reduces the demand on the electron beam delivery somewhat. Preforming the plasma also leaves more energy available in the drive beam to be transferred to the plasma wake, which ultimately means a higher efficiency of energy transfer from the drive to the witness beam. Finally, a preformed plasma will also mitigate the head-erosion of the drive beam, allowing for much longer plasma interaction lengths [3, 6].

The laser was focused into the plasma using an axicon lens [7], which focuses the laser toward the central axis at the same convergent angle over all radii. Figure 3 shows a schematic demonstrating the axicon focusing method. This produces a radial intensity distribution that follows a Bessel function of the zeroth order and persists for over a meter of length before the laser diverges away from the axis in a ring shape and is dumped into an annular neutral density filter. A circular mask just before the axicon lens is used to control the start of the line focus, and the diameter of the laser beam determines the end of the line focus.

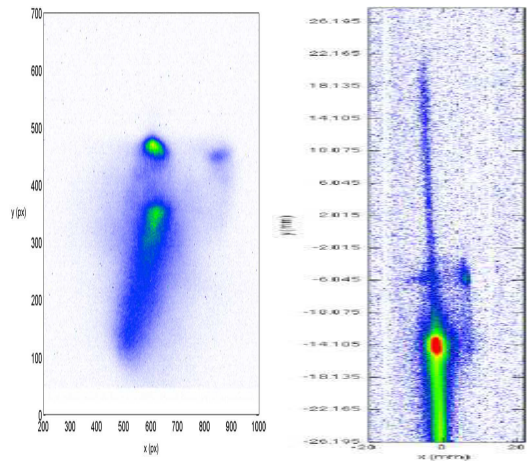

Figure 4: Left: Accelerated witness beam (top feature) with decelerated drive beam (bottom feature) produced in a preformed lithium plasma. Right: Energy doubled tail with decelerated beam core produced in self-ionized plasma generated in argon gas. In both plots energy increases with height.

ACCELERATION OF A WITNESS BEAM

An imaging spectrometer comprising a quadrupole doublet and a 1 m dipole was used to disperse the beam at the experimental dump table while imaging a plane at the exit of the plasma source. The imaging condition only holds for a given (adjustable) energy, however, so portions of the beam above and below the set energy are defocused. CCD cameras were used to image the Cherenkov light produced by the dispersed beam as it traveled through the air from the beam pipe exit window to the dump.

A drive beam with a peak current of 1.2 kA and a witness beam of several hundred pC trailing 126 μm (420 fs) behind it were sent into a pre-formed lithium plasma on the order of $\sim$40 cm in length with a density of 5.0×10^{16} cm^{-3}. The witness beam was accelerated by a few GeV over this distance, corresponding to average accelerating fields on the order of $\sim$5 GV/m. Portions of the drive beam were decelerated by as much as several GeV, and nearly all of the electrons in the drive beam lost at least some energy, an indication of efficient energy transfer to the wake. Figure 4 shows a typical shot of two-bunch PWFA, where the vertical axis corresponds to energy with higher energy toward the top.

ENERGY DOUBLING IN A NOBLE GAS

The FACET beamline can accommodate many different beam optics profiles, one of which is tailored to provide the highest possible compression of a single bunch. With this configuration in place, it was found that the density of the electron beam could reach values that were high enough to ionize the noble gas buffer medium in the oven bypass line. Further, the beam produced a strong wakefield in the plasma it generated, drastically decelerating the bulk of the

Copyright © 2013 CC-BY-3.0 and by the respective authors

beam and accelerating the rear tail of the beam to more than double its initial energy. Figure 4 shows the dispersed beam after driving a wake in argon gas over about 20 cm. The estimated longitudinal field strength inside the wake was on the order of $\sim 150\,\mathrm{GV/m}$.

The ability to drive a wake in a noble gas was due to a self-focusing process that the beam underwent as soon as it began to ionize even a small fraction of the argon gas. The wake produced in the low density plasma focused the beam transversely, and as the beam density increased, it ionized a larger fraction of the gas, which in turn led to a higher plasma density and larger focusing forces in the plasma wake. The process continued on in a positive feedback loop like this until eventually reaching a point where the beam could drive a non-linear wake in the blowout regime, after having nearly reached the matching condition for the plasma [8]. This description of the evolution of the beam was supported by simulations in the quasi-static 3D particle-in-cell code QuickPIC [9].

After focusing to its minimum size, on the order of a few microns, the beam could drive a fully non-linear wake, and experienced virtually no head erosion. Thus, it was able to continue to drive the wake over a very long distance, limited by the betatron function of the unfocused head of the beam that provided the ionized plasma medium. The avoidance of the head erosion limitation that is predicted in the literature [10] is particularly interesting because it may loosen the previously presumed high density requirement for an electron beam to drive a self-ionized plasma wake. In addition, a plasma stage made from a room temperature gas is far simpler and cheaper than an alkali metal vapor which must be maintained at hundereds of degrees Celcius. Further, a room temperature gas can have a perfectly flat longitudinal density profile throughout the stage, which is impossible with an alkali metal vapor inside a heat-pipe oven due to the density ramps near the oven boundaries.

SUMMARY AND OUTLOOK

FACET has succeeded in accelerating a distinct witness beam of electrons with multi-$\mathrm{GV/m}$ fields produced in a non-linear plasma wake produced by a high current drive beam in a pre-formed lithium plasma. This is the first experimental demonstration of acceleration of a high energy, high charge beam via beam-driven PWFA. FACET has also demonstrated that through the self-focusing mechanism, an under-dense beam can evolve through interaction with the plasma to achieve densities sufficient to drive a non-linear wake over long distances, even in media with high ionization potentials, such as noble gases. This result shows that head erosion is able to be suppressed without having to generate an over-dense, pre-matched drive beam before sending it into the plasma stage, which could open new possibilities for the design of a more optimal particle beam driver. It could also lead to the design of simpler, cheaper plasma stages, eschewing the heat pipe oven for a plain tube of gas.

The next FACET run will begin in late 2013 and will continue where the previous run left off by studying the effects of beam loading on the acceleration of the witness beam, as well as the ability to preserve the beam's emittance and minimize the final energy spread. Further, an upgrade in the ionization laser and a longer heat pipe oven will allow the plasma wake to be driven over much longer distance than in previous runs, which should lead to significantly higher net energy gain in the witness bunch. Improved diagnostics will also allow for better measurements of the beam before and after entering the plasma source, allowing for a deeper insight into the beam-plasma interaction in all of the PWFA experiments.

Abstract

Plasma wakefield accelerator experiments at FACET at the SLAC National Accelerator Laboratory have shown a correlation between ionization-injected electrons and the betatron x-ray yield. Emittance spoiling foils were inserted into the beam and the x-ray yield, excess charge, and beam energy loss was measured. The excess charge and x-ray yield are attributed to the beam envelope oscillations where at the minima, the field of the beam is strong enough to create secondary ionization, and at the electron oscillation maxima, the beam electrons spontaneously radiate x-rays. Large amplitude beam oscillations are expected to yield more x-rays and create more excess charge, but the results show beam head erosion strongly limits the wakefield excitation.

INTRODUCTION

An important feature of any "blow out regime" plasma-based accelerator is the strong radial fields of the ion column, which creates electron betatron motion and x-ray radiation. This effect can be used to create MeV photons [1] and the x-ray characteristics can be used as a diagnostic of the electrons transverse motion. For example, matched beam propagation would be characterized by minimizing the x-ray radiation signal. Also, mismatched beams will collapse in size to where secondary ionization produces excess charge (i.e. dark current) [2]. Larger emittance beams have larger oscillation amplitudes and therefore they are expected to produce more x-rays and more excess charge. However, large emittance beams also have shorter head erosion lengths [3], which limits the distance over which x-rays and excess charge can be generated. In this paper we study experimentally which of these factors prevail.

SETUP

The experiments were performed at FACET at the SLAC National Accelerator Laboratory during the 2013 E200 PWFA experimental run. The 20.3 GeV electron bunch contained 2.0×10^{10} electrons with an rms bunch length of ~40 um. The x and y normalized emittances, ε_N, were designed to be 50 and 5 mm-mrad, respectively. Typically, the beam betas where 0.10 meter in x and 1.0 meter in y, giving a spot size at the plasma entrance of 11 μm in x and y. The beam was sent through a ~30 cm long rubidium heat pipe oven where the plasma was formed by the field of the beam via tunneling ionization. The Rb vapor was contained using argon as a buffer. The primary diagnostic measurements discussed here are: the x-ray radiation, beam charge, and beam energy. The x-ray yield was measured with a Lanex screen and CCD camera. A 1 mm thick Tungsten foil was placed in front of the screen, which gives a photon detection threshold of 200- 300 keV. SLAC toriods were used to measure the beam charge upstream and downstream of the plasma. The excess charge was measured using the difference between the toriod signals. The change in beam energy was measured with an imaging dipole spectrometer. To study emittance effects, emitttance spoiler foils were inserted into the beam 1 meter upstream of the plasma entrance. The foils and thickness used in the experiment were: Foil 1 Nicusil 3, 25.4 μm; Foil 2 25/75Au/Cu, 50.8 μm; and Foil 3 Nocoro, 80, 38 μm. The calculated rms scattering angles are 35, 58, and 64 μrad respectively. A figure showing the set up and the data analysis and methods can be can be found in [4, 5].

DENSITY RAMPS AND BEAM MATCHING

For a plasma with a sharp boundary, the beam matching condition is $\beta_{match} = 1/k_b$, where k_b is the plasma betatron wavenumber (Eqn. 2). For our experimental parameters, $\beta_{match} = 0.3$ cm. Beam matching on this scale is difficult to produce, but as shown in [1, 6] a density ramp can significantly reduce the oscillation amplitude of an unmatched beam, thereby reducing the expected x-ray yield. For the right beam parameters, the ramp can be used to produce matched beam propagation. A larger β can be used in proportion to the scale length of the ramp. For the plasma ramp at FACET, the matched β is 3.38 cm.

CALCULATION OF THE BEAM SIZE AND EMITTANCE WITH SPOILER FOIL INSERTED

When a foil is inserted, the new beam parameters at the plasma entrance can be calculated by propagating the no foil parameters from the beam waist back to the foil and then calculate the new beam parameter due to foil scattering θ. The new beam parameters at the foil are calculated using [7]

$$\varepsilon^2 = \varepsilon_0(\varepsilon_0 + \beta_0\theta^2)$$
$$\beta^2 = \beta_0^2\varepsilon_0 / (\varepsilon_0 + \beta_0\theta^2)$$
$$\alpha^2 = \alpha_0^2\varepsilon_0 / (\varepsilon_0 + \beta_0\theta^2) \quad (1)$$

After scattering, the new beam parameters can be propagated back to the oven entrance. The foils increase the beam emittance and the beam size at the plasma entrance, creating a greater mismatch. The beam envelope oscillation for a mono-energetic electron beam can be calculated using Eqn. 2 and is plotted in figures 1 and 2.

$$\frac{d^2\sigma}{dz^2} + k_b^2\sigma = \frac{\varepsilon_N^2}{\gamma^2\sigma^3} \qquad k_b = \frac{\omega_p}{c}\frac{1}{\sqrt{2\gamma}} \quad (2)$$

The figures illustrate how the beam envelope changes after inserting a foil. Figure 1 is plotted, using the experimental parameters in x, without the spoiler foil. Figure 2 shows the beam envelope with foil 1 inserted. With the foil inserted, the oscillation amplitude inside the plasma increases in proportion to the emittance ratio, $\varepsilon_{vacuum}/\varepsilon_{foil}$. Also, when the foil is inserted, the envelope minimum inside the plasma does not change. This is because, although β at the oscillation minimum is smaller, the emittance is proportionally larger and so σ_{min} is unchanged ($\sigma^2 = \beta\varepsilon$). Excess charge can be created when the drive beam pinches and the field exceeds the ionization threshold for secondary electrons from RbII and ArII. Injection of plasma electrons into the wake can limit the wake amplitude and reduce the accelerating gradient [4].

PARTICIPATING CHARGE AND, HEAD EROSION

If the head of the beam is not dense enough to ionize the Rb vapor, the beam electrons contained in that region will not participate in the wake formation. This causes a reduction in the bunch length, σ_z (but not necessarily the peak beam current).

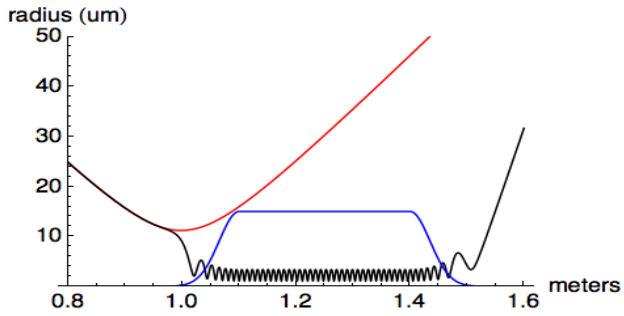

Figure 1: Plot of beam size envelope for 20.3 GeV and $2.7\text{x}10^{17}$ cm^{-3} plasma without spoiler foil (black). The beam envelope in vacuum (red). The plasma profile (blue).

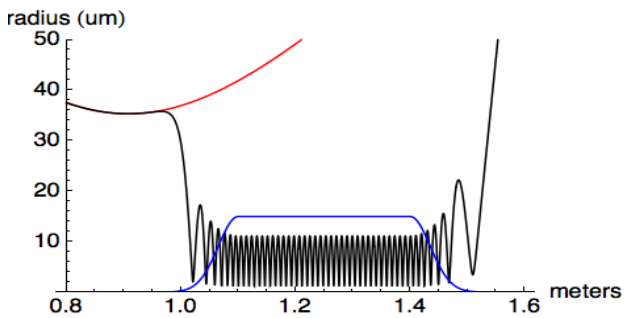

Figure 2: Same as figure 1 with spoiler foil inserted.

Head erosion is a physical effect that limits the length of the wake excitation [3]. It is due to the fact that the ionizing front of the beam is not in the blow out region and is not focused or guided by the ion channel. The unguided front of the beam expands, as it would do in vacuum, and the ionizing front moves back in the beam frame at a rate v_{etch} [3]. The head erosion length is given by $L_{he} \sim \sigma_z / v_{etch}$, where σ_z contains only the participating charge.

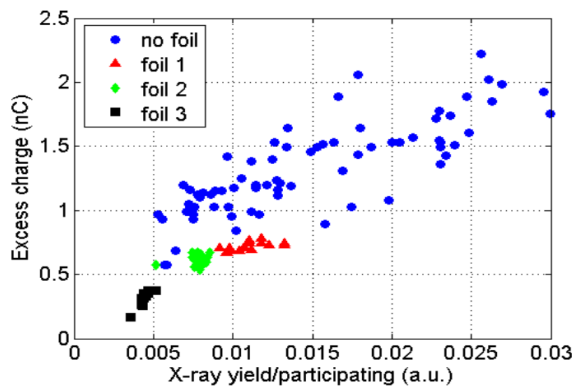

Figure 3: Experimental plot showing measured correlation of the excess charge verses x-ray yield.

Copyright © 2013 CC-BY-3.0 and by the respective authors

EXPERIMENTAL RESULTS

Figure 3, shows the correlation between the measured x-ray yield and the excess charge which takes into account the reduced participating charge. The measured participating charge is 90% for no foil, 70% with foil 1, 65% with foil 2, and 50%, with foil 3. The inferred σ_z is reduced 30 to 50% when the foils are inserted.

Both x-rays and excess charge are reduced as foils are added. Even accounting for the lower participating charge, the x-ray yield should increase with larger emittance since the oscillation amplitude increases with larger emittance. Figure 3 shows this expectation is not the case. This is because increasing emittance reduces L_{he} in three ways. First, the large beam size will reduce the participating charge causing a reduction in σ_z, second the etch rate is higher (v_{etch}~ε_N) and third, large beam mismatch causes emittance growth as the beam propagates. Head erosion theory [3] assumes matched beam propagation. However, for these experiments the beam was not matched. Simulations show mismatched beams have emittance growth and will erode faster than matched beams. Applying Eqn. 1, to foil 1, the emittance grows from 5 to 22.5 mm-mrad in y and from 50 to 165 mm-mrad in x, thus shortening the head erosion length by 3.3 to 4.5 times. As for the x-ray production, the effective length over which x-rays are produce is ~½ L_{he}. Emittance spoiling also showed a reduction in beam energy loss. Typical energy loss without foils was >12 GeV. This indicates the beam propagated approximately the entire length of the Rb vapor. The energy loss for with foil 1, 2 and 3 was approximately 7, 5, and 3 GeV, respectively. Although some of this reduction could be due to a smaller wake amplitude (resulting from reduced participating charge) simulations show, the main effect is the reduction in the length of wake excitation as emittance is increased. This implies the length of the wake formation was reduced as foils were inserted, further emphasizing the effect of head erosion on the experiments.

SUMMARY

While emittance spoiling would seem to increase the x-ray yield, the experiment shows a significant reduction in x-ray signal. Emittance spoiling also reduces the excess charge. The reduced energy loss indicates reduced wakefield excitation length. The entirety of the results, x-rays, excess charge and energy loss, imply severe beam head erosion when spoiler foils are used. With a preionized plasma head erosion is strongly mitigated. Recent results [8] with preionization show the participating charge is nearly 100%.

EXPERIMENTAL PROGRESS ON STAGED LASER-PLASMA ACCELERATION*

S. Shiraishi†, T. Sokollik‡, C. Benedetti, A. J. Gonsalves, N. H. Matlis, K. Nakamura, B. H. Shaw, S. Steinke, J. van Tilborg, C. G. R. Geddes, C. B. Schroeder, Cs. Tóth, E. Esarey, and W. P. Leemans
LOASIS Program, LBNL, Berkeley, CA 94720, USA

Abstract

Recent progress on a staged laser-plasma accelerator (LPA) experiment is reported. The experiment utilizes a 40 TW class laser which is split into two pulses. The first laser drives the first LPA stage to produce an electron beam. The second laser drives the second LPA stage in a dark-current free regime and accelerates the electron beam from the first LPA. Injection from the first stage, triggering of plasma mirror and reflection of the second laser, and laser guiding in the second stage have been demonstrated. Optical spectral redshift of driving laser has been analyzed to estimate the wakefield amplitude and electron energy gain in the second stage.

INTRODUCTION

Laser-plasma accelerators (LPAs) have demonstrated accelerating gradients thousands of times greater than those of conventional accelerators [1]. Employing a capillary discharge waveguide, a high-quality GeV electron beam (e-beam) has been produced within a few centimeters, demonstrating that LPAs have great potential for reducing accelerator size and cost.

For applications such as high energy colliders, LPA designs will rely on sequencing multiple acceleration stages, each driven by its own laser [2, 3]. Limitations to the energy gain in a single stage include diffraction, dephasing, and pump depletion. Using a capillary waveguide to create a preformed plasma channel, laser pulses have been guided over many Rayleigh lengths ($z_{\rm R}$), minimizing diffraction and extending the accelerating length. If the laser is guided, and the e-beam dephasing controlled, energy gain is limited by depletion. To overcome pump depletion, staged acceleration is necessary to supply fresh laser pulses. Experiments performed so far utilize a single laser that drives the wakefield for both injection and acceleration. The on-going staging experiment at the LOASIS Program at Lawrence Berkeley National Laboratory will demonstrate driving of two modules with two independent laser pulses and coupling of the e-beam between them. Staged acceleration not only supplies fresh laser pulses to LPAs but it also allows independent control of electron injection and acceleration.

Experimental demonstration of staged LPAs requires understanding electron injection, performance of a plasma mirror (PM), and acceleration of externally injected e-beams. Controlled electron injection is an active area of research and various techniques such as self-trapping, density gradient, and ionization injections have been demonstrated [4, 5, 6, 7]. The PM is triggered when the leading edge of the pulse generates plasma on a solid target, reflecting the remainder of the pulse at the critical surface. The second laser pulse is coupled in to the acceleration beam line using the PM to keep the LPA compact [8]. Post-acceleration of e-beams requires understanding the amplitudes of wakefileds in the second stage. Laser spectra are analyzed as a diagnostic of plasma waves.

This paper reports the recent progress of the staged acceleration experiment at the LOASIS Program. Basic theory of laser propagation and redsfhit are presented to support the use of redshift as a wakefield diagnostic. Then, the experimental setup at the LOASIS Program is described. Initial results for electron injection, plasma mirror in-coupling and wake excitation performed independently of each other are presented in the results section followed by a concluding summary.

LASER PROPAGATION IN A PLASMA CHANNEL

Laser guiding is used to extend acceleration lengths in LPAs. However, accelerating fields, and hence redshifting of the laser, evolve differently depending on the guiding condition. In a capillary waveguide, the laser pulse transverse size can oscillate if the density profile is not matched to the laser spot size. The channel is characterized by a parabolic plasma density profile, $n(r) = n_0 + \Delta n r^2/r_{\rm m}^2$, where r is the radial position, n_0 is the on-axis density [9], and Δn is the channel depth at a matched spot size, $r_{\rm m}$ [10]. Such channels can provide guiding for a laser pulse with a Gaussian intensity profile, $|a|^2 = (a_0 r_0/r_{\rm s})^2 \exp(-2r^2/r_{\rm s}^2)$, where a_0 is the normalized laser vector potential given by $a_0^2 \simeq 7.3 \times 10^{-19}\ (\lambda[\mu{\rm m}])^2 I_0[{\rm Wcm}^{-2}]$, r_0 is the focal spot size, $r_{\rm s}$ is the spot size, and λ is the laser wavelength. Perfect guiding is achieved when $r_0 = r_{\rm m}$ and the laser is focused at the entrance of the channel ($r_{\rm i} = r_0$, ${\rm d}r_{\rm s}/{\rm d}z = 0$). Considering a low power pulse (without self-focusing), the laser pulse propagates in the channel according to

$$r_{\rm s}^2 = \frac{r_{\rm i}^2}{2}\left[1 + \frac{r_{\rm m}^4}{r_{\rm i}^4} + \left(1 - \frac{r_{\rm m}^4}{r_{\rm i}^4}\right)\cos\left(\frac{2\lambda z}{\pi r_{\rm m}^2}\right)\right], \quad (1)$$

where $r_{\rm i}$ is the spot size at the entrance of channel, and z is the propagation distance [10]. Examples of matched and mismatched guiding are shown in Fig. 1. The entrance of the capillary is set at $z = 0$, and the plasma channel is indicated with a cyan box. For matched guiding,

$r_i = r_m = 18\ \mu$m, the laser retains its spot size as it propagates through the channel. For mismatched guiding with r_i = 18 μm and r_m = 41 μm, the transverse spot size oscillates between r_i and r_m^2/r_i. The mismatched guiding leads to excitation of significant plasma waves only at localized regions of high intensity, creating an accelerating gradient that depends on the propagation distance. While

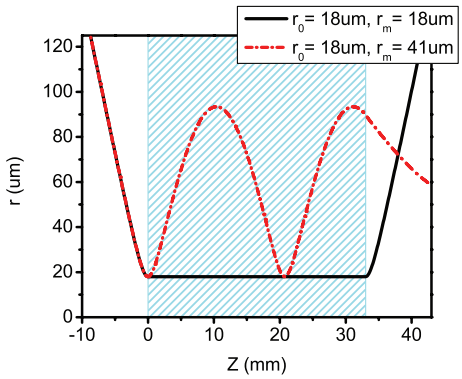

Figure 1: Laser spot size as a function of z.

matched guiding allows the most efficient coupling of laser energy to plasma waves, experimental conditions do not always allow the matched condition.

When the laser excites plasma waves, the laser energy is transferred to the wakefield and spectrally redshifts. In one-dimension, the evolution of the laser energy normalized to initial energy, ϵ, of a short laser pulse propagating in an underdense plasma is related to the amplitude of the wakefield as [11]:

$$\frac{\partial \epsilon}{\partial \omega_p t} = -\frac{k_p^2}{k_0^2}\left(\frac{E_{max}}{E_0}\right)^2, \qquad (2)$$

where k_p is the plasma wavenumber, k_0 is the central wavenumber of the input laser, ω_p is the plasma frequency, and E_{max}/E_0 is the maximum accelerating field normalized by the cold nonrelativistic wave breaking field. In addition, the mean wavenumber $\bar{k} = \varepsilon/A$ where A is the wave action, which is constant provided $\bar{k}/k_p \gg 1$. Therefore, E_{max} can be estimated through the redshift of optical spectra.

In experiments, the estimation of E_{max} is much more complex due to the transverse and longitudinal dynamics of the laser pulse. Particle-in-cell (PIC) simulations using INF&RNO were performed to study wake excitation and its relation to spectral redshifting [12]. INF&RNO is a two-dimensional cylindrical (r-z) code that adopts an envelope model for the laser pulse. Details are found in [12]. The laser pulse was focused 4.8 mm into the capillary with vacuum focus of r_0 = 18 μm and the channel was 33 mm long, r_m = 41 μm and $n_0 \sim 1.5 \times 10^{18}$cm^{-3}. Figure 2 shows simulated peak accelerating field E_{max} (solid black curve), normalized laser energy ε (dashed black curve) and mean wavenumber $\bar{k}$ (red dots) as functions of z. Since the guiding condition is mismatched, the laser intensity oscillates. There are two regions where the laser is strongly focused to excite a large plasma wave. The ε evolution shows that the majority of laser energy is deposited at locations of large wakefield and $\bar{k}$ tracks the ε. Even with mismatched guiding, one can gain insights into E_{max} by comparing simulated and measured spectra [13].

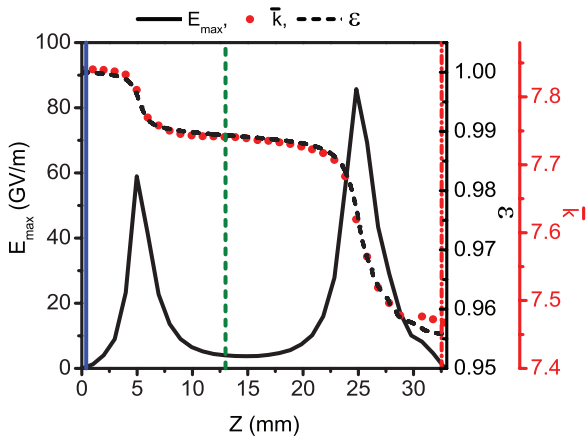

Figure 2: Simulated E_{max}, ε and $\bar{k}$ as a function of z.

EXPERIMENTAL SETUP

The staged acceleration experiment is on-going at the LOASIS Program and is performed using a 40 TW class Ti:sapphire laser system. A schematic of the experiment is shown in Fig. 3. A laser pulse is split into two pulses.

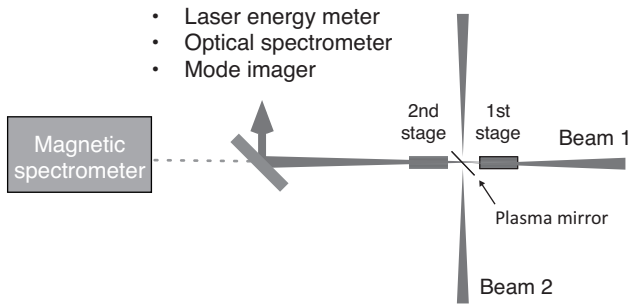

Figure 3: A schematic of the experiment.

Beam 1 drives the first stage to produce e-beams and Beam 2 reflects off the PM and drives the second stage for post-acceleration. Both laser pulses are focused on the entrance of capillary discharge waveguides [14, 15] by off-axis parabolic mirrors used at f/20. Focal spot sizes are $r_0 \simeq 20\ \mu$m. Injection in the first stage was performed with a pulse duration of 67 fs at full width at half maximum (FWHM), resulting in $a_0 \sim 0.9$. Beam 2 underwent a modulation in the splitting optic which lengthened the pulse duration to 130 fs for the initial experiments. Fluence of the Beam 2 impinging on PM was $\sim$ 500 J/cm^2 and excited plasma waves at $a_0 \sim 0.4$. The coupling distance between the two capillaries is $2-3$ cm. Preliminary experiments on electron injection, the plasma mirror reflectivity, and wake

Copyright © 2013 CC-BY-3.0 and by the respective authors

excitation performed independently of each other will be discussed.

Each LPA module used a capillary waveguide to guide the lasers. The capillaries were 33 mm long and 250 μm in diameter. For the injection experiment, various gases such as hydrogen, helium, and a mixture of nitrogen and helium were studied along with tailored plasma density. For the wake excitation experiment, hydrogen gas was used to optimize the guiding condition. A high voltage discharge ionized the gas and formed plasma $\sim$ 200 ns before the arrival of the laser. The plasma evolved from hydrodynamic motion and formed a plasma channel. The on-axis plasma densities for both experiments were $\sim 3 \times 10^{18}$ cm^3 and $r_{\rm m} \sim 35$ μm based on a scaling law derived from the simulation in [16]. Requirements for the plasma mirror were high reflectivity and good reflected mode [17]. The tape drive based plasma mirror was characterized, and the reflected laser was guided through the second stage.

RESULTS

For the injector study (1st stage), e-beams were produced by ionization of nitrogen atoms with tailored longitudinal plasma density channel. The averaged e-beam spectrum collected for 22 shots is shown in Fig. 4. The charge was 0.15 ± 0.13 pC, mean momentum 221 ± 22 MeV/c with $\sigma_p = 34 \pm 10$ MeV/c. The divergence was $\sigma_\theta = 1.4 \pm 0.2$ mrad. The fluctuation of the peak momentum was 14%. Optimizations to reduce the fluctuation in the e-beam peak energy are currently in progress.

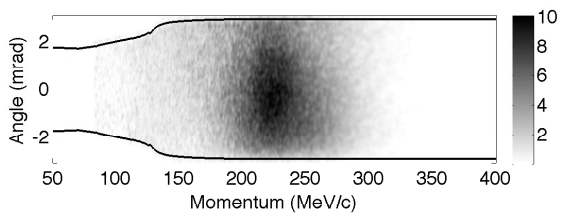

Figure 4: Averaged spectrum [nC/SR/(MeV/c)] of e-beams produced from the first stage.

The PM experiment showed fluence dependent reflective properties. When the fluence was lower than optimum, the PM triggered too late with respect to the arrival of the main pulse, transmitting a larger fraction of laser energy. When the fluence was higher than optimum, the plasma absorbed too much energy, resulting in a lower reflectivity as well as a poor surface quality. Optimum fluence of $\sim 300 - 500$ J/cm^2 resulted in 80% reflectivity and the reflected laser mode was as good as the input mode. This performance is believed to be sufficient for the experiment.

Laser beam 2 reflected off the PM and was coupled into the second stage. Optical spectra of the laser exiting the second stage is shown in Fig. 5 along with an input spectra. Based on a preliminary spectral analysis using simulations, the average accelerating field is $\sim$ 1 GV/m, and the energy gain of the e-beam would be $\sim 10 - 30$ MeV. Since the laser pulse duration was not optimized in the experiment shown here, various optimizations for wake excitation are in progress.

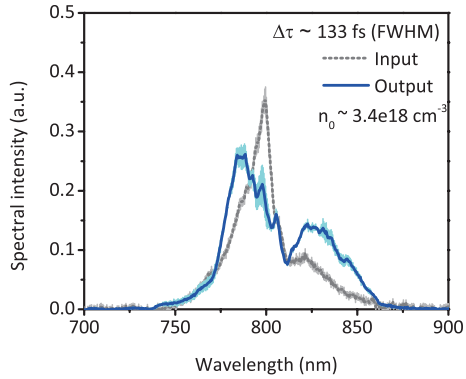

Figure 5: Input and output laser spectra guided through the second stage.

CONCLUSION

Recent progress of staged LPA was reported. Electron injection, plasma mirror in-coupling, and wake excitation in the acceleration stage were demonstrated independently of each other. Along with the experiments, the analysis of optical spectra to estimate energy gain from the acceleration stage was discussed. Optimizations to improve e-beam stability and efficiency of wakefield excitations are in progress.

GENETIC ALGORITHMS AND THEIR APPLICATIONS IN ACCELERATOR PHYSICS*

A.S. Hofler†, Thomas Jefferson National Accelerator Facility, Newport News, VA 23608, USA

Abstract

Multi-objective optimization techniques are widely used in an extremely broad range of fields. Genetic optimization for multi-objective optimization was introduced in the accelerator community in relatively recent times and quickly spread becoming a fundamental tool in multi-dimensional optimization problems. This discussion introduces the basics of the technique and reviews applications in accelerator problems.

GENETIC ALGORITHM OVERVIEW

Genetic and evolutionary algorithms (GAs and EAs, respectively) are examples of adapting models for processes observed in nature to create novel approaches to solving seemingly unrelated problems. These methods mimic biological reproduction, the theory of evolution, and the behavior of biological populations to solve mathematical optimization problems. Sets of solutions to an optimization problem are considered successively. The solutions from set i that more closely meet the optimization goal(s) are considered fitter, more inclined to survive, and are used to create the next $i+1$ set of solutions. As the selection and reproduction cycle repeats, the solutions produced are refined, and the defining characteristics for the best solutions coalesce to the optimal value(s). While not an immediately obvious method for optimization, GAs and EAs have proven to be highly effective in solving engineering and accelerator physics problems. Two recommended references on GAs, EAs, and optimization in general are [1, 2].

Optimization Problem Statements

Commonly, optimization problems are cast as minimizing or maximizing a cost function, and optionally, the independent variables may be subject to boundary constraints. Real world optimization problems tend to be multi-objective meaning there are multiple cost functions that must be minimized or maximized simultaneously subject to bounds and inequality constraints. Written generally, a multi-dimensional, multi-objective optimization (MOO) problem is

$$\begin{aligned} &\text{Optimize } f_j\left(x_1, x_2, ..., x_N\right) && j = 1, 2, ..., J, \\ &g_k\left(x_1, x_2, ..., x_N\right) \geq 0 && k = 1, 2, ..., K, \\ &x_{\min}^{(n)} \leq x_n \leq x_{\max}^{(n)} && n = 1, 2, ..., N, \end{aligned} \quad (1)$$

where Optimize can be either Minimize or Maximize for each objective function f_j, J is the number of objective functions to be simultaneously optimized, g_k are K inequality constraints, and x_n are the N independent variables to vary subject to a set of bounds constraints, $x_{\min}^{(n)}$ and $x_{\max}^{(n)}$. For a single-objective optimization (SOO), $J = 1$ and $K = 0$. GAs and EAs can be applied to both single- and multi-objective problems.

Solution existence and uniqueness is not guaranteed for SOO and MOO making them difficult to perform, but MOO has the additional complication that the objectives may conflict, meaning a set of independent variables that satisfies one objective goal causes another to move away from its optimal value. An example is minimizing two objective functions that inversely depend on the same independent variable, e.g. $f_1 = x_1$ and $f_2 = x_1^{-1} + x_2$ for $0.5 \leq x_1 \leq 1$ and $0 \leq x_2 \leq 1$. No single combination of x_1 and x_2 clearly minimizes both f_1 and f_2 simultaneously. In contrast, changing the problem to minimize one function and maximize the other creates two different optimization problems where the objectives do not conflict, and fortunately, both problems have unique solutions ($x_1 = 0.5$ and $x_2 = 1$ minimize f_1 to 0.5 and maximize f_2 to 3, while $x_1 = 1$ and $x_2 = 0$ maximize f_1 to 1 and minimize f_2 to 1).

For the simultaneous minimization problem, each possible x_1 value gives an equally valid solution to the minimization problem for $x_2 = 0$. Absent additional information about a preferred solution or system behavior, there is nothing to differentiate any particular solution from the rest in the x_1 interval. For instance, at $x_1 = 0.5$ and $x_2 = 0$, while $f_2 = 2$ is not its minimum value on the x_1 interval, f_1 is minimized to 0.5. This is the best solution for $x_1 = 0.5$ since $f_2 > 2$ for $x_2 > 0$. Similarly, $f_1 = 1$ and $f_2 = 1$ comprise the best solution for $x_1 = 1$. For the remaining values of the x_1 interval with $x_2 = 0$, neither f_1 nor f_2 attains its individual minimum value, but their values are the optimal ones for each fixed value of x_1. These solutions for $0.5 \leq x_1 \leq 1$ and $x_2 = 0$ are equivalent in terms of the optimization goals, and they form the set of solutions to this optimization problem. When objective functions conflict, a series of individual optimizations must be considered and solved, and the set of solutions is called the Pareto optimal front. The Pareto optimal front is important because it elucidates trade-offs between objectives.

Comparison to Standard Techniques

Historically, standard techniques used for multidimensional optimization problems are either iterative derivative-based methods or systematic parameter scans. GAs and

EAs are iterative but not derivative-based. They analyze a series of relatively large sets of solutions or populations to identify candidate solutions to produce new sets of solutions. Each new population is a generation and represents an iteration. Populations are composed of individuals, realizations of Eq. (1). A systematic parameter scan produces one very large exhaustive population in a single generation, and the data are analyzed at the end. GAs and EAs are smarter parameter scans because interleaving parameter space sampling and objective value analysis allows them to identify and concentrate on promising parameter space regions as they progress.

Genetic Algorithm Processing

The distinguishing characteristic of GAs and EAs is the simple but effective process by which the N-dimensional parameter space is sampled and the resulting objective values are analyzed. By way of caveat, there is great variability in algorithm designs, and this discussion may describe features and concepts that are not explicitly used or are omitted in a particular algorithm or application. The general process starts with an initial population created from a set of independent variable values that are randomly produced within the bounds constraints. This generation is a random sample of the N-dimensional parameter space. The objective values are ranked against the optimization goals, and a new population is generated from favorably ranked individuals. The cycle of ranking objectives and generating new populations repeats until the optimization goals are met within some specified tolerance or the maximum number of generations limit is reached.

Fitness is used to rank individuals in a population and indicates the relative strength of an individual. It is a function of the objectives and can include the constraints. Its exact form varies with algorithm and application. In the single objective case, the fitness function can be the objective value itself. Alternatively, fitness may be a measure of how well the objective values meet the optimization goals and adhere to the problem constraints [1, 3, 4]. Typically, stronger individuals have larger fitness values, but not always [3]. In some cases, the fitness concept is not explicitly invoked [5] but can be assumed to be the objective function value(s).

Some general fitness definitions for MOOs use the dominance concept [1] because it is suited to systems with conflicting objectives. An individual is said to dominate another if it is better in at least one objective and no worse in the others where the sense of "better" and "no worse" depends on the optimization goal for each objective. For an objective to be minimized, better means "$<$", and no worse means "$\leq$". In the minimization example above, $A = (x_1, x_2, f_1, f_2) = (0.5, 0, 0.5, 2)$ dominates $B = (0.5, 1, 0.5, 3)$ and $C = (1, 1, 1, 2)$ but not $D = (1, 0, 1, 1)$. Also, D dominates C but not A or B. B and C do not dominate each other, A, or D. If a dominance-based fitness function, for example, tallies for each individual the number of other individuals in a generation that dominate it, then the tally can be used to identify individuals that best approximate the Pareto optimal front because their tallies will be zero [3]. Applied to A, B, C, and D, the tallies are 0, 1, 2, and 0, respectively. A and D are the best estimates of the Pareto optimal front and are in fact on the Pareto optimal front. The individuals on the Pareto optimal front are said to be non-dominated with respect to each other and dominate at least one other individual in the generation.

With fitness values calculated, the selection and reproduction process starts. First, individuals are chosen to form the mating pool through a competition mechanism. For example, in tournament selection, individuals are picked at random, and a comparison of fitness values decides the winner. Only competition winners are placed in the mating pool, and only members of the mating pool are selected to reproduce. Thus it is possible to lose good individuals either through losing a competition or failing to be selected to participate. Elitist strategies counter this by giving the best individuals an advantage specific to the algorithm. Strength Pareto Evolutionary Algorithm 2 (SPEA2) [3] creates an archive of past and present best individuals, and only individuals from the archive are considered for the mating pool.

Next, individuals are chosen pair-wise from the mating pool to produce offspring through crossover, also known as recombination. GAs typically operate on binary encoded string representations of the independent variables, while EAs operate on vectors of decimal values. In the GA form, crossover mirrors the biological process. The two parent strings are split at the same randomly selected locations, and the substrings are exchanged to make the offspring. In the EA equivalent, the values of the two parents are directly exchanged to create the offspring, or linear combinations of the parent values are passed to the offspring. Offspring mutation follows. For the binary string, mutation is a randomly flipped bit ($0 \rightarrow 1$ or $1 \rightarrow 0$), and a randomly applied and generated offset for the EA version. Probability density functions (pdfs) determine the behavior of the EA crossover and mutation. The pdf configuration parameters can be tuned to affect the convergence behavior.

Differential Evolution (DE) [5] is often used for SOOs in accelerator applications while SPEA2 and Non-Dominated Sorting Genetic Algorithm II (NSGA-II) [4] are preferred for MOOs. SPEA2 and NSGA-II are elitist strategies, and now, an elitist DE is available for MOOs [6].

BEAMLINE COMPONENTS

Most beamline component GA- and EA-based design and optimization applications center on magnets and radio frequency (RF) and acceleration related devices. Early examples concentrate on magnet design and construction, and later ones are geared more toward acceleration systems.

Two magnet examples are wiggler and undulator magnet ordering and superconducting magnet design. Wiggler and undulator magnets are constructed from several smaller dipole magnets, and it is important to arrange the constituent magnets to minimize field errors. GAs and EAs

Copyright © 2013 CC-BY-3.0 and by the respective authors

can search through the many magnet order permutations and find the optimal arrangement [7], and GA-based magnet sorting and shimming continue to be integral to wiggler and undulator construction [8, 9, 10]. One of the earliest uses of Pareto optimality is a GA-based superconducting magnet design tool [11]. The tool identifies and creates multiple similar conceptual magnet designs meeting specified criteria that a magnet designer can then further evaluate with respect to manufacturing considerations. With this tool, a new magnet coil design was identified for use in the Large Hadron Collider.

The first application of GAs to RF devices was to optimize cavity designs based on higher order mode and resonance requirements [12]. With the renewed interest in GA and EA methods, the number of RF cavity optimizations has grown recently to include a variety of RF and superconducting RF (SRF) cavity designs: crab cavities [13], spoke cavities [14], choke-mode damped structures [15], microwave tubes [16], and klystron interaction structures [17]. Lastly, geometric dimension and relative dielectric permittivity optimizations for cylindrical and slab wakefield accelerators provide insights into the tradeoffs between transformer ratio and maximum accelerating wakefield electric field amplitude [18].

ACCELERATOR DESIGN

There are two modes of accelerator design using GAs and EAs. The first assumes a machine element layout where the field behavior of the magnets and accelerating devices is known, and the optimization searches for optimal set points, field amplitudes and phases, and element spacings to achieve specific beam quality and operating conditions. In other words, the optimization acts to tune the machine. The other mode builds on the first additionally varying physical features of beamline elements and systems to discern optimal designs or requirements for them; beamline element and operational set point optimizations are combined. Most applications fall in the first category, and with the growing appreciation for the power and flexibility of GAs and EAs in the accelerator field, the number of more holistic machine design applications is growing. Pareto optimality is especially important here because the front provides information about the many possible configurations and capabilities letting the designer choose the most suitable combination. In some cases, the front has even revealed unorthodox operating schemes that are comparable to or better than the standard solutions [19, 20, 21].

The ability to optimize a known machine layout is extremely useful. This form of optimization is well established, and only a fraction of the many examples will be highlighted here. The earliest application determines the quadrupole settings in injection and transfer lines for BESSY-II [22].

The tuning approach is used in mainly four ways. The most obvious use establishes the expected performance of a proposed or upgraded machine. A sample shows: positron momentum selection in a continuous wave positron source [23]; dynamic aperture optimization for a storage ring upgrade [24]; asymmetric distribution of longer insertion device straight sections in a storage ring light source [25]; a superconducting tape undulator-based light source [26]; a two-loop compact energy recovery linac (ERL) [27]; an electron linac for a gamma-ray source [28]; compression schemes for a free electron laser (FEL) [29]; and a bunch compressor for electron beam slicing [30].

Second, optimizing operational settings and relative element spacing can establish that a particular technology is suitable for a new or more demanding accelerator application. Most examples are direct current (DC) and RF gun injectors for FEL [31, 32, 33] and ERL light sources [34].

Third, accelerator physicists look for performance improvements for existing machines through alternative machine settings. Storage ring light sources benefit from this most to optimize brightness [20] and increase dynamic and momentum apertures [21, 35].

Lastly, this mode can identify tuning knobs or their settings to correct or avoid operational problems. Identification is needed for storage ring orbit bumps [36] and collider final focus optics tuners [37]. Finding knob settings is useful for controlling transport optics for muon experiments [38], restoring machine performance until failed components can be repaired [39], protecting equipment [40], and making machines insensitive to destructive beam instabilities such as beam break-up [41].

The second more encompassing accelerator design approach allows beam and beamline element performance to be considered together. This flips the model described above determining the suitability of a given technology or machine layout for an application. Instead the desired beam performance directly drives element design. Two advance examples of this approach are a preliminary spallation neutron source accumulator ring design study [42] and a muon solenoidal decay channel optimization [43].

The watershed accelerator physics applications showcasing the power of EAs, GAs, and Pareto optimality in general and this combined beam and element performance optimization are a laser profile and DC gun injector optimization for an ERL light source [19] and a damping ring optics evaluation tool that creates all viable optics layouts fitting in a given machine circumference [44]. They demonstrate that automating accelerator design is possible because GAs and EAs can manage the complexity of these problems and organize the results in a way to help the accelerator designer choose the best design among all possible designs meeting a set of criteria. The success and flexibility of these two optimizations led to the explosive growth in accelerator EA- and GA-based optimizations of all kinds. These two examples led to beam performance-based systems devoted to finding optimal: geometries for injector guns [45, 46] and accelerating elements [47, 48]; field profiles for storage ring dipoles [49] and fixed-field alternating gradient accelerator magnets [50]; undulator tapering profiles [51]; and an RF pulse time structure to compensate for beam loading

Copyright © 2013 CC-BY-3.0 and by the respective authors

in a linac [52].

REAL TIME AND DIAGNOSTIC APPLICATIONS

Two very successful real time applications of GAs are photocathode laser profile generation [53, 54] and phase space reconstruction [55]. Both examples configure several similar or identical elements. The shear number of permutations on the settings precludes enumerating and evaluating each setting in turn, so a GA is used to sample the available permutations and identify an optimal configuration. A third example extracts cavity parameters from pass band data for an SRF cavity installed in a multi-cavity assembly [56].

ACCELERATOR DESIGN TOOLS AND COMPUTATIONAL CONSIDERATIONS

Execution time is an important factor to consider when choosing GA and EA tools and the underlying computational structure. These population-based methods assume computations for individuals are independent and self-contained, so they are amenable to parallelization. The maximum time to calculate all results for a single individual determines the level of necessary parallelization. If an individual is modeled with a few finite polynomial expressions for example, serially processing individuals in a population is reasonable, and optimization extensions for Excel [57], MATLAB, and Mathematica are appropriate to use. Most problems in accelerator physics require simulation codes to model the underlying physical system and involve non-negligible execution times. For these situations, the results for individuals must be produced in parallel.

Several parallel frameworks are available affording various levels of flexibility and abstraction. The basic design has two main parts. The first is the GA or EA wrapped around a simulation job management system. The job management system handles communication between the optimization processing and the simulation code(s), and it dispatches simulations for individuals to available computer resources. Program and script based systems include: Alternate PISA (A Platform and Programming Language Independent Interface for Search Algorithms [58]) (APISA) [19, 45] and variations from TRIUMF [59] and Jefferson Lab [46], geneticOptimizer [60], and OPT-PILOT [61]. APISA and variants mainly use SPEA2, and the others use NSGA-II. Note OPT-PILOT has a Python-based graphical interface for viewing Pareto optimal fronts and associated decision variable values.

The parallel frameworks commonly assume access to a large number of compute nodes found in batch farm and high performance computer cluster configurations. Alternatively, idle desktop computers in an organization can be co-opted with APISA or Condor [17], a system that coordinates, monitors, and dispatches simulations to underutilized desktop computers. The advent of commercial cloud computing resources may provide on-demand high performance computer clusters to extend existing systems or obviate the need for local installations [62].

Some accelerator simulation systems include GAs and EAs in their optimization suite: TAO [63], COSY-GO [64], G-optimizer in TRACK [65], GeneticTRACY [62], elegant COGA [66], and a symbolic beam propagator [67]. Lastly, libraries are available such as PGAPack [68] and pikaia [69] to build custom systems.

CONCLUSION

The use of GAs and EAs is well established in accelerator physics as demonstrated by the variety of applications and tools presented here. The expanded capability of GAs and EAs to directly solve MOOs and identify inherent trade-offs has substantially increased their utility in the field and enables automated optimization of systems that are complex in terms of dynamics and the number of variables involved. The basics of GAs and EAs have been introduced to facilitate understanding of how these algorithms work and interpreting the results they produce.

A SPECIALIZED HIGH-POWER (50 kW) PROTON BEAMLINE FOR BNCT

Morgan P. Dehnel, Thomas M. Stewart, Tue Christensen, David E. Potkins, D-Pace, Inc.,
PO Box 201, Nelson, BC, Canada
Hirofumi Seki, Shinji Shibuya, Steve Domingo, Glenn James, Pat Creely, Steve Bucci, AccSys Technology, Inc., 1177 Quarry Lane, Pleasanton, CA 94566, USA

Abstract

D-Pace has developed a specialized high-power beamline for transporting a 20 mA, 2.5 MeV, CW proton beam for a Boron Neutron Capture Therapy (BNCT) application. The 2 m horizontal by 4 m vertical layout transports the space-charge dominated beam with less than 1% beam-spill using two sets of 10 T/m quadrupole doublets, DC XY steerer, 90 degree bending magnet, and AC XY magnets for raster-scanned, flat-topped, round or square intensity distributions deposited over targets with 40 – 100 mm maximum dimensions. Diagnostics include New Parametric Current Transformers (NPCT), graphite, water-cooled, electrically-isolated collimators with readbacks, and a low-power sapphire beam profile monitor for macro-pulsed beams (~100 micro-second wide pulses at low frequency). This paper describes the specialized: beam-optics, intensity distributions, and device designs.

INTRODUCTION

BNCT is a non-invasive therapeutic treatment of cancer (high-grade gliomas, cerebral metastases of melanoma; and head, neck, and liver cancer) [1] that involves two steps. First, tumour-localizing non-radioactive boron-10 delivery agents (such as boronophenylalanine i.e. BPA, or sodium borocaptate i.e. BSH) are injected into the patient [1]. Second, the patient is exposed to epithermal neutrons, which have a very high probability of reacting with the concentrated boron-10 residing in the cancer cells. This yields an energetic alpha particle, and a recoiling lithium nucleus which ionize a tremendous number of atoms and molecules within 5-9 microns (~size of cancer cell). This results in cancer cell death [1,2].

BNCT has a 50 year history at research nuclear reactors [3], and is established i.e. 16th International Congress on Neutron Capture Therapy, ICNCT (2014), is to be held in Helsinki. For widespread use of BNCT better delivery agents, improved dosimetry, and independence of nuclear reactors is required [3]. Barth [3], IAEA [4], Blue and Yanch [5] all emphasize the development of particle accelerators for BNCT. Strong growth in BNCT implementation in hospitals is anticipated since it can now be de-coupled from nuclear reactors through low energy (p,n) reactions provided by relatively inexpensive safe compact particle accelerator systems that can be turned off (as compared to a reactor) [6].

This paper describes the High Energy Beam Transport (HEBT) beamline developed for the BNCT treatment system utilizing an AccSys 2.5 MeV, 20 mA, CW proton Linac and the Li-7(p,n)Be-7 reaction.

HEBT BEAMLINE

The 10 rms RFQ beam was modeled thru HEBT (Figure 1) with 1st order Beamline Simulator [7] using acceptances greater than 3x the 10 rms emittances in both transverse phase-planes to define conservative apertures. TRACE-3D [7] simulations confirmed high beam transmission at 20 mA CW space-charge conditions. The finalized system in Figure 2 follows the principles [8-10].

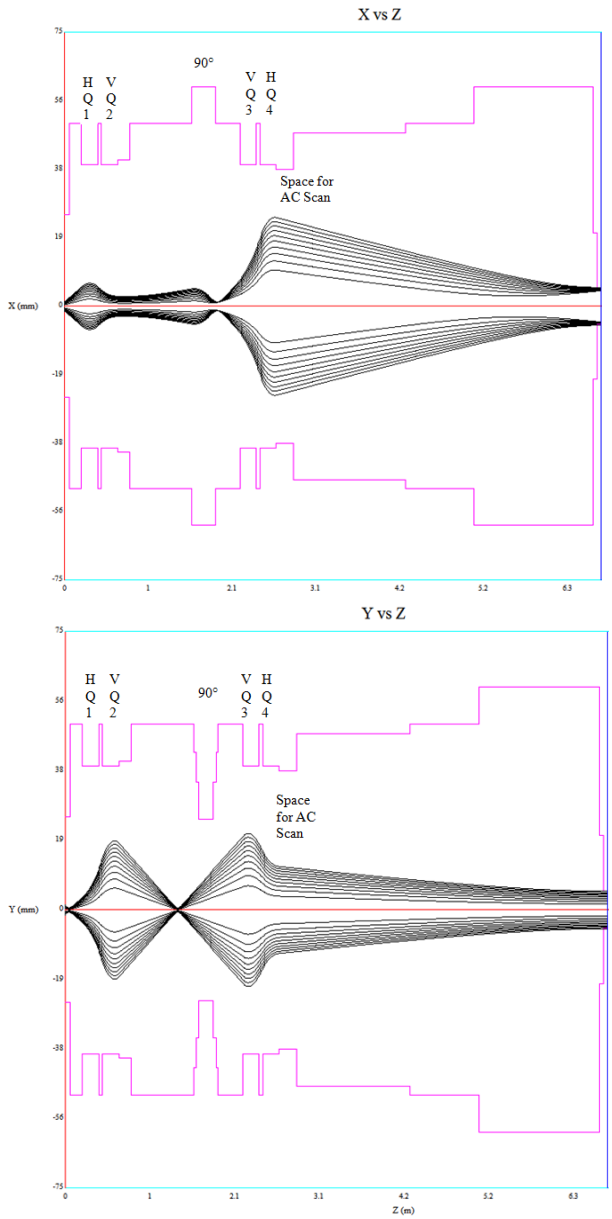

Figure 1: HEBT Horizontal & Vertical 1-10rms Beams.

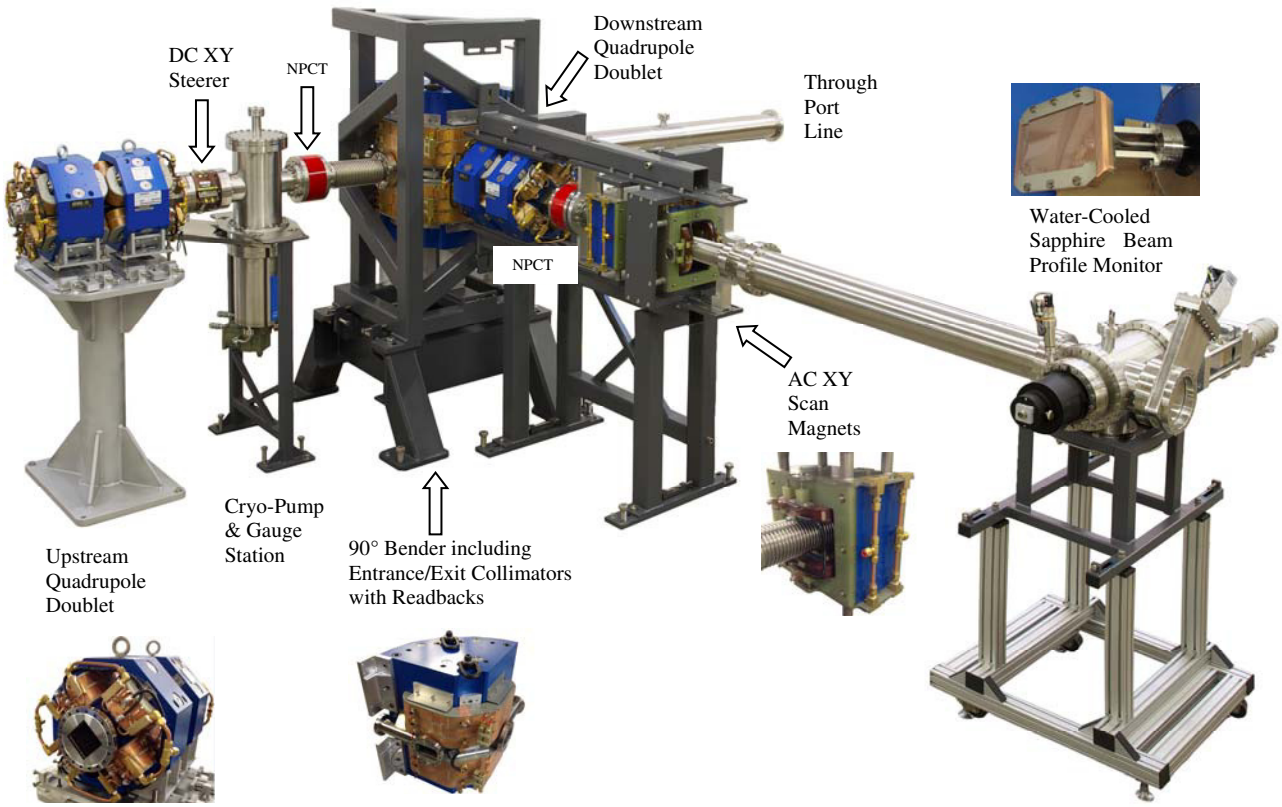

Figure 2: The HEBT system. The proton beam is injected into the HEBT from the RFQ at upper left, and the scanned beam exits at right (downstream of Beam Profile Monitor). The supports can be arranged in a horizontal format for factory testing as shown, or in a format where components downstream of the 90° Bender are in the vertical direction.

Ion-Optical Elements

The ion-optical elements are as follows: (1) Upstream Quadrupole Doublet {Bore = 82.3 mm, Effective Length (EL) = 202.3 mm, B_{Max} = 0.4 T}, (2) DC XY Steering Magnet {Iron Gap = 105 mm, EL = 184 mm, B_{Max} = 0.01 T}, (3) 90° Bender Magnet {Iron Gap = 52 mm, EL = 300 mm, B_{Max} = 1.3 T, Rogowski Pole Face Rotations = 0°}, (4) Downstream Quadrupole Doublet {Bore = 82.3 mm, EL = 202.3 mm, B_{Max} = 0.4 T}, and (5) AC XY Scan Magnet {Iron Gap = 97 mm, EL = 212 mm, B_{Max} = 0.0165 T, Frequency = 45 Hz}. All magnets designed with alignment fiducials for Ball Mounted Reflectors (BMR) used during final alignment with a laser tracker.

Upstream Horizontal Section Description

The Upstream Quadrupole Doublet is placed close to the RFQ (~200 mm space for a VAT™ gate valve, bellows, and flanging) since it serves to capture the diverging RFQ beam and to focus it through the 90° Bender which has a narrow gap resulting in reduced magnet cost, size, and power consumption. The transverse beam envelopes are largest through the Quadrupole Doublets and thus they are fitted with diamond-shaped beampipes that afford a larger acceptance than round beampipes for the very same magnet bore diameter (refer to lower left of Figure 2).

Immediately after the upstream doublet is the DC XY Steering Magnet which provides ± 8 mrad of steering capability. It is located downstream of the first doublet where a sensitivity analysis has shown it to be efficacious.

A cryo-pumping station with ports for gauges and leak testing are provided. The cryo-pump is separated from the beamline by a gate valve, so that it is not necessary to be purged to atmosphere if the HEBT is vented.

A Bergoz NPCT (96 mm diameter) provided by GMW measures the beam current in the upstream portion of the line. It comes with Conflat™ flanging as does all of the vacuum equipment. Experiments shall be undertaken to ensure H2+ is not affecting the proton beam current measurement [11].

A bellows is located immediately upstream of the 90° Bender Magnet. The bender magnet vacuum box is outfitted with electrically-isolated water-cooled 46 mm diameter graphite entrance and exit collimators with beamspill current readbacks to the control system. The device's handle greater than 2 kilo-watt beamspill power on average, but shall be used as a threshold interlock at 0.5% of total beam current for rapid "beam off" in the case of a component failure (i.e. power supply). The collimator ceramic insulators are protected by metal shrouds to prevent short-circuiting in the event of any migration of metal vapour from the targets. The bender vacuum box also has a thru port with gate valve and beampipe with pumping station port for DC beam experiments when the bender is off.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Downstream Vertical Section Description

The Downstream Quadrupole Doublet captures the strongly diverging beam immediately downstream of the bender magnet. A Bergoz NPCT is next and provides a 2nd beam current measurement to establish transmission rates. The support structure can be used in both a horizontal and vertical configuration. A sapphire water-cooled low-power beamstop with a radhard MegaRAD3 Thermo CIDTEC camera for viewing low frequency macro-pulsed beams (~100 micro-second) is provided. The downstream vertical section is shielded to contain the neutron flux from the target.

D-Pace's standard <100 Hz AC XY Scan Magnet product can provide both generic raster and circular scanned beams as shown in Figures 3 and 4.

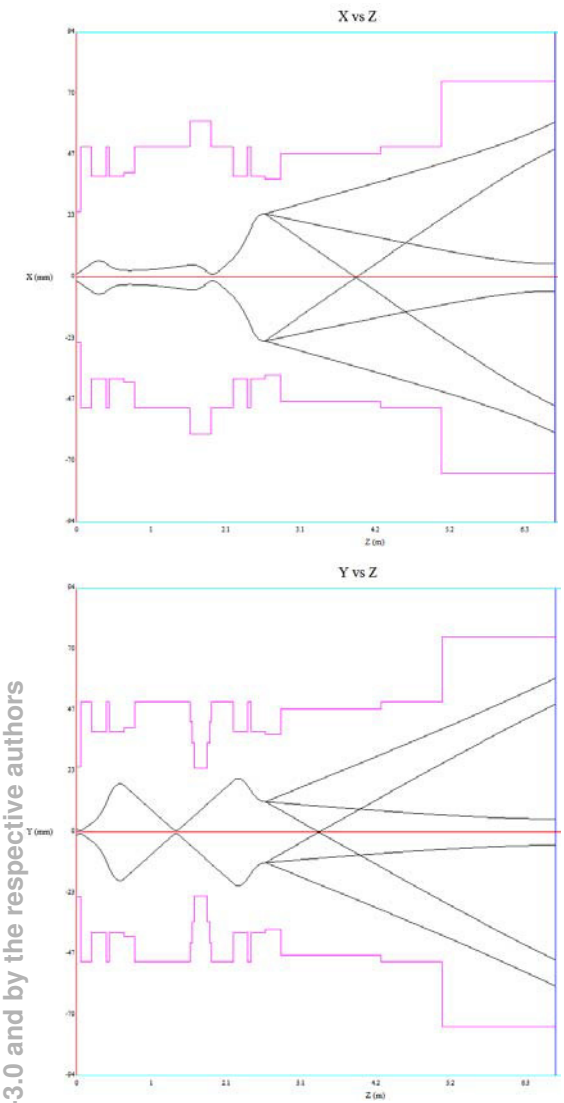

Figure 3: Horizontal and vertical 10 rms beam profile extents of AC Scanning (θ_{Max}= ±13.4 mrad) with 10 mm DC beam spot on target. Apertures confirmed.

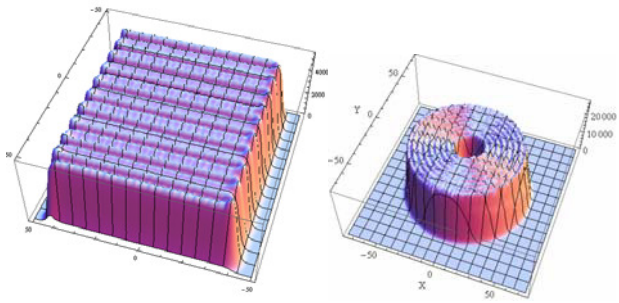

Figure 4: An example of generic square raster-scanned beam (left), and generic circular scanned beam (right) that D-Pace's standard product AC Scan Magnets can deliver. The customer shall tailor the undisclosed beam distributions on target according to their own proprietary algorithms through D-Pace's programmable two channel signal generator.

ACKNOWLEDGMENTS

We wish to gratefully acknowledge: the Canadian Government's R&D funding programme SRED; Buckley System's Ltd (BSL) for excellent development, manufacturing and testing work; Kurt J. Lesker, Bergoz, GMW, Thermo/CIDTEC & Testforce staff for wonderful support and equipment; and P. Schmor, B. Gyles, M. Stokely, J. Peeples, C. Humphries, J. Theroux and C. Hollinger for high-level technical consulting support.

LARGE MOMENTUM ACCEPTANCE SUPERCONDUCTING NS-FFAG GANTRY FOR CARBON CANCER THERAPY*

Dejan Trbojevic, Brett Parker, BNL, Upton, New York, 11973, USA
Marco Pullia, CNAO, Pavia, Italy

Abstract

Carbon cancer radiation therapy has clear advantages with respect to the other radiation therapy treatments. Cost of the ion cancer facility is dominated by the delivery systems. New superconducting carbon ion gantry designs, based on the Non-Scaling FFAG (NS-FFAG) principle, are presented. The magnet size and weight is dramatically smaller with respect to existing gantries. The weight of the transport elements of the carbon isocentric gantry is estimated to be 1.5 tons to be compared to the 130 tons of the top-notch gantry in the Heidelberg ion therapy facility.

INTRODUCTION

A number of ion cancer therapy facilities are rapidly rising due to a clear advantage to any other radiation treatment of the cancerous tumors. This is due to a very localized energy deposition of ions at the "Bragg peak-as suggested by R. Wilson 1946 [1]. The ion cancer facility starts with an ion source, accelerator, and the delivery system (major cost). The Coulomb scattering and struggling define the final beam spot size–penumbra at the tumor. The best results in the cancer treatment are obtained by use of the spot size "pencil" beams with the transverse and longitudinal scanning technique. Usually the treatment time is of the order of couple of minutes. In proton cancer therapy the minimum beam volume size-voxel at the tumor (for the maximum distance of 27 cm in the patient) is ~715 mm^3, while for carbon ions it is ~14 mm^3. The transverse intrinsic spot for 206 MeV protons is ~11 mm, while for carbon ions is 2.9 mm. Carbon ions have advantage in the patient treatment, as they are more precise. Normal angle of ion arrival to the patient reduces the skin radiation. The Source to Axis Distance (SAD) parameter in the cancer treatment shows an optimum with SAD=∞ (beam arrives with normal angle of incidence to the patient skin).

A recommendation from the Workshop on Ion Therapy [1] in Bethesda MD (organized by Department of Energy (DOE), National Cancer Institute (NCI), National Institute of Health (NIH), and Department of Health & Human Services DHHS) was that the carbon or other ion therapy facility should include rotatable gantry, possibly made of superconducting magnets (to be able to reduce the size and cost) and with a large momentum acceptance.

This is a report on a large momentum acceptance superconducting NS-FFAG gantries. They have many advantages like: reduced size and weight, large momentum acceptance (200-400 MeV or 100-200 MeV/u etc.), fixed magnetic field, with the angle of incidence always normal to the patient (SAD=∞), and easy to operate, as the magnetic field is fixed during the treatment. We present two examples: the isocentric gantry and an eccentric gantry proposed, by Marco Pullia (CNAO-Italy). Both gantries have a large momentum acceptance – for one fixed magnetic field setting they can operate covering a large kinetic energy range (either between 200-400 MeV/u or 100-200 MeV/u). The normal angle of incidence is obtained by use of two scanning dual plane scanning magnets.

NS-FFAG PRINCIPLE

In recent years there has been a clear revival of the previous concept of the FFAG's, developed mostly in the 1950's. A concept of the NS-FFAG is based on strong focusing principle with a small dispersion function. The relationship: $\Delta x = D\ \delta p/p$ shows that the beam offset is small even for the large $\delta p/p$. Major differences between the NS-FFAG's with respect to the scaling FFAG's are variations of the tunes, time of flight, dispersion and amplitude functions with a momentum as shown in a gantry cell in Figure 1.

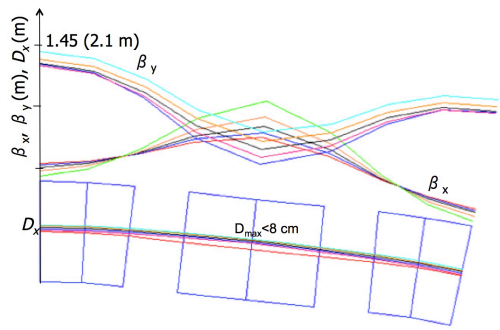

Figure 1: Betatron and dispersion functions in a gantry cell for the treatment energies.

BEAM DELIVERY - ION GANTRIES

The delivery system is the most expensive part of the ion cancer therapy facilities. Figure 2 shows the top-notch proton gantry at PSI in Switzerland. The scanning magnets are placed usually in front of the large 90°-bending magnet above the patient. This is to allow for the SAD=∞. To avoid the large magnet above the patient (for the proton gantries its weights is ~60 tons) a scanning system is placed above the patient. This solution (submitted to the Patent Office) not only removes the necessity of the large magnet but also always provides normal angle of incidence to the patient skin. A proton gantry design is shown in Figure 3.

* Work performed under Contract Number DE-AC02-98CH10886 with the auspices of the US Department of Energy

Figure 2: The proton top-notch proton therapy facility at PSI, with the large bending magnet at the end.

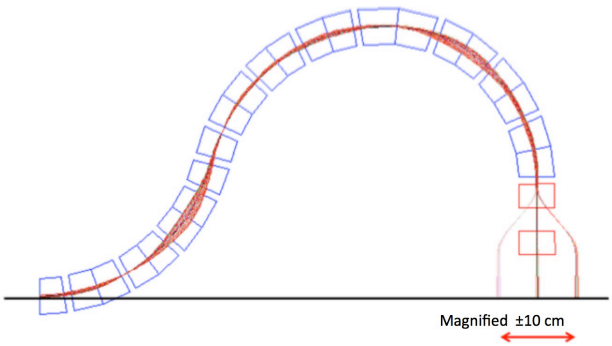

Figure 3: Our proton gantry design eliminates need for the large dipole and provides always 90° angle to the skin.

The carbon gantry operating at the Heidelberg ion cancer facility is of a large size as at the time when it was built and designed, relied on the existing safe warm magnet technology. The maximum kinetic energy of the carbon ions in Heidelberg is 430 MeV/u with a corresponding $B\rho$=6.624 Tm. For the magnetic field of 1.6 T produced by the warm magnet the radius of a curvature is R=4.1 m. To better perceive the size of this gantry in figure 4 a visitor is shown. The NS-FFAG superconducting gantry design is shown together with the Heidelberg gantry in Figure 6. A large number of small superconducting combined function magnets will reduce the size of the gantry. The number of magnets is 31, including the two scanning and the triplet magnets for defining the beam size. The superconducting magnets are made by superconducting wire wound directly onto the beam pipe, without using any iron. This reduces the weight. They have a small aperture r~3 cm. The dipole field in the defocusing magnet is B_{yD}= 4.55 T with gradient of G_d= −90 T/m, while the focusing magnet has opposite bending field of B_{yF}=-0.385 T with a gradient of G_F=150 T/m. The length of the focusing magnet is 20 cm while the defocusing one is 26 cm long. The bending angle of the defocusing magnet is θ_D=0.233 rad while the focusing combined function magnet has an angle of the opposite sign of θ_F=−0.152 rad. The magnetic field in the defocusing combined function magnet is equal to: $B_{DTOT} = B_D + (G_D * x)$, while for the focusing magnet it is: $B_{FTOT} = B_F + (G_F * x)$. The maximum magnetic field in the defocusing magnet is equal to B_{Dmax}=4.55 T at the lowest energy and B_{Dmax}=5.63 T at the highest energy (this is a combination of the bending field plus gradient multiplied by the orbit offsets for energies other than the central energy). The maximum field in the focusing combined function magnet is, for the lowest energy, B_{Fmax}=2.34 T, while for the highest energy it is B_{Fmax}=-3.4 T.

Figure 4: The Heidelberg gantry with a visitor. The large 45° magnet is shown above.

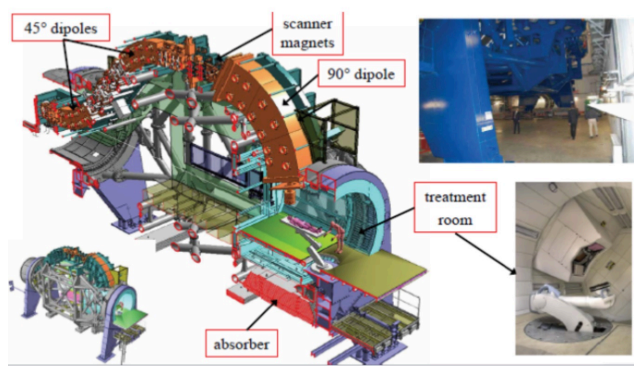

Figure 5: The whole structure of the Heidelberg carbon gantry with detail of the treatment room on the right side.

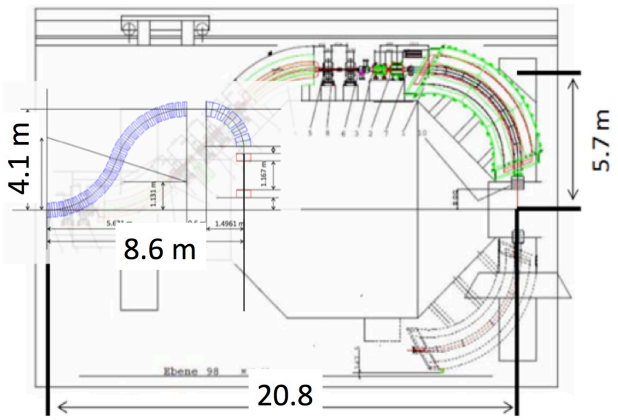

Figure 6: The carbon ion gantry with superconducting magnets is shown together with the Heidelberg gantry.

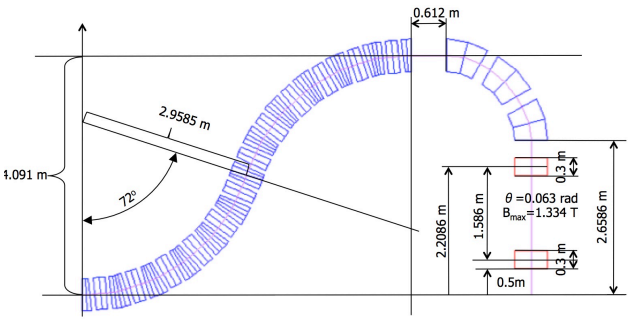

Figure 7: The carbon ion superconducting fixed field isocentric gantry layout. The scanning magnets are 30 cm long with a maximum required magnetic field of 1.35 T for the kinetic energy of 400 MeV/u (to be able to bend the beam ±10 cm at the patient (a distance between the two magnets is 1.566 m).

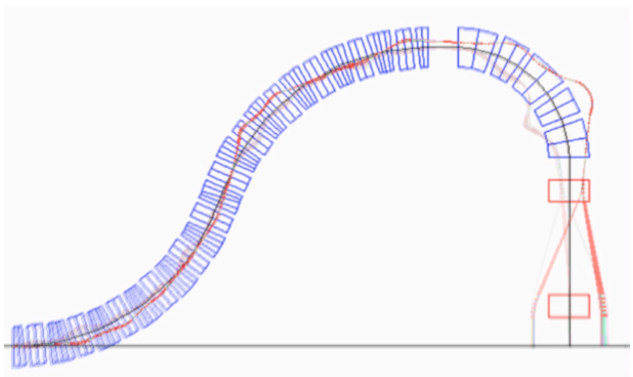

Figure 8: The fixed filed superconducting carbon isocentric gantry with beams of 202, 270, and 400 MeV/u. With the magnified (x10) scanning ±10 cm positions.

Two examples of the superconducting carbon ion gantries: the isocentric gantry (the same as in Fig. 6) and the eccentric one are shown in Figures 7&8, and Figures 9&10, respectively.

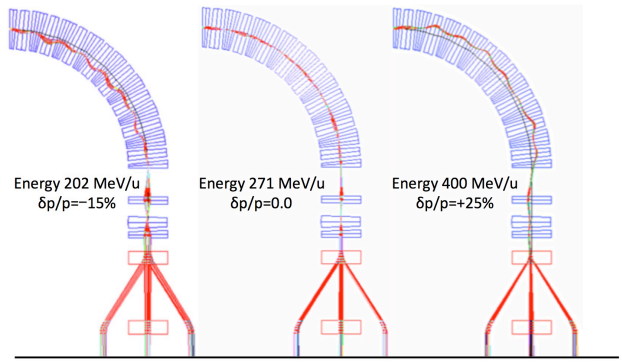

Figure 9: The 90°-superconducting gantry shown with carbon ions passing with three energies 202, 271, and 400 MeV/u under the fixed magnetic field, with scanning magnets. Positions of ±10 cm at the patient are magnified.

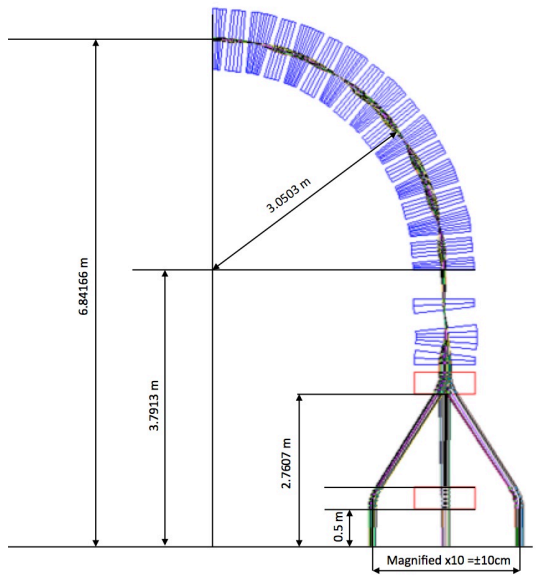

Figure 10: The layout of the 90° superconducting fixed field carbon gantry designed to fit to the CNAO eccentric gantry.

SUMMARY

The NS-FFAG superconducting gantries for carbon ion design with isocentric and eccentric case are presented. The gantry design fulfills a requirement of the very large momentum acceptance with a fixed magnetic field. Major advantages of the proposal are reduced size, weight, and easier operation as the magnetic field is fixed during the treatment time. New scanning system with SAD=∞ is presented. It reduces the size of the gantry, as it does not need the very large magnet at the end. The triplet magnets, placed above the scanning system, are used to define the beam size at the patient.

CYCLOTRON PRODUCTION OF POSITRON EMITTING RADIOMETALS

S. E. Lapi and T. Voller, Washington University in St. Louis, MO, 63110, USA

Abstract

The increase in use of Positron Emission Tomography (PET) for medical imaging has led to the development of numerous radiopharmaceuticals for use in preclinical and clinical research for oncology, cardiology and neurology [1]. While many of these biological processes can be investigated with probes radiolabeled with the more commonly used positron emitters, ^{18}F ($t_{1/2}$ = 110 min) and ^{11}C ($t_{1/2}$ = 20 min), imaging at longer timepoints requires radionuclides with longer half-lives. Thus, the production and purification of longer-lived position emitting radiometals has been explored to allow for imaging of peptides, antibodies and nanoparticles. This brief review will focus on the production and purification of ^{64}Cu ($t_{1/2}$ = 12.7 h) and ^{89}Zr ($t_{1/2}$ = 3.27 d).

INTRODUCTION

Positron Emission Tomography (PET), with its high sensitivity and resolution, is growing rapidly as an imaging technology for the diagnosis of many disease states. The success of this modality is reliant on the development of effective imaging compounds. Initially, research in this area was focused on the relatively short-lived PET isotopes ^{11}C and ^{18}F, but the short half-lives of these isotopes limit radiopharmaceutical development to those that probe rapid biological processes. To overcome these limitations, there has been a rise in alternative radionuclide tracer development in recent years. Below, in Table 1, are some examples of radiometals for use in nuclear imaging (all data from [2]).

Table 1: Examples of Positron Emitting Radiometals

Isotope	Production Route	Half-Life
^{64}Cu	^{64}Ni(p,n)	12.7 h
^{68}Ga	^{68}Ge Generator	68 min
^{86}Y	^{86}Sr(p,n)	14.7 h
^{89}Zr	^{Nat}Y(p,n)	3.27 d

While ^{68}Ga use has also increased recently, this short review will focus on the cyclotron produced isotopes, namely ^{64}Cu and ^{89}Zr.

Washington University in St. Louis has been producing and distributing longer-lived PET radionuclides to the research community for over 15 years. The radionuclides that have been produced include ^{64}Cu, $^{76/77}$Br, ^{66}Ga, ^{86}Y, ^{124}I, and ^{89}Zr. Presently, ^{64}Cu and ^{89}Zr are produced on a regular basis (weekly and biweekly respectively), while ^{86}Y and ^{76}Br are produced intermittently in lower quantities. The recent increase in production and shipping of ^{64}Cu to external institutions is illustrated in Figure 1 and is mainly due to the increase in clinical trials with this isotope.

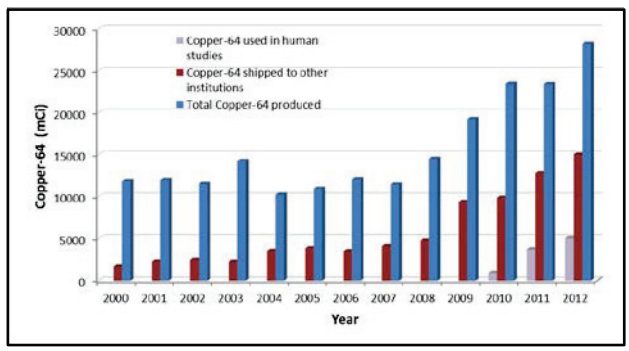

Figure 1: Production and Distribution of ^{64}Cu from Washington University in St. Louis.

TARGET PREPARATION AND BOMBARDMENT

Radiometal production starts with preparation of the target material on a suitable support for cyclotron bombardment. This may be an electroplated deposit, pressed powder pellet, or a foil placed in a suitable holder.

Preparation of ^{64}Ni Targets for Production of ^{64}Cu

Targets are prepared for ^{64}Cu production as per McCarthy *et al* [3]. Briefly ^{64}Ni metal is dissolved in 10 ml of 6.0 M nitric acid. The solution is then evaporated to dryness. The residue is dissolved in 1 ml of concentrated sulphuric acid and 5 mL deionized water and evaporated until slurry is formed. The resulting solution is diluted in 5 ml of deionized water. The pH was then adjusted to 9 with concentrated ammonium hydroxide (25%). Then 0.2 g of ammonium sulphate is added to the solution. This solution was transferred to an electrolytic cell with a graphite electrode as anode and a gold disc (target backing) as cathode. The cathode is cleaned with 6N HNO_3 to remove any metal residue on the surface. The cell is operated at 2.5 V with a starting current between 70-80 mA/cm^2. Final target weights are typically between 20 and 80 mg with a spot diameter of 5 mm.

The ^{64}Ni target is irradiated at a beam current of 20 µA for 60 to 80 µA-h with a Cyclotron Corporation CS-15 positive ion cyclotron, with a pneumatically-controlled cylinder sealing the back of the disc and providing cooling with recirculating chilled water. After irradiation,

*Work supported by the Department of Energy, Office of Science, Isotope Program under grant DESC0008657

Copyright © 2013 CC-BY-3.0 and by the respective authors

the cylinder is retracted, and the disk is ejected into a transfer line via pressurized nitrogen. The disc is brought up from the cyclotron vault to a shielded cell using vacuum. The target is then transferred manually to the processing hotcell.

Preparation of Y Foils for Production of ^{89}Zr

For the production of ^{89}Zr, a 0.64 mm thick ^{nat}Y disc is placed inside a niobium target holder. Nb was selected because of its high melting temperature (Tm = 2,468 °C) and high chemical inertness. Before each target holder was reused, it was scrubbed by hand using a cotton swab dipped in a slurry of Al_2O_3 powder and water. The target holder was placed in 6 M HCl for 1–4 h for cleaning and oven dried before mounting in the CS-15 cyclotron. During bombardment (typically 20 µA for 40 to 60 µA-h), the target holder assembly is cooled on the beam side by a He gas jet and on the reverse side by flowing chilled water. Following irradiation, the target remains in the solid target station for several hours to allow for the decay of short-lived contaminants, (^{89m}Zr) prior to processing as described below.

PURIFICATION

Following irradiation of the targets, the radionuclide of interest is separated from the target material by chemical processing.

Purification of ^{64}Cu

^{64}Cu is purified via an in-house automated system using a procedure adapted from the manual separation described in McCarthy *et al* [3] for use in a hotcell with remote operation [4].

The automated purification module consists of a series of PTFE or Kel-F based solenoid valves that direct liquid, gas, and vacuum flow. Processing of the irradiated enriched ^{64}Ni targets involves the dissolution of the nickel in 6M HCl in a custom made, heated PTFE vessel (30 min), active cooling of the dissolved nickel solution with a vortex tube (20 min), then recovery of the nickel via ion chromatography with 6M HCl, followed by an additional 6M HCl rinse of the dissolution vessel for higher recovery and removal of nickel from the resin, and elution of copper from the resin with 0.5M HCl. The entire chromatography process takes 40 minutes, and the liquid level is monitored via a camera to prevent the resin from drying out. The collected ^{64}Cu solution is then evaporated under argon (20 min) and reconstituted in 0.1M HCl. Another camera monitors the progress of the evaporation. Three radiation detectors are located by the dissolution vessel, column, and nickel recovery vial and provide real-time feedback on how well the process is proceeding. On average, the entire process takes about 2 hours from target introduction. The components required for these steps are located within the hot cell shown in Figure 2, while the control components and computer are located outside of the hot cell.

Figure 2: ^{64}Cu purification system.

The components are controlled using a USB digital input output (DIO) data acquisition unit and digital output modules. The in-house developed control program is easy to navigate and affords the operator flexibility during the synthesis. At the launching of the program, a series of dialog windows guide the operator in the preliminary preparation of the module. Once this procedure is fulfilled, the module is ready to start the synthesis. The operator also has the possibility to pause / abort the synthesis at any time during the sequence if a critical condition occurs. A diagnostic window is available to the operator for troubleshooting during synthesis, permitting the remote actuation of each step in the sequential procedure if adjustment is required due to a faulty condition.

Typical recoveries with this system are 96% or better of starting radioactivity and 98.6% of enriched ^{64}Ni target material.

Purification of ^{89}Zr

We have automated the ^{89}Zr purification method of Holland et al [5] on an in-house constructed system [6]. Using a custom software program made in LabVIEW, running on a laptop outside the hot cell 10 mL 2 M HCl is added to the dissolution vessel to dissolve the ^{nat}Y target. After waiting ~1 h for complete dissolution, the dissolved target is transferred to the separation column containing 100 mg of hydroxamate resin) through tubing using compressed air. Then, the Y is eluted from the column in 10 mL 2 M HCl and collected in a waste vial, leaving the ^{89}Zr bound on the column.

The column is rinsed with 10 mL water, which is collected in the same waste vial, and then ^{89}Zr is eluted in 1 mL 1 M oxalic acid and collected in a product vial as ^{89}Zr-oxalate. A schematic of the automated module for the separation of ^{89}Zr from the yttrium target material is shown in Figure 3.

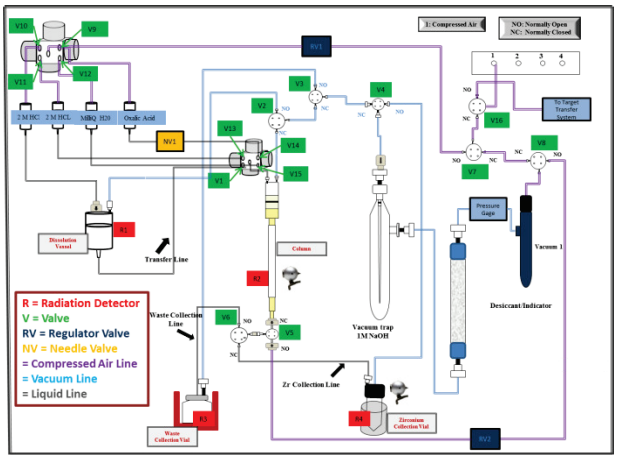

Figure 3: ^{89}Zr purification system.

QUALITY CONTROL

All isotopes undergo quality control procedures including radioisotopic purity and effective specific activity.

Radioisotope Purity

The radiochemical purities of the produced radioisotopes are assayed after end of purification via gamma spectroscopy with a high purity germanium well detector coupled to a multichannel analyzer. "Clean" ^{64}Cu spectra should show only the characteristic gamma ray at 1364 keV and the 511keV annihilation photon, while the ^{89}Zr spectra should display only the 909 keV characteristic gamma ray and the 511 keV annihilation photon. Figure 4 shows a typical high purity ^{89}Zr gamma ray spectrum.

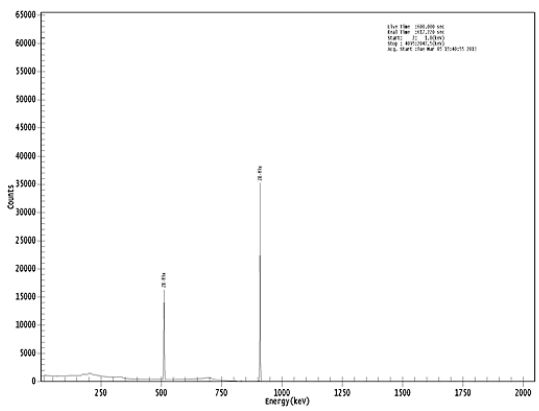

Figure 4: Gamma ray spectrum of ^{89}Zr.

Effective Specific Activity (ESA)

Effective Specific Activity (ESA) for radiometals can be defined as the amount of metals present that will bind to a suitable ligand per unit radioactivity. Determination of ESA involves titration with a suitable chelator. In this manner we can determine the amount of total metals that many interfere with the chemistry of each isotope. For example, below, in Fig. 5, is a titration curve for measurement of ^{64}Cu ESA with TETA.

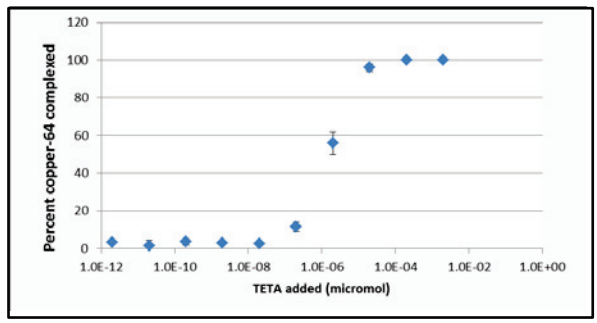

Figure 5: TETA titration for the determination of ESA for ^{64}Cu.

To determine the ESA, the point at which 50% of the radioactivity is complexed and doubled to determine the amount required to complex 100%. The total amount of transition metal complexed is determined and the users are supplied with an ESA in mCi/mmol total metal ions. Typical ESA varies from 7680 to 38400 mCi/µmol total binding metals from ^{64}Cu and from 45 to 1780 mCi/umol for ^{89}Zr.

CONCLUSION

Radiometal isotopes have enabled the investigation of various biological processes in the area of oncology, cardiology and neurology. Widespread use and clinical translation of these radionuclides requires robust optimized target preparation and purification methods for routine production.

ACKNOWLEDGMENTS

The authors would like to acknowledge Bill Margenau, Patricia Margenau, and David Ficke for operation of the CS15 cyclotron and Paul Eisenbeis, Evelyn Madrid and Efrem Mebrahtu for target preparation and isotope purification.

LOW ENERGY FUSION FOR A SAFE AND COMPACT NEUTRON SOURCE

S. Albright* and R. Seviour, IIAA, University of Huddersfield, UK, HD1 3DH

Abstract

Neutrons are primarily produced at large international facilities using either spallation reactions or nuclear fission. There is a demand for small scale neutron production for use at hospitals and borders for a variety of applications. Isolated fission sources and sealed tube deuterium-tritium fusors are able to provide a reliable neutron flux at small scale but are impractical due to the associated radioactivity. A beam of protons or deuterons accelerated onto a thin target will undergo a fusion reaction resulting in the emission of a quasi-monochromatic neutron beam. The total flux and energy spectrum of the neutrons produced through fusion is primarily dependent on target material, target thickness, beam energy and projectile. The use of neutrons for security screening at border crossings, ports and airports has the potential to drastically improve threat detection and contents verification. Monte Carlo code MCNPX is being used to investigate the most suitable target and beam characteristics for a neutron source for security applications.

INTRODUCTION

There are many areas of both science and industry which use neutron beams. There is growing interest in using neutrons for medical applications, such as Boron Neutron Capture Therapy (BNCT) [1], and for security applications, such as Pulsed Fast Neutron Analysis (PFNA) [2]. Medical and security applications in particular are not easily served by current neutron sources which tend to be either large and expensive or have radiotoxicology concerns.

For use in medical and security environments two important properties of a neutron source are that it be:

- Compact: Hospitals and airports in particular have limited space available.
- Clean: Radiotoxicity must be kept to a minimum to protect operators and reduce necessary safeguards.

Recently there has been an increased interest in using low energy accelerators (¡10MeV) to produce neutrons. There are sealed tube neutron sources on the market at present (such as the ING013 produced by the VNIIAA [3]) which use a Tritiated Titanium target bombarded by a deuteron beam to produce a high flux of quasi-monochromatic neutrons at $\approx$ 14MeV. Sealed tube sources are not practical for mass deployment due to both the radiotoxicology of Tritium and the legislative controls around their use and transport [4, 5].

In this paper we present simulated results showing that fusion reactions are capable of providing neutrons suitable for a range of industrial applications. Keeping the energy of the incident particles low enables the use of small accelerators and choosing the projectile/target combination correctly will prevent build up of any long lived radioisotopes.

Proton induced fusion reactions were simulated in the Monte Carlo code MCNPX [6] to show the effect of varying target and beam parameters on the neutron beam. The optimum parameters of the neutron beam depend upon the application. Fusion based neutron sources have been shown to satisfy the requirements of two very different applications. For PFNA the primary concern is that the neutron spectrum be both narrow and high energy. For BNCT the neutrons are moderated into the epithermal region therefore the spectrum from the source is unimportant and only the total flux and size of the source are of concern.

The nuclear inventory package EASY-II [7], which uses the fispact-II code [8], has been used to investigate the build up of isotopes in targets to ensure no long-lived radioisotopes are produced. EASY-II enables the build up, decay, and subsequent re-activation of isotopes to be simulated reducing the risk of potentially hazardous decay and transmutation chains being unidentified.

APPLICATIONS

A brief description of two valuable applications of a fusion based neutron source is given along with details of the optimum neutron beam properties for both applications. The two applications discussed are BNCT, a cancer treatment, and PFNA, a security technique.

BNCT uses a boronated drug, preferentially taken up by tumour tissue, and then bombarded by epithermal neutrons. The reaction ^{10}B + n $\rightarrow ^{7}$Li + α causes a massive dose of radiation to be delivered to the tumour whilst leaving surrounding tissue relatively untouched. As BNCT requires epithermal neutrons the beam must be moderated, the sourced neutron spectrum is therefore unimportant and instead maximising the flux whilst minimising the size of the source is the principle concern.

PFNA is a security technique which uses a high energy, monochromatic neutron beam to stimulate the emission of prompt gammas (γs) from material. The γs emitted in PFNA are unique to the element being interrogated allowing the precise content of cargo to be identified. By pulsing the source a volume can be broken into voxels giving a 3D breakdown of what is in a container and where it is located. For PFNA it is important that the neutron beam be; high energy, to maximise prompt gamma emission and minimise transmutation rates; and monochromatic, to minimise both voxel sizes and uncertainties in gamma emission rates.

MONTE CARLO SIMULATION

Monte Carlo code MCNPX has been used to demonstrate the effect of changing beam and target parameters on neutron spectrum. The parameters which can be varied are target element, target thickness, beam energy and projectile. The two elements discussed are Magnesium and Beryllium as the results are representative of what most targets will produce.

The plots in Figure 1 and 2 show the change in neutron spectrum and flux with increasing beam energy. The very thin target used in these simulations (5μ m) meant that little energy was lost as protons travelled through the target. Since very little energy was lost the protons which reacted all had approximately the same energy.

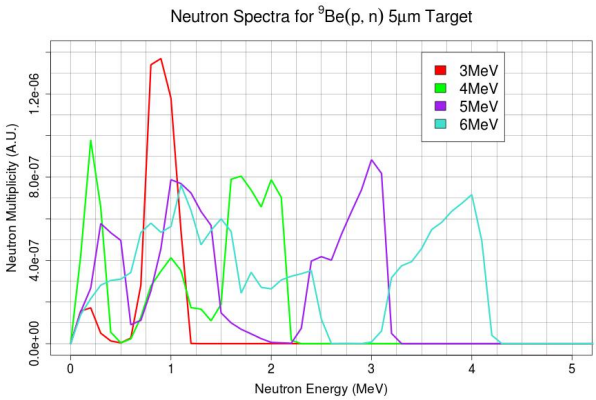

Figure 1: The neutron energy spectrum produced by a thin Beryllium target bombarded with protons with energy from 3-6 MeV.

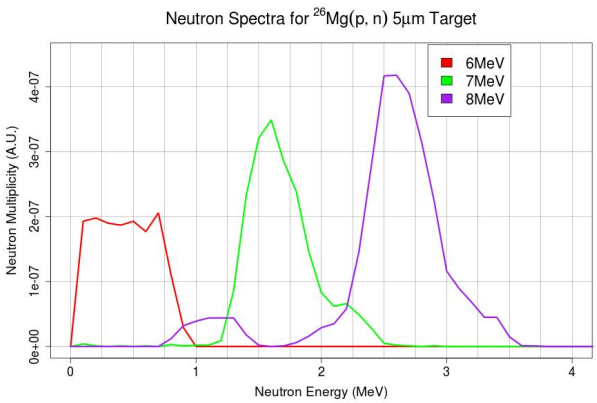

Figure 2: The neutron energy spectrum produced by a thin Magnesium target bombarded with protons with energy from 6-8 MeV.

The results in Figure 1 show that the ^{9}Be(p,n)^{9}B reaction very produces a broad spectrum of neutrons. Due to the spectral characteristics of a ^{9}Be target it would be most suited to an application like BNCT where the spectrum of the sourced neutrons is unimportant. The results in Figure 2 show that, for a thin target, the ^{26}Mg(p,n)^{26}Al reaction maintains a relatively narrow spectrum up to much higher beam energy and neutron energy than the ^{9}Be(p,n)^{9}B reaction. Due to the narrow spectrum the ^{26}Mg(p,n)^{26}Al reaction would be more suitable to an application like PFNA where spectral characteristics are the primary concern.

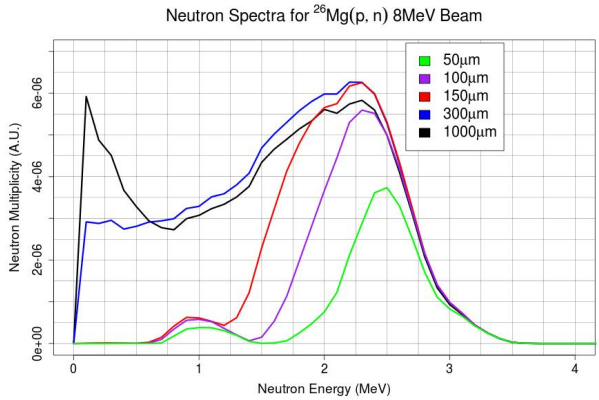

Figure 3: The neutron energy spectrum produced by a Magnesium target with thickness $50-1000\mu m$ bombarded by 8MeV protons.

The results plotted in Figure 3 show the impact of increasing target thickness on the neutron spectrum of the ^{26}Mg(p,n)^{26}Al reaction. The results in Figure 3 are characteristic of all accelerator based fusion reactions. As the thickness of the target increases the total flux and spectral width increase. Once the target is thick enough to slow incident projectiles below the fusion threshold energy the maximum neutron flux is reached ($\approx 300\mu$m in Figure 3), after this the only effect of increasing target thickness is increased neutron moderation.

ISOTOPE INVENTORY

As well as a thorough understanding of the neutron production properties of a target it is vital that the isotope production be well characterised. Under constant bombardment the target nuclei will transmute which may lead to a build up of radioactivity. Not only will the intended reaction occur (e.g. ^{26}Mg(p,n)^{26}Al) but other first generation reactions (e.g. ^{26}Mg(p,α)^{23}Na) and higher generation reactions (e.g. ^{26}Mg(p,n)^{26}Al(p,n)^{26}Si). The presence of additional decay channels and the production of higher generation isotopes poses a potential threat to the safety, and therefore applicability, of a fusion based neutron source.

Simulations were carried out in EASY-II to identify the isotopes produced in a selection of targets under proton bombardment. After 72 hours of continual 8 MeV proton bombardment on ^{9}Be and ^{26}Mg targets the isotopes shown in Table 1 were identified. The ^{9}Be target would be expected to have no latent activity, the initial fusion reaction and subsequent decays are:

$$^{9}\mathrm{Be} + \mathrm{p} \rightarrow ^{9}\mathrm{B} + \mathrm{n}$$

Copyright © 2013 CC-BY-3.0 and by the respective authors

$$^{9}\mathrm{B}(t_{\frac{1}{2}} \approx 8 \times 10^{-19}\mathrm{s}) \rightarrow ^{8}\mathrm{Be} + \mathrm{p}$$

$$^{8}\mathrm{Be}(t_{\frac{1}{2}} \approx 6 \times 10^{-17}\mathrm{s}) \rightarrow 2\alpha$$

The extremely short half lives of the products in the decay chain prevents any latent activity building up in the target. Table 1 shows that under proton bombardment ^{9}Be will also produce the radioisotope ^{7}Be($t_{\frac{1}{2}} \approx 53$d) through the interaction chain ^{9}Be(p,γ)^{10}B(p,α)^{7}Be.

Table 1: The Isotopes (Z>2) Produced after 72 Hours of 8 MeV Proton Bombardment of ^{9}Be and ^{26}Mg

^{9}Be	^{26}Mg
^{6}Li	^{16}O
^{7}Be($t_{\frac{1}{2}} \approx 53$ d)	^{20}Ne
^{10}B	^{23}Na
	^{24}Mg
	^{25}Mg
	^{26}Al($t_{\frac{1}{2}} \approx 7 \times 10^{5}$ y)
	^{26m}Al ($t_{\frac{1}{2}} \approx 6$ s)
	^{27}Al

As ^{9}B decays nearly instantaneously and ^{26}Al has a very long half life it would at first be assumed that ^{9}Be was a preferred target in terms of radiotoxicology. The 2nd generation isotope ^{7}Be is potentially more dangerous than ^{26}Al as, due to the differing decay rates, a larger amount of ^{26}Al would be required to take the activity above safe limits. In an industrial environment, be it medical, security or other, the residual activity of the target must not exceed safe limits but different applications may have different limits.

FUTURE WORK

At present there are no Monte Carlo codes able to accurately simulate low energy deuteron interactions and proton interactions can only be reliably simulated with nuclear data files. There is a loose trend for more energy being released (and therefore lower acceleration voltages needed) in deuteron induced reactions than proton induced reactions. Due to the higher energy release deuterons may be a better projectile for applications which require a high energy neutron beam.

Whilst cross-sections are known for most (d, n) reactions the energy spectra and angular distributions of the emitted neutrons remain mostly unpublished. Additional experimental data will broaden the range of projectile/target combinations which are understood and so enable neutron sources to be more effectively tuned to the application.

CONCLUSION

Two potential applications of low energy fusion based neutron sources have been discussed. For example in medicine neutron can be used for the cancer treatment BNCT, this requires an epithermal neutron beam which can be achieved by moderating a higher energy beam. For BNCT the sourced spectrum is unimportant so instead a high flux, low energy (and therefore compact) source can be used. The discussed ^{9}Be(p,n)^{9}B reaction would be suitable for this application as even at 3 MeV a fair neutron flux is achieved.

In security the neutron scanning technique PFNA requires a high energy, monochromatic beam. As the spectrum of the beam is most important for PFNA it would be acceptable to use a lower flux target which has better spectral properties. A target with characteristics similar to the ^{26}Mg(p,n)^{26}Al would be suitable for this application.

For either of these technologies to become a reality a low-cost compact source of neutrons need to be developed, and a key way in which both of these conditions can be achieved is through the use and development of neutron sources that utilise low energy reactions. A concern with any device based on nuclear interactions is the production of radioisotopes. Whilst radioisotopes are produced by both ^{9}Be and ^{26}Mg the level of activity may not be sufficient to pose a safety concern.

ACCELERATOR-BASED NEUTRON DAMAGE FACILITY USING LEDA*

N. Pogue, P. McIntyre, A. Sattarov, Texas A&M University, College Station, TX 77845, USA

Abstract

An accelerator based neutron damage facility (AND) is proposed to generate a high-dose fast neutron flux for testing of advanced reactor materials. The facility will be implemented in two stages. In AND-1, the 350 MHz LEDA RFQ will be re-commissioned to deliver 100 mA CW proton beam at 6.7 MeV. The beam will be targeted on a sheet-flow of Lithium to produce fast neutrons. Samples located at a target station behind the sheet flow will receive up to 10 dpa/year of neutron damage with a mean neutron energy of 2.37 MeV. In AND-2, the LEDA beam will be modulated to produce three 116 MHz bunch trains where they will be injected to three 100 MeV strong-focusing cyclotrons (SFC). The beams extracted from the three cyclotrons will be targeted 120 degrees apart onto sheet-flow Pb targets. Twenty one tensile samples located in the space between the three targets will receive up to 150 dpa/year of fast neutron damage with mean neutron energy ~8 MeV. AND-1 and AND-2 can provide the fast neutron flux needed for life-cycle damage studies for advance reactor technologies and for first-wall simulations for fusion systems.

INTRODUCTION

A design for an accelerator-based neutron damage (AND) facility has been devised to test advanced reactor materials. Since Three Mile Island there have been no new licenses issued for new construction in the US until just recently (2 reactors). Materials testing is one of the biggest hurdles and is of the utmost importance for two reasons: 1) The original lifetime for a nuclear power plant is 40 years and thus the current fleet has only remained operation due to lifetime extension every ten years, and 2) New reactor designs (Gen 4 and ADS systems) that are more efficient and clean require materials that remain unproven up to 200 dpa (displacement per atom). Currently, testing of materials to be used in advanced reactors is underway at facilities around the world such as HFIR and BOR60. However to reach 200 dpa within the sample takes over 15 years domestically and 10 years internationally. A decade long evaluation process enormously extends the selection process and material evolution.

As a consequence of this timeline, nuclear engineers have turned to the only method readily available, ions. Ions produce significantly more dpa per incident particle than neutrons. However, the mechanisms that ultimately dictate how the material swells and embrittles function differently for the two flavors of particles. Defect production, defect migration, defect annealing, production of interstitial clusters and loops, and H and He production, as well as how damage induced is effected by their presence, are all different for neutrons vs. ions. *Much has been learned about mechanisms that control damage from ion studies, but one cannot predict the damage a given neutron spectrum and dose will produce in a new material solely by experiments with ion damage.* Therefore, without a fast, high fluence neutron source, the ultimate lifetime and failure modes for materials to be used in advanced reactions cannot be ascertained.

Texas A&M Accelerator Research Lab (ARL) has devised an accelerator that can produce 200 dpa via neutron bombardment on several samples in less than 16 months, while also providing control of the temperature and chemical environment of the samples during exposure (problematic in reactors). The spectrum can be tuned to fully mimic conditions anticipated in future fission and fusion (currently not possible) reactors.

AND OVERVIEW

AND is comprised of two stages that utilizes several technologies developed by several groups. In the first stage the LEDA accelerator will be re-commissioned at ARL and send a 100 mA 6.7 MeV proton beam to a liquid Lithium sheet target similar to that developed by ANL. The second stage takes the proton beam from LEDA and accelerate 45 mA of the beam to 100 MeV using a set of 3 flux coupled Strong Focusing Cyclotrons (SFCs) developed at Texas A&M. The three beams are then directed to liquid Lead targets. The result of these two stages is a facility that can generate ~150 dpa/year using fast neutrons. An image of the facility is shown in Figure 1.

AND – PHASE 1

LEDA

The Low Energy Demonstration Accelerator, or LEDA, is one of the few RFQ accelerators that have achieved high current CW operation [1]. Initially built as the front end of the Accelerator Production of Tritium (APT), the accelerator was commissioned in 2003 and achieved in accelerating ~100 mA of beam to 6.7 MeV. In 2004, LEDA was decommissioned and remains in pristine condition within a high strength support structure, to maintain internal alignment among the cavity sections, while in storage (Figure 2). The current state of LEDA should assure that the time to re-commission at low power should be less than a year. Los Alamos National Lab (LANL) has agreed to make a 10-year loan of the LEDA system to Texas A&M University. ARL plans to move LEDA to Texas A&M along with pulsed RF power source, power supplies, transformers, and waveguides from LANL. The RF power loaned will be a pulsed system, but A&M has received commitment from CERN for two 1 MW 350 MHz CW power sources.

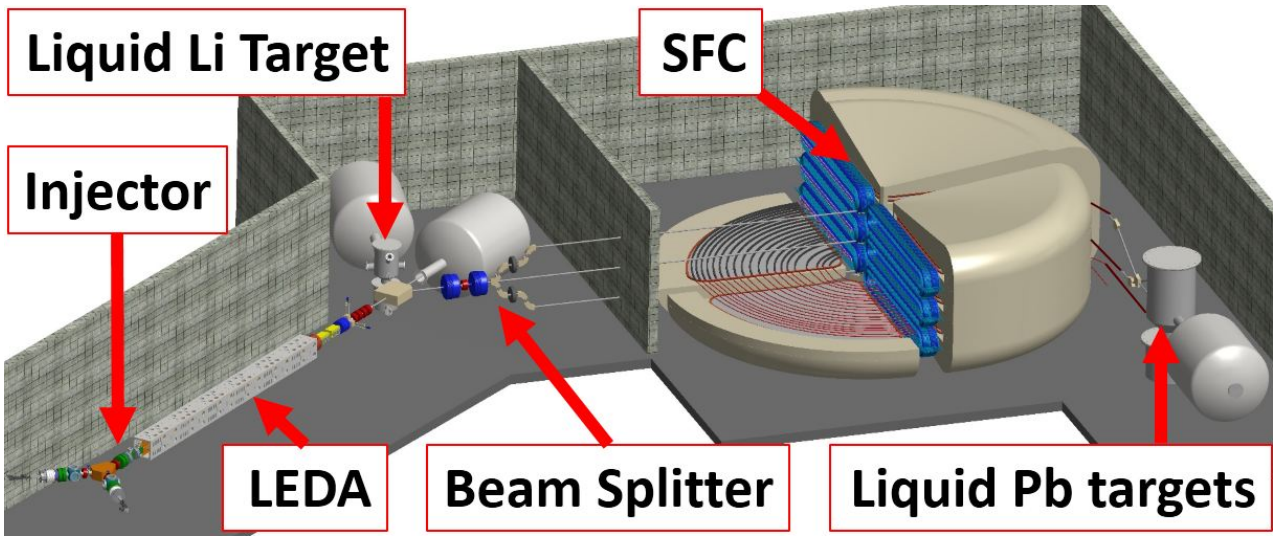

Figure 1: A diagram of the AND facility which identifies the critical system components. The LEDA and liquid Lithium target comprise Phase 1 and the SFC and Lead targets would be added to as Phase 2.

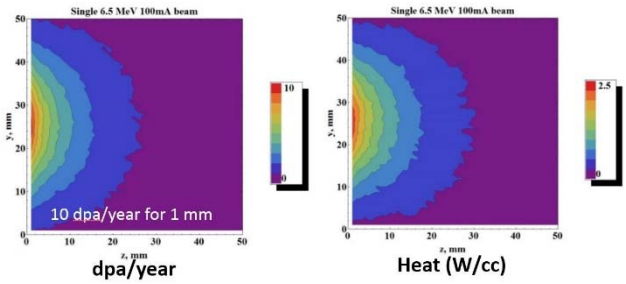

Figure 2: ~10 dpa/year is generated through a thickness of 1 mm. Such a rate is equivalent to current US capability.

Liquid Lithium Target

The 100 mA proton beam will be directed to a windowless liquid Li target to generate the neutrons for Phase 1. Li is used at this energy because the cross section is very large compared to other materials. The target must be molten so it can support the ~700 kW delivered by the beam. The Li is forced through a slit forming a flowing sheet of molten metal approximately 5 cm wide into a reservoir tank. The liquid in the tank is pumped through a heat exchanger and then pumped back to the slot iris. This approach has been developed at ANL and is planned to be used at facilities such as FRIB and RIKEN, but for stripping purposes. The AND system can produce at most 1.5 MW/cc. This power density is substantially lower than the 4.1 MW/cc electron beam used to test the device [2].

Neutron Damage – AND Phase 1

The Li window is ~2 mm thick and contains the Bragg peak of the protons and thus only neutrons bombard the sample. Dpa calculations were performed using a modified Kinchin and Pease model as is performed in the code SPECTER. The mean neutron energy for the AND-1 is 2.37 MeV and produces 10 dpa/year within the first 1 mm of the sample.

AND - PHASE 2

In Phase 2 the 350 MHz, 100 mA beam is split into 3 separate 116 MHz 15 mA beams. Each beam is then sent to TAMU100, a flux coupled stack of three strong focusing cyclotrons (SFCs). Using the SFC the beam is accelerated to 100 MeV and delivered to a molten Pb sheet flow target.

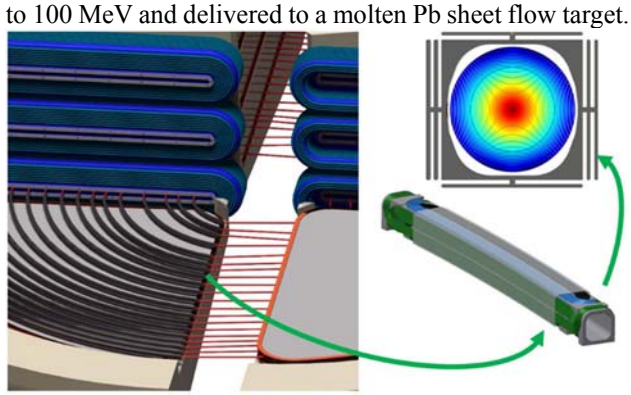

Figure 3: Left: SRF cavities (blue) and quadrupole channels are shown covering the proton projected orbits. Right: Detail of quad and the focusing field produced.

SFC – Strong Focusing Cyclotron

The SFC design incorporates three innovations (Figure 3) to bring the benefits of strong focusing to the cyclotron: 1) flux-coupled sector dipoles that permits one to stack multiple cyclotrons with a common footprint. 2) high-gradient superconducting RF cavities to increase the beam energy enough in each orbit (~2 MV/cavity) such that the succeeding orbits are fully separated; 3) As a consequence of the large separations, a set of beam transport channels are inserted in the aperture of the sector dipoles [3].

Each sector magnet has a pair of windings that each have a cold iron flux plate and generate ~1 Tesla. The sector dipoles of successive cyclotrons can thus be stacked upon one another and share a common warm-iron flux return. All magnet windings utilize MgB_2 superconductor, operating

Copyright © 2013 CC-BY-3.0 and by the respective authors

in the temperature range 15-20 K. The stack of flux plates is supported within a warm-iron flux return using low-heat-load tension supports in a magnetic design that cancels the Lorentz forces above and below each flux plate.

Each SRF cavity accelerates the 24 spiral orbits simultaneously, providing a minimum orbit separation of 5.6 cm for curved beam transport channels located in the aperture of each sector magnet. Each transport channel houses a pair of alternating-gradient Panofsky quadrupole lenses to provide an F-D strong-focusing doublet, and a window-frame dipole winding to facilitate correction of the dipole field for isochronicity. These winding also provides a built in septa for low-loss for injection and extraction.

The beam transport channels in the SFC are used to control beam size and achieve transport of larger beam current. Our simulations show that these innovations will provide reliable low-loss acceleration and transport of a 15 mA proton beam to 100 MeV in each SFC by using emittance management provided by the beam transport channels.

The beam is then extracted from each cyclotron and delivered to three molten Pb targets similar in nature to those described in the Lithium target section.

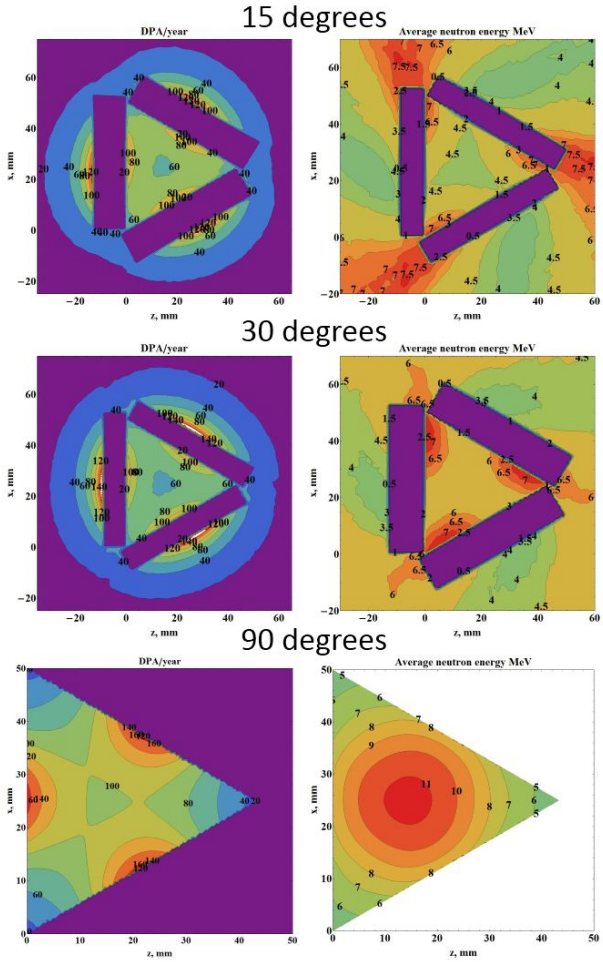

Figure 5: Angle dependence of damage and mean energy.

Neutron Damage – Phase 2

The angle at which the beam is brought to the Pb target has a dramatic effect on the mean energy and damage produced in the 21 tensile samples that are located within individually controlled environments (temperature and chemical). Three angles a re shown in Figure 5. The 15° version produced an average neutron energy of 4.5 MeV and a minimum of 50 dpa/year. The 30° had 5.5 MeV mean -60 dpa/year minimum, and the 90° case produced 8 MeV and a maximum of 160 dpa/year.

Comparing these results to the available user facilities, AND has higher fluence and average energy. If fact, AND would provide for the first time the capability to study neutron damage produced at the first wall of fusion reactors (14 MeV). AND out performs existing and designed (IFMIF) facilities at a fraction of the cost (Figure 4).

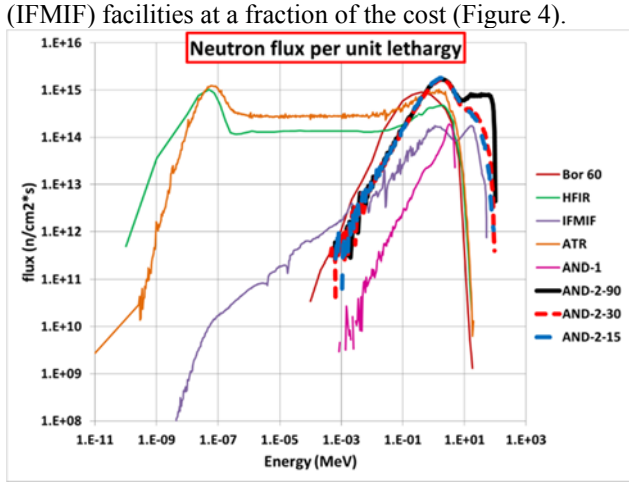

Figure 4: Comparison of AND 1&2 to other facilities around the world that are used for neutron irradiation.

SUMMARY

Ions are unable to predict damage type, ultimate lifetime, mechanical properties, and failure modes of candidate materials for advanced reactors. A high fluence fast neutron source is needed to provide critical data and reduce decade long experiments to ~1 year. ARL has devised such a facility using LEDA, SFCs, and liquid metal targetry. AND facility can provide over 150 dpa/year of damage (level needed for advanced reactors) on samples located with individually controlled environments that would uniquely support the advanced materials development for both fission and fusion.

ACKNOWLEDGMENT

Thanks to ANL, LANL, and CERN for their contributions as well as the Mitchell Foundation and the State of Texas for funding this work.

DEVELOPMENT OF LOW ENERGY ACCELERATOR-BASED PRODUCTION OF MEDICAL ISOTOPES

N. Ratcliffe*, R. Barlow, R. Cywinski, University of Huddersfield, Huddersfield, HD1 3BH, UK
P. Beasley, Siemens AG, Oxford, OX1 2EP, UK

Abstract

Here we present methods for production of new and existing isotopes for SPECT (Single Photon Emission Computed Tomography) and PET (Positron Emission Tomography) imaging using accelerator-based systems. Such isotopes are already widely used in medical diagnostics and research, and there is constant development of new drugs and isotopes. However the main production method for ^{99m}Tc, is currently in research reactors and is at risk due to scheduled and unscheduled shut downs. Therefore, a low cost an alternative accelerator-based system could provide many advantages. Various compact low energy proton machines are being proposed to enable cheap and accessible production: here we present a discussion of potential new SPECT isotopes and simulations of suitable targets for their manufacture.

INTRODUCTION

Currently the production of medical tracer isotopes for use in imaging techniques such as SPECT (Single Photon Emission Computed Tomography) and PET (Positron Emission Tomography) [1] relies principally upon an ageing fleet of nuclear reactors. For example the most common medical isotope ^{99m}Tc, used in over 80% of all radiopharmaceutical procedures, is currently produced, via its generator ^{99}Mo, by nuclear research reactors such as NRU-Canada and HFR-The Netherlands, which together produce over 60% of the worlds ^{99}Mo/^{99m}Tc supply. Both of these reactors are old (>50yrs) and close to decommissioning, and while several projects are looking at other production routes for this isotope, as yet there is no real replacement in place [2, 3]. As these reactors near their decommissioning, currently set at 2014-2016, there is considerable concern that we will soon be facing a similar situation to that of the 2010 isotope crisis, when both reactors were offline simultaneously resulting in a significant decrease in the supply of ^{99m}Tc and the postponing or cancelation of many vital radioisotope procedures [1–5]. Due to ^{99m}Tc monopolising the medical isotope market little work was done developing other isotopes and many potential isotopes fell by the wayside. The aim of this work is to resurrect some of these isotopes as alternatives to ^{99m}Tc as we head into another shortage in the hope of preventing another crisis. There are several short lived SPECT and PET isotopes that have the potential to take some of the workload from ^{99m}Tc.

* naomi.ratcliffe@hud.ac.uk

LOW ENERGY ISOTOPE PRODUCTION

We believe that the solution to this impending problem could lie in accelerator-based production methods, of both ^{99m}Tc and possible replacement isotopes. A collaboration with Siemens is focusing on the potential of a compact, low energy proton device for the generation of radioisotopes [6]. Such a machine could provide many more localised isotope production centres and allow for the use of isotopes with shorter halflives. A study of optimal target designs for such a system has been undertaken using GEANT4 simulations of low energy (<10MeV) proton induced reactions.

^{113M}INDIUM

^{113m}In is a metastable radioactive isotope that decays via a 392 keV γ into stable ^{113}In with a half life of 1.7hours [7]. In 1965 it was first proposed for use as an alternative medical tracer isotope to ^{99m}Tc for SPECT imaging in several applications such as brain and lung scanning. Trials of this isotope showed it to give results comparable to ^{99m}Tc images [7]. ^{113m}In showed several advantages over ^{99m}Tc such in terms of chemical properties. A successful generator production system for In was developed using ^{113}Sn [7, 8].

Generator Production

There are several advantages of a longer lived generator system, such as the Sn/In system. The longer gap between parent half life and daughter half life makes it easier to separate the two nuclei. It also increases the longevity of the system for example the Sn/In(parent half life approximately 118 days) system only needs replacing once every 6 months where as the Mo/Tc(parent half life approximately 3 days) system needs replacing weekly. However due the plentiful and cheap supply of Tc at the time very little serious work was carried forward with this isotope. The simplicity of the generator production system and the advantages available from such a system has prompted the exploration of a low energy method of production for this generator using the reaction:

^{113}In(p,n)^{113}Sn $\rightarrow$ ^{113m}In $\rightarrow$ ^{113}In

Preliminary simulation results from the TALYS data libraries show that such a reaction at 10 MeV gives a production cross section of 570mb. Further GEANT4 simulations have been used to study target designs and feasibility of this reaction using a <10MeV proton beam. In terms of daughter yield the most appropriate target thickness is that of just

Copyright © 2013 CC-BY-3.0 and by the respective authors

over the stopping distance, which from these simulations is given to be approximately 0.5mm. The generator and daughter activity for this reaction after a 30min irradiation of the target can be seen in Fig. 1.

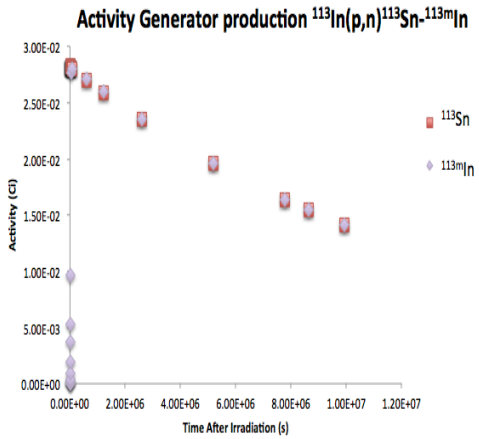

Figure 1: Activity of parent ^{113}Sn and daughter ^{133m}In produced from the generator reaction.

The lifetime of a typical Sn/In generator system is 3-6 months [9]. The activity for this time after irradiation can be seen in Fig. 1. Even after this time this small sample generator is producing an activity of 0.9 mCi which in comparison to a typical single dose of microcuries per gram [10], shows the potential of a low energy accelerator based system for the generator production of ^{113m}In.

Direct Production

Direct production of ^{113m}In appears to be less common due to the short halflife of the isotope and the lack of local facilities in which to produce it. However with the introduction of our proposed system it should be possible to make this a much more feasible production route. Both the TENDL and EXFOR libraries can be seen to agree that a cross section of just over 200mb can be obtained for the following reaction:

^{113}Cd(p,n)^{113m}In

for a proton beam between 9 and 10 MeV. The corresponding activity of In for a 0.5mm thick target after a 30min irradiation can be seen in Fig. 2.

The activity obtained for direct production is significantly larger than that of generator production. Such activity should be enough to service the needs for a local facility as is the proposed purpose of a low energy isotope production system.

^{87M}STRONTIUM

Strontium 87m is a metastable radioactive isotope that decays via a 388keV γ into stable ^{87}Sr with a half life of 2.8hours [11]. Several different strontium isotopes have an application in nuclear medicine as due to the similar

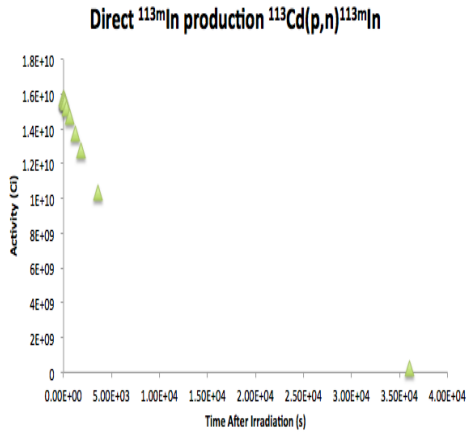

Figure 2: Activity of ^{113}In produced from the direct reaction.

chemistry to calcium it is readily taken up in bone. There are some isotopes such as ^{90}Sr which are undesirable for medial use as replace calcium in the bone and are toxic. Others however such as ^{87m}Sr can be used in both diagnostic and therapeutic techniques for various skeletal diseases [11–14].

Generator Production

^{87m}Sr is produced primarily using the ^{87}Y/^{87m}Sr generator. Literature shows many different possible methods of producing this generator. However these are all at higher energies ($>$20 MeV). This work is focusing on low energy techniques e.g. reactions such as

^{87}Sr(p,n)^{87}Y $\rightarrow$ ^{87m}Sr $\rightarrow$ ^{87}Sr

According to the TALYS/EXFOR libraries this reaction has a cross section of approximately 600mb at 10 MeV. Further study of target design were carried out using GEANT4 to obtain a suitable target that provides a viable yield for medical applications. The activity obtained from a 0.9mm thick metal target can be seen in Fig. 3.

Activity of the generator route from our simulations is of the order of curies whilst a diagnostic dose is of the order of millicurie. However from previous studied such as [11] it is apparent that this target is impractical and a compound target such as $SrCl_2$ would be more appropriate. This reduces the number of Sr nuclei within the target requiring a thicker compound target to keep the activity sufficient for the 2 week lifespan that is typical of this type of generator system.

Direct Production

It is also proposed that direct production of ^{87m}Sr is possible through the reaction:

^{87}Rb(p,n)^{87m}Sr

which according to the EXFOR libraries has a cross section of approximately 200mb in the energy range $<$10MeV. The TALYS libraries also gave a cross section of 240mb at

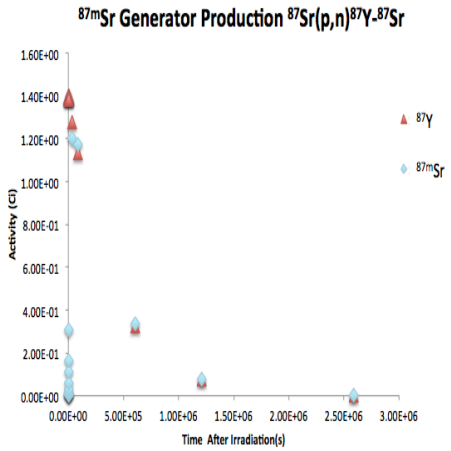

Figure 3: Activity of ^{87m}Sr produced using the ^{87}Y/^{87m}Sr generator.

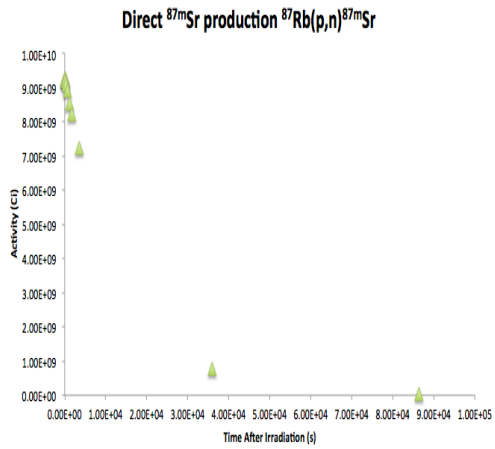

Figure 4: Activity of ^{87m}Sr produced using the direct reaction.

10MeV from which the activity of ^{87m}Sr that is produced after a 30min irradiation of a 0.5mm thick target can be seen in Fig. 4.

Even with such a simple, crude design such a large activity is obtained with this reaction. With more adjustment a suitable target could be configured so as to optimise the activity. An isotope with such a short half life is much more likely to be produced using the direct reaction on demand and so any effort to minimise the production time such as short irradiation time, from these initial results this time could be less than 30mins.

CONCLUSION

This work has shown a first test case of the feasibility and practicality of using a low energy proton accelerator system as a method of producing radioisotopes in quantities suitable for medical applications. This work will go on to optimise the low energy production routes for these isotopes in the hopes of minimising the reduction of SPECT isotopes in the predicated crisis. We will also go on to study the potential of using this system to manufacture potential isotopes to be introduced for both SPECT and PET.

AN OVERVIEW OF LIE METHODS FOR ACCELERATOR PHYSICS*

Alex J. Dragt, Department of Physics, University of Maryland, College Park, MD, USA

Abstract

We sketch how Hamiltonian mechanics can be formulated in Lie algebraic terms (indeed Poisson and Jacobi almost invented Lie algebras without knowing it), and how this formulation can be applied to the description and computation of particle orbits in accelerators in a way that both unifies linear and nonlinear theory and leads to explicit results for realistic machines [1–5].

WHAT IS A LIE ALGEBRA?

In grade school we learned how to add numbers to get other numbers, and how to multiply numbers to get other numbers. Mathematicians call an *algebra* any collection of entities for which addition-like and multiplication-like operations are defined.

The concept of numbers and their addition can be extended to the concept of vectors and vector addition. With vectors in mind, is it possible to define multiplication for vectors in such a way that multiplication of any two vectors again yields a vector? There are various possibilities. We will select one. Suppose, for the moment, we denote such multiplication by the symbol $\circ$. Thus, we denote the product of two vectors u and v by the symbols $u \circ v$.

Consider a multiplication rule that has the two properties

$$v \circ u = -u \circ v, \tag{1}$$

$$u \circ (v \circ w) + v \circ (w \circ u) + w \circ (u \circ v) = 0. \tag{2}$$

A multiplication rule with the two properties (1) and (2) is called a *Lie product* rule, and a vector space equipped with a Lie product rule is called a *Lie algebra*. We remark, for reasons which will become evident, that the condition (2) is called the *Jacobi* condition or identity.

IS THERE A LIE ALGEBRAIC STRUCTURE IN HAMILTONIAN MECHANICS?

Notation

Consider a $2n$-dimensional phase space with position coordinates $q_1 \cdots q_n$ and momentum coordinates $p_1 \cdots p_n$. Also, for convenience, introduce the notation

$$z = (q_1 \cdots q_n; p_1 \cdots p_n). \tag{3}$$

That is, z denotes a collection of $2n$ variables with the first n of them being the q's and the remaining n being the p's.

* Work supported in part by the University of Maryland and the U.S. Department of Energy Grant DE-FG02-96ER4DOE.

The Set of Phase-Space Functions Forms a Vector Space

Next let $f(z,t)$ be any function of z and possibly the time t. Evidently, since phase-space functions can be added together and the result is again a phase-space function, the set of all phase-space functions forms a vector space.

The Poisson Bracket Provides a Lie Product

Is there a way of "multiplying" phase-space functions that will satisfy the Lie product requirements (1) and (2)? There is. The *Poisson bracket*, denoted by the symbols $[f,g]$, of any two phase-space functions f and g is defined by the rule

$$[f,g] = \sum_{k=1}^{n} (\partial f/\partial q_k)(\partial g/\partial p_k) - (\partial f/\partial p_k)(\partial g/\partial q_k). \tag{4}$$

Then, it is obvious from its definition that the Poisson bracket has the property

$$[g,f] = -[f,g]. \tag{5}$$

What is not so obvious, and was observed by *Jacobi*, is that the Poisson bracket also has the property

$$[f,[g,h]] + [g,[h,f]] + [h,[f,g]] = 0. \tag{6}$$

Evidently (5) and (6) are analogs of the properties (1) and (2). Only the symbols for a product have been changed, with $\circ$ replaced by $[,]$. We conclude that the set of all phase-space functions with the Lie multiplication rule (4) constitutes a Lie algebra.

The Fundamental Poisson Brackets

Simple calculation shows that for the phase-space coordinates themselves there are the Poisson bracket results

$$[z_a, z_b] = J_{ab}, \ a,b = 1 \cdots 2n \tag{7}$$

where J is the $2n \times 2n$ matrix, called the Poisson matrix,

$$J = \begin{pmatrix} 0 & I \\ -I & 0 \end{pmatrix}. \tag{8}$$

Here 0 and I denote the $n \times n$ zero and identity matrices.

A RELATED LIE ALGEBRA IN HAMILTONIAN MECHANICS

Lie Operators

Given any phase-space function $f(z,t)$ there is a related differential operator, called a *Lie operator* and denoted by the symbols $:f:$, defined by the rule

$$:f: = \sum_{k=1}^{n} (\partial f/\partial q_k)(\partial/\partial p_k) - (\partial f/\partial p_k)(\partial/\partial q_k). \tag{9}$$

Copyright © 2013 CC-BY-3.0 and by the respective authors

Evidently, the action of $: f :$ on any function $g(z,t)$ is given by the relation

$$\begin{aligned} : f : g &= \sum_{k=1}^{n} (\partial f/\partial q_k)(\partial g/\partial p_k) - (\partial f/\partial p_k)(\partial g/\partial q_k) \\ &= [f,g]. \end{aligned} \tag{10}$$

We may view a Lie operator as a Poisson bracket waiting to happen.

Lie Operators Form a Lie Algebra

Since differential operators can be added and the result is again a differential operator, Lie operators form a vector space. Can the set of Lie operators also be given a Lie product rule? Let $\{: f :, : g :\}$ denote the *commutator* of the Lie operators $: f :$ and $: g :$,

$$\{: f :, : g :\} =: f :: g : - : f :: g : . \tag{11}$$

It is easily verified that the commutator satisfies requirements analogous to the Lie product requirements (1) and (2). Therefore one suspects that Lie operators might also form a Lie algebra with the Lie product symbol $\circ$ replaced by the symbols $\{,\}$. But is the commutator of two Lie operators again a Lie operator? It is. It can be shown from the Jacobi identity (6) that there is the beautiful relation

$$\{: f :, : g :\} =: [f,g] : . \tag{12}$$

Powers of Lie Operators

Based on the definition of a Lie operator, we can also define powers $: f :^{\ell}$ of Lie operators by the rules

$$: f :^{0} g = g, \tag{13}$$

$$: f :^{1} g =: f : g = [f,g], \tag{14}$$

$$: f :^{2} g = [f,[f,g]], \text{ etc.} \tag{15}$$

Lie Transformations

With powers of Lie operators defined, we can also define power series. A particularly important power series, called a *Lie transformation*, is that based on the Taylor coefficients of the exponential function and given by the rule

$$\exp(: f :) = \sum_{\ell=0}^{\infty} : f :^{\ell} /\ell!. \tag{16}$$

When applied to any function g, it follows that there is the result

$$\begin{aligned} \exp(: f :) g &= \sum_{\ell=0}^{\infty} : f :^{\ell} g/\ell! \\ &= g + [f,g] + [f,[f,g]]/2! + \cdots . \end{aligned} \tag{17}$$

INTEGRATING HAMILTON'S EQUATIONS OF MOTION AND SYMPLECTIC MAPS

Transfer Maps Arising from Hamiltonians

Suppose $H(z,t)$ is some Hamiltonian. Following Hamilton, it produces the set of first-order equations

$$\dot{q}_j = \partial H/\partial p_j, \tag{18}$$

$$\dot{p}_j = -\partial H/\partial q_j, \tag{19}$$

which can be written more compactly in the form

$$\dot{z}_a = - : H : z_a. \tag{20}$$

Let z^{in} denote a set of *initial* conditions at the initial time t^{in}, and suppose the equations of motion (20) are integrated to a *final* time t^{fin} to find final conditions z^{fin}. We may view the relation between z^{fin} and z^{in} as a *map* $\mathcal{M}$, often called a *transfer map*, that sends phase space into itself, and write

$$z^{fin} = \mathcal{M} z^{in}. \tag{21}$$

Effect of Small Changes in the Initial Conditions

Suppose we make small changes dz^{in} in the initial conditions. According to calculus, doing so will produce small changes dz^{fin} given by the relation

$$dz^{fin} = M(z^{in}) dz^{in} \tag{22}$$

where $M(z^{in})$ is the *Jacobian matrix* defined by

$$M(z^{in})_{ab} = \partial z_a^{fin}/\partial z_b^{in}. \tag{23}$$

The Symplectic Condition

If $\mathcal{M}$ arises from integrating Hamilton's equations of motion (20) for some Hamiltonian, as we have assumed, then it can be shown that $M(z^{in})$ must satisfy the (nonlinear) condition

$$M^T(z^{in}) J M(z^{in}) = J \tag{24}$$

for all z^{in} where M^T denotes the transpose of M. Matrices M that satisfy (24) are called *symplectic* matrices, and correspondingly maps $\mathcal{M}$ whose Jacobian matrices $M(z^{in})$ satisfy (24) for all z^{in} are called sympletic maps.

We have learned that integrating Hamilton's equations of motion produces symplectic maps. Conversely, it can be shown that every symplectic map arises from integrating Hamilton's equations of motion for some Hamiltonian. Thus, finding symplectic maps and solving Hamilton's equations of motion are equivalent tasks.

Taylor Representation of Transfer Map

Suppose some design orbit has been found, and now let the quantities z_a be *deviation* variables about the design orbit. In terms of these variables, $\mathcal{M}$ sends the origin into

Copyright © 2013 CC-BY-3.0 and by the respective authors

itself. Moreover, suppose the Hamiltonian is analytic in z so as to have a convergent Taylor expansion of the form

$$H(z,t) = \sum_{m=2}^{\infty} H_m(z,t) \tag{25}$$

where each $H_m(z,t)$ is a homogeneous polynomial (in the components of z) of degree m. Then the final and initial conditions will be related by Taylor expansions of the form

$$\begin{aligned} z_a^{fin} &= \sum_b R_{ab} z_b^{in} + \sum_{bc} T_{abc} z_b^{in} z_c^{in} \\ &+ \sum_{bcd} U_{abcd} z_b^{in} z_c^{in} z_d^{in} + \cdots . \end{aligned} \tag{26}$$

We note that the Taylor coefficients R_{ab}, T_{abc}, U_{abcd}, etc., occurring in (26) are not all independent, but rather are interrelated by the symplectic condition (24). The matrix R must be symplectic, and the entries in R, T, U, etc. are interrelated in a complicated way.

IS THE LIE ALGEBRAIC STRUCTURE OF HAMILTONIAN MECHANICS OF ANY USE?

Lie Representation of Transfer Map

Suppose $\mathcal{M}$ is a symplectic map that sends the origin into itself. It can be shown that any such map has the factorization

$$\mathcal{M} = \mathcal{R} \exp(: f_3 :) \exp(: f_4 :) \exp(: f_5 :) \cdots \tag{27}$$

where $\mathcal{R}$ is a linear symplectic map whose action is described by the symplectic matrix R and the f_m are homogeneous polynomials of degree m in the phase-space variables z^{in}. Moreover, unlike the Taylor representation (26), the homogeneous polynomials f_m are all independent. Any choice for the f_m produces a symplectic map, and every (origin preserving) symplectic map has a unique factorization of the form (27). Thus, in the case of accelerator physics, the effect of any beam-line element or collection of such elements, including the one-turn map for a circular machine, is characterized by a symplectic matrix R and a collection of polynomials f_m; and the symplectic condition is automatically built into the description. In particular, it can be shown that $\mathcal{R}$ describes linear behavior about the design orbit, f_3 describes second-order (such as might be caused by sextupoles) and yet higher-order effects, f_4 describes third-order (such as might be caused by octupoles) and yet higher-order effects, etc.

We also remark, in passing, that $\mathcal{R}$ can be written in terms of Lie transformations. In general there are two unique quadratic polynomials called f_2^c and f_2^a (where the superscripts c and a characterize the matrices associated with the polynomials as *commuting* or *anti-commuting* with J) such that there is the relation

$$\mathcal{R} = \exp(: f_2^c :) \exp(: f_2^a :). \tag{28}$$

In some important cases a single f_2 suffices, and its coefficients are related to phase advances and *Twiss* parameters.

Finally, in the case that $\mathcal{M}$ does not send the origin into itself, there is a first-degree polynomial f_1 such that $\mathcal{M}$ has the unique factorization

$$\mathcal{M} = \exp(: f_1 :) \mathcal{R} \exp(: f_3 :) \exp(: f_4 :) \cdots . \tag{29}$$

It can be verified that the Lie transformation $\exp(: f_1 :)$ produces translations in phase space, and describes the error effects of beam-line element misplacement or misalignment or (in the case of dipoles) mis-powering.

Lie Formulas for Multiplying/Concatenating Symplectic Maps

Given any two Lie transformations there are Lie algebraic rules for combining them. In particular there is a rule for manipulating exponents, called the *Baker-Campbell-Hausdorff* (BCH) theorem/series, that along with (12) leads to the result

$$\exp(: f :) \exp(: g :) = \exp(: h :) \tag{30}$$

with

$$\begin{aligned} h &= f + g + (1/2)[f,g] \\ &+ (1/12)\{[f,[f,g]] + [g,[g,f]]\} + \cdots . \end{aligned} \tag{31}$$

In the context of accelerator physics, suppose the transfer map for each beam-line element is known in the standard forms (27) or (29). Then the BCH theorem can be used to manipulate the various exponents appearing in the individual maps to again rewrite the product of the maps in standard form. That is, there are procedures for finding the net map for a full beam line, or any portion thereof, given the maps for the individual elements. In the case of case of a circular machine, one can combine all the maps for the individual beam-line elements together to find a full one-turn map, or even a several-turn map. Finally, the BCH theorem also provides a procedure for inverting symplectic maps.

Normal Form for a Symplectic Map

Suppose $\mathcal{M}$ is the one-turn map for a circular machine, and the machine tunes are not resonant. Then there is symplectic map $\mathcal{A}$, called the *transforming* or *normalizing* map, such that the map $\mathcal{N}$ given by

$$\mathcal{N} = \mathcal{A}\mathcal{M}\mathcal{A}^{-1} \tag{32}$$

has a particularly simple form, called a *normal* form. The normal-form process is the nonlinear analog of the concept of matrix diagonalization.

It can shown that $\mathcal{N}$ contains all information about tunes, anharmonicities, and chromaticities to any desired order; and $\mathcal{A}$ contains all information about linear and nonlinear lattice functions. The map $\mathcal{A}$ can also be used to construct nonlinear generalizations of the Courant-Snyder invariants, to analyze tracking data for the presence of KAM tori, and to generate matched beams including nonlinear effects.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Computing Symplectic Maps $\mathcal{M}$

Given a Hamiltonian H, it can be shown that $\mathcal{M}$ obeys the equation of motion

$$\dot{\mathcal{M}} = \mathcal{M} : -H : . \tag{33}$$

Suppose H expanded in the form (25). How does one find the corresponding map $\mathcal{M}$ in the form (27)? We will first describe how R can be found, and then describe how the f_m can be found. Actually, it is computationally simpler to write $\mathcal{M}$ in the *reverse* factorized form

$$\mathcal{M} = \cdots \exp(: g_5 :) \exp(: g_4 :) \exp(: g_3 :) \mathcal{R}, \tag{34}$$

and then find the g_m. Once they are known the f_m can be found from the g_m by using concatenation formulas to bring (34) to the standard forward factorized form (27).

Finding R Since $H_2(z,t)$ is quadratic in the variables z, it can be written in the form

$$H_2(z,t) = (1/2) \sum_{ab} S_{ab}(t) z_a z_b \tag{35}$$

where $S(t)$ is a symmetric matrix. It can be shown that R is the solution to the matrix differential equation

$$\dot{R}(t) = JS(t)R(t) \tag{36}$$

with the initial condition

$$R(t^{in}) = I. \tag{37}$$

If S is time independent, (36) with the initial condition (37) can be integrated immediately to give the result

$$R(t) = \exp[(t - t^{in})JS]. \tag{38}$$

If S is time dependent, as will be the case if one wishes to include fringe-field effects (recall that here t plays the role of s, distance along the design orbit), then (36) must be integrated numerically.

Finding the g_m In general to find the g_m one must first transform the $H_m(z,t)$, with $m \geq 3$, to the *interaction picture* specified by $H_2(z,t)$ in a manner analogous to similar calculations in Quantum Mechanics. Define interaction picture Hamiltonian pieces $H_m^{int}(z,t)$ by the rule

$$H_m^{int}(z,t) = H_m(Rz,t) \text{ with } m \geq 3. \tag{39}$$

Then it can be shown that the g_m with $m \geq 3$ obey equations of motion of the form

$$\dot{g}_3 = -H_3^{int}, \tag{40}$$

$$\dot{g}_4 = -H_4^{int} + (: g_3 : /2)(-H_3^{int}), \text{ etc.} \tag{41}$$

with the initial conditions

$$g_m(z, t^{in}) = 0. \tag{42}$$

Presently explicit differential equations of this kind for the g_m have been worked out through $m = 8$.

In the approximation that $H_m(z,t)$ is t independent within each beam-line element, which amounts among other things to the neglect of fringe-field effects, there are a variety of ways for obtaining the g_m either analytically or numerically. If $H_m(z,t)$ is t dependent, as will be the case if fringe-field effects are to be taken into account, then the equations of the form (40), (41), etc. must be integrated numerically with the initial conditions (42).

Computing $\mathcal{M}$ for Realistic Beam-Line Elements: Use of Surface Methods

In this final subsection we will describe how to compute accurate transfer maps for realistic beam-line elements including all fringe-field and multipole effects. For simplicity we will limit our discussion to magnetic beam-line elements. Analogous treatments can be applied to the cases of electrostatic and RF electromagnetic fields.

In the previous subsection it was assumed that the $H_m(z,t)$ are given, which is equivalent, in the case of accelerator physics and the treatment of magnetic beam-line elements, to the assumption that the vector potential $\boldsymbol{A}$ for the the magnetic field $\boldsymbol{B}$ is known in analytic form so that a Taylor expansion can be performed to find the $H_m(z,t)$. That is, high-order spatial derivatives of $\boldsymbol{A}$ are needed about the design orbit.

However suppose, as is often the case, that only $\boldsymbol{B}$ is known, and moreover it is only known at a 3-D collection of grid points. For example, when iron is present, $\boldsymbol{B}$ can only be found numerically at a collection of grid points with the aid of some three-dimensional electromagnetic solver. What can be done then to find $\boldsymbol{A}$ and its high-order derivatives?

At first thought one might contemplate using numerical differentiation of grid-point data to determine $\boldsymbol{A}$ and its spatial derivatives. But it is well known to numerical analysts that numerical differentiation of grid-point data is intolerably sensitive to numerical noise in the data. Each differentiation operation amplifies noise. And it is high-order derivatives that are needed to compute $\mathcal{M}$ to high order.

This problem can be overcome, at least to reasonably high order, by the use of *surface methods*. By a theorem of *Neumann* the values of $\boldsymbol{B}$, and accordingly the associated values of $\boldsymbol{A}$, can be found within any volume V if the normal component of $\boldsymbol{B}$ is known on any surface S that bounds V. Moreover, it can be shown that the process of determining interior fields from fields on a surrounding surface is *smoothing*. That is, the interior field values are relatively insensitive to noise in the surface data. Finally, it can be shown that this smoothing overcomes the amplification of numerical noise associated with differentiation.

Straight beam-Line Elements There are two cases to be considered: straight (or essentially straight) beam-line elements, and curved beam-line elements with significant

Copyright © 2013 CC-BY-3.0 and by the respective authors

sagitta. In the case of straight beam-line elements it is possible to surround the design orbit by an imaginary cylinder. This cylinder can be conveniently assumed to have a circular, elliptical, or rectangular cross section. Circular cylinders are natural for the case of quadrupoles, sextuples, octupoles, etc. Cylinders with elliptical or rectangular cross sections may be more appropriate for elements for which the bore width is larger than the gap height. See Figure 1 for the case of a wiggler.

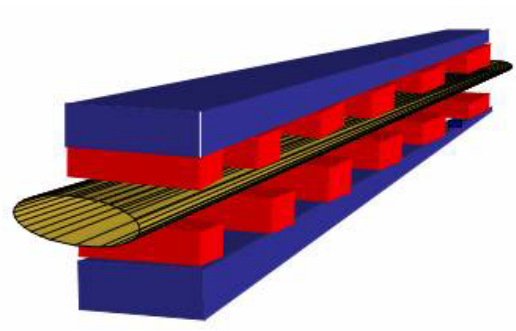

Figure 1: An elliptical cylinder, centered on the z-axis, fitting within the bore of a wiggler, and extending beyond the fringe-field regions at the ends of the wiggler.

For these cylindrical volumes V and their associated surfaces S it is possible to solve *Laplace's* equation by separation of variables. From these solutions it is possible to generate explicit formulas that determine $\boldsymbol{A}$ and its spatial derivatives at any interior point in terms of values of the normal component of $\boldsymbol{B}$ at selected grid points on S, and consequently the $H_m(z,t)$ can be found. The required surface values can be determined by extrapolation of the 3-D grid-point numerical values of $\boldsymbol{B}$ onto the selected grid points on S. Finally, the equations (36), (40), (41), $\cdots$ can be integrated to yield $\mathcal{M}$.

Curved beam-Line elements For curved beam-line elements with significant sagitta it is impossible to fit a straight cylinder within the bore of the element. In this case it is necessary to employ volumes V, and their associated surfaces S, that have a more complicated geometry. Figure 2 shows a convenient surface for the case of dipoles with significant sagitta, the surface of a bent box with straight end legs.

Unfortunately, for curved beam-line elements there are no geometries for which the Laplace equation is separable and therefore, while the results of Neumann still hold, there is no way to exploit them by explicit formulas. However, according to a theorem of *Helmholtz*, interior fields can also be computed from surface data providing *both* the normal component of $\boldsymbol{B}$ and the scalar potential ψ associated with $\boldsymbol{B}$ are known on the surface. Moreover, in this case the interior vector potential and its spatial derivatives can be found by multiplying the surface data by *known geometry-independent* kernels and then integrating the results over S.

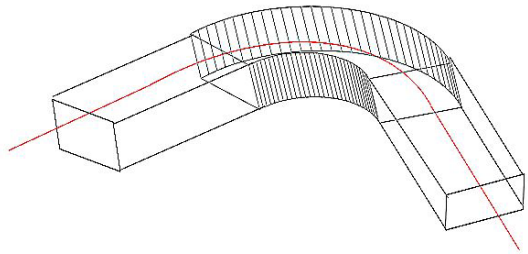

Figure 2: A bent box, fitting within a dipole, and having straight end legs that extend beyond the fringe-field regions at the entry and exit of the dipole.

Finally, this process is also smoothing: the interior values of $\boldsymbol{A}$ and its spatial derivatives so obtained are also relatively insensitive to noise in the surface data.

In practice, the procedure is as follows: First set up cubature points (specially selected grid points) on S, interpolate the numerical 3-D grid data for $\boldsymbol{B}$ onto the surface cubature points, and compute the normal component of $\boldsymbol{B}$ at these cubature points. In addition interpolate 3-D grid data for ψ, which can also be provided by 3-D electromagnetic solvers, onto the surface cubature points. Next multiply the surface data by the known kernels and integrate the results over the surface using cubature formulas. The result will be the interior vector potential and its spatial derivatives, and consequently the $H_m(z,t)$ can be found. Finally, the equations (36), (40), (41), $\cdots$ can be integrated to yield $\mathcal{M}$.

CONCLUSION

For both straight and curved beam-line elements, the use of Lie and surface methods makes it possible to compute, for the first time, accurate high-order transfer maps for realistic elements including all fringe-field and multipole error effects.

LONGITUDINAL EMITTANCE MEASUREMENT SYSTEM FOR THE ARIEL ELECTRON LINAC

A. Vrielink, Y.C. Chao, C. Gong, R. E. Laxdal, V. Zvyagintsev, TRIUMF, Vancouver, Canada

Abstract

As part of the ARIEL e-LINAC project at TRIUMF, a 1.3 GHz single-cell, room-temperature deflecting cavity has been developed to study the temporal distribution of an electron beam from a 300 kV thermionic gun. Beam bunches on the order of 100-200 ps long are produced from a biased grid with a 650 MHz RF voltage superimposed to periodically allow release of electrons. The RF deflector operates in a TM110-like mode, deflecting the electrons vertically with a magnitude dependent on their arrival phase. The cavity RF performance has been characterized through signal level and beam testing. The deflector is installed as part of a longitudinal emittance measurement system with beam collimation, a 90 degree analyzing magnet, the deflecting cavity and a final view screen. Initial beam bunch length measurements using this RF cavity, conducted in conjunction with the initial commissioning using a 100kV electron-gun and a 1.3GHz buncher, are presented. The beam bunch length was extracted by comparing data collected at a screen downstream of the deflector to an analytical model based on linear time-invariant system theory.

INTRODUCTION

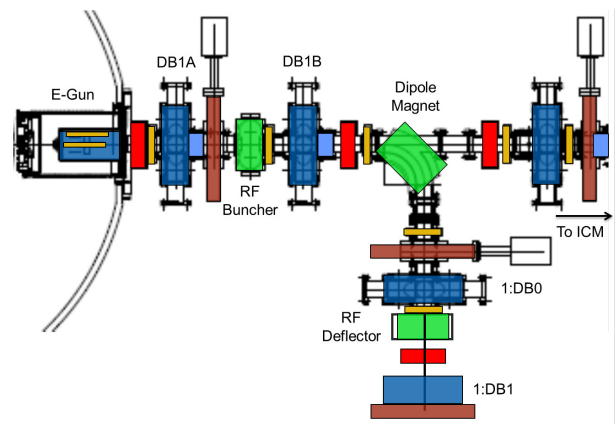

Figure 1: Low Energy Transport Line in the VECC Test Area.

The ARIEL project at TRIUMF is well under way, including a 50MeV linear accelerator using 1.3 GHz superconducting technology to accelerate a 10mA electron beam. TRIUMF is currently developing a 10MeV injection line for this electron linac in collaboration with the Variable Energy Cyclotron Center (VECC). A test area has been set up in the ISAC II building to commission various beamline components before installation in the ARIEL injection line and in Kolkata. The VECC Test Area consists of a 100kV (now 300kV) thermionic e-gun with an RF modulated gridded bias on the cathode at 650MHz, a low energy beam transport (LEBT), an injector cryomodule with a 1.3GHz superconducting 9 cell cavity, and a medium energy beam transport. Electron bunches ranging from 100-200ps long are emitted at a 1kHz repetition rate with a duty factor between 0.1% and 100%.

The LEBT section, pictured in Fig. 1, contains various beam diagnostics including linear profile monitors (LPMs), faraday cups, YAG screens and non intercepting beam profile monitors. The LPM consists of a vertical slit, horizontal slit and collimating hole which can be scanned across the beam to sweep the beam profile or inserted into the beam to select a beam profile.

THE LONGITUDINAL EMITTANCE MEASUREMENT SYSTEM

As part of the LEBT diagnostics, a longitudinal emittance measurement system was designed. It consists of an RF bunching cavity, dipole magnet, RF deflecting cavity in a 90° analyzing leg and downstream screen. The RF buncher manipulates the bunch length at a point downstream by accelerating late electrons in the bunch and decelerating early electrons. The dipole bends the beam into the analyzing leg, mapping the electron energy to the x axis through the dependence of the radius of curvature on electron energy, $\rho = \frac{\gamma\beta E_0}{qBc}$.

Circular apertures of 2mm diameter at the diagnostic boxes DB1A and DB1B (see figure 1) are used to limit the transverse emittance. The dipole magnet horizontal focusing is designed so an object at DB1B forms a dispersed focus at 1:DB0, such that a slit at 1:DB0 will select an energy slice of the beam.

In the analyzing leg, a 1.3GHz room temperature RF deflecting cavity maps the time spread of the beam to the vertical axis using E_y and B_x fields. A screen at 1:DB1 images the beam in the transverse plane. Using the deflector in conjunction with the dipole magnet, the beam energy and time spread can be extracted from the horizontal and vertical beam size, respectively. A solenoid upstream of 1:DB1 can be used to focus the beam at 1:DB1 with the RF devices off, producing a slight rotation of the $\Delta E/\Delta t$ (x/y) reference frame.

THE RF DEFLECTOR

The 1.3 GHz single cell deflecting cavity has been designed to analyze the temporal distribution of an electron

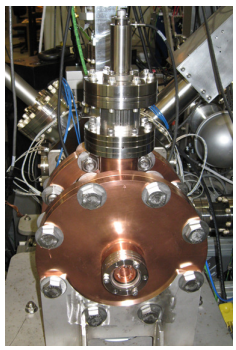

Figure 2: The deflecting cavity during installation.

beam bunch. The cavity is located in the analyzing leg of the injector line, as shown in figure 1. Pictured in Fig. 2, the cavity was designed after the Cornell deflector [1]. Similar in shape to a pillbox cavity, nose cones at the beam entrance and exit strengthen the on axis transverse fields. The cavity is operated in a TM_{110} like mode, resulting in a vertically deflected beam with the magnitude of deflection a sinusoidal function of the arrival phase of the electrons. Through CST simulations, for a β=1 particle the expected $\frac{R_\perp}{Q} = \frac{V_\perp^2}{\omega U}$ and transit time factor, T_0, were 930Ω and 0.51, respectively. $V_\perp$ is defined in equation 1, differing from a traditional potential to account for the effect of the magnetic fields on the beam.

$$V_\perp = \left| \int_{-\infty}^{\infty} c\beta B_x(z) e^{\frac{ikz}{\beta}} - iE_y(z) e^{\frac{ikz}{\beta}} \mathrm{d}z \right| \quad (1)$$

Signal Level Measurements

The deflector was manufactured at TRIUMF and after assembly and quality factor optimization, signal level measurements were conducted. While the quality factor of the cavity was 8800 before ultrasonic cleaning, close to the simulated value of $Q = 9766$, it is believed that soap residue has caused the current low quality factor of 5400.

The electromagnetic fields in the cavity were confirmed experimentally using the beadpull method. Magnetic fields on axis necessitated using both a dielectric and metallic bead. The dielectric bead only perturbs the electric field which can then be subtracted from the total perturbation with the metal bead to obtain the magnetic fields.

The results of the beadpull are shown in figure 3, normalized to emphasize the difference in field shape. Compared to simulation, the peaks of the experimentally determined fields are narrower. This is due to a slightly different nose cone length than in the CST model. As a result, the transit time factor of the cavity is increased and for $v = c$, T_0=0.56 ± 0.03. The effective shunt impedance of the cavity is smaller than expected though, with an $\frac{R_\perp}{Q}$ of 120 ± 10 Ω, 390 ± 20 Ω and 710 ± 30 Ω for a particle with a β of 0.51, 0.78, and 1 respectively.

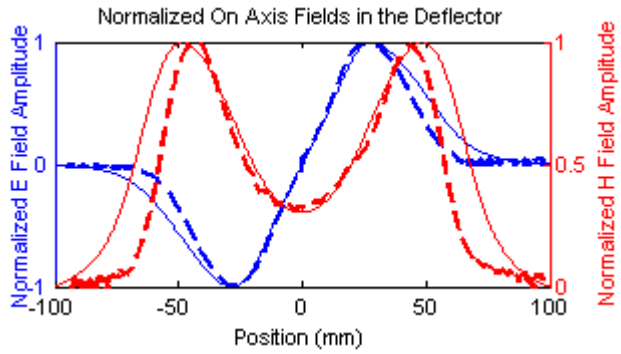

Figure 3: Fields along the beam axis of the deflector. The dashed line corresponds to the experimentally determined fields while the solid line corresponds to simulation.

Beam Loaded Measurements

Beam loaded commissioning of the cavity began in September, 2012, in conjunction with the commissioning of the LEBT section and 100keV e-gun [2]. The beam was bent into the analyzing leg using the dipole magnet, and images of the beam were taken using the screen at 1:DB1.

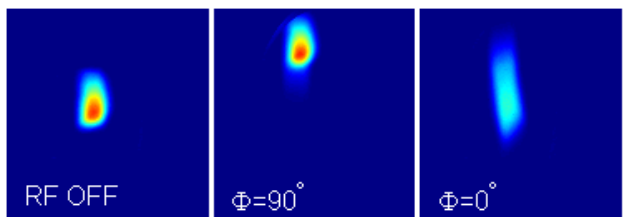

Figure 4: The effect of the deflector on the beam.

Turning on the deflector and scanning the RF phase produces a noticeable effect on the beam, even at low input powers. Figure 4 shows the effect of the deflector at an input power of 21W and RF phases of 90° (maximum centroid deflection) and 0° (diagnostic phase). The deflector imparts a vertical deflection to the beam given by $\frac{\Delta y}{\Delta z} = \frac{V_\perp}{\beta^2 E_T}$ where E_T is the total beam energy.

By measuring the maximum deflection at several deflector power levels, the deflector effective voltage can be obtained using the above equation. Figure 5 shows a plot of the deflecting voltage versus input power from which an effective shunt impedance of 0.71±0.05 MΩ was obtained. This agrees with the expected $R_\perp$ for a $\beta = 0.51$ electron of 0.65±0.03 MΩ from the beadpull.

INITIAL MEASUREMENTS

With the deflector commissioned, initial longitudinal emittance measurements have been conducted. By inserting the vertical LPM slit at DB1B, all particles have the same initial horizontal position. Their final position at the screen on 1:DB1 is thus, to first order, only a function of the particle energy and time of arrival at the deflecting cavity for a constant deflector power.

Copyright © 2013 CC-BY-3.0 and by the respective authors

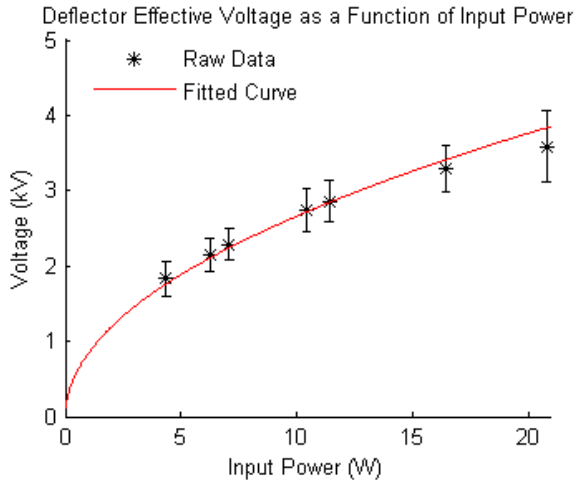

Figure 5: The effective voltage of the deflecting cavity.

The time spread is calibrated by sweeping the deflector from 0 to 360°. Comparing the maximum spread at the diagnostic phase (0°) with the maximum centroid deflection (±90°), the bunch length in RF degrees is obtained. The energy spread can be calibrated by sweeping the RF buncher from 0 to 360° or by scanning the e-gun voltage. Given the effective voltage of the buncher, the energy spread of the beam at 1:DB1 can be obtained by comparing the maximum horizontal spread at the bunching phase (0°) with the beam position at the accelerating phase (90°).

Since energy couples to x and time couples to y, the final image gives a representation of the longitudinal emittance. This is depicted in figure 6, where the RF deflector is on at constant power in the first three images and the indicated buncher power is increased to rotate the longitudinal phase space. For these images the focusing solenoid was on and the image is corrected for the rotated x-y frame. As expected from the Liouville theorem, longitudinally compressing the beam will inherently increase the bunch energy spread. Note that with the RF buncher and deflector off, the beam spot is much smaller than the perturbed images, indicating that the sampled longitudinal emittance is not significantly affected by the transverse emittance.

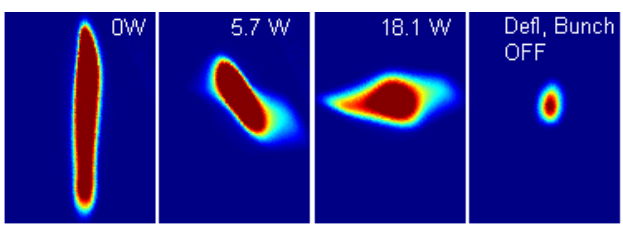

Figure 6: Rotation of the beam with the deflector on and the buncher power varied.

An alternative analysis method to determine the bunch length uses linear time invariant theory. For low space charge, the beam optics in the analyzing leg and the RF deflector can be considered a linear system and the maximum centroid deflection and maximum particle deflection over all arrival phases is time invariant. Such a system can be entirely characterized by its impulse response (i.e. the effect of the deflector on a single electron), which is well known. The output of the system will be the convolution of the input beam distribution with the impulse response function. For a uniform beam distribution of length Θ, measured in degrees RF, the centroid deflection over the maximum deflection is thus given by equation 2.

$$\frac{\Delta\bar{y}\,(\alpha)}{\Delta y_{max}} = (f * \Delta y_{\text{impulse}})(\alpha) \tag{2}$$

$$= \int_{-\infty}^{\infty} f\,(t)\, g\,(\alpha - t)\, dt \tag{3}$$

$$= \int_{-\infty}^{\infty} \text{Rect}\left(\frac{t - \theta/2}{\theta}\right) \sin\,(\alpha - t)\, dt \tag{4}$$

$$= \frac{\sin\,(\alpha) - \sin\,(\alpha - \theta)}{\theta} \tag{5}$$

Using this method, the bunch length can be determined by comparing the ratio of the maximum centroid deflection over the maximum particle deflection to theoretical predictions. Figure 7 shows an example of the maximum particle deflection as a function of phase offset for two different tests, highlighting the effect of bunch length in smoothing out the sinusoidal dependence. The ratio between centroid deflection and maximum particle deflection for the shorter and longer bunches is 0.9 and 0.6, respectively, corresponding to a 60° and 180° bunch length.

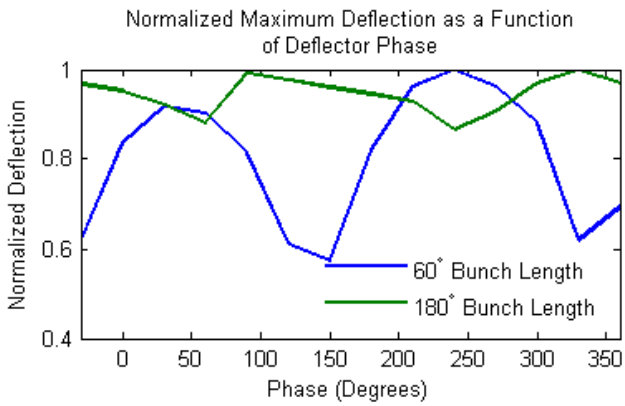

Figure 7: Maximum particle deflection as a function of RF phase for a short bunch (blue) and longer bunch (green). The phase is relative to the E-gun RF.

BEAM DUMP DESIGN FOR THE IN-FLIGHT FRAGMENT SEPARATOR USING HIGH-POWER BEAM*

J.Y. Kim, M. Kim, J.W. Kim#, Institute for Basic Science, Daejeon, Korea

Abstract

The beam dump is a critical component for the in-flight fragment separator using high-power primary beams at the rare isotope science project (RISP) in Korea. The maximum beam power is planned to be 400 kW, and a third of the primary beam power deposits at the isotope production target and the rest are dissipated at the beam dump. The beam dump is designed to be a rotating water drum, which is movable in the perpendicular direction to the beam to select the isotope beam of interest. The main primary ion beam is U, and its range at the energy of 200 MeV/u is only a couple of mm after passing through the shell structure of the drum. This short range requires its internal structure to confine water flow on the wall and to keep high-pressure. Some detailed thermo-mechanical and thermo-fluid analysis has been done using ANSYS and other codes.

INTRODUCTION

Rare isotope science project (RISP), which is to produce rare isotope beams by using both the in-flight fragment (IF) separation and isotope separation on-line (ISOL) methods is undergoing in Korea [1]. The main accelerator, which can provide a wide range of heavy ion beams, accelerating ^{238}U beam to 200MeV/u and proton to 600 MeV, is a superconducting linear accelerator for the IF separator. The IF separator uses a thin target to produce rare isotope beams and a beam dump is located after the first dipole magnet so as to remove unwanted primary beam.

The design of beam dump for in-flight separator using high power primary beam has been performed considering high power density deposited in beam dump. Approximately 30% of the primary beam power, which is used to produce RI beam, will be dissipated in a production target with typical thickness of d/R = 0.3, whereas the rest of primary beam that does not react with production target, will pass through magnetic system and be absorbed in beam dump. The maximum beam power deposited in the beam dump is up to about 300 kW for 200 MeV/u ^{238}U beams and the beam size on beam dump is expected to be around 10 mm in diameter.

Removal of high power primary beam in an IF separator is complicated due to different charge states in primary beam, short range in material and high power density at beam dump. Furthermore, if assuming the primary beam directly impacted on beam dump in the case of target malfunction, the beam dump should be capable of absorbing up to 400 kW during a short time. The cooling system, which can handle high power, is required to avoid structural breakdown and thermal runaway.

If wanted fragment beam is close to the primary beam in rigidity, the task of separation becomes more difficult. Trajectories of off-rigidity fragments and non-reacted beam can overlap with that of the isotope beam of interest at the beam dump. Beam dump system is required to intercept unwanted fragments and non-reacted primary beam minimizing the loss of wanted beam. For the purpose of intercepting the primary beam and off-rigidity fragments with different trajectories, it is necessary that the beam dump has two units and is movable.

A conceptual design of beam dump, and thermal analysis using ANSYS [2] and PHITS [3] are described.

DESIGN OF BEAM DUMP

Figure 1 shows a schematic layout of the separator, which has been designed to consists of two-stages. The purpose of the first stage, pre-separator is to produce RI beams and then to separate the primary and unwanted RI beams, while the second stage, main separator serves to identify the RI beam of interest. The momentum and angular acceptance of the separator have been designed to be ±5 % and ±50 mrad, respectively.

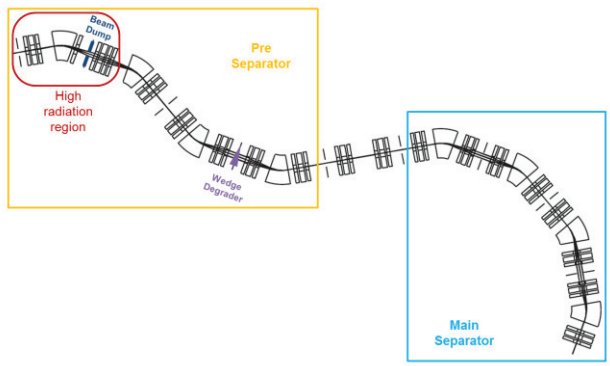

Figure 1: Schematic layout of the fragment separator.

As shown in Fig. 1, a dispersive focal plane is located after the first dipole magnet, and the beam dump is placed near the focal plane. The isotope beam of interest is separately by magnetic rigidity, but unwanted beam with the same Bρ is overlapped.

To remove the heat efficiently, we considered the beam dump consisting of two rotating water-filled cylinder as was adopted for FRIB [4]. A conceptual drawing of the beam dump system is shown in Fig. 2. The beam dump system will be located in a common vacuum space together with the dipole magnet and the production target. The beam dump rotates to prevent localized heating, and cooling water directly absorbs the beam power acting as a liquid beam dump. Titanium is chosen for the material of

the beam dump. The thickness of titanium shell is set to be 1 mm and the outside diameter is 60 cm. The depth of water chamber is 10 cm. The water flows into beam dump through the tube in the side plate, and flows along the helical blades, remove the heat deposited close to the drum surface and water itself.

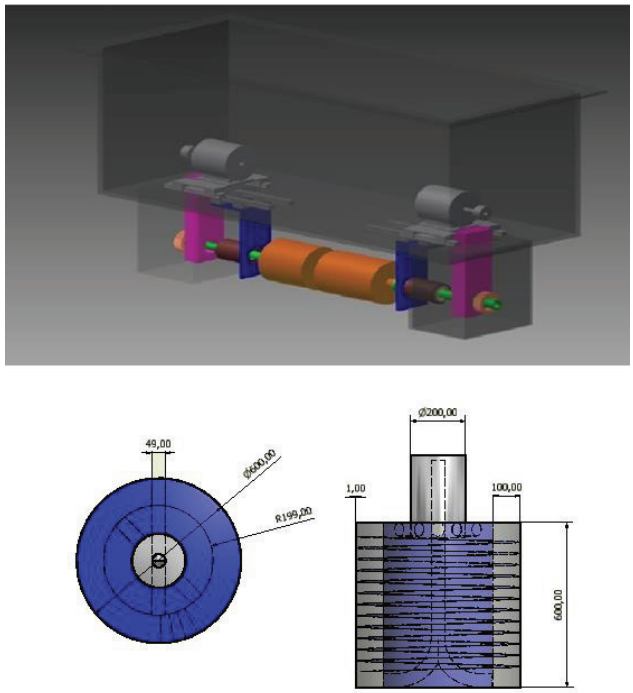

Figure 2: Schematic layout of the beam dump.

ENERGY LOSS AT THE BEAM DUMP

The non-reacted primary beam impacting the beam dump has a diameter of about 10 mm and a power of about 300 kW, which depend on chosen nuclear reaction and the thickness of the production target. Simulation using the codes LISE++ [5] and TRIM [6] was performed to study the energy loss at the beam dump assuming the target thickness corresponding to approximately 30% of the primary beam range.

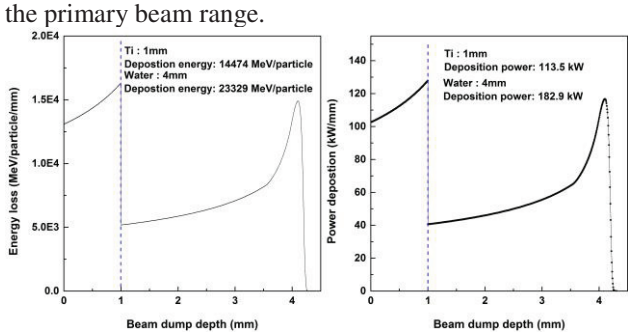

Figure 3: The energy loss (a) and the power deposition (b) of non-reacted ^{238}U beam at beam dump.

In the case of ^{238}U beam with 200 MeV/u, 400 kW, the energy and power of the non-reacted primary beam passing through the target are about 160 MeV/u, 300 kW. The energy loss and power deposition of ^{238}U beam at the beam dump are shown in Fig.3. When the ^{238}U beam hits the beam dump, about 40% of the ^{238}U beam power is lost in the 1-mm thick shell of beam dump and the rest is deposited in water. The energy loss and the range of charged particles depend on the incident particle and, its energy and on the material. The energy loss of different primary beams in the Table 1 assuming a full power beam hits the bam dump, which is an accident scenario.

Table 1: The energy loss and the power deposition assuming a 400 kW beam hitting the beam dump

Primary beam	Energy (MeV/u)	Intensity (pps)	Energy loss (MeV)		Power deposition (kW)	
			Ti	Water	Ti	Water
$^{238}U^{79+}$	200	5.17E+13	12453	35871	103.1	297
$^{124}Xe^{54+}$	235	8.58E+13	4053	25065	55.6	344.1
$^{112}Sn^{50+}$	242	9.22E+13	3412	23670	50.3	349.3
$^{40}Ar^{18+}$	268	2.33E+14	403	10307	15	384.6
$^{18}O^{8+}$	266	5.22E+14	79	4709	6.6	393.4

THE HEATING AND FLUX DISTRIBUTION IN THE BEAM DUMP

The radiation heating was estimated by using PHITS which simulate radiation transport. The beam dump was assumed to be a simple cylinder with 30 cm diameter and 60 cm high. The flux of unwanted fragments produced via in-flight fission of ^{238}U beam at 200 MeV/u, 400 kW, and the flux secondary particles which were produced by the reaction of ^{238}U beam and components of a beam dump is shown in Fig. 4. The flux is expressed in units of 1/cm^2/second, and the major flux of secondary particles is forward directed. The scattered in wide distribution in the outside of the beam dump, radiation is dominated by neutrons. Figure 4 (b) is the distribution of energy deposition due to absorb the primary beam and secondary particles in the beam dump.

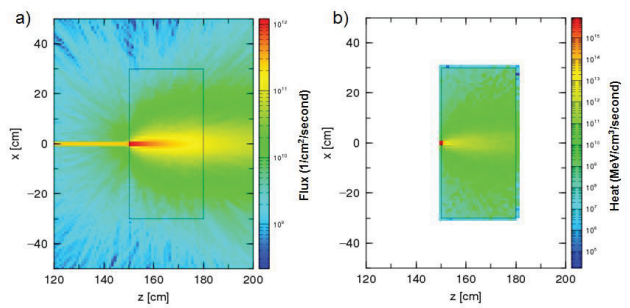

Figure 4: The distribution of the radiation flux (a) and the heat (b) on the beam dump.

Figure 5 shows, the flow velocity in the beam dump, which was calculated by using ANSYS in the same geometry as used PHITS calculation. We assumed that the deposited power is about 110 kW on titanium and about 290 kW on the water. The inlet temperature of cooling water was assumed 295 K. To cool beam dump considering margin of safety, the velocity of cooling

Copyright © 2013 CC-BY-3.0 and by the respective authors

water needs to be much higher than 5 m/s considering the melting point of Ti is about 1940 K. The energy deposition is highly concentrated on the titanium and the adjacent of the water.

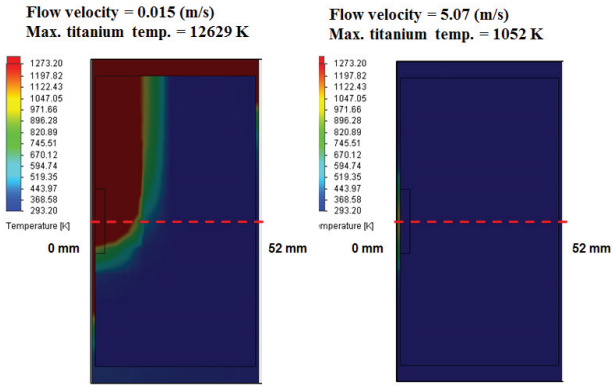

Figure 5: The temperature distribution in the beam dump due to absorption of 400 kW primary beams

The water is activated by nuclear reaction with the primary beam in the beam dump. The activity in water as function of cooling time is presented in Fig. 6. The activity calculation by using the PHIS was performed assuming 5600 h of irradiation with ^{238}U beam (200 MeV/u, 400 kW), which is an expected operation time of separator. With waiting time increasing, the activity of the tritium is dominant because the life time of tritium becomes relatively longer than others. Therefore, for the purpose of decreasing the activation level of the water used to cool the beam dump, there are essentially needed a filtering system to remove long-lived isotopes from water

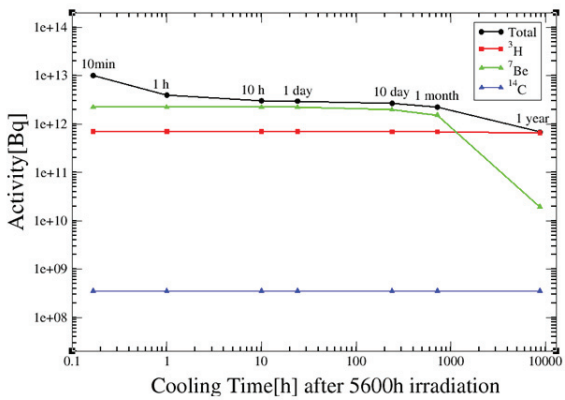

Figure 6: Activity of the beam dump as function of waiting time.

CONCLUSIONS

The designs of beam dump and water cooling loop in the IF separator for the RISP have been studied. As a first step, we calculate the power density deposited in beam dump, heat deposit distribution and cooling water flow. Considering the energy loss of a few different primary beams, it was decided that the path length inside the beam dump needs at least 150 mm to stop the primary beam. Based on this result, some mechanical design and thermo-fluid analysis on the beam dump system was performed. Since the activation of cooling water is significant, we will plans to filter some isotopes from activated water, which is included in the design of the water loop system.

BEAM POSITION ELECTRONICS BASED ON SYSTEM ON CHIP PLATFORM

M. Cargnelutti*, G. Jug, R. Hrovatin, Instrumentation Technologies#, Solkan, Slovenia

Abstract

With the advances in system-on-chip (SoC) technology, the CPU and FPGA are today enclosed in the same device. This enables high-speed processing, inherent fast communication and memory sharing between the two entities. However, dedicated tools for implementation are needed as the CPU and FPGA functionalities cannot easily be decoupled.

We used the advantages of the new architecture in the development of a booster BPM electronics. Its requirements are relaxed compared to up-to-now Libera beam position monitors. Proper design of the RF part of the instrument is still a challenge. Furthermore, with optimized FPGA design we target low overall power consumption so that the instrument can be cooled passively.

INTRODUCTION

Instrumentation used in particle accelerators is today one of the most demanding fields for electronic devices and of system integration. Required performances are usually at the cutting edge in terms of signal-to-noise ratio, computational power and data throughput. Even more impressive are the requirements in terms of reliability, long term stability and fault tolerance. As a consequence, instruments are usually a complex inter-connection of different boards that host RF circuits, field programmable gate arrays (FPGAs), communication buses and CPUs. Every logical component from hardware to software is optimized for the specific application.

On the other hand, not every accelerator, or at least not every part in it, needs a top-level device to work properly. A natural example here concerns beam position monitors (BPMs) used in synchrotrons boosters and injectors, compared to those used in the storage ring. Furthermore, a lot of applications have figures of merit such as low power consumption, no need for HW and SW maintenance, and user friendliness. This can be the case for a beam loss monitor (BLM), for example.

In this paper we introduce a compact platform that aims to host a wide range of applications, being able to cover all the points presented above. Details about the system design are presented in the third section. In order to give a real picture, we will consider the development of a BPM instrument for the European Synchrotron Radiation Facility (ESRF) booster [1] as an example.

A NEW PLATFORM

Looking at the beam instrumentation used to monitor and stabilize an accelerator, every device suits a specific role, but it is possible to identify some key components that are always present:

- digital signal processing and elaboration units (e.g. FPGAs and CPUs)
- RF front-end and analogue signal processing chains
- internal communication buses
- power supply unit
- crate and cooling system (often is an active system with fans).

In this new development, we take advantage of the latest advances in SoC technology to introduce a compact platform that combines a high level of hardware integration with our knowledge regarding reconfigurable analogue signal processing.

HW and SW integration

Hardware and software are designed taking in account the balance between generality and optimization. It will be always possible to add specific features to customize it, opening at the same time the way for developing different applications, as shown in Fig. 1.

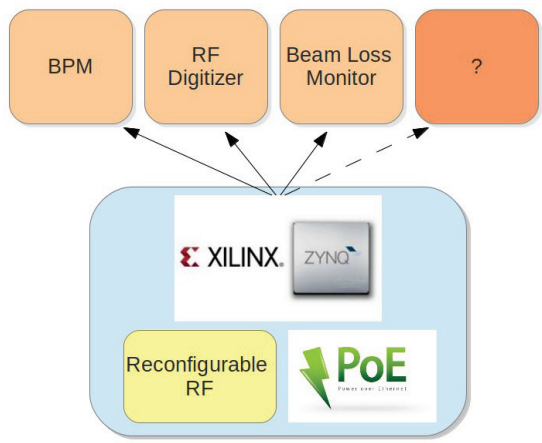

Figure 1: Platform concept based on SoC.

The core part is the SoC Xilinix Zynq 7020 [2] which combines the high-speed processing of the FPGA together with the flexibility of a CPU, all within the same chip. The inner communication between the two entities and the chance to share the same memory removes at the same time two of the biggest bottle-necks that still characterize separate-chip solutions:

- no communication protocols needed
- no data copy between FPGA and CPU.

Copyright © 2013 CC-BY-3.0 and by the respective authors

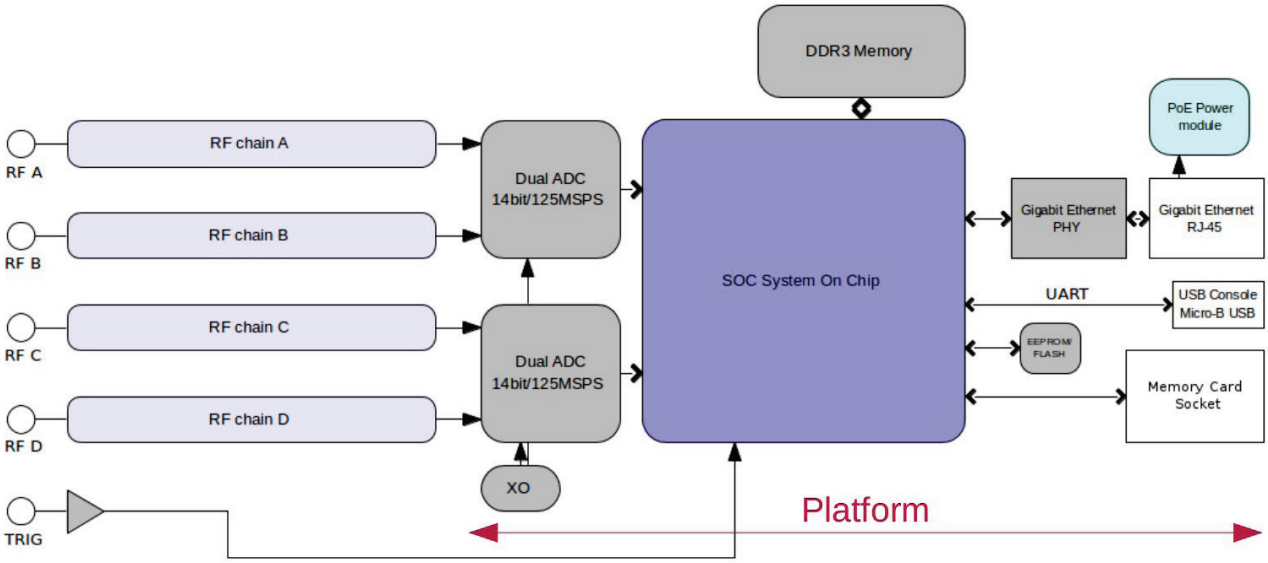

Figure 2: Basic HW architecture of the BPM instrument.

The specifics of the analogue front-end will cover the user requirements. Integrations with specific band-pass filters, phase-locked-loop and variable attenuators are possible if the application requires them. Figure 2 shows an example of the HW architecture of a BPM application.

Low power instrument

SoC requires less power than a multiple-board solution, and a proper selection of the RF components (amplifiers, analog-to-digital-converters (ADCs), etc.) reduces the amount of heat that the cooling system has to treat. This enables the way towards passive cooling with the integration of the heat sink in the crate. Consequently fans are no longer needed, and from the system point of view, the main advantages are:

- no moving parts means no maintenance required
- fans-induced noise is no longer present on the signals
- less space and less power required from the system.

With the low power requirement, precisely less than 15 Watt, the system can be powered over Ethernet according to the PoE standard IEEE802.3af.

In the case of accelerator applications, if the unit is powered over Ethernet, it is possible to put it closer to the machine (e.g. 5m), reducing at the same time the cost of cables and noise on the signal.

Easy SW maintenance

The unit software can be basically divided in the design that configures the FPGA and application and other interfaces supported by the operating system on the CPU side. The operating system running on Xilinx Zynq SoC is Linux OS.

In the presented platform, the software packages will not be installed in the device memory, but both FPGA and Linux code will be loaded from the same image when the unit is turned on. In more details two different boot procedures will be supported:

- ***memory card boot***: if a memory card is inserted in the device socket (see Fig. 2), then the Linux OS will boot from the image contained in the memory
- ***trivial File Transfer Protocol (TFTP) boot:*** if no memory is inserted, the boot procedure will start from the FLASH memory, and the software image will be downloaded from a configured TFTP server.

In both cases a software update can easily be realized replacing the software image in each unit, with no need to deal with packages and configuration files in the operating system. In particular for a complete set of units configured to use TFTP, only one image should be modified.

DESIGN CONCEPT FOR A BPM

The beam position monitor is the first application developed on this new platform, and 75 units will be installed in the ESRF booster ring [3].

Generally, the requirements for boosters are more relaxed compared with storage rings, and a resolution in the range of micrometers is more than enough. With a slight simplification of the measurement concept and the performances offered by this new platform, it is possible to match the requirements with an excellent price-to-performance ratio. Table 1 recaps part of the booster specifications that are important for the development.

Table 1: ESRF booster specifications

Parameter	**Value**
Circumference	300 m
Energy gap	200MeV – 6 GeV
RF frequency	352.2 MHz
Repetition rate	10 Hz
Required resolution	< 0.5 mm

Copyright © 2013 CC-BY-3.0 and by the respective authors

The RF front-end should deliver the signals to the ADCs, achieving both wide bandwidth and good signal quality. With the low power constraint, a clever design of each stage is necessary, and the use of filters and amplifiers should be limited to the strictly necessary. Obtained bandwidth ranges from 300 MHz to ~500 MHz, and special Surface Acoustic Wave (SAW) filters will be placed to enhance the signal quality at required frequency, in this case 352.2 MHz.

Sampling frequency is programmable in a range from 80 MHz to 125 MHz. Selected ADCs support such sampling frequency and output 14-bit data.
Data acquisition is started either providing an external trigger signal (see Fig. 2) or using the SW trigger functionality, with a 10 Hz maximum rate that meets the ESRF specifications. Samples acquired through ADCs are then processed in the FPGA through three different data paths and stored in different memory buffers, as shown in Fig. 3.

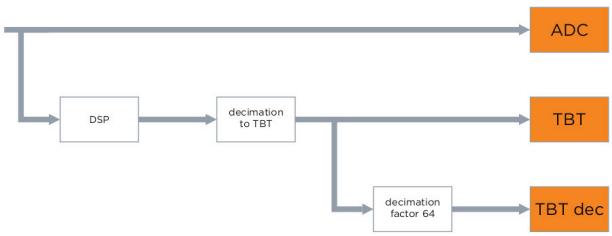

Figure 3: Data-paths and buffers overview.

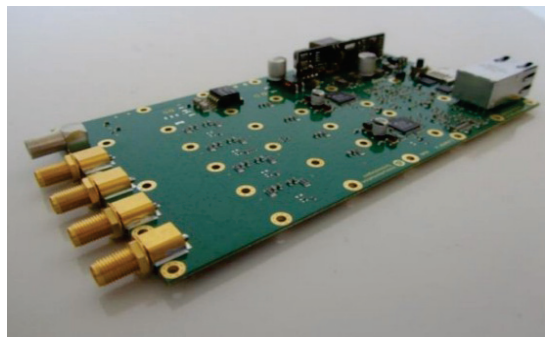
- ***ADC raw data***: raw samples acquired at the sampling frequency, stored in a buffer with capacity 1 Msample.
- ***TBT data***: ADC samples regarding a whole turn in the ring are processed by a digital-down-conversion (DDC) algorithm using filters whose parameters are optimized for the machine physical dimensions and RF frequency. Data stored in the buffer are I and Q samples of each chain. Reducing the bandwidth, also the noise contribution is lower, and a better position resolution is then achieved. Its capacity is 256k samples.
- ***TBT-decimated data***: this buffer contains the data stored in the TBT buffer, after a decimation with factor 64. Its capacity is the same as the TBT buffer.



On the CPU side, data stored in the buffers can be further processed in order to deliver a more complete set of information to the user: from I and Q, also X and Y and sum signals are available. The position is computed using difference over sum formulas, and proper parameters can be tuned to remove offsets and adjust the gain.

The upper software layer provides the communication interface with the instrument. This is based on Standard Commands for Programmable Instruments (SCPI) specifications. Integration in the accelerator control system environment (EPICS, TANGO, etc.) can easily be done either implementing a specific server in the unit or using an external device server.

The development of the instrument is on the way with first prototype boards produced – see Fig. 4. First results of the measurements of the HW and ADC buffer part are within the specifications:

- crosstalk between RF channels is better than -60 dB
- expected position resolution at turn-by-turn frequency of 1 MHz is in the range below 10 micro-meters
- PoE functionality and boot options work properly.

Figure 4: BPM prototype board.

CONCLUSIONS

The development of a new compact electronics based on the SoC technology has been presented in this article. The introduced platform combines knowledge about reconfigurable RF front-ends with the advantages of a compact and passively cooled instrument that can be powered over Ethernet and booted from a server using only one SW image.

It is intended to be the base for several applications, but the BPM case is the first of these and is described in details. Many others such as RF digitizers, BLMs and beam current monitors will come in the future. FPGA and CPU software will be provided to the user in order to give the opportunity to extend and optimize the instrument's original functionalities.

As a first development, the BPM prototype is a promising application that shows very good performance, simple and straightforward architecture and an interesting price-to-performance ratio.

COMPARISON OF SIMULATIONS AND ANALYTICAL THEORY OF RADIATION HEATING ON THE ADVANCED PHOTON SOURCE SUPERCONDUCTING UNDULATOR*

Laura Boon†, Purdue University, West Lafayette, IN 47907, USA
Roger Dejus, Katherine C. Harkay and Mark Jaski, ANL, Argonne, IL 60439, USA

Abstract

Synchrotron radiation can potentially introduce large heat loads on the beam chamber of the superconducting undulator (SCU0) at the Advanced Photon Source (APS). With the photon absorber mask, a well-aligned centered beam in the upstream bending magnet allows only a small amount of radiation power, less than 1 W, to intercept the walls of the beam vacuum chamber in the cryostat, assuming no photon scattering. But beams with vertical orbit errors, especially, can deposit much higher heat loads on the beam chamber, above 100 W. An analysis was carried out to calculate the power on the vacuum chamber when the beam has an orbit error through the upstream bending magnet. This paper presents these analytical results compared to simulations that were performed using a 3D photon tracking code, Synrad3d.

INTRODUCTION

As part of the Advanced Photon Source Upgrade project [1], a test superconducting undulator (SCU0) was developed at Argonne National Laboratory [2]. The test SCU0 was installed in December 2012 [3]. To reduce heating on the superconducting coils, the beam chamber is thermally isolated from them. The cryo-coolers used to cool the beam chamber are able to handle up to 40 W of power (at 20 K) from transient and continuous wave sources. Radiation from the upstream dipole produces high amounts of power that can be incident on the beam chamber inside the SCU0 cryostat. SCU0 is in the downstream end of the straight section in sector 6, see Fig. 1. The upstream end of the straight section has a hybrid permanent magnet undulator (HPM). A photon absorber (PA) in the downstream end box of the HPM is used to shield the beam chamber outboard wall from direct, on-axis radiation.

CALCULATIONS

The power incident on the SCU0 beam chamber from primary photons can be calculated through ray tracings and analytically. Ray tracings are 2D projections of the dipole radiation fan on the 3D vacuum system layout. Ray tracings do not typically include the vertical distribution of the dipole radiation. So analytical calculations were performed to include the photon vertical distribution. Figure 2 shows the elliptical shape of the beam chamber in the SCU0 cryostat. The shape was taken into account for all the calculations and simulations shown in this paper. All calculations assume a beam current of 100 mA. Beam orbits are referenced to the dipole exit.

Ray Tracings

The layout of the radiation fan is seen in Fig. 1. By applying an off-axis electron beam orbit through the radiation source, the horizontal steering offset (x) and angle (x') limits can be determined. The steering limit is defined by when the radiation fan begins to intercept the outside edge of the beam chamber. The steering limit defined by ray tracings is shown in Fig. 3 (red dotted line). Due to the wide horizontal aperture of the beam chamber, only for very large steerings is there a concern about radiation heating. For positive offsets the photon absorber shields the beam chamber. The power incident on the beam chamber is calculated as follows. The APS main dipole magnet generates 6.65 kW of synchrotron radiation power per 100 mA. The horizontal fraction of energy that is incident on the SCU0 chamber is calculated using α/θ_{dipole} where $\theta_{dipole} = 77.54$ mrad is the full bending angle and α is the angle subtended by the SCU0 chamber. The power incident on the beam chamber is greatest for an electron beam that has a negative orbit offset. The power on the outside edge ranges from 0.3 W to 22.8 W. The power increases for larger negative offsets.

Analytical Calculations

The radiation heating load is calculated analytically using the method described in [4]. The following equation is integrated over the vertical opening angle in which the photon beam is incident on the beam chamber:

$$F = P_0 \frac{1}{(1+X^2)^{5/2}} \left[1 + \frac{5}{7}\frac{X^2}{1+X^2}\right]. \qquad (1)$$

In Eq. 1, P_0 is the fraction of total power produced by the dipole magnet that passes the photon absorber, and $X = \gamma\psi$, where γ is the relativistic factor, and ψ is the vertical opening angle between the radiation source and the SCU0 beam chamber.

Figure 3 is a contour plot of the power incident on the SCU0 chamber when the beam has a horizontal offset. The vertical photon distribution is included in the calculation. Radiation intercepts the top and bottom of the beam vacuum chamber and not just the outside edge. Again the contour plot shows that large negative offsets through the

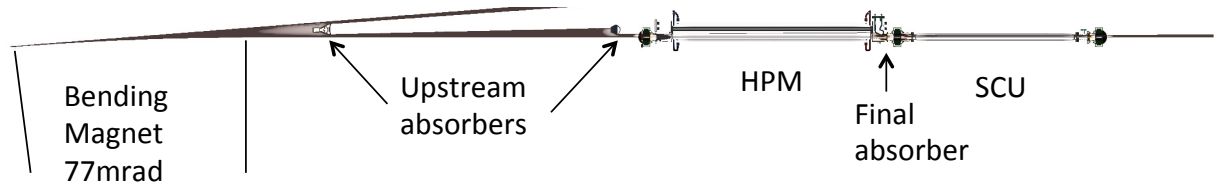

Figure 1: Top view schematic layout of the sector where the SCU0 is installed. The radiation is produced in the bending magnet, and photon absorbers are used to shield the SCU0 cryostat from direct radiation.

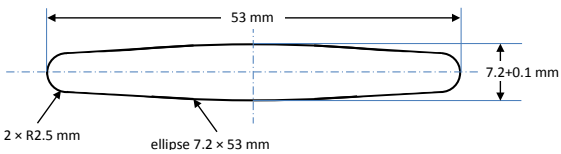

Figure 2: Elliptical shape of the beam chamber in the SCU0 cryostat.

dipole magnet produce the most power incident on the SCU0 beam chamber.

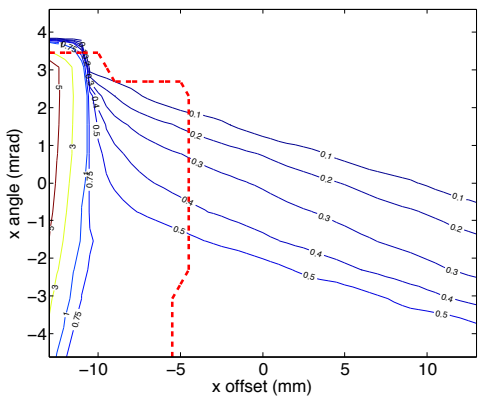

Figure 3: Comparison between ray tracings (dotted line) and analytical calculations (solid contours) of radiation power incident on the SCU0 beam chamber for a beam horizontally offset in the upstream bending magnet. To the left of the red dotted line is where radiation is incident on the outside edge of the SCU0 beam chamber. Power is shown in Watts. ($y = y' = 0$)

Figure 4 shows the power incident on the SCU0 chamber when the beam has a vertical steering error, offset (y) and angle (y') in the dipole magnet. Due to the small vertical aperture (7.2 mm) of the beam chamber, the incident power can reach over 100 W of power for relativity small vertical angles in the dipole. The vertical 'cut-off' of the heating on the SCU0 chamber is at 4 mm for two reasons. First, the upstream HPM has a vertical aperture comparable to that of the SCU0. This acts as a shield to the top and bottom of the SCU0 chamber. Second, the SCU0 chamber only has a vertical half aperture of 3.6 mm. Photons produced above that position will be absorbed in the taper before the SCU0 chamber.

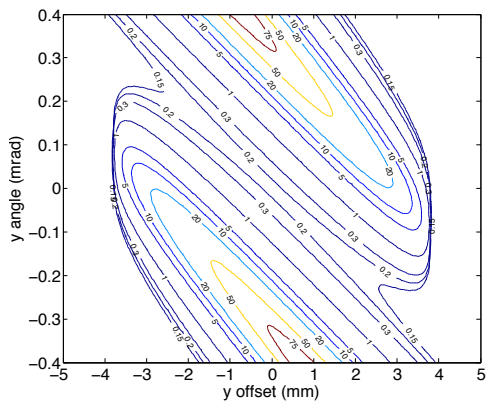

Figure 4: Power incident on the SCU0 cryostat for a beam that is off-axis vertically through the upstream bending magnet. Power is shown in Watts. ($x = x' = 0$)

The analytical results were compared with simulations in order to confirm our analytical model. Comparing Figs. 3 and 4, we note that vertical orbits in the dipole produce more heating on the beam chamber than comparable horizontal orbits. For this reason simulations were only done in the vertical plane.

SIMULATIONS

Synrad3d [5] was used to calculate the power of photons incident on the beam chamber. The total power on the beam chamber was calculated from the incident photon distribution and energy [6]. To simulate an off axis beam through the dipole magnet, an optimization of the correctors' strength was completed using BMAD [7]. The simulations included the electron beam trajectory through the entire sector. Coupling in the sector sextupoles creates a horizontal offset in the electron beam orbit for vertical steering. The horizontal offset was minimized through the choice of correctors and tolerance value in the optimization. For comparison with simulations, the analytical calculations account for the residual offset in x as well as the intended vertical offset or angle trajectory through the magnet. In the simulations, any photon reflections off the beam chamber were ignored because reflections are not included

Copyright © 2013 CC-BY-3.0 and by the respective authors

in the analytical model.

Figure 5 shows the comparison between the primary photon power calculated analytically and from the simulation. The incident power peaks at an offset of 2.8 mm. Then the power incident on the beam chamber drops to zero when the beam is offset more than 4 mm. The upstream undulator chamber shields the SCU0 beam chamber from the photon beam, similar to a photon absorber.

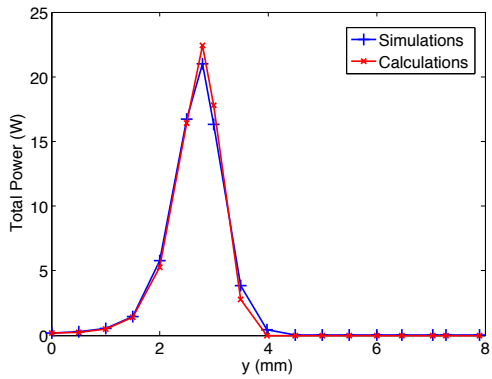

Figure 5: Analytical calculations and simulations of total synchrotron radiation power on the beam chamber wall for a vertical position offset in the upstream bending magnet.

Figure 6 is a comparison of analytical calculations and the corresponding simulations when an electron beam has a vertical angle through the upstream bending magnet. The incident power increases more slowly with just an angle offset in the electron beam. However, the maximum power is almost 4 times greater than an offset beam. The total power is greater for an angle because the highest-energy photons have the smallest opening angles from the electron beam trajectory. With an angle steering error the highest-energy photons intercept the beam chamber instead of passing though. Both sets of simulations have good agreement with the analytical values.

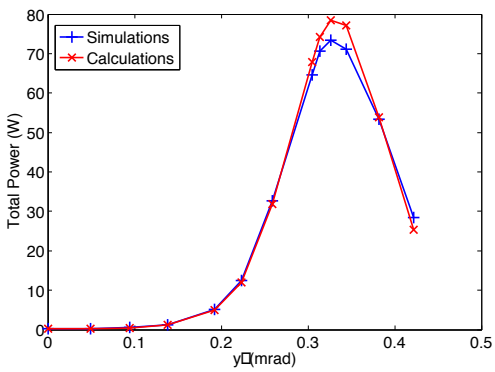

Figure 6: Analytical calculations and simulations of total synchrotron radiation power on the beam chamber wall for a vertical angle in the upstream bending magnet.

CONCLUSIONS

During user operation beam-position-limiting detectors are armed and limit the electron beam motion to ± 0.85 mm in x and ± 1.8 mm in y [8] at the exit of the bending magnet. According to the results shown here, the maximum power incident on the beam chamber is 25 W at these orbit limits, below the 40-W cooling capacity. Therefore, the greatest concern for radiation heating is during machine studies when the limits on beam motion are from the physical aperture of the beam chamber ($\pm 8 \times \pm 8.6$) mm [8]. Steering errors of this magnitude produce more radiation heating. To protect the SCU0 during machine studies, the current is turned off. Comparison of analytical calculations to simulations show that we have a good model for primary photon heating when the electron beam is off axis through the upstream bending magnet. In future work, photon scatting will be included in the analysis.

ACKNOWLEDGMENT

The authors would like to thank David Sagan and James Shanks for their guidance in running simulations in Synrad3d and BMAD.

THERMAL MODELING OF THE PROTOTYPE SUPERCONDUCTING UNDULATOR (SCU0)*

Y. Shiroyanagi, C. Doose, J. Fuerst, K. Harkay, Q. Hasse, Y. Ivanyushenkov, M. Kasa
Argonne National Laboratory, Argonne, IL 60439, USA

Abstract

A cryocooler-cooled superconducting undulator (SCU0) has been built, and cryogenic and magnetic tests have been completed. The device is currently installed in the Advanced Photon Source (APS) beamline. The device consists of a dual-core 42-pole magnet structure that is cooled to 4.2K with a system of four cryocoolers operating in a zero-boil-off configuration. In this paper, a thermal model of the beam chamber and its cooling circuit are presented. A temperature profile of the cooling circuit and heat load to cryocoolers are calculated based on steady-state temperatures. Comparison with cryogenic test results and future improvements will be discussed.

BACKGROUND

The superconducting undulator (SCU0) consists of a dual-core 42-pole magnetic structure that is cooled to 4.2K with a system of four cryocoolers operating in a zero-boil-off configuration. The design of the cryostat is based on a concept developed at the Budker Institute, Novosibirsk [1]. Figure 1 shows the overall cooling scheme of the cryostat. The beam chamber is cooled by the two bottom cryocoolers (Sumitomo RDK-408S) together with the inner thermal radiation shield, which is called the 20K circuit. The main and correction magnet leads and the thermal transitions of the beam chamber are connected to the first stages of all four cryocoolers through the outer thermal radiation shield, which is called the 60K circuit. The 4K circuit consists of the helium vessel, the magnetic structure, and the superconducting part of magnet leads. These are cooled by the 2nd stage of the top cryocoolers (Sumitomo RDK-415D). The magnet is cooled by circulating LHe, and it is thermally isolated from the beam chamber [2-4].

FEA MODEL

Finite element analysis (FEA) was conducted using ANSYS 14.5. Initially, heat loads at individual parts of the cryostat were calculated with fixed end temperatures. Thermal radiation heat was calculated in a separate model. Joule heating of the resistive parts of the current leads was also calculated separately. Then using these results, the 20K and 60K circuits were modeled including a simulated heat load imposed by the circulating electron beam. Temperatures and heat load at each cryocooler were calculated and compared with measured data. Table 1 is the calculated heat load of the individual parts of the cryostat based on the original design before the installation [1]. The 60K circuit heat loads are dominated by the magnet current leads. Static heat load through the main current leads are 47 W and through the correction current leads are 8.0 W. Main current lead heat increases to 63.85 W when they are energized to 650 A. The correction current lead heat increases to 12.2 W when they are energized to 70 A. Other sources include beam tube conduction and radiation from 295K to the outer shield. The 20K circuit heat loads are primarily the beam-induced heat load in the beam chamber that goes to the second stages of the bottom cryocoolers (408S) through the copper busbar and thermal links. The beam heat load is predicted to be 10 W at the 20K circuit and 6 W at the 60K circuit. The 4K circuit heat loads consist of the high-temperature superconducting (HTS) section of the magnet current leads, a very small portion of the beam heat through the beam chamber supports, heat through the cold mass supports made of Kevlar strings, and radiation from the inner shield to the cold mass.

In order to calculate the 20K and 60K circuit temperatures and heat, the magnet leads, the beam chamber, and the outer shield are modeled at steady state conditions. Figure 2 shows the overall temperatures of the 20K and 60K circuits as well as boundary conditions of this model. The outer shield is included in the calculation but not shown. Temperatures of the end flanges of the beam chamber and the top of the magnet leads are fixed at 295K. The coldest ends of the magnet leads are fixed at 3.42K, which is the measured temperature of the 2nd stage of the top cryocooler (415D). The load maps of the 1st stage top and 1st and 2nd stages of the bottom cryocoolers are implemented as temperature-dependent heat flow at each cold head.

Total	0.526	10.43	69.97 (91)

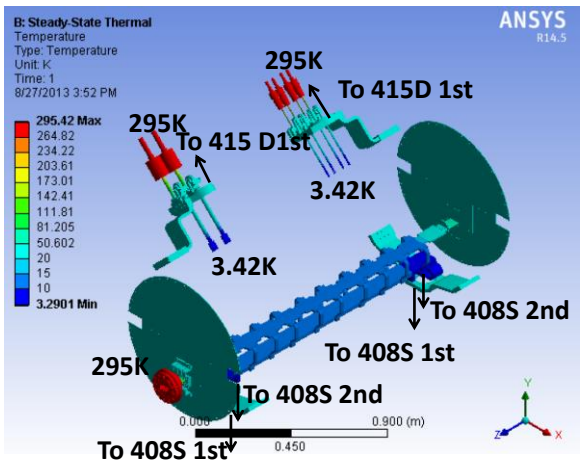

Figure 2: Calculated temperatures at the 20K and 60K circuits and their boundary conditions.

The cold head temperatures and heat loads at each cryocooler, except the top cryocooler 2nd stages, were calculated. The temperatures of the beam chamber were calculated based on the predicted beam-induced heat load [5,6]. The static heat load is calculated first, then the two dynamic heat loads. One is with beam on and the other is with both the beam and the magnet current on.

BEAM CHAMBER TEMPERATURES

Figure 3 shows the 20K circuit and the locations of temperature sensors. The sensors are numbered from the beam upstream to downstream. The main current leads are at the downstream side. Sensors 0 and 8 are on the stainless steel (SS) taper sections of the beam chamber while sensors 1 and 7 are on the stainless steel flat sections. These sections are linked to the outer shield and then to the 1st stages of the cryocoolers. The aluminum section is between the stainless-to-aluminum bi-metallic joints. Five sensors (2, 3, 4, 5, and 6) are on the aluminum section of the beam chamber and sensor 4 is near the center of the chamber. The aluminum section of the beam chamber is (thermally connected to the copper busbar through 20 copper links. The copper busbar is connected to the two bottom cryocooler 2nd stages (not shown).

Initially the beam heat was implemented in the model as a uniform heat flux in the beam chamber. However, the model calculated much lower temperatures at the stainless steel flat section than the measurement. So instead, the beam chamber inner surface is divided into three sections (aluminium, stainless steel flat, and stainless steel taper), and the heat load is applied based on S.H. Kim et al.'s beam-induced heat load calculation [5,6]. The SS taper heat load is 6.2 W, the SS flat heat load is 5.9 W, and the Al heat load is 4.7 W at 24-bunch mode and 100-mA beam current.

To reflect the circular beam shape, the beam chamber inner surfaces are divided into several strips and heat flux is distributed only on the center strips. The calculated temperatures are compared with the measurement by Harkay et al. in Fig. 4 [6]. For the static case, sensors 3 to 5 show ~7K. So the temperatures in the aluminum sections are uniform. Sensors 1 and 7 in the SS flat section are ~23K. When the beam current is on and the SCU magnet main current is at ~650 A, temperatures at sensors 2 and 6 rise above 20K since these are outside of the thermal links. Temperatures at 3, 4, and 5 rose to 13K. The SS flat sections 1 and 7 show as high as ~70K. Sensors 0 and 8 do not show the same temperatures in the measurement because the sensor positions are not known with sufficient accuracy. However, the average of these numbers agrees with the calculated values. So the calculated temperatures and measured temperatures have shown good agreement. Higher temperatures at sensors 1 and 7 suggest that more heat goes to the outer shield than originally designed [1]. An additional thermal link will be

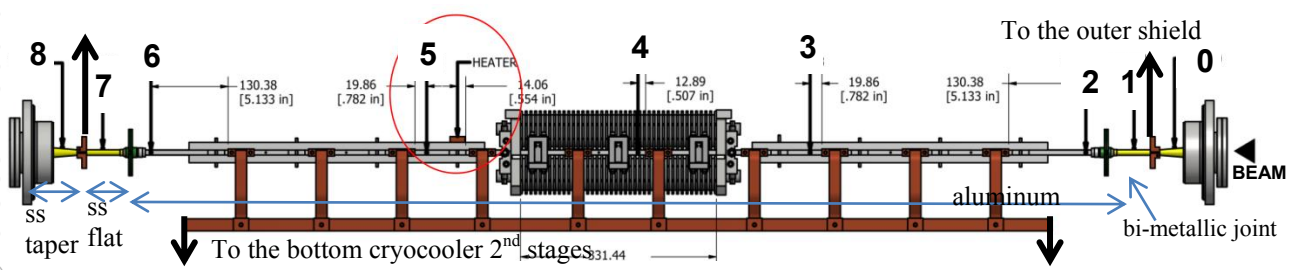

Figure 3: A schematic of the beam chamber, copper busbar, and locations of temperature sensors.

Copyright © 2013 CC-BY-3.0 and by the respective authors

attached to the end of the aluminum section of the beam chamber to lower the temperatures at sensor locations 1, 2 and 6, 7.

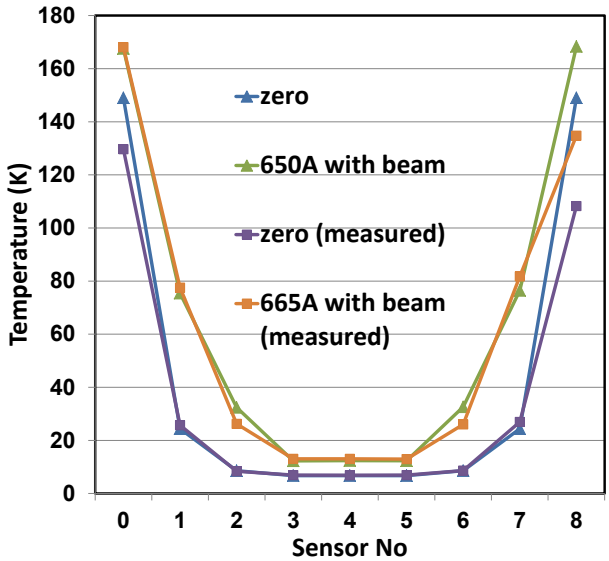

Figure 4: Calculated beam chamber temperatures are compared with measured temperatures.

COLD HEAD TEMPERATURES

Table 2 shows the calculated cold head temperatures based on the 20K and 60K circuit model and measured heat loads with 24-bunch mode beam and 665 A of SCU main current.

Table 2: Summary of Cold Head Temperatures [K]

	Static		Beam		Beam and current	
	Calc.	Meas.	Calc.	Meas.	Calc.	Meas.
TP1US	30.5	30.82	31.4	32.16	33.5	33.829
TP1DS	35.2	33.57	37.2	34.88	41.9	40.057
BT1US	30.0	30.18	30.9	32.16	32.7	33.736
BT1DS	31.1	30.83	32.3	34.88	34.7	35.116
BT2	6.75	6.715	10.38	10.09	10.40	10.335

In the actual system, the 20K circuit operates at ~10K and the 60K circuit at ~31K. The cold head temperatures show good agreement with measurement. Since measured heat is derived from the measured temperatures, the heat load at each cryocooler cold head agrees as well. A higher temperature at the top cryocooler downstream 1st stage (TP1DS) indicates the existence of a higher heat load from the main current leads. The bottom cryocooler downstream (BT1DS) also shows a slightly higher temperature than the upstream one (BT1US). However overall they are ~31K. So the magnet lead heat is well distributed to the 1st stage of all four cryocoolers as designed. A summary of heat loads is shown in Table 3. The 4K heat load is the sum of the heat loads of the individual parts from Table 1. The 20K and 60K heat loads are from the 20K and 60K circuit model. The calculated 60K static heat load was 63.66 W. The dynamic heat load with 650 A is 89.88 W. The measured static heat load is 63.01 W, and the dynamic heat load is 90.26 W. The calculated 20K heat load is 15.54 W due to the beam-induced heat. It agrees with the measured heat load of 15.09 W. Since the stainless steel flat sections show much higher temperature than expected, the beam heat going to the 60K circuit needs to be considered.

Table 3: Summary of Heat Loads [W]

	Static		Beam		Beam and current	
	Calc.	Meas.	Calc.	Meas.	Calc.	Meas.
4K	0.526	0.66	0.526	0.72	0.526	0.98
20K	0.188	-0.63	14.55	14.35	15.54	15.09
60K	63.66	63.01	68.13	68.0	89.88	90.26

DISCUSSION

The FEA calculated temperatures and heat loads show good agreement with the heat loads based on temperature measurements. The 4K heat load may include a larger error since the cryocooler load map does not have enough data points at this temperature range. The cryocooler cooling capacity is 3 W (1.5 W ea) at 4K, 40 W (20 W ea) at 20K, and 224 W (57 W ea for 415D and 55 W ea for 408S) at the 60K circuit. Thus, these heat loads are within the range. The 4K circuit model will be established in the next phase of this work. This FEA thermal model will be used for the future development of 1.1-m and 2-m devices (SCU1 and SCU2).

ACKNOWLEDGMENTS

We appreciate the useful discussions with L. Boon, R. Kustom, and S. H. Kim at the Advanced Photon Source. We also thank particularly Emil Trakhtenberg and Denise Skiadopoulos for the detailed design of the cryomodule.

MODERNIZATION OF THE BERGOZ MULTIPLEXED BPM SYSTEM FOR THE APS UPGRADE*

X. Sun#, R. Lill, H. Bui, R. Keane, G. Decker, B. Yang, ANL, Argonne, IL 60439, USA

Abstract

The APS upgrade includes improvements to the Bergoz Multiplexed BPM system, which presently suffers from an aging data acquisition system. The upgrade leverages off the development of an eight-channel data acquisition system featuring modern FPGA flexibility that was designed for the monopulse BPM system. This upgrade also provides an external clock signal synchronized to the APS revolution clock that will eliminate the aliasing caused by the Bergoz asynchronous multiplexing interacting with different accelerator fill patterns. The upgrade will revitalize this system and demonstrate a cost-effective approach to improved beam stability, reliability, and enhanced postmortem capabilities. In this paper we will discuss the upgrade system specifications, design, and prototype test results.

INTRODUCTION

The Advanced Photon Source Upgrade (APS-U) project includes improvements to the commercial narrowband (Nb) Bergoz multiplexed Beam Position Monitor (BPM) systems [1], which were installed in 2000. The APS storage ring now makes use of 80 Bergoz modules that are connected to 10-mm buttons on a large-aperture, standard elliptical (42 mm by 85 mm) vacuum chamber. This NbBPM system presently suffers from an aging data acquisition system. The upgrade leverages off the development of an eight-channel data acquisition system featuring modern field-programmable gate array (FPGA) flexibility that was designed for the monopulse BPM system [2]. The new FPGA-based Beam Signal Processor (BSP100) will replace the old data acquisition system and controls for the existing Bergoz receivers located at P1s on the standard elliptical vacuum chambers.

The upgrade will revitalize this system and demonstrate a cost-effective approach to improved beam stability, reliability, and enhanced postmortem capabilities.

The noise floor, fill-pattern dependence, and intensity dependence of the prototype upgrade NbBPM system will be investigated.

UPGRADE SYSTEM SPECIFICATIONS

Beam stability improvement is an important part of the APS-U project, which will be supported by new and upgraded BPM electronic systems. Listed in Table 1 [3] are APS-U beam stability performance and goals for ID sources. To achieve these goals, the obsolete BPM electronics for the NbBPM, located at the standard elliptical vacuum chambers, will be replaced with a modern system providing improved resolution and drift characteristics.

Table 1: APS-U Beam Stability Performance and Goals

* Measurement up to 767 Hz

DESIGN

The BSP100 is a standalone Experimental Physics and Industrial Control System (EPICS) input/output controller (IOC), an FPGA-based (Altera Stratix® II), a C-sized VXI form factor, with eight high-speed 14-bit digitizers (Analog Device AD6645) running at 88 MSPS (one-fourth of the APS rf frequency) [2, 4]. The baseline design replaces the aging Bergoz data acquisition with the BSP100. The position signals from four Bergoz BPMs will be digitized with a single module. The BSP100's FPGA has five major blocks, the APS timing system receiver, the acquisition control block, the preliminary processing block, the continuous signal processing block, and the triggered processing block.

The turn-by-turn average from the preliminary processing block, which is same as that in the monopulse BPM system, is passed through a first-order low-pass filter with a cutoff frequency of about 1.4 kHz. Then it is converted to the engineering units and sent to several other blocks for processing, as shown in Figure 1.

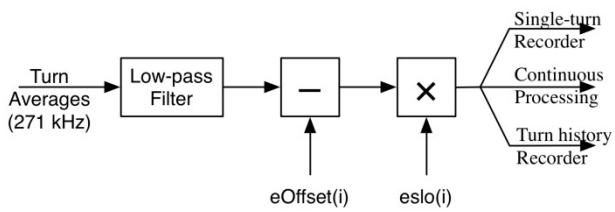

Figure 1: BSP100 Bergoz signal processing block diagram.

In the continuous processing block (shown in Figure 2), acquired data from the Bergoz BPMs will be available at EPICS rate and at a fast data stream. The BSP100

provides a 100-Mb/s TAXI-compatible link that carries data to the feedback system.

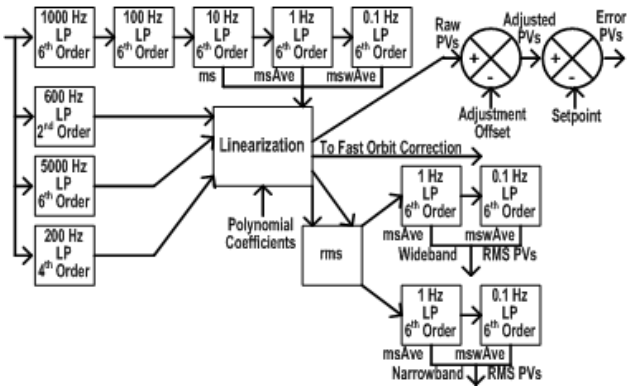

Figure 2: Continuous signal processing block diagram.

The BSP100 provides one second (262144 samples) turn-by-turn beam history, a virtual digital oscilloscope (4096 samples @ 88 MHz), single-turn acquisition, and slow beam history for machine studies and postmortems.

PROTOTYPE TEST RESULTS

The prototype of the NbBPM with BSP100 was installed at sector 38. The four 10-mm-diameter pickup electrodes were mounted on the standard elliptical vacuum chambers and connected to the 4-into-1-into-4 splitter with a variable attenuator between the four-way combiner/splitter, as shown in Figure 3. This setup minimized the physical noise from real beam motion, and only electronics noise was measured. Varying the attenuator simulated change in the intensity and noise.

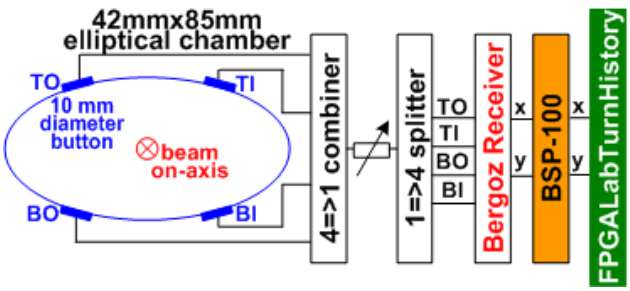

Figure 3: Measurements setup at Sector 38.

The signals from the 4-into-1-into-4 splitter combo went to the Bergoz receiver with BSP100 interface and simulated a beam on-axis. The FPGALabTurnHistory controlled the BSP100 module to clock the Bergoz BPM taking data using 324- or 24-singlet fills and eliminating aliasing lines caused by the Bergoz multiplexer beating against the fill pattern. The Bergoz receiver operated properly to an external frequency of 33.94 kHz, while varying an attenuator over the range 0 to 50 dB.

The sensitivities of 10-mm-diameter buttons in the standard elliptical chamber on horizontal and vertical planes are 0.058 mm^{-1} and 0.055 mm^{-1}, respectively [5]. The calibration factor formula of NbBPM is

$$d = \frac{1}{\text{Gain}} \frac{1}{\text{Sensitivity}}, \quad (1)$$

where d is the calibration factor, Gain is the Bergoz BPM module X/Y gain, and Sensitivity is the vacuum chamber sensitivity.

The gains of the Bergoz modules used in the measurement are $\text{Gain}_x = 0.148\text{V}/\%$ and $\text{Gain}_y = 0.161\text{V}/\%$.

The overall calibration factor of the NbBPM and the electronics system is 1.165 mm/V and 1.129 mm/V on horizontal and vertical planes, respectively. They were used in the following measurements.

The Fill Pattern Dependence

Figure 4 illustrated the root-mean-square (RMS) of the cumulative integral of the power spectral density (PSD) with 24- or 324-singlet fill patterns on the vertical plane. It shows the fill pattern dependence. The performance on the horizontal plane was similar.

The Intensity Dependence

Figures 5 and 6 represented the RMS of the cumulative integral of the PSD for various attenuations on the horizontal and vertical planes with 24- or 324-singlet fill patterns, respectively. They show the intensity dependence.

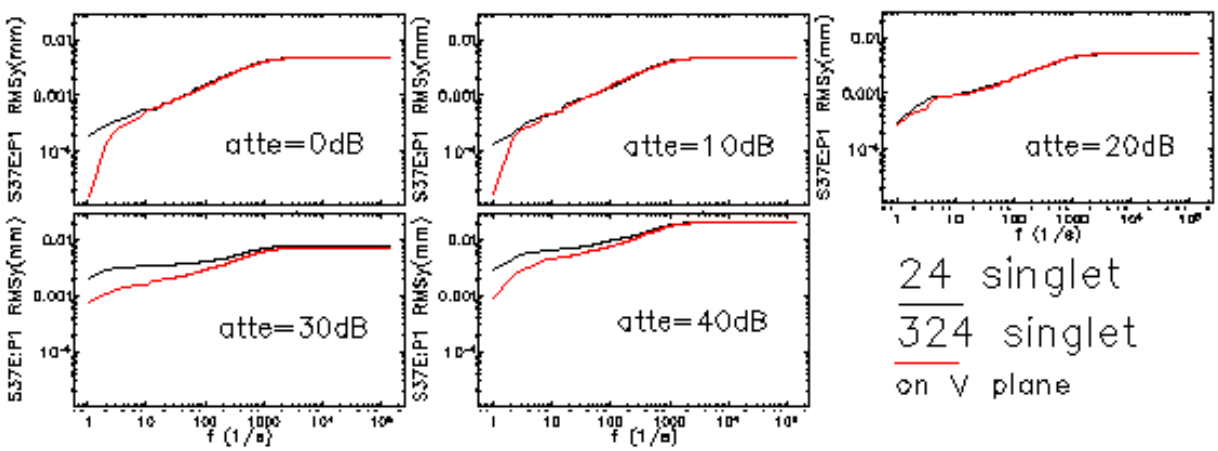

Figure 4: Cumulative RMS for different fill patterns on the vertical plane.

Copyright © 2013 CC-BY-3.0 and by the respective authors

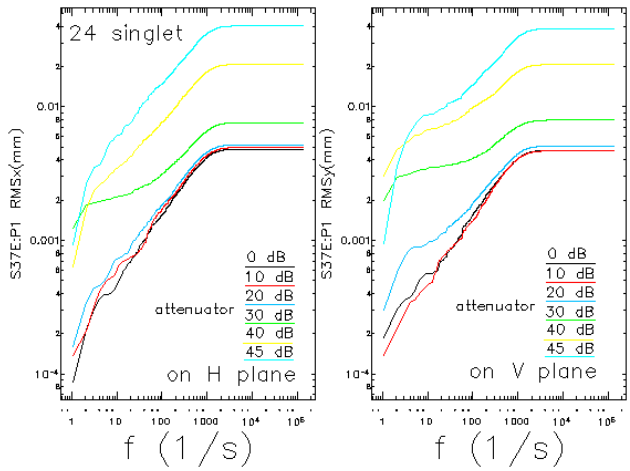

Figure 5: Cumulative RMS for different intensities with a 24-singlet fill.

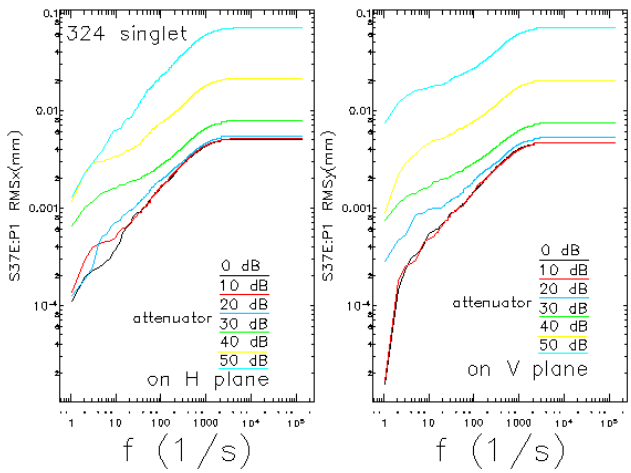

Figure 6: Cumulative RMS for different intensities with a 324-singlet fill.

The Synchronous and Asynchronous

Using the existing data acquisition system, aliasing spikes were observed in some P1 NbBPMs located at the standard elliptic vacuum chambers. The aliasing is caused by the beating of the Bergoz internal clocks with various other processing clocks residing within the NbBPM chassis and by different accelerator fill patterns, especially the hybrid fill pattern [6].

The upgrade prototype with BSP100 was provided an external clock signal synchronized to the APS revolution clock with the expectation of eliminating the aliasing. The noise data were taken with the 24-singlet fill pattern, shown in Figure 7.

There is no obvious difference on the vertical plane at sector 38 for the 24-singlet fill pattern with and without the external clock synchronized to the APS revolution clock. It may be because the aliasing appeared serious only in some sectors, especially for a hybrid fill.

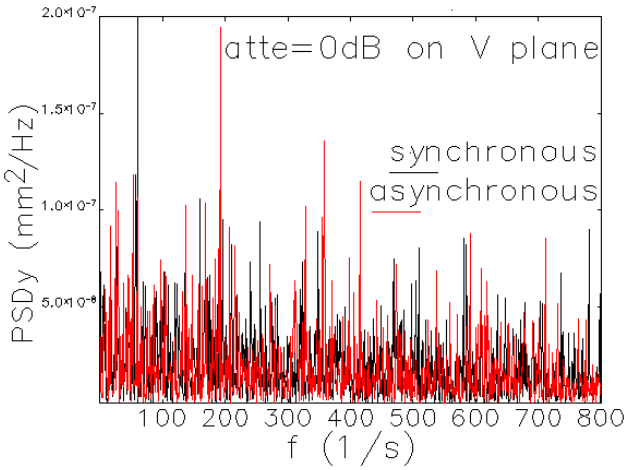

Figure 7: PSD for a 24-singlet fill on the vertical plane with and without the external clock synchronized to the APS revolution clock at sector 38.

SUMMARY

Using the 4-into-1-into-4 splitter with a variable attenuator between the four-way combiner/splitter, a prototype of an NbBPM with BSP100 was connected to the 10-mm-diameter buttons mounted on the standard elliptical chamber. A varying-intensity on-axis beam was simulated by changing the attenuator. The noise was measured with 24- and 324-singlet fill patterns. The intensity dependence and fill-pattern dependence were studied. More data for different fill patterns and off-axis beam will be conducted in the future.

ULTRA-HIGH VACUUM SEAL FOR LONG CHAMBERS USING WIRE SEALS*

H. Fernandes#, P. Cappadoro, T. Corwin, D. Harder, P. He, C. A. Kitegi, W. Licciardi, M. Musardo, G. Rakowsky, J. Rank, C. Rhein, and T. Tanabe,
National Synchrotron Light Source II, Brookhaven National Laboratory, Upton, NY 11793, USA

Abstract

As the length of insertion devices (ID's) increase for synchrotron light sources, so does the need to have larger ultra high vacuum (UHV) sealed chambers, which in turn necessitates the use of creative ways of sealing these large chambers in the UHV range (10^{-11} torrs).The method specified below was used to seal a 4-meter test vacuum chamber successfully in the ultra high vacuum range. This method could be used for sealing ID chambers of lengths larger than 4 meters in the UHV range due to its simplicity and reduced cost advantage. This test chamber was also baked for 3 cycles to check for the integrity of the seals and final vacuum levels.

INTRODUCTION

The ultra high brightness NSLS-II storage ring is under construction at Brookhaven National Laboratory. It will have 3GeV, 500mA electron beam circulating in the 792m ring, with very low emittance (0.9nm.rad horizontal and 8pm.rad vertical). Significant increases in brightness requirements for the third generation ID has led to increased length of ID and hence increased length of vacuum chambers. The wire seal method outlined below depicts a way of sealing these long vacuum chambers in a cost efficient way. Other sealing methods for chambers such as Helicoflex ™ seals, metal gaskets, metal O-ring seals and differential pumping methods were studied as potential sources for sealing large vacuum chambers (>2.5 meters) [4]. Of these methods, only the wire seal made it to manufacturing, testing and optimization; the other methods were ruled out due to their high cost, difficulty in manufacturability by vendors due to low production quantities, or failure to meet UHV requirements in terms of operational efficiency and difficulty in installation. The wire seal was able to seal a 4-meter-long vacuum chamber in the UHV range and was also able to maintain the same vacuum specifications during and after baking. Here, we outline the procedure used to seal a 4 meter test vacuum chamber, specify the test results for this chamber, and mention possible methods to improve the wire seal.

TEST CHAMBER CONSTRUCTION SPECIFICATIONS

The seal was tested on a 4-meter test chamber that had a modular design. This design reduces the cost of the R&D chamber to a minimum, as it consists of mainly steel plates. The modular design of the vacuum chamber consists of a base plate as shown in Figure 1. A spacer plate has grooves cut for o-ring seals, which are placed between the front plate and the back plate. The distance between the front plate and the base plate is 0.75". This is maintained to a minimum in order to keep just enough room for bowing of the chamber inwards.

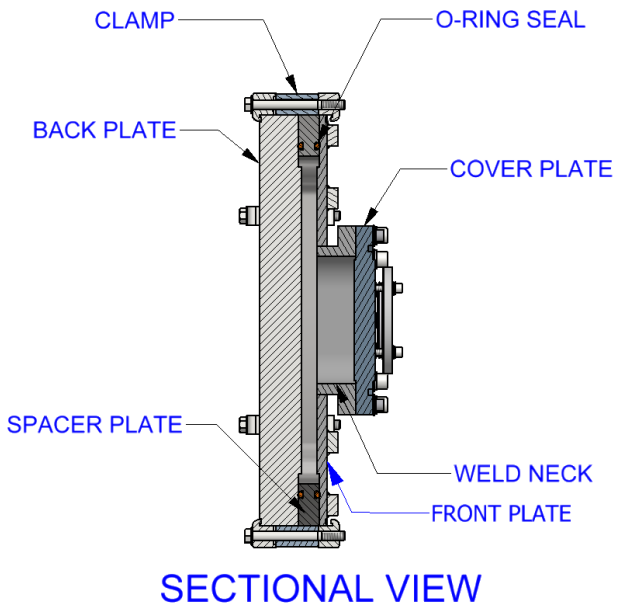

Figure 1: Construction details of test chamber.

O-ring seals were used on either side of the spacer plate to seal the spacer plate with the front plate and back plate. A weld neck was welded onto the front plate. During the first phase of the testing procedure, the top surface of the cover plate and the mating face of the weld neck were polished to 32 micro-inches surface finish because a wire seal would be placed and tested on this surface. During the second phase of the testing procedure, the two mating surfaces were polished to a 16 micro-inch surface finish. The length of the testing surface for the wire seal is approximately 3.6 meters. The entire vacuum chamber from end to end is 4 meters, as shown in Figure 2 below. Stiffening ribs were welded onto the surface of the front plate toward the cover plate. The main reason for the stiffening ribs was to have a chamber with adjustable stiffness which could be either increased or decreased by inserting stiffeners along the length of the stiffening ribs.

Copyright © 2013 CC-BY-3.0 and by the respective authors

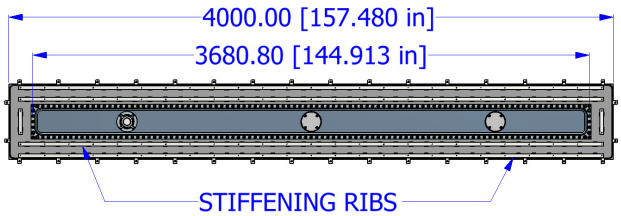

Figure 2: Construction details of test chamber.

In order to seal the face, it is essential to have a regular bolting pattern for the sealing face. 3/8 inch socket head cap screws along with washers were used with spacing between the bolts of 1.457 inches [2], as shown in Figure 3 below. At each of the corners of the cover plate, two set screws were used in order to prevent the cover plate from coming in contact with the wire during initial alignment. The set screws were loosened initially, so as to maintain a gap of more than 1 mm, which is the thickness of the wire.

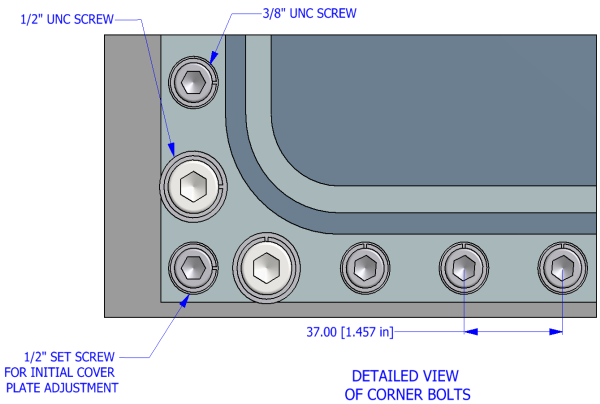

Figure 3: Corner bolt configuration.

Four wire seal adjusting fixtures are set at each end of the cover plate. The wire fixtures are designed such that the tension in the wire as well as the position with reference to the wire placed on the cover flange is adjustable using spring-held linkages, as shown in Figure 4. This design is a novel idea to adjust the tension in the wire seal, which in turn helps reduce sag in the wire, as well as positioning it as close as possible to the bolting pattern. This is a critical component in the installation and testing process, as the position of the wire has direct effects on the attainable vacuum pressure within the chamber.

Two annealed wire seals (aluminum) of different purity were tested on this chamber. Pure aluminium (99.95% pure and 1 mm thick), as well as pure aluminum (99.995% pure and 1 mm. thick, and much softer than the former) were tested.

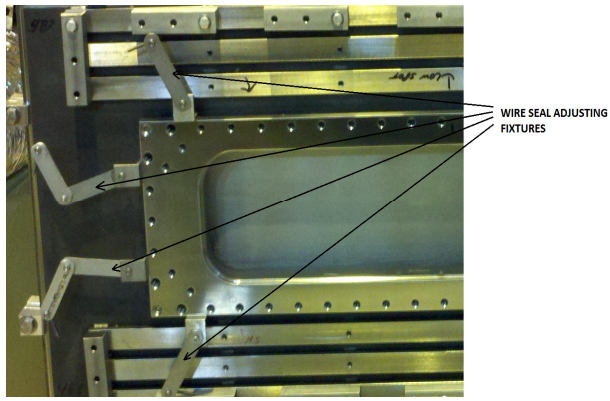

Figure 4: Wire seal adjusting fixtures.

TESTING PROCEDURE

The chamber was tested in the vertical position in order to replicate the actual ID chambers sealed while in operation. This also helps in determining the effect of sag of the wire, which is maximum at the center of the 3.6-meter sealing face.

The O-rings were placed in the spacer plate groove and the corresponding back plate and front plate were aligned with the spacer plate. Clamps were then installed to seal the back plate, spacer plate, and front plate. The cover plate was then aligned with the bolting pattern of the mating bolting pattern of the weld-neck flange. Wire seal adjusting fixtures were then installed with the wires and their position was adjusted with the linkages. It is critical to have the wire not more than 1/8 of an inch away from the edge of the center bolting hole.

Figure 5 illustrates the wire position with reference to the cross bolting hole pattern. Since the maximum sag in the wire is at the center, the wire would be further away from the edge of the center bolting hole. It is absolutely essential to adjust the tension and position in the wire, which in turn helps in keeping this distance to a minimum. Observations have shown that this is the critical position where vacuum leaks occur in the UHV range, if the wire seal is not aligned well during installation. The custom-designed dual linkage Wire Seal Adjusting Fixtures help in aligning and tensioning the wire to the correct tension and position.

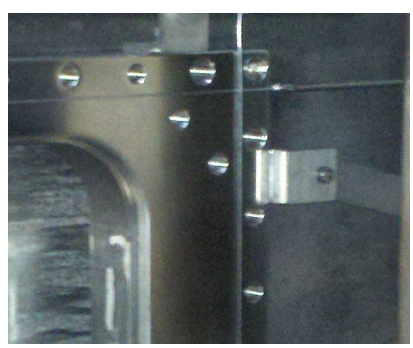

Figure 5: Cross wire configuration at the corner.

Copyright © 2013 CC-BY-3.0 and by the respective authors

At the cross point of the wire seal, as shown in Figure 5, ½-inch bolts were used to provide the required torque necessary to bolt the chamber at the cross point seal . A definite bolting pattern was followed, as mentioned by Savino [2]. The bolting sequence mentioned by Savino [2] helps in moving the crushed wire material away from the center and towards either end of the chamber. This is essential to maintain a uniform seal. The chamber was then pumped down to the UHV range through pump ports on the cover plate. A leak test was done to determine if the chamber was UHV compatible. This was followed by three baking cycle tests.

BAKING PROCEDURE

The chamber was then baked in an oven to 150 degrees C. This was done to replicate the actual baking procedure for all ID vacuum chambers at NSLS-II and study the effect of baking on the wire seal. During the baking process, the temperature was ramped to 150 degrees C in steps of 10 degrees per minute from a room temperature of 25 degrees C [1]. The pressure within the chamber was monitored during the entire baking process. The chamber was baked for a period of approximately 4 hours at 150 degrees C. The chamber was then left to cool down in the oven for a day. The vacuum chamber was then removed from the oven and tested for leaks. Three bake cycles were carried out on this chamber.

RESULTS AND CONCLUSION

Softer annealed aluminum wire seal which is 99.995% pure gave the same results as 99.95% pure wire. An important factor for UHV seals for large vacuum chambers was the surface flatness. The first test was conducted on a 32 micro-inch surface finish, which sealed the chamber. Chambers were leak tested to approx. 1.9×10^{-10} Torr Lit/sec. However, there were a few leaks observed at critical points, mainly around the center of the chamber where the sag in the wire was maximum, as well as around surface imperfection where the 32 micro-inch surface finishes were not maintained. These leaks were negotiated by increasing the torque on the bolts in this area and testing for leaks [5]. These leaks spots would seal if this process was used. However, on polishing the surface to 16 micro-inch, better results were obtained wherein the chamber was leak tested to 6.9×10^{-11}Torr Lit/sec, an improvement of ~ 64 %, compared to the 32 micro-inch surface finish.

It was also observed that the vacuum chamber pressure reduced from 2.15×10^{-5} Torr to 8.7×10^{-6} Torr, as seen in Figure 6, when the surface finish was reduced from 32 micro-inches to 16 micro-inches. This value is dependent on the elastomer O-ring seal. The position of the seal from the bolt edge also affects the seal. For optimal results, it was observed that the wire seal should not be placed any more than 1/8" away from the edge of the sealing bolt. Bolts used for sealing should have washers, and it is advisable to have bolts with maximum permissible torque (>250 inch-lb),; in case of a leak at certain spots, torquing down the bolts around the leak spots would mostly seal the leak. Vacuum levels of 10^{-6} torrs were obtained, as shown in Figure 6. After the first baking cycle, a few leaks were noticed at the edges; these were eliminated by progressively tightening the bolts in sequence. On doing so, vacuum level was maintained to the 10^{-6} torr range after the second and third baking cycle.

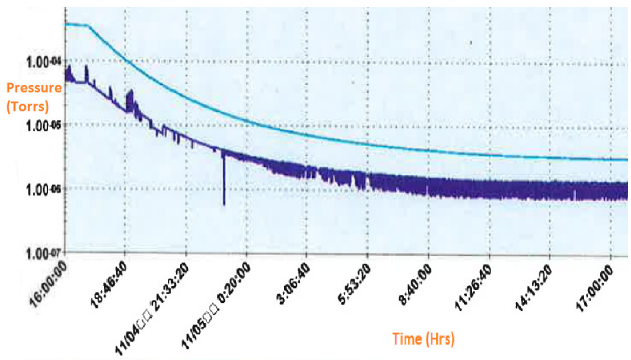

Figure 6: Pressure measurement.

ACKNOWLEDGMENT

The authors are grateful to key personnel at GNB, mainly Eric Raymond(Production Manager), Ken Harrison(President) and Larry Gilbert of Vacuum Solutions Group for manufacturing and conducting preliminary tests on the vacuum chamber as well as machining it to the specifications required by BSA.

The authors are also grateful to Jim Savino from CHESS for all the valuable support and feedback in designing and testing the vacuum seal test system.

The work at Brookhaven Nationals Laboratory was supported by the U.S. Department of Energy, Office of Science under contract 171565.

DESIGN AND TESTING OF FARADAY'S CUP FOR NSLS-II LINAC AND BOOSTER*

H. Fernandes#, B. Belkacem, W. Cheng, W. Guo, B. Kosciuk, J. Rank, S. Sharma, O. Singh, T. Tanabe and G. Wang
National Synchrotron Light Source II, Brookhaven National Laboratory, Upton, NY 11793, USA

Abstract

NSLS-II will provide 500 mA, 3 GeV beam of 1 nm emittance. It's planned to have top-off operation. To ensure bunch uniformity and constant current, the precise measurement of the charge becomes necessary. There are three Faraday Cup's at the end of the transport line in the Linac and Booster transport lines which serve this purpose. The details of the design consideration are presented in this paper. The Diagnostic group at NSLS-II, designed, prototyped and tested the Faraday Cup (FC). Power density calculations and FEA simulations were carried out for the three cases.

INTRODUCTION

At NSLS-II, the FC's serve as a beam dump and a charge measuring device, therefore we have three such devices at the end of each of the test beamlines. The beam energy in the Linac area is 200 MeV [1]. The beam size at FC1 and FC2 in the Linac transport line was found to be 0.2 mm horizontally and 0.5 mm vertically. Figure1 below indicates the location of FC1 and FC2 in the Linac area. Figure 2 indicates FC3 in the Booster area. The beam energy in the Booster area is 3 GeV with a beam size of 2.3 mm in the horizontal direction and 0.27 mm in the vertical direction.

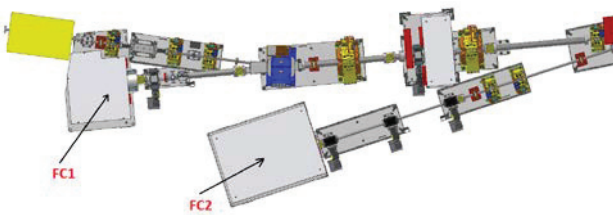

Figure 1: Location of Faraday's Cup in the linac area.

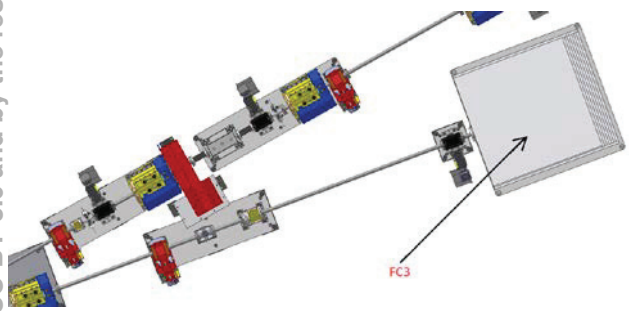

Figure 2: Location of the Faraday's Cup in booster area.

- Different devices are used to measure beam current. One way to measure the total charge of the beam in normal operation is by non intercepting devices such as current transformers (ICT, and DCCT). This non destructive method is independent of beam energy. These devices have to be calibrated to a device that will collect the totality of the electrons. For this reason an FC have to be installed close to the device to be calibrated (unknown losses between the two instruments introduce systematic errors).
- Another method to measure the charge is by using FCs. In this case, we need to stop and dump the electron beam for a certain period, preferably at full energy and bunch repetition rate. FCs are installed at the end of the transport lines. The beam will be sent to the FC during beam tune ups. Beam stops are used to absorb the entire beam.

MECHANICAL DESIGN

The designed Faraday Cup consists of a beam stop (graphite and copper pieces), which is essentially used to stop the beam. This is followed by a beam dump (stainless steel pieces). Details of this design are indicated in Figure 3.The radiation shower produced after stopping the beam must be absorbed. This is achieved by using layers of lead and borated polyethylene sheets. The third most critical component of the Faradays cup is its electrical circuit, which consists of an integrator followed by a digitizer. The ceramic brake isolates the beam dump from the rest of the assembly. The charge is measured by integrating the output voltage across the ceramic break. The beam dump consists of six plates which are one inch thick made of SS-304 and are bolted together. A knife-edge seal would ensure that the integrity of vacuum is maintained. This is machined on the first plate face of the SS-304 plate.

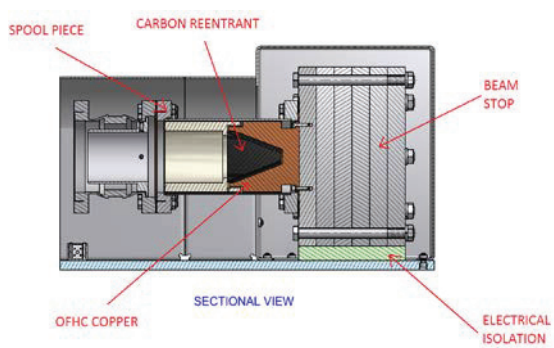

Figure 3: Construction details of FC.

Copyright © 2013 CC-BY-3.0 and by the respective authors

A carbon graphite cone is used mainly to reduce backscatter after beam stop shower. A spool piece is used to attach the components downstream of the beam stop. To prevent ozone generation, the front of the cup is in vacuum. Lead bricks are used for blocking the radiation and these bricks are surrounded by High Density Polyethylene (HDPE) sheets for shielding neutron radiation. The thickness of the lead and poly shields is based on the Linac and Booster beam parameters and was determined using Monte Carlo simulation. Typical lead and HDPE shielding configuration is shown in Figure 4. Shielding was provided in layers of lead and poly thickness to each of these dumps to block the radiation remaining from the steel plates, which is around 67.6KeV for FC3. The carbon re-entrant cone was machined at a cone angle of 30 degrees [2].

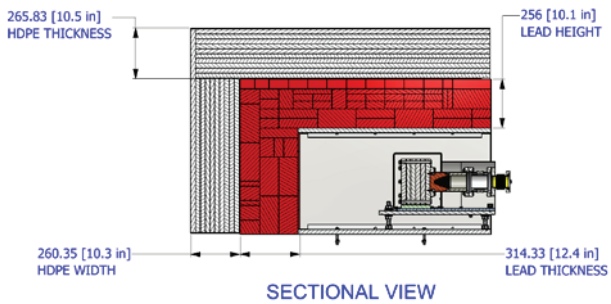

Figure 4: Shielding thickness for FC.

TESTING AND CALCULATION RESULTS

While penetrating the layers of the Faraday's Cup, the electrons interact with the material atoms both elastically and inelastically. For electrons with energy higher than tens of Mev, the energy loss is mostly through Bremsstrahlung, and can be well described by

$$E(x) = E_0 e^{-x/x_0} . \quad (1)$$

Where E0 is the initial energy and the radiation length

$$X_0 = \frac{716.4A}{Z(Z+1)\ln(287\sqrt{z})} g \cdot cm^{-2} . \quad (2)$$

With A as the atomic number and z the charge number.

The beam divergence, however, is mostly affected by the frequent Coulomb scattering with the nucleus. The angle growth rate is given by

$$\Delta\theta = \frac{13.6MeV}{\beta cp} z\sqrt{x/x_0}\,[1+0.038\ln(x/x_0)] . \quad (3)$$

To calculate the heat deposition and radiation issues, we consider FC3, which is subjected to most severe conditions. The initial beam size is calculated from the lattice functions, i.e., the emittance from the Booster is 40/4 nm in x/y; the relevant lattice functions at the entrance of the dump are $\beta_{x/y}$ =128.2/176.0, and $\gamma_{x/y}$=1.7/1.0. The subsequent angle and beam size were obtained by integrating Eq.(3). The beam property for FC3 is summarized in the following table.

Table 1: Beam Parameters through Materials for FC3

Material	L mm	X_0	ΣX_0	E_0 eV	σ_x mm	σ_y mm
start	0	0	0	3G	2.3	0.27
Graphite	76.8	0.45	0.45	1.9G	10	2.8
Copper	23.8	1.65	2.1	0.36G	44	23.4
Steel	151.2	8.6	10.7	67.6K	*	*

*The beam turns into a shower at the end of the steel plates. Beam size was also calculated based on the thicknesses and materials of each of these components. For the Linac FC, the beam size on the graphite surface was found to be an ellipse of 20 mm width and 24 mm height. The beam power is deposited on the surface as a conservative approximation. As can see in fig. 3, for a charge of 15 nC in the linac area, the maximum temperature was found on the graphite is 35 Degree C.

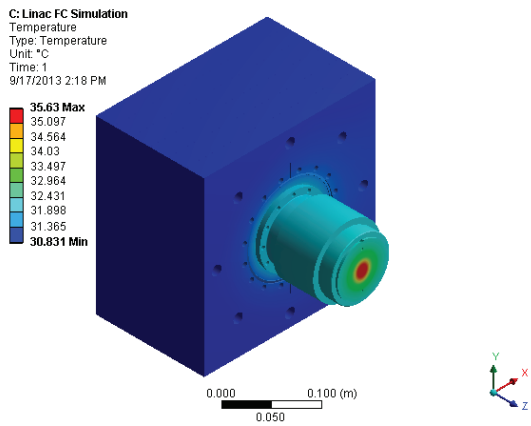

Figure 5: FEA simulation of linac transport line FC.

For the Booster FC, considering the charge of 10 nC, the total power was around 30 W, with maximum Temperature of around 196 Degree C.

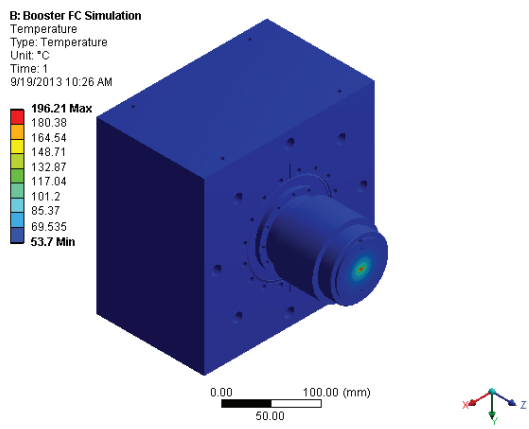

Figure 6: FEA simulation of booster transport line FC.

DESIGN OPTIMIZATION

Ensuring the accuracy of charge measurements require careful attention and accounting for all the error sources. In reality there are multiple reasons for electrons losses that must be considered during the design phases.

Copyright © 2013 CC-BY-3.0 and by the respective authors

- Penetration losses: Adequate size (radius and length) of the beam stop with a safety margin was calculated for preventing penetration losses. The design ensures that the width of the dump is 5 times the radiation length on both sides.
- Backscatter losses: The conical shape of the beam stopper reduced the electrons escape solid angle [3]. Graphite used has a low atomic number than the high Z value which helps the beam stop to slow the incoming beam and allow all the particles to flow to the conductive dump.
- Current leakage: Charge leakage due to insufficient impedance to ground may occur in the FC system: FC itself (support structure and enclosure), RF cables, integrator, or digitizer. The insulation is made of very high resistance material (G10 plate 0.75 inch thick). A known source was connected in parallel to the Faraday cup during integration tests, and leakage charge was found to be negligible (< 1pC).

BEAM MEASUREMENT

An RC network integrates the cup output voltage for measurement by a digitizer DC252 (4GS/channel, 2 GHz bandwidth, 10 bit resolution). The FC will be used to cross check the ICT's reading. To reduce signal loss, a low loss RF cable LMR900 is used to connect the FC to the digitizer. Figure 7 illustrates the bloc diagram of the FC system. The charge is calculated by integrating the voltage pulse area over a designated region of interest (ROI). $Q = \frac{1}{R}\int v.dt$, where R = digitizer input impedance. The digitizer output waveform is displayed in the control room from the appropriate CSS panel. Figure 8 is a screen shot of beam measured by the transport line FC2.

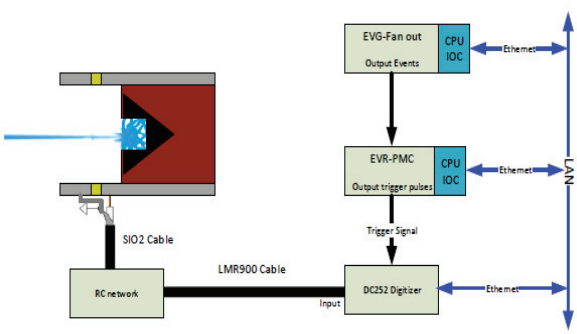

Figure 7: Block diagram of the FC measuring system.

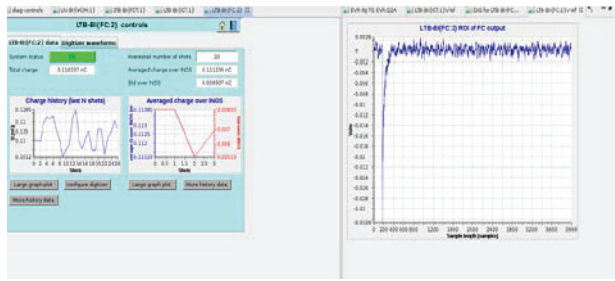

Figure 8: Transport line FC measured beam.

Figure 9: BINP FC VSWR measure- 20 GHz span.

CONCLUSION

During LINAC commissioning we have seen that FC1 does capture close to 100% of the beam seen at ICT1, while FC2 captures about 85% of the beam (FC1 closer from ICT1 than FC2). To measure the time structure of the beam FC1 will be replaced in the future by a wide bandwidth coaxial Faraday cup [3].

The heat simulation studies outlined above also indicate that the booster dump is much hotter than Linac dump but well within the melting point of graphite, hence a safe design.

PREPARATION AND INVESTIGATION OF ANTIMONY THIN FILMS FOR MULTI-ALKALI PHOTOCATHODES

X. Liang, M. Ruiz-Osés, I. Ben-Zvi, Stony Brook University, Stony Brook, NY, 11794, USA

Abstract

Multialikali antimonide photocathodes exhibit high quantum efficiency in the visible light range, with low thermal emittance and are excellent candidate materials for high average current next generation ERLs or high repetition rate FELs. Although these materials have some excellent characteristics, control of the growth mode of the thin film and ultimately the surface roughness is difficult and will affect the emittance that can be obtained in high gradient fields. Being the first step in multi-alkali photocathode growth, the morphology of Sb films was investigated. X-ray diffraction pole figure (PF) measurement was used to determine the crystallinity of the Sb films. The measurements were complemented by atomic force microscopy (AFM) to determine the roughness and particle size. This study demonstrates how minor changes in deposition rate, thickness and substrate temperature can influence the Sb film properties.

INTRODUCTION

A.H. Sommer discovered that alkali metals such as Sodium (Na), Potassium (K), combined with antimony (Sb) result in photocathodes with high sensitivity and wide spectral response. Although methods for producing high QE films were established long ago, the remaining problems are mainly how to achieve good stoichiometric control so that long wavelength behaviour is reproducible and how to make very smooth films as required for high gradient photoinjectors. A collaboration of Stony Brook University, Brookhaven National Lab and Lawrence Berkeley National Laboratory aims to improve the performance of alkali antimonide photocathodes by using the tools of modern materials techniques such as X-ray diffraction (XRD), grazing incidence small angle X-ray scattering (GI-SAXS), X-ray reflectivity (XRR), AFM and X-ray photoelectron spectroscopy (XPS). [1-5]

This report will focus on recent progress in the analysis of the relationship between evaporation rates, film thickness and roughness.

EXPERIMENTALS

Ex-situ X-ray diffraction pole figure measurement was performed at the National Synchrotron Light Source (NSLS) X20A beam line at Brookhaven National Laboratory (BNL). For the PF measurement, the incident X-ray flux is approximately $8*10^{10}$ photons/second and the energy of the X-rays is 8.05KeV (λ = 1.5406Å). The size of the incident X-ray beam is 0.7 mm high and 0.7mm wide. The incident angle at the center of the linear detector was 20 degrees.

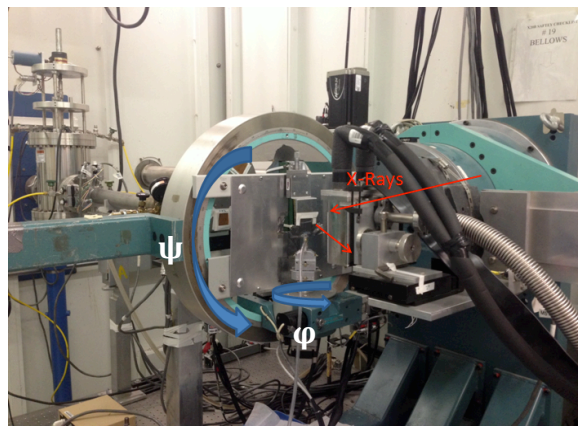

Figure 1: The experimental set up at the X20A beam line at NSLS. The beam line has a 4 circle Huber diffractometer, here just ψ and φ are moveable.

Si (100) wafers were used as the substrate, and all wafers were cleaned using hydrofluoric acid (HF), rinsed in deionized water and dried. The deposition was performed in a UHV chamber with a base pressure of 4×10^{-9} mbar; a Pfeiffer® Prisma QMG 200 residual gas analyzer (RGA) was used to monitored contaminants during growth. Values of H2O never exceeded 5.8×10^{-10} mbar, and CO/CO2 partial pressures were $< 1\times10^{-10}$ mbar during deposition. Deposition rates were monitored using an INFICON® quartz crystal film thickness monitor (FTM).

Surface topography was measured in air over a 1.5 × 1.5 micron area using a Nanosurf® Easyscan 2 AFM with a pyramidal Si (A-CLA mode) probe in BNL building 911 room 210A.

GROWTH PROCESS AND ANALYSIS

Ex-situ XRD PF measurement has been used to characterize the phases and texture changes of Sb thin films. The substrate size of 2cm ×1cm was used. Sb thin films were deposited on these in the UHV chamber by thermal evaporation, with the Sb being evaporated from

PtSb beads. To cover a wide range of growth parameters, Sb films were deposited at different evaporation rates at 100C substrate temperature. For each evaporation rate, film thicknesses of 3nm and 10nm were produced; see table 1.

Table 1: Sb Thin Film Sample Preparation

Sample	Evaporation Rate	Thickness
a	0.2Å/s	3nm
b	0.2Å/s	10nm
c	0.4Å/s	3nm
d	0.4Å/s	10nm
e	1Å/s	3nm
f	1Å/s	10nm

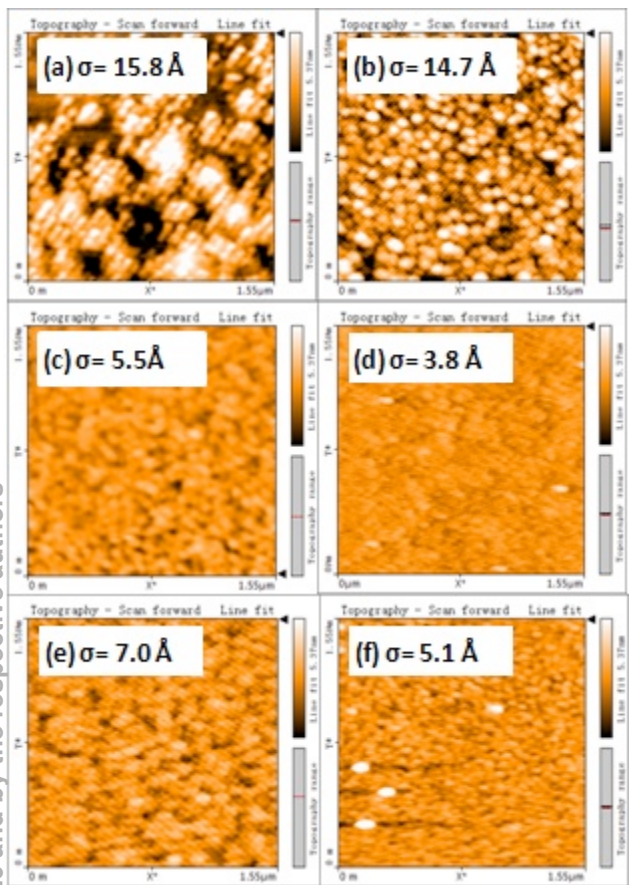

Figure 2: surface topography of six samples. (a) 0.2 Å/s, 3nm , σ=15.8Å;(b) 0.2 Å/s, 10nm, σ=14.6Å; (c) 0.4 Å/s, 3nm, σ=5.5Å; (d) 0.4 Å/s, 10nm, σ=3.8Å; (e) 1 Å/s, 3nm, σ=7.0Å; (f) 1 Å/s, 10nm, σ=5.1Å.

Figure 2 shows the topography and rms roughness of the sample. In general, the highest roughness values were measured for the lowest (0.2Å/s) evaporation rate samples. With the same evaporation rate, thicker films were smoother.

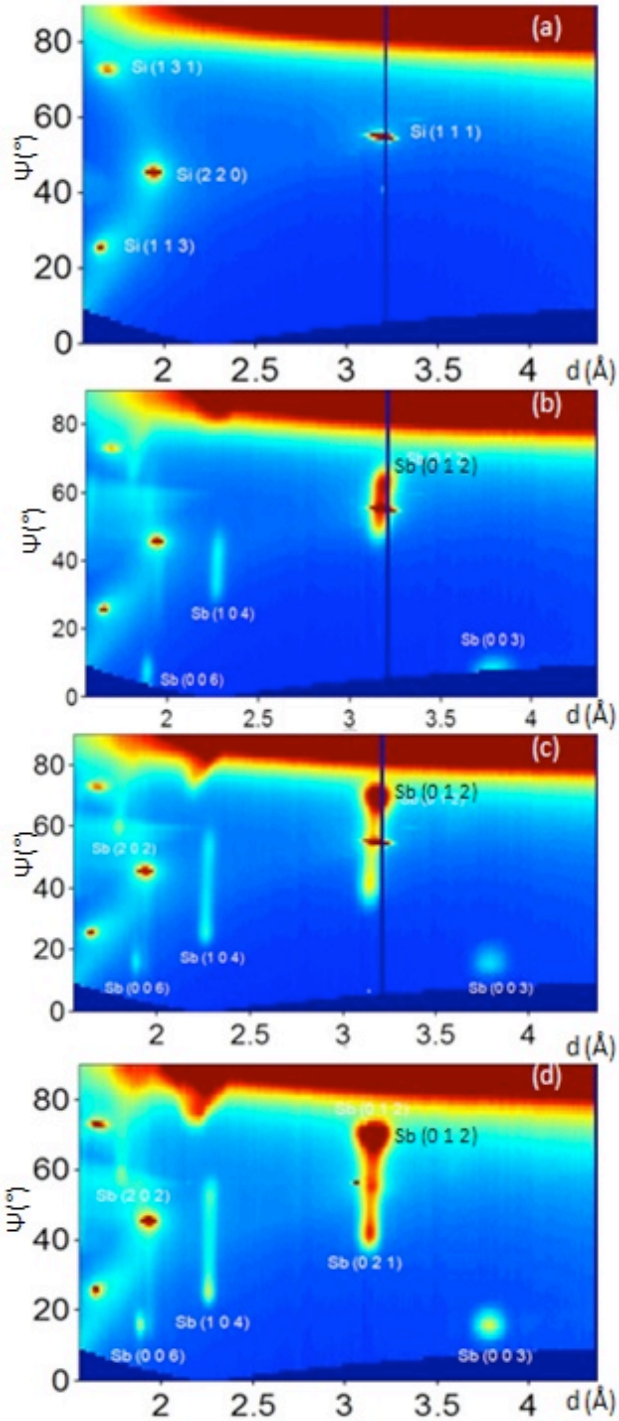

Figure 3: 2D reciprocal space maps; d is the spacing between the planes in the atomic lattice. (a) 0.2 Å/s, 3nm (b) 0.2 Å/s, 10nm; (c) 0.4 Å/s, 10nm; (d) 1 Å/s, 10nm.

The reciprocal space for the Sb films was acquired using radiation with λ=1.5406Å. In these measurements, the incidence angle ω=20° and 2θ=40°. Figure 3 shows the 2D reciprocal space maps. From these graphs, the crystal structure of the thin films can be identified. Figure 3 (a) shows an example of a 3nm Sb film. From this graph, strong Si diffraction peaks were detected. Si (131),

(220), (113) and (111) planes can be identified. No Sb peaks were found from films of this thickness, as their thickness was less than the critical thickness for an amorphous to crystalline transition in this material. Figure 3(b) is for a 10 nm Sb film evaporated at 0.2Å /s corresponding to fig 2 (b); the diffraction peaks for the (012), (003), (006) and (104) planes are visible. (c) 10 nm Sb film evaporated at 0.4 Å /s corresponding to figure 2(d); this is the same as (b) but the (202) and (021) diffraction peaks are present. The intensity of other Sb peaks such as (012) (104) and (003) are increased. The strongest crystalline features are exhibited by the 10 nm Sb film evaporated at 1 Å /s, see figure 3(d); this figure is corresponds to figure 2(f). In figure 3(d), the diffraction intensity of plane Sb(0 12) is the highest.

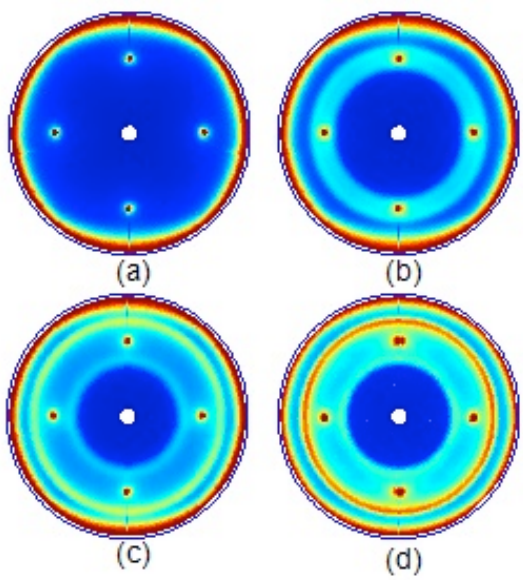

Figure 4: Pole figures of four samples with the same d-spacing. (a) 0.2 Å/s, 3nm; (b) 0.2 Å/s, 10nm; (c) 0.4 Å/s, 10nm; (d) 1 Å/s, 10nm.

Figure 4 presents the pole figure covering a range in d-spacing values from 3.0812 Å to 3.1435 Å. These values cover the Sb (012) peak. (a), (b), (c) and (d) respectively corresponding to figure 3 (a), (b), (c) and (d). The sharp spots in the image correspond to the Si (001) peak. As shown on (a), the background intensity observed is nearly flat and showed no Sb crystalline features. From (b) to (d), the ring structure due to polycrystalline Sb became narrower and sharper, perhaps due to the increase of particle size, though figure 3 makes it clear that there are two (012) orientations present in (c) and (d).

CONCLUDING REMARKS

The evolution of the crystalline structure and topography of Sb films with different evaporation rates and thicknesses at a substrate temperature of 100C has been investigated via X-ray diffraction pole figure and AFM measurements.

AFM measurements indicate the final surface roughness is mainly affected by the evaporation rate. The highest roughness values were measured at the lowest deposition rate of 0.2Å/s. Multi-alkali photocathodes are usually grown from Sb films. In order to avoid a high roughness surface, high deposition rates should be used.

Pole figure measurement shows that the deposition rate affects the crystallinity of the Sb film. The thickness also influences the final texture of the Sb film. When the Sb thickness is small, there is no fiber texture. When approaching a film thickness of 10nm, a significant fiber texture develops.

A wide parameter space still remains to be investigated, such as using different substrate temperatures and a wider range of deposition rates. The specific relationship between the initial Sb layer structure, roughness and the final performance of the cathodes also needs to be determined. Further to this, other sources of roughness will be measured, such as that which results from thin film strain on reaction with K and Cs.

SIMULATION AND OPTIMIZATION OF MULTI-SLIT BASED EMITTANCE MEASUREMENT FOR BNL ERL*

C. Liu†, D. Gassner, D. Kayran, M. Minty, P. Thieberger, BNL, Upton, NY 11973, USA

Abstract

A code for determining the beam emittance from a multi-slit image has been developed. To verify its validity, we simulated a beam distribution in 4D phase space at the multi-slit position and the resulting image at a downstream profile measurement device. We applied the algorithm to this image pattern to recover the beam emittance at the slit position. The dependence of the relative difference of the inferred emittance and the input emittance on the slit width and drift length are studied in detail and presented in this report.

INTRODUCTION

At the BNL ERL, a multi-slit device will be used for direct measurement of two dimensional beam phase space, which samples particles at discrete horizontal (or vertical) positions and projects the sampled beam on a downstream screen. The beam size and divergence of the sampled beam can be determined using the image acquired by the downstream profile device and the mask pattern dimensions. The emittance of the beamlets sampled by the multi-slit mask will be shown to be representative of the emittance of the beam incident on the mask. Here we will present the algorithm and its application using simulated data, and a study of geometry-dependent systematic errors in the inferred emittance.

ALGORITHM

The schematic for a multi-slit emittance measurement device is shown in Fig. 1. The incoming beam is sampled by a multi-slit mask. Beamlets formed by the mask project onto a profile measurement device and the resulting image is recorded. The beam size at the slits can be determined by the dimension of the slit pattern and the intensity of the beamlets. The beam divergence can be determined by the intensity distribution on the profiler.

The well accepted rules for multi-slit mask design [1, 2] are: the slit spacing is chosen such that beam is divided to 4-8 beamlets; the slit width is as narrow as possible as limited by current fabrication techniques; the drift length between mask and profiler is such that beamlets will spread out on the profiler until they overlap; the mask thickness is thick enough to stop most incoming particles; and the opening angle of the slit is comparable to the anticipated beam divergence.

Detailed formulas for slits emittance measurement can be found in Ref. [3]. The projection of the recorded image is usually treated as a multi-Gaussian distribution. The average divergence of each beamlet is calculated based on slit positions and peak positions. The rms divergence of the beamlets is calculated from the rms of the fitted Gaussian peaks. Suppose we get three arrays of parameters from multi-Gaussian fits of the projection, a, b and c, which are the intensity, peak position and sigma of the peaks. The slit positions are represented by an array x. The centroid of the beam at the mask is $< x >= \frac{1}{\sum_{i=1}^{n} a_i} \sum_{i=1}^{n} (a_i * x_i)$, here n is the number of beamlets. The rms size at the mask is

$$< x^2 >= \frac{1}{\sum_{i=1}^{n} a_i} \sum_{i=1}^{n} (a_i * (x_i - < x >)^2)$$

The average divergence of the beamlets is given by $x'_i = (b_i - x_i)/L$. The average divergence of the sampled beam is $< x' >= \frac{1}{\sum_{i=1}^{n} a_i} \sum_{i=1}^{n} (a_i * x'_i)$. The rms divergence of the beamlets is $\sigma'_i = c_i/L$. The rms divergence of the sampled beam at the mask is

$$< x'^2 >= \frac{1}{\sum_{i=1}^{n} a_i} \sum_{i=1}^{n} (a_i * \sigma_i'^2 + a_i * (\sigma'_i - < x' >)^2)$$

The position angle correlation term is

$$< xx' >= \frac{1}{\sum_{i=1}^{n} a_i} (\sum_{i=1}^{n} a_i * x_i * x'_i - \sum_{i=1}^{n} a_i < x >< x' >)$$

Then the emittance is calculated by

$$\epsilon = \sqrt{< x^2 >< x'^2 > - < xx' >^2}$$

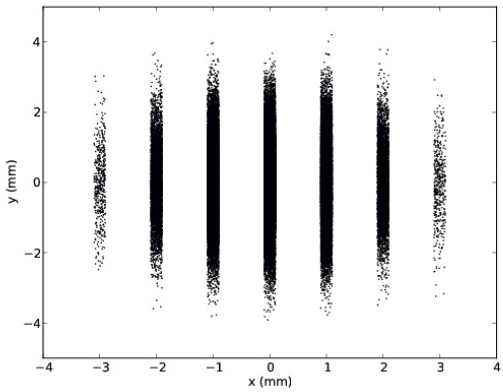

Figure 2: The intensity distribution of sampled beamlets at the mask.

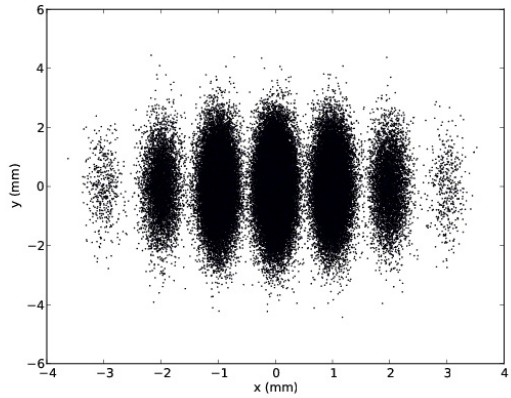

Figure 3: The intensity distribution of sampled beamlets at the profiler for a drift length of 0.15 m.

SIMULATION

It turns out to be difficult to implement cylindrically non-symmetrical masks in particle tracking code. Therefore, a standalone Python code has been developed to simulate a beam distribution in phase space and to track the distribution through a drift space. Space charge effects are not considered. The statistical error is minimized by generating and tracking 500,000 particles. The density distribution is set to be Gaussian in 4D phase space with standard deviation of 1 mm for position and 1 mrad for divergence for both planes (numbers are chosen according to the expected BNL ERL beam parameters). In the following, we will try to recover horizontal emittance with the algorithm presented in previous section.

The exact horizontal emittance of initial beam is 1.001 mm·mrad. The vertical multi-slit mask is designed with a slit width of 0.1 mm and a spacing between slits of 0.9 mm. One of the slits is set to be centered on the beam. The intensity distribution of the sampled beamlets at the mask is shown in Fig. 2. The horizontal emittance of the sampled beam is 0.998 mm·mrad. This shows that the sampled beam represents the real beam well in terms of emittance.

After propagation in a drift space (L =0.15 m), the beamlets project onto a profiler (YAG screen for the BNL ERL) with a 2D image shown in Fig. 3.

The projection of the 2D image at the profiler on the horizontal plane produces a 1D distribution of multiple quasi-Gaussian peaks. A Python program fits the distribution to multiple Gaussian peaks (a good approximation for our case with narrow slits). In the process, one finds the intensity of each beamlet, rms width and peak location. The Gaussian fits of the original distributions are shown in Fig. 4. The calculated emittance is 1.067 mm·mrad.

Slit Width Dependency

The Gaussian peak assumption and calculation of rms divergence of beamlets are possible due to the fact that the slit width is relatively small. Therefore, the finite slit width may introduce a systematic error in the final determined beam emittance; in principle, the narrower the slit, the closer the measured and real emittances will be. We studied the slit width dependency of the retrieved beam emittance with results shown in Table 1. In these simulations, the sum of slit width and slit spacing is kept constant at 1 mm so that total number of beamlets is always seven. Real emittance refers to the emittance of the initial beam, the sampled emittance is the emittance of the beam sampled by multi-slit mask, the simulated emittance is the emittance determined by the algorithm introduced. Deviation refers to the relative difference between simulated emittance and sampled emittance.

The slit width correction has been developed and will be presented in a separate note.

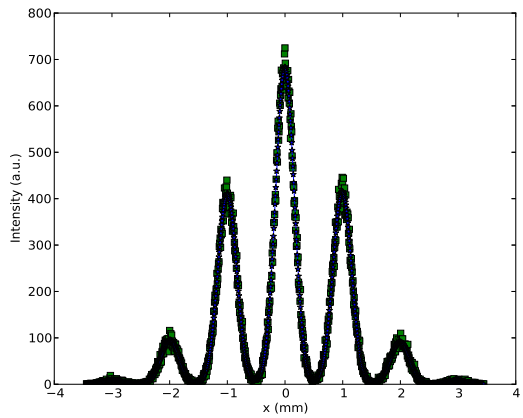

Figure 4: The horizontal projection of 2D image on the profiler and its multi-Gaussian fitting for a drift length of 0.15 m.

Drift Length Dependency

Slit widths smaller than 80 µm are difficult to produce due to mechanical fabrication limitations. For the BNL ERL, the slit width is designed to be 100 µm. One other parameter which has impact on the simulated emittance is the drift length. The well accepted criteria is that the drift length should be long enough until the beamlets overlap.

Table 1: Slit Width Dependency of Simulated Emittance

Slit Width	Slit Spacing	Drift Length	Real Emittance	Sampled Emittance	Simulated Emittance	Deviation
0.05 mm	0.95 mm	150 mm	1.000 mm·mrad	0.993 mm·mrad	0.996 mm·mrad	0.3 %
0.08 mm	0.92 mm	150 mm	1.000 mm·mrad	0.995 mm·mrad	1.009 mm·mrad	1.4 %
0.10 mm	0.90 mm	150 mm	0.998 mm·mrad	0.991 mm·mrad	1.012 mm·mrad	2.1 %
0.12 mm	0.88 mm	150 mm	1.003 mm·mrad	1.006 mm·mrad	1.037 mm·mrad	3.1 %
0.15 mm	0.85 mm	150 mm	1.001 mm·mrad	0.993 mm·mrad	1.037 mm·mrad	4.4 %

Table 2: Drift Length Dependency of Simulated Emittance

Slit Width	Slit Spacing	Drift Length	Real Emittance	Sampled Emittance	Simulated Emittance	Deviation
0.10 mm	0.90 mm	100 mm	1.002 mm·mrad	1.005 mm·mrad	1.043 mm·mrad	3.8 %
0.10 mm	0.90 mm	120 mm	1.003 mm·mrad	0.997 mm·mrad	1.024 mm·mrad	2.7 %
0.10 mm	0.90 mm	150 mm	1.000 mm·mrad	0.997 mm·mrad	1.013 mm·mrad	1.6 %
0.10 mm	0.90 mm	180 mm	0.998 mm·mrad	0.990 mm·mrad	0.998 mm·mrad	0.8 %

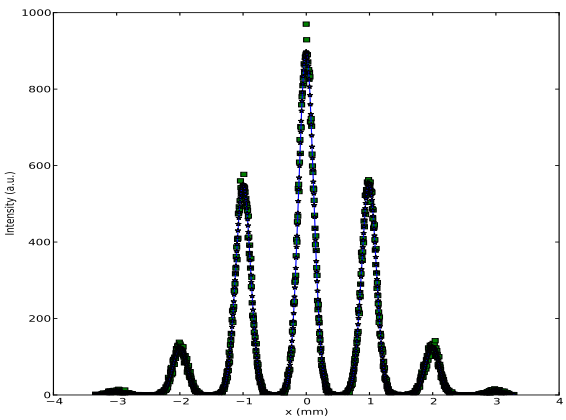

Figure 5: The horizontal projection and its multi-Gaussian fitting for drift length 100 mm case.

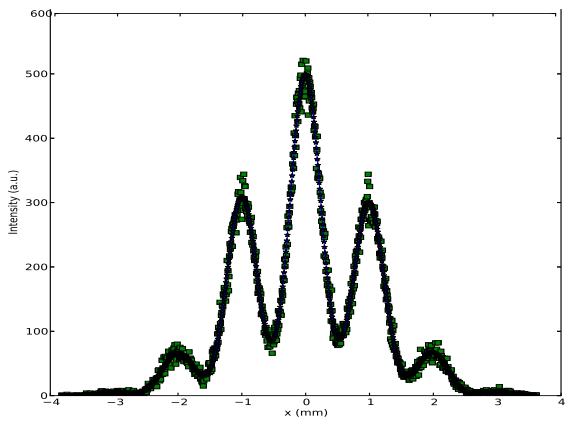

Figure 6: The horizontal projection and its multi-Gaussian fitting for drift length 230 mm case.

The following study explores the drift length dependency with results shown in Table 2.

The horizontal distribution and its multi-Gaussian fitting for 100 mm and 230 mm drift length are shown in Fig. 5 and 6. The beamlets overlap significantly with each other at a 230 mm drift length. We were able to determine a more accurate emittance from the fitting at 230 mm than at 100 mm. We believe this is due to the fact that the slit width contribution is less when the drift length is longer. Therefore, beamlet overlap is acceptable and desirable as long as reasonable fitting can be produced.

SUMMARY

We developed a program for analyzing a multi-slit image for emittance measurement. The functionality was verified in simulations. From these we conclude that the narrower the slit width the better precision of the emittance measurement and that beamlets overlap on the profile screen is to some extent desirable. In the future, we will include space charge effects in the simulation.

3D HALL PROBE CALIBRATION SYSTEM AT INSERTION DEVICE MAGNETIC MEASUREMENT FACILITY AT BNL *

M. Musardo#, T. Corwin, D. Harder, P. He, C. A. Kitegi, W. Licciardi, G. Rakowsky and T. Tanabe,
National Synchrotron Light Source II, Brookhaven National Laboratory, Upton, NY 11793, USA

Abstract

Hall probes are commonly used to measure local magnetic field, however they need to be calibrated. This paper describes the accurate 3D Hall probe calibration system developed by the NSLS-II Insertion devices group. The calibration system and the calibration curves are presented. An Arepoc 3D Hall probe used to characterize the Insertion Devices (IDs) has been calibrated. The probe contains three sensors oriented perpendicular to each other in order to measure three components of the magnetic field. The three Hall sensors are mounted on a circuit board and their active area dimensions are 0.05 mm x 0.05 mm with a linearity error up to 1 T less of 0.2%.

INTRODUCTION

The 3D Hall probe calibration system consists of a GMW dipole electromagnet, a precision magnet power supply system, a nuclear magnetic resonant teslameter (NMR) and a motorized probes supporting stage.

In order to perform an absolute and precise calibration, the Arepoc 3D Hall probe must be positioned in a known magnetic field. The coordinate frame of the probe is indicated in Fig. 2. Sensor 1 is perpendicular to z direction (longitudinal direction), sensor 2 is perpendicular to x direction (horizontal direction) and sensor 3 is perpendicular to y direction (vertical direction).

HALL PROBE CALIBRATION SYSTEM

GMW dipole electromagnet (see Fig. 1) and a low noise and high stability Danfysik System 8500 Power Supply are used to create a constant and uniform magnetic field in the region around the point midway between the coils. The maximum magnetic field obtained with a current of 140 A at pole gap of 30 mm is of about 2.148 T and the uniformity achieved is of 110 ppm in 10 mm^3. The magnet and the power supply are water cooled.

A Metrolab PT-2025 NMR Teslameter System (Fig. 1) precisely measures the absolute magnetic field produced by the GMW dipole magnet. It is based on the nuclear magnetic resonance effect and achieves 5-ppm absolute accuracy and 1mG resolution for measurements in the range from 430 G to 137 kG. A multiplexer with different NMR probes is used, because the magnetic field value could be in one of several probe's ranges. So the proper NMR probe needs to be chosen and positioned within the magnetic field in the right position. A motorized *NMR Probe Supporting Stage* (see Fig. 3) is used to manage the NMR probe and to position it in the center of the electromagnet.

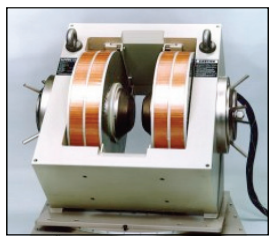

Figure 1: GMW dipole electromagnet and metrolab NMR teslameter.

An integrated digital multimeter is used to measure the Hall voltages of the sensor under calibration and a *Hall Probe Supporting Stage* (see Fig. 4), needed to move and rotate the probe during the calibration, provides precise controlled linear and angular motions in all required directions.

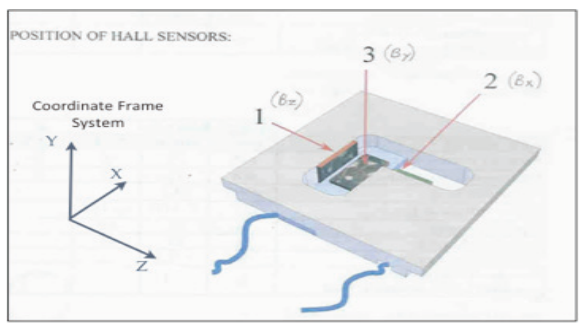

Figure 2: Coordinate frame system.

The system is linked to a PC via GPIB for the NMR teslameter and a serial interface for the power supply and motion control system.

The control system synchronizes the readings of the sensor's voltage with the NMR probe signal and collects and processes the measurement data.

CALIBRATION PROCEDURE

Hall probe's output signal is a voltage that is proportional to the strength of the magnetic field in which the probe is placed. The calibration curve is a function that relates the Hall voltage to the strength of the field. For a 3D Hall probe is necessary to determine separate calibration curves for each of the three sensors. Knowing the calibration curve, you will be able to use the probe to measure the strength of an arbitrary magnetic field in the calibration range. The system calibration procedure includes the following steps: *System Setup*, *Alignment* and *Calibration.*

In the System Setup step the connections of all devices must be checked and powered on. After the setup, the system needs to be properly aligned before calibration scan can be executed. Alignment of the sensors into the electromagnet consists in three following steps:

- Align the NMR probes in the center of the electromagnet.
- Align the Hall probe in the rotating stage.
- Adjust the probes so that they are parallel to the electromagnet surfaces.

Imperfect alignment obviously leads to an underestimate of the field. Therefore is important to align the Hall probe as well as possible. Instead alignment is not an issue for the NMR probe, which measures the total magnetic field.

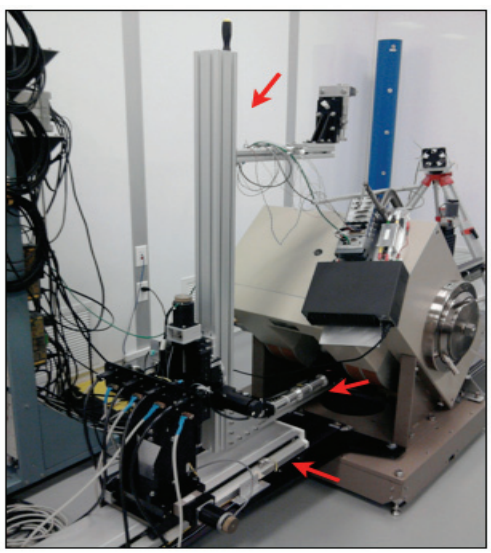

Figure 4: Hall probe supporting stage

The angular alignment of the Hall sensors with the transverse magnetic field of the electromagnet is made rotating the sensor around the z-axis and the y-axis until to maximize the reading of the multimeter (Hall probe voltage). In this way the deviation of the sensor from the perpendicular field direction can be reduced, because it is very sensitive to misalignment.

The calibration positions of the sensors along to the direction of the magnetic field of the electromagnet are obtained by rotating the probe of 90˚ around the axis of sensor. If the sensors are precisely perpendicular to the direction of magnetic field of the electromagnet then the maximum Hall voltage is measured. In this way for each sensor in the proper calibration position were determined the alignment angles.

A Hall sensor is not only sensitive to perpendicular magnetic field component $\mathbf{B}_{\perp}$, but also to the parallel component $\mathbf{B}_{\parallel}$. If magnetic field vector is not precisely orthogonal to the Hall probe, an additional voltage is added to the Normal Hall voltage (V_{NH}), due the field component in the plane of Hall sensor. This is known as Planar Effect (V_{PHE}) [1].

$$\begin{aligned} V_{NH} &= GR_H IB_{\perp} \\ V_{PHE} &\propto IB_{\parallel}^2 Sin(2\xi) \end{aligned} \qquad (1)$$

For low magnetic field (< 2T), the basic equation describing the relation between the local electric field **E,** the local current density **J** and the flux density **B** in a Hall sensor is given, neglecting the anisotropy effect, by

$$\mathbf{B} = \rho J - R_H(\mathbf{J}\times\mathbf{B}) - M\rho\mathbf{B}\times(\mathbf{B}\times\mathbf{J}) \qquad (2)$$

where ρ is the material resistivity, R_H is the Hall coefficient an M is the transversal magnetoresistance coefficient. The Hall voltage and the Planar effect are calculated from equation 2 and for materials with a low carrier mobility, the equation that describing the Planar Hall voltage may be written as [3]:

$$V_{PHE} = \frac{M\rho}{2t} IB^2 Sin^2\Theta Sin(2\xi) \qquad (3)$$

where t is the plate thickness, I is the applied current, Θ is the angle between B and axis perpendicular to the sensor and ξ is the angle between $\mathbf{B}_{\parallel}$ and the current.

To remove this error during the calibration, two configurations are considered: *Normal* and *Reverse* position. The *Reverse* position is obtained with a rotation of 180˚ around the orthogonal direction of the magnetic field of electromagnet. In *Reverse* position the polarity of the magnetic field and the Hall voltage changes sign, but does not change the planar Hall voltage, because is proportional to the square of the field. So the difference of the two voltages removes the Planar Effect:

$$\begin{aligned} V_{NH} &= \frac{V^{Norm} - V_H^{Rev}}{2} \\ V_{PNH} &= \frac{V^{Norm} + V_H^{Rev}}{2} \end{aligned} \qquad (4)$$

Copyright © 2013 CC-BY-3.0 and by the respective authors

The calibration step, for each sensor, can be described with the following operations:

1. Select the current on the Magnet Power Supplies System.
2. Choose the relevant probe according to the magnitude of the field.
3. Place the proper NMR probe at the center of the electromagnet.
4. Start the measurement scans with NMR teslameter in *Automatic Mode*: This mode sweeps the radio frequency over the whole range of the FINE potentiometer. This represents a variation of ± 5 % of the frequency actually selected by the COARSE potentiometer [2].
5. Read the NMR magnetic field locked.
6. Place the Hall sensor in the center of the electromagnet at alignment angles. Read the *Normal Hall Voltage.*
7. Rotate the sensor of 180º around the orthogonal direction of magnetic field in order to have the *Reverse* position.
8. Read the *Reverse Hall Voltage.*
9. Change the current of electromagnet and repeat the previous steps for whole calibration range.
10. Rotate the sensor of 90˚ respect to each other, in order to have the next calibration position and repeat previous steps.

The calibration was performed in the measurements range ± 1.9 T. The calibration at zero field was done using a zero-gauss chamber.

AREPOC CALIBRATION CURVE

The magnetic field from Hall probe voltage measurements can be written as: $B=f(V)$, where B is magnetic field, V is the voltage of Hall sensor and $f(V)$ is a nonlinear function: $f(V)=K_0+K_1V+...+K_nV^n$.

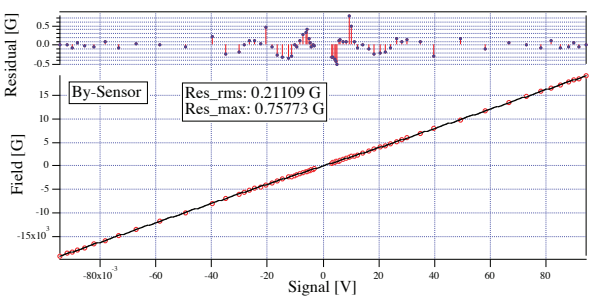

Figure 5: Calibration curve of By-sensor.

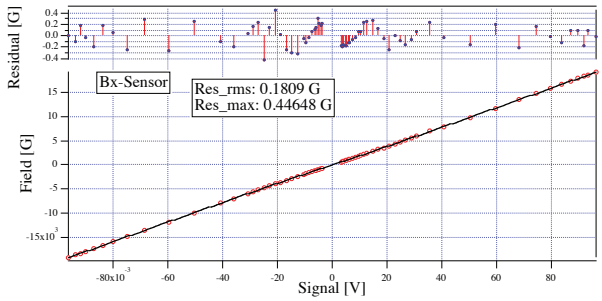

Figure 6: Calibration curve of Bx-sensor.

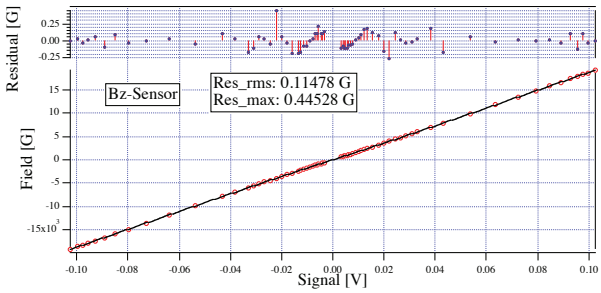

Figure 7: Calibration curve of Bz-sensor.

A polynomial fit of $B=f(V)$ was done to determine the coefficients (see Fig. 5, 6 and 7). Using the equation 4, the voltage due to the Planar Hall effect was cancelled. The best order of the polynomial fit is the minimum value that does not involve significant changes to the residual. The main nominal parameters of the probe (current 10 mA) are shown in table 1.

Table 1: Main Nominal Parameters

Sensors	Sensitivity [mV/T]	Offset Voltage [µV]
By-Sensor	63.3	< 60
Bx-Sensor	64.7	< 100
Bz-Sensor	66.9	< 20

CONCLUSION

The 3D Hall probe calibration system has been successfully used to calibrate an Arepoc 3D Hall probe. The system works very well and is capable of calibrating probes with high degree of accuracy.

NSLS-II MAGNETIC MEASUREMENT SYSTEM FACILITY*

M. Musardo#, T. Corwin, D. Harder, P. He, C. A. Kitegi,
W. Licciardi, G. Rakowsky, J. Rank, C. Rhein and T. Tanabe,
National Synchrotron Light Source II, Brookhaven National Laboratory, Upton, NY 11793, USA

Abstract

The National Synchrotron Light Source II at Brookhaven National Laboratory (BNL) is a storage ring of 3 GeV electron beam energy that will provide ultra high brightness and flux and exceptional beam stability using advanced insertion devices (IDs). The magnetic characterization of these devices is important to achieve these performances. In order to perform precise and accurate measurements of the NSLS-II IDs, several recent improvements on actual magnetic measurement system have been developed. The system includes a flipping coil bench to measure the first and second magnetic field integrals and a Hall probe bench to perform magnetic field measurements of different types of IDs.

The main features of the hardware system, control program and the recent improvements in the magnetic measurements system are presented.

INTRODUCTION

All insertion devices for NSLS-II have been bought from different vendors. It is planned to measure these devices at NSLS-II in order to confirm vendors. Our magnetic measurements are the final verification of the complex design and fabrication process, so that proper certification of device can be made. The magnetic measurement system facility at BNL consists in a Hall probe bench MMB-6500, built by Kugler, GmbH and an Integrated Field Measurement System (IFMS), provided by ADC [1].

HALL PROBE BENCH

The Hall probe mapping bench has an ultra-precision granite guide beam. There are nine conrolled axes. The air-ride Z axis has a travel distance of 6.5 meters. The trajectory deviation for the Z axis carriage is ± 7 µm and the positioning accuracy is ± 1 µm. The X and Y axes are high precision stages. Mounted to the Y stage carriage is a rotary stage. Mounted to the rotary stage is a small X-Y stage. Mounted to that is a pair of goniometers. Thus the extended Hall probe can be positioned in any orientation and then translated (see Fig. 1). The Z' axis is used as a follower stage for transporting the cables, so that cable loading does not affect the Z axis trajectory. Instrumentation is also carried on the follower stage (see Fig. 2).

The Z axis has two encoders. A linear scale encoder is used for the motion control and a laser interferometric encoder is used for generating triggers. A Delta Tau controller is used for motion control. A Senis 3D probe is used as the Hall sensor.

Each Hall sensor, arranged along X-axis, has been accurately calibrated to provide a calibration curve of its response to the strength of the magnetic field up 1.9 Tesla. The magnetic field sensitive volume for each sensor is 150x150x1 µm and the angular accuracy of axes with respect to the reference surface is about of ± 2°.

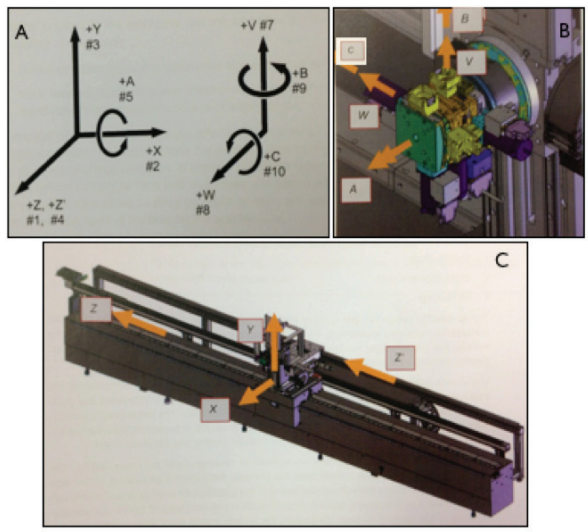

Figure 1: A: Machine coordinate system. Axis movements viewed from undulator towards granite. B: Arrangement of the goniometer head axes V, W, A, B and C. C: Arrangement of the three main linear axes X, Y, Z and auxiliary axis Z'.

In order to improve the accuracy and the repeatability of the Hall probe measurements, the electronics of the data acquisition have been upgraded. In particular a new time synchronization system has been developed in order to optimize the first integral repeatability and the precision of magnetic field measurements. Figure 3 shows the vertical field of a Damping Wiggler with period length of 100 mm at the minimum gap of 15 mm (blue line) and the field difference between two consecutive Hall scans (red line), which represents an absolute error of the magnetic field, measured with the initial triggering method. This error is a periodic and systematic curve with precise harmonic frequencies (see Fig. 4). The peak-to-peak amplitude is about of 30 G and occurs around the magnetic field gradient. It is a strong indication of a small jitter in the start trigger of the Hall probe measurements. This trigger jitter was reduced by changing from a motion controller generated trigger to a trigger generated by external Hardware, the parallel digital signal from the laser encoder is processed in external logic which feeds a trigger signal into an FPGA aboard a National Instruments CompactRIO real-time PAC. The

Copyright © 2013 CC-BY-3.0 and by the respective authors

CompacRIO also houses the digital-to-analog convertor which is used for data acquisition. In this fashion trigger latency for data capture is reduced to less the 1 μs.

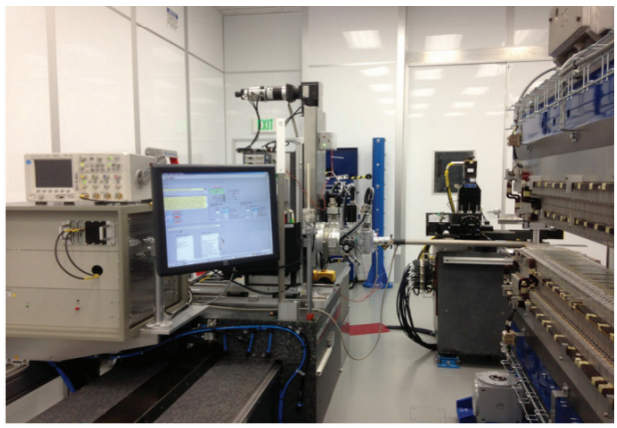

Figure 2: Hall probe measurement bench.

The magnetic measurements made with the new triggering system were carried out with a step of 1 mm and a scan speed of 24 mm/s.

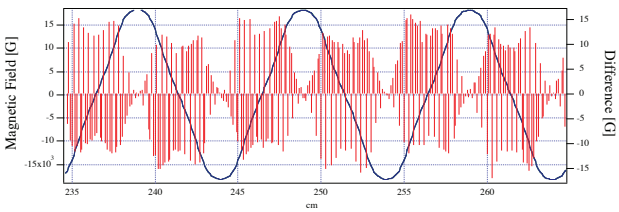

Figure 3: Magnetic field (blue line), difference of consecutive Hall measurements (red line).

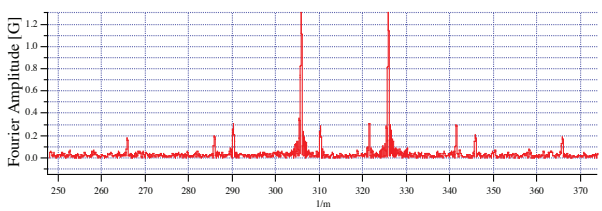

Figure 4: Spectral analysis of the difference.

Using this new system the error peak-to-peak is decreased to 5 G. (see Fig. 5), and also a improvement of the field integral repeatability was achieved.

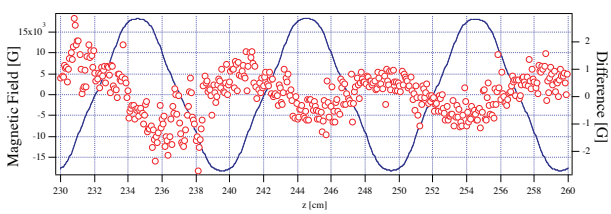

Figure 5: Magnetic field (blue line), the difference of consecutive Hall measurements (red dot).

The standard deviation for first field integral measurement of four consecutive scans is of 0.10 G m and for the second field integral is about 0.15 G m^2.

Figure 6 shows the horizontal electron trajectory of a Damping Wiggler obtained from four consecutive Hall probe measurements. The maximum absolute deviation is of few μm.

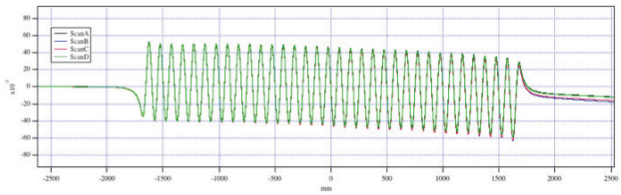

Figure 6: Horizontal electron trajectory of Damping Wiggler with period length of 100 mm at gap of 15 mm.

FLIPPING COIL BENCH

The flipping coil bench is typically used to characterise the integrated field of long insertion devices [2,3,4]. A long coil is stretched between the two ends of the device. The bench consists of two supports located at each end of an ID. The pedestals are made from granite with extremely flat ±10 μm tolerance on the top surface. Each pedestal has 3 leveling feet that also provide ±10 mm adjustment in the Z (longitudinal) and X (transverse) directions and 50 mm in the vertical direction. The six linear stages have Renishaw RELM linear encoder feedback with 0.1 μm resolution and ±1 μm accuracy. All axes have limit switches and a home limit switch that is used to tell the motion controller that it is near the home pulse located on the encoder. Two rotary direct drive servos are used to achieve 1 revolution per second with an angular accuracy of 40 arc-sec and encoder resolution of about 0.005 deg. These eight servomotors are controlled by a Delta Tau GeoBrick PMAC-2. A Keithley DVM 2701 integrator is used for data acquisition with a custom switching card to select the measurement source. A Stretched 38 AWG beryllium copper wire is used to support the flip coil given to it mechanical rigidity and to reduce its sag. Coil rigidity is desired to attenuate its vibrations, swings and curvature.

Some recent upgrades have been carried out to improve the accuracy and the repeatability of the field integrals at high measurement speed. In particular a new control software has been developed to perform "on-the-flight" measurements of both horizontal and vertical field integrals. The "on-the-fly" measurements are faster than the traditional "step-by-step" measurement, shortening significantly the measurement time of an ID. The measurement of the two field integral components in a range of 60 mm, with a measurement step of 1 mm and a scan speed of 55 mm/s is of 90 seconds against the 91 minutes using the old method "step-by-step".

Lot of measurements with different integration time and velocity were carried out in order to optimize the accuracy and the reproducibility of the field integral measurement. A maximum velocity of 55 mm/s and an integration time of 16.67 msec provide the best compromise between higher sensitivity (large step) and better spatial resolution (small step). These settings also ensure a good signal/noise ratio and a good repeatability.

Copyright © 2013 CC-BY-3.0 and by the respective authors

The integration time affects the amount of reading noise, as well as the reading rate of the instrument. So a digital filter has been used to stabilize noisy measurements. The digital filter places a specified number of A/D conversions into a memory stack. These A/D conversions occur consecutively within a selected reading window. The readings in the stack are then averaged to yield a single filtered reading. The stack has be filled using the "repeating average filters". To further reduce the high frequency electrical noise, created primarily from the several motors of the system, a capacitor of 1μF has been used (see Fig. 7, left).

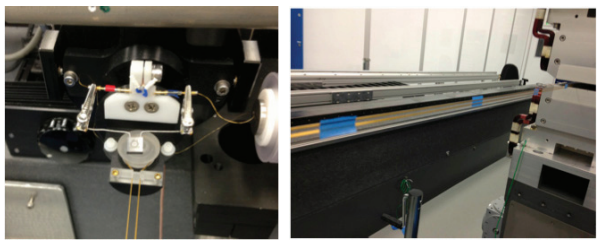

Figure 7: (Left) Electrical noise reduced by fitting a capacitor of 1 μF. (Right) Adhesive tape.

The function of the capacitor is to dampen random electrical noise, which causes small voltage fluctuation. In addition the capacitor helps to filter and remove the alternating currents caused by ripple voltage.

The disadvantage of an "on-the-fly" measurement is the vibration induced by the acceleration/deceleration at beginning and end of each movement. Electromechanical resonance was detected in the motors during the coil acceleration, causing small coil vibrations. To reduce this undesired effect, some pieces of adhesive tape were applied on the coil (see Fig. 7, right), it's a very simple and cheap solution, but efficient.

Figure 8 shows the horizontal (red line) and the vertical (blue line) field integrals as function of the transverse position. The standard deviation of five measurements is 7 G cm for the vertical field integral and of 3 G cm for the horizontal component. The repeatability of the measurement using just the coil rotation mode (Fig. 9) is 3.5 G cm for the vertical field integral and 2.5 G cm for the horizontal component.

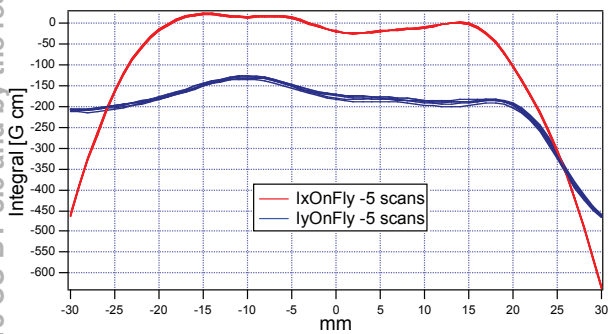

Figure 8: Horizontal field integral (red line), vertical field integral (blue line).

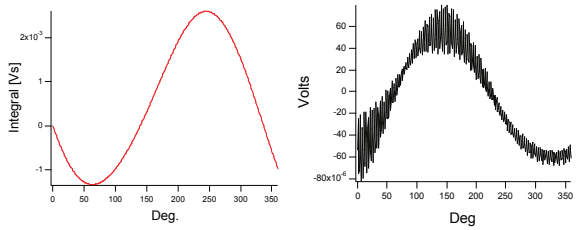

Figure 9: Voltage integrated (red line). Voltage readings (black line).

CONCLUSION

Replacing actual power supplies of the converter with DC batteries is an additional improvement of the Hall probe bench. The accuracy shall be increased as the use of DC batteries will eliminate time varying interference coupled into the converter via the power lines.

UPGRADE OF BEAM INJECTION DIAGNOSTICS AT BNL NSLS

S. Seletskiy#, Y. Hidaka, B. Podobedov, X. Yang, BNL, Upton, NY 11973, USA

Abstract

In this paper we report the upgrade of the diagnostics of the beam injection system at BNL NSLS. Installation of commercially available turn-by-turn beam position monitors (BPMs) in the VUV and X-Ray rings allowed us to build the detailed injection models for each of the rings. In addition we built the tools for real time monitoring of and troubleshooting the beam injection into the rings.

INTRODUCTION

The NSLS accelerator complex consists of the 120 MeV linac, the booster accelerating the beam to 740 MeV and the two storage rings: 800 MeV VUV ring and 2.8 GeV X-Ray ring. Injection into each of the rings is performed at 740 MeV energy. The injection hardware in each of the rings consists of an injection septum (DC-magnet in case of the VUV ring and pulsed one for the X-Ray ring) and three fast multi-turn kickers. A single turn-by-turn (TBT) BPM was added to each ring for the purpose of injection monitoring. As a result a set of tools was created which are successfully used for troubleshooting injection problems. In this paper we discuss the operation of this diagnostics using the VUV ring as an example.

VUV RING INJECTION SETUP

The beam is injected into the VUV ring through the septum (BUISH) when the amplitudes of the three injection kickers (bumps BUIFB1, BUIFB2 and BUIFB3) are close to their peak values. Fig. 1 schematically shows the locations of the injection hardware and the fast kicker waveforms.

Since the duration of the kicker pulse is 1.3 us and the electron orbital period in the VUV ring is 170 ns the injected beam is affected by the kickers on multiple turns after the injection. This substantially complicates the injection process. At pick-up 5 (see Fig. 1) we installed a dedicated turn-by-turn BPM (Libera Electron [1]) to study and monitor the injection. The Libera unit is synchronized with the VUV ring orbital period and is triggered by the Booster extraction kicker trigger.

Since we can communicate to the machine from MATLAB through the "middle layer" software [2] and since the Libera settings and readings are easily accessible from MATLAB, Accelerator Toolbox (AT [3]) is a natural environment to model the ring injection. Thus we built the injection model by integrating the fast kickers into the AT model of the VUV ring.

The AT provides tools for beam tracking and calculation of lattice functions. Our AT model includes the linear ring lattice as well as kicks from sextupoles. It was calibrated with MATLAB-based LOCO [4].

#seletskiy@bnl.gov

BUILDING INJECTION MODEL

Since the kicker waveforms are nearly identical up to a scaling factor, we used the measured BUIFB2 waveform for each modelled bump. In simulations we only use half-wave of the sinusoid and ignore the residual kicker field. Each kicker's amplitude in the model is scalable, but the width of the waveform is kept constant.

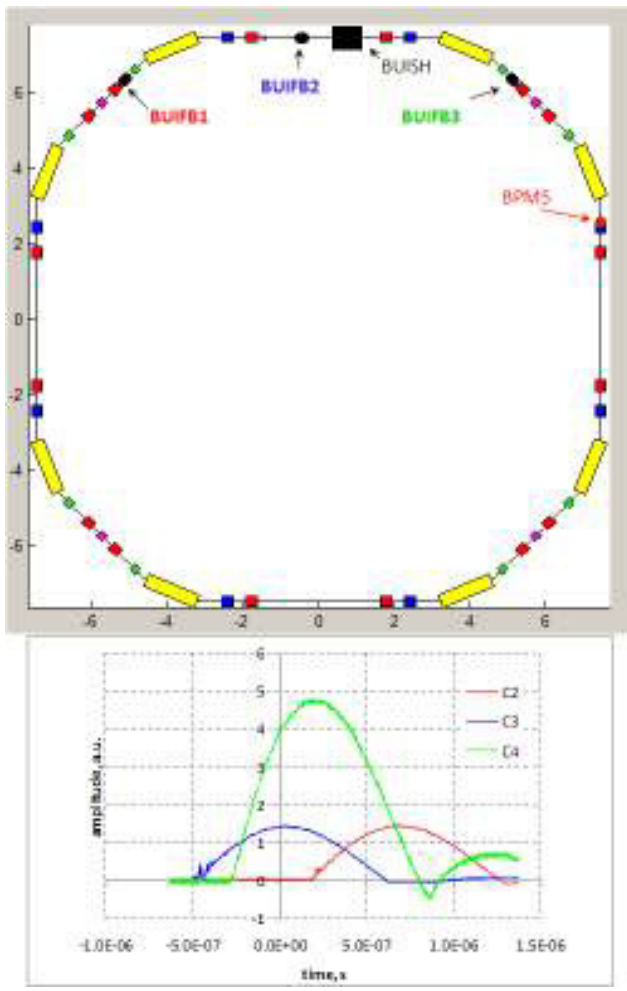

Figure 1: Locations of injection septum and fast injection kickers in the VUV ring (upper plot). The turn-by-turn diagnostics is connected to BPM5. Lower plot shows measured fast kicker waveforms in arbitrary units. Red line is BUIFB1, blue is BUIFB2 and green is BUIFB3.

Initial benchmarking of the model was performed with the stored single-bunch beam. Fig. 2 shows the readings of the TBT BPM over 20 turns versus the model predictions for the stored beam kicked with BUIFB1.

As one can see, there is a good agreement between the model predictions and the measured data. The same level of agreement was obtained for BUIFB2 and BUIFB3, as well as all three kickers turned on simultaneously. The benchmarking was performed both at the stored beam

Copyright © 2013 CC-BY-3.0 and by the respective authors

energy of 800 MeV and at injection energy of 740 MeV. Good agreement between the model and the measurements was also obtained at various beam currents, from a few milliamps typical for injected beam to more than hundred milliamps.

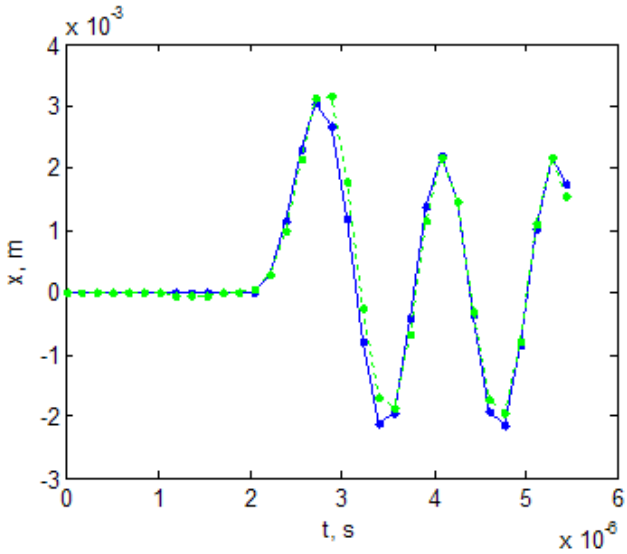

Figure 2: The oscillations of the stored beam kicked by BUIFB1 as read by TBT BPM #5 (green trace) and modelled (blue trace). Each dot represents BPM reading on a single turn.

Our next step was to measure the actual injection with the TBT BPM. We turned off the RF, to make sure that the beam is not accumulating in the ring. The obtained Libera readings are shown in Fig. 3.

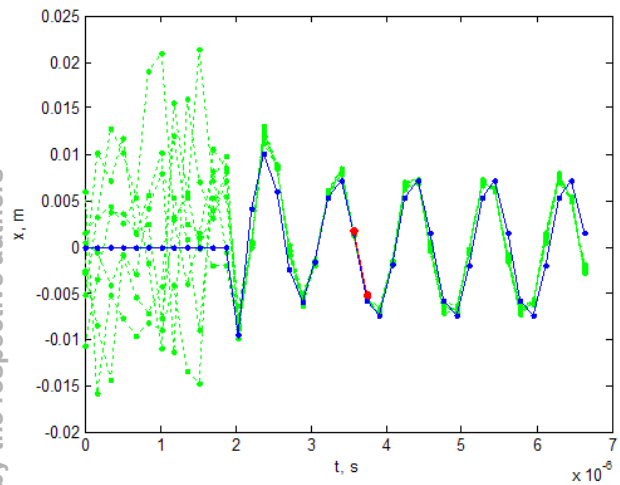

Figure 3: TBT BPM readings of the beam injected into the empty ring (green traces) taken over multiple injections. The noise up to the 12th turn (t≈2 μs) from beginning of the plot shows that there is no beam in the ring. Two red dots show the data we use to calculate the beam coordinates at injection point. The blue line shows the simulated trajectory of the beam injected with these initial coordinates.

As one can see, the injection readings are quite repeatable. The readings taken over multiple injections show that the beam is entering the ring on the 12th turn after the trigger comes to the Libera. This conclusion is confirmed by the sum signal from the TBT BPM buttons.

To find the initial horizontal coordinates (x, x') of the beam at the injection point we first determine x' at the BPM#5 location at the 21st turn (after Libera trigger) from the x-readings at the 21st and 22nd turn. Note, since the kickers are already off by this time we can use a simple single-turn matrix between the turns 21 and 22. Next, we find beam (x, x') at the exit of the injection septum on the 21st turn. Finally, we backtrack, taking into account the effects of the kickers, beam with found (x, -x') through the inversed ring lattice from turn #21 to turn #12 (from the Libera trigger). This gives us the initial beam coordinates at the moment of injection. We also use the found coordinates to simulate the trajectory of injected beam. As Fig. 3 demonstrates, the simulated readings of TBT BPM coincide with the experimental data quite well.

INJECTION MONITORING AND TROUBLESHOOTING

A dedicated software tool was created to monitor and to troubleshoot the injection. It is a MATLAB-based GUI that allows one to control the injection settings, take the readings of TBT BPM and analyze the obtained results by comparing them to the latest injection model. The user interface is shown in Fig. 4.

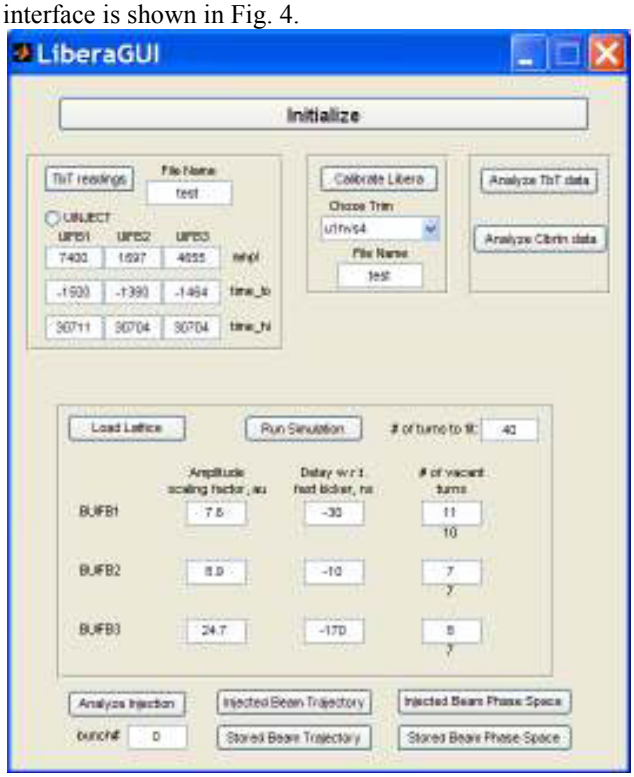

Figure 4: A GUI for the software tool to monitor, analyze and troubleshoot the injection process.

One of the most interesting examples demonstrating the power of the developed injection troubleshooting tools was during the failure of one of the kickers. As a result for some limited period of time we had to operate with two-bump injections, which is fairly unconventional.

Copyright © 2013 CC-BY-3.0 and by the respective authors

The failure of BUIFB1 caused a sharp decline in the injection rate. The measurements of the TBT BPM sum signal showed that a substantial part of the injected beam was lost on the 6th turn after the injection. The analysis of the measured injection data showed that on this turn the beam horizontal trajectory was deflected too much in the injection septum region, causing the beam loss (see Fig. 5).

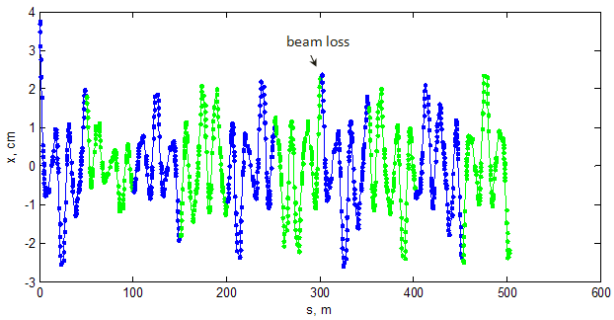

Figure 5: The betatron oscillations of injected beam obtained from the injection analysis. Only two kickers (BUIFB2 and BUIFB3) are operating at nominal settings. New turns start where the line colour changes. The initial s-coordinate corresponds to the injection septum exit on the first turn.

Scanning the kicker settings in our model with BUIFB1 off we found (Fig. 6) that increasing the nominal amplitude of BUIFB3 by a factor of ~1.7 significantly reduces the amplitude of the betatron oscillations of the injected beam.

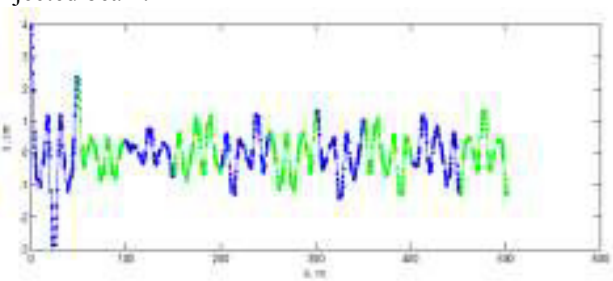

Figure 6: The projected betatron oscillations of the injected beam with only two kickers (BUIFB2 and BUIFB3) operating. BUIFB3 amplitude is set to its nominal value, while BUIFB2 amplitude is increased by factor of ~1.7. New turns start where the line colour changes. The initial s-coordinate corresponds to the injection septum exit on the first turn.

Indeed, when the kickers were set to the settings found in our simulations the beam loss disappeared and the injection rate increased significantly, as demonstrated in Fig. 7.

After BUIFB1 was repaired, as an additional test of our model, we simulated and performed a two-bump injection with BUIFB1 and BUIFB3. Our simulations showed that adjusting the BUIFB3 timing by -340 ns and increasing the amplitude of BUIFB3 by a factor of ~1.4 one can perform a two-bump injection with almost no loss. Measurements with found kickers' settings confirmed our analysis (see Fig. 7).

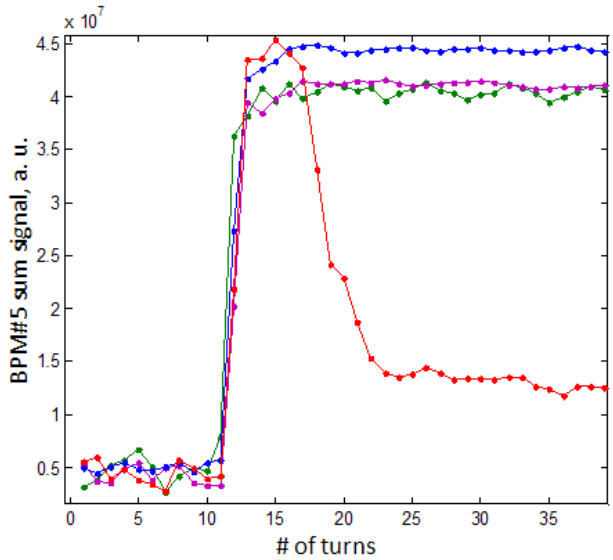

Figure 7: Sum signal of TBT BPM for the injected beam. Each point represents a BPM reading on a single turn. The injection is happening on the 12th turn. The green line represents the nominal 3-bump injection. Red line is two bump injection with BUIFB1 off. The magenta line is the modified two bump injection with increased BUIFB2 amplitude. The blue line is two bump injection with optimised settings of BUIFB1 and BUIFB3.

CONCLUSIONS

In this paper we presented the injection diagnostics tools based on the turn-by-turn beam position monitors installed at the NSLS storage rings. Using the example of the VUV ring we described the procedure of building the relevant injection model. We discussed the software that we developed for monitoring, analysis and troubleshooting of the injection process. As an ultimate demonstration of application of the developed tools we described our successful experience with optimizing a fairly unconventional two-bump injection, which was temporarily used during a kicker failure.

ACKNOWLEDGEMENTS

We are grateful for support from the NSLS. This work is supported in part by the U.S. Department of Energy (DOE) under contract No. DE-AC02-98CH1-886.

Abstract

The next generation of x-ray light sources will need reliable, high quantum efficiency photocathodes. These cathodes will likely be from the alkali antimonide family, which currently holds the record for highest average current achieved from a photoinjector. In this work, we explore a new option for delivering these cathodes to a machine which requires them: use of sealed commercial vacuum tubes. Two sealed tubes have been introduced into a vacuum system and separated from their housing, exposing the active photocathode on a transport arm suitable for insertion into an injector. The separation was achieved without loss of QE in one case. These cathodes are compared to those grown via traditional methods, both in terms of QE and in terms of crystalline structure, and found to be similar.

INTRODUCTION

Alkali antimonide photocathodes have a long history in low-light photodetection, including image intensifiers. These needs have been met by commercial production; principally by RCA and its successors. The accelerator community also has great interest in alkali antimonide photocathodes – they are a prime candidate for use in high-brightness photoinjectors of free electron lasers and 4th generation light sources [1-3]. However, within the accelerator community, cathodes have traditionally been grown in dedicated vacuum systems tied to specific injectors. In some cases cathodes have been transferred from one system to multiple injectors, typically on a limited basis [2,4].

We have developed tools to understand the formation of these materials, both structurally and chemically, with the goal of altering the growth to produce cathodes with less roughness, better stoichometry, and larger crystal grains. The *in situ* techniques being used are x-ray diffraction (XRD), grazing incidence small angle x-ray scattering (GISAXS) and x-ray reflection (XRR). These tools enable determination of the crystal form of the cathode at each phase of growth, the film thickness and roughness, the texture and grain size of the film, and the presence of "imperfectly reacted" material. This work has been carried out at the National Synchrotron Light Source (NSLS) using beamline X21 and at the Cornell High Energy Synchrotron Source (CHESS) using beamline G3.

The goal of this work is to enable the large scale production of identical photocathodes, using recipes developed in the *in situ* analysis chamber, which will provide high QE while minimizing the surface roughness which can dominate the intrinsic emittance [5,6]. One aspect of this effort is collaboration with an industrial partner to produce photocathodes in sealed tubes which can be separated in vacuum.

Figure 1 shows a prototype photocathode in a sealed vacuum capsule. The substrate for growth is polycrystalline Molybdenum, which is brazed to the copper plug shown in the picture to the left. The capsule is sealed with a low temperature solder visible around the copper. A window on the isolated top electrode enables the QE of the device to be measured while the capsule is still sealed. The photocathode is visible as the blue area in the picture on the right, through this window.

Figure 1: Sealed photocathode.

EXPERIMENT

In the interest of space, the growth chamber with *in situ* x-ray analysis is described elsewhere [7]. This chamber has been used to measure both the capsule photocathodes, and to grow cathodes for comparison. The comparison cathodes are grown in a UHV chamber, with a typical operating pressure of 0.2 nTorr. Residual gas analysis confirms that the partial pressures of reactive gases (H_2O, CO) are better than 0.05 nTorr. Silicon [100] wafers 1x2 cm^2 are used as substrates; these are exposed to HF prior to installation, and baked to 500 C for an hour prior to growth. Once the substrate has cooled to 160 C, a further cleaning of the substrate is achieved by an initial potassium evaporation – XRR measurements confirm that this K does not remain resident on the surface, however the QE of cathodes grown is significantly improved by this initial step. Antimony is evaporated from PtSb beads; alkali-Bi sources from Alvatech are used to supply Potassium and Cesium. Deposition is sequential, with Sb evaporated, then K, then Cs, all at ~0.2 Å/s. The QE is observed during K and Cs evaporation, and the deposition is halted when the QE reaches a plateau. The "traditional" cathode is a multi-layer growth on a single substrate, with the first cathode "baked off" (substrate raised to 500 C for 10 min) prior to the growth of a second (recipe in Table 1).

Copyright © 2013 CC-BY-3.0 and by the respective authors

Table 1: Traditional Cathode Recipe

1st Layer	Temp	QE	2nd Layer	Temp	QE
15 nm Sb	100		15 nm Sb	125	
62 nm K	125	0.14	60 nm K	125	0.37
118 nm Cs	125	4.1	120 nm Cs	125	7.5

The Photonis photocathodes are also grown via sequential depositions, but on a Molybdenum substrate. The recipe used is similar to that used by the company for its transmission-mode cathodes (traditionally grown on glass substrates), and has yet to be optimized for this application. The spectral response of this cathode as delivered is shown in Figure 2.

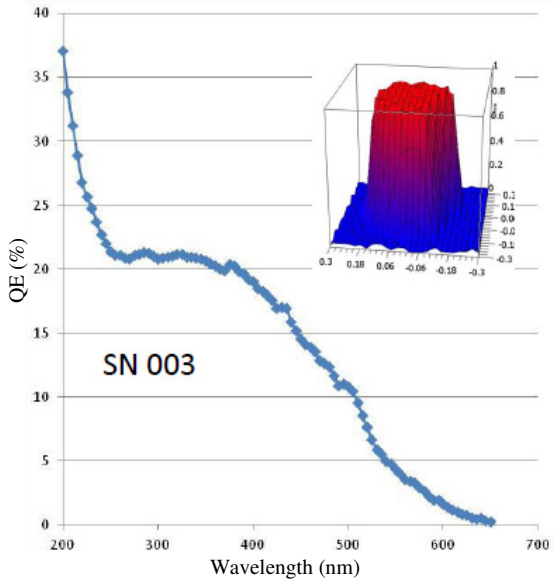

Figure 2: Spectral response of Photonis photocathode within the sealed tube. Inset shows spatial uniformity.

RESULTS

Transfer and Separation

The initial and final stages of the capsule loading and separation are shown in Figure 3. On the left is a capsule loaded onto the platen. On the right is the cathode ready to be transferred off the platen and into an injector. This design is compatible with the transfer system for the BNL 112 MHz Gun [8], and future iterations of this design will be tested in this gun (some design modifications are required to mask the solder joint from the gun).

Figure 3: Left – sealed cathode mounted on platen. Right – Cathode after cap is removed, still attached to platen.

The sequence of cap removal is shown in figure 4. First the platen with capsule is loaded onto the heater. Second, the platen temperature is increased slowly to ~100 C (the solder eutectic temperature is 72 C; thermal conduction from the platen to the solder joint as well as alloying of the solder with the base materials likely explains this difference). A manipulator is used to gently pry at the cap (bottom left), eventually resulting in the cap tipping away from the cathode (bottom right). The QE of the cathode is measured using a green (532 nm) laser immediately after the removal process (figure 5). The QE of the cathode initially decreases due to the rise in temperature (to 3.1% for cathode 1 and 1.8% for cathode 2); the first cathode recovered fully (actually slightly higher) once it cooled to room temperature. The second attempt resulted in a permanent degradation with a final QE of 3%, thought to be due to excessive overheating of the photocathode during the cap separation process.

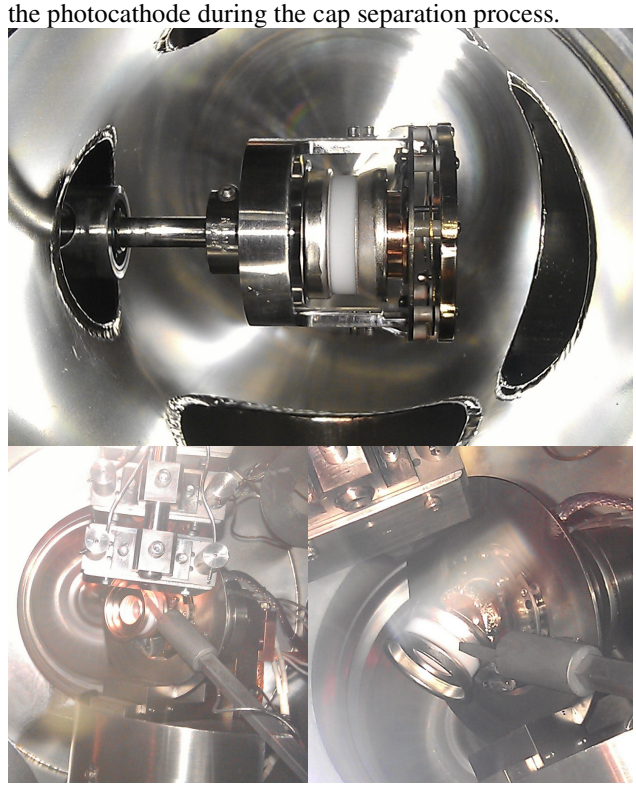

Figure 4: Top: Capsule loaded onto platen and mounted for insertion. Bottom Left: Finger positioned to remove cap. Bottom Right: Cap partially off.

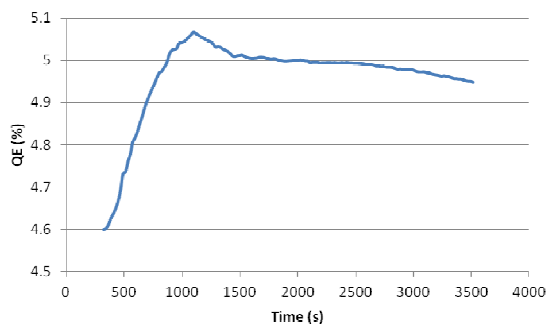

Figure 5: QE of cathode after cap removal. The QE rises due to the post-separation cooling of the substrate.

X-ray Diffraction

Figure 6 shows the crystalline structure of both capsule cathodes, along with the "traditional" recipe cathode described above. For the traditional recipe, the cathode is cubic phase K_2CsSb with a mixed 222 and 220 surface textures. The grain size estimated from Scherrer analysis is 49.3±2.0 nm. No unreacted K_3Sb is observed in this cathode. The capsule cathodes are similar, except that they have a more pronounced 222 texture. The broader peak widths likely imply smaller grains (38.9±0.5 nm for cathode 1, 36.8±0.2 nm for cathode 2). The strong peak at 32.4 degrees is from the Molybdenum substrate.

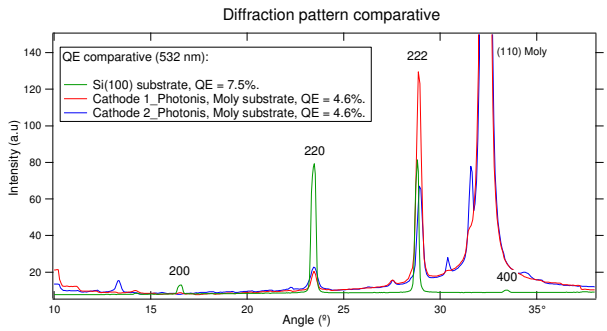

Figure 6: XRD results of two capsule cathodes after cap removal, along with a "traditional" recipe photocathode for comparison.

CONCLUSIONS

Sealed "Phototube like" photocathodes have been prepared to be separated in vacuum, allowing the photocathodes to emit electrons into a test system. The removal process can preserve the QE of the cathodes; 4.6% QE in the green was observed both before and after opening. While this QE is somewhat inferior to purpose-grown cathodes, the process has not yet been optimized and is expected to improve significantly. This technique has the potential to allow injector projects to purchase photocathodes that are produced commercially in batches, providing quality control and reproducibility, and dramatically reducing costs.

Further, the ability of these cathodes to be studied and compared to existing recipes using *in situ* materials diagnostic techniques will allow the evaluation and optimization of the cathode properties relevant to accelerator applications. These are somewhat different than traditional phototube attributes – in particular, the eventual ability to use GISAXS to evaluate surface roughness will provide insight into the expected intrinsic emittance of these cathodes. This was not possible on the current samples, as the growth substrate was "rough" polycrystalline Molybdenum. Samples grown on single crystal Molybdenum are already in production, and roughness measurements are part of the near-term future plan. In addition, other materials, such as Cs_3Sb and K_2NaSb, will soon be grown and evaluated in sealed-tube form. In the somewhat longer term, these cathodes will be tested in the BNL 112 MHz SRF injector.

Abstract

K_2CsSb is a robust photocathode capable of generating electron beams with high peak, high average current and low thermal emittance. During the last two years, a great improvement in the design and fabrication of a reliable deposition system suitable for K_2CsSb cathode growth and its insertion into BNL high current ERL SRF gun has been achieved. A standard procedure for the growth of multi-alkali cathodes combined with another procedure to transport these cathodes into the SRF gun was developed. The first cathode is planned to be grown on a copper insert and mounted into the 704 MHz gun. In this article, we will describe the progress of cathode growth and transport for ERL project. In particular, effect of excimer laser exposure and the cathode growth on Ta will be included.

INTRODUCTION

The multi-alkali photocathode is considered to be suitable for high current applications due to its high quantum efficiency at visible wavelengths. The photocathode of choice for BNL-ERL photo-injector is K_2CsSb due to its capability to generate high average current and low emittance electron beams. The 704 MHz SRF photoinjector is built for testing ERL concept up to 500 mA high average current. A multi-alkali photocathode deposition system for this gun was built by Advanced Energy Systems (AES) [1]. In last two years, we assembled entire system and grew several cathodes to find the optimal cathode preparation parameters. We also tested the transport cart and insertion of the cathode plug through the load-lock system. 0.2% QE was obtained from a K_2CsSb cathode grown on the copper substrate. Currently, the gun is being conditioned for CW SRF operation with a copper cathode plug and the vacuum in both the deposition chamber and the transport cart is maintained in low 10^{-10} torr range. The cathode will be deposited on this plug soon after the conditioning. The first cathode test in the gun is scheduled for November.

DESCRIPTION OF THE DEPOSITION SYSTEM

The K_2CsSb deposition system consists of a main deposition chamber and three source chambers attached to the main chamber but isolated from each other and the main chamber through gate valves. The main chamber is equipped with two view ports, an RGA, a quartz crystal monitor, anode, resistive heater and load-lock port. Ion pumps integrated with NEG pumps maintain the vacuum in low-10^{-10} torr scale. Each of the source chambers has one ion pump keeping the vacuum in mid-10^{-10} torr range. Bellows coupled manipulator can move the sources into the deposition chamber and locate them in front of the substrate. We use Alvatec Alkali metal source of type S and 99.999% purity pellets antimony source. The alkali sources are evaporated by resistive heating of the source container and the Sb is evaporated by heating a boat which holds the crucible containing Sb pellets. Each alkali arm contains two Cs or K sources to increase the evaporation area and cathode uniformity. To protect the sides of the cathode plug from being coated with the cathode material, an aperture is placed between the substrate and the source to limit the deposition area to a 0.75 inches diameter. The substrate can be heated or cooled by flowing dry N_2 gas through a pipe in contact with the stalk. With the same pipe, the stalk is maintained at LN_2 temperature when in the SRF gun. The stalk can be heated up to 200° C and maintained at optimal temperature for evaporation. To determine the initial quantum efficiency, the cathode is irradiated with a low power CW laser. Emitted electrons are collected at the anode in front of the cathode. The whole deposition system is placed in a class 10,000 clean room shown in Figure 1. The load lock connection port is inside a class 100 clean room to avoid accumulation of the particulates in section that comes in contact with the SRF gun.

We use a specially designed transport cart to transfer the cathode between the deposition system and the SRF gun. The cathode substrate is an integral part of a grooved choke joint structure mounted inside the transport cart as shown on Figure 2c. The diameter of the copper stalk is 1 inch. The transport cart consists of a bellow manipulator and an intermediate section, which is connected to either the deposition system or the gun. The vacuum plenum of the cart is made up by two ion pumps and one TSP. During baking of the intermediate section prior to transferring the cathode, the cathode is protected from the gas load by a cold shield near the isolating valve. The QE of K_2CsSb cathode will be preserved for a few weeks in the low 10^{-10} torr vacuum achieved in the load-lock. Two identical transport carts have been fabricated to allow the gun to be tested with one cathode while the second is being prepared. The transport cart is shown in Figure 2a. Currently, the transport cart is attached to the gun for RF condition, see Figure 2b.

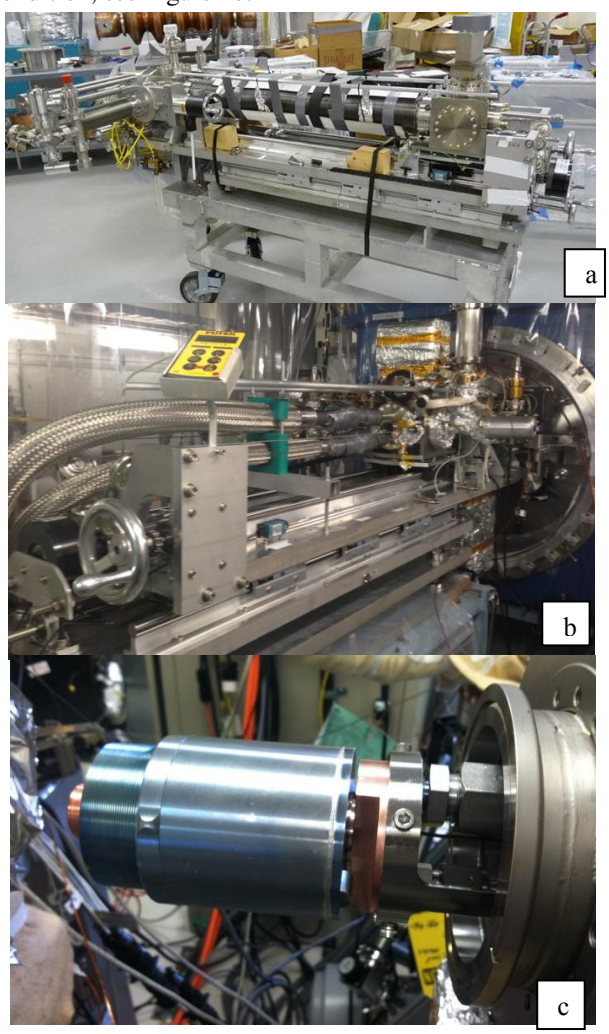

Figure 2: Photographs of the cathode and transport cart: a) The cathode transport cart; b) The transport cart attached to the gun and the cathode stalk inserted. Two line attached to the manipulator are for cooling the cathode in the gun. Same port will be used for heating the substrate during cathode preparation; c) The cathode stalk mounted on the transport cart.

STANDARD CATHODE GROWTH PROCEDURE

- Heat up the stalk to 100°C.
- Evaporate Sb layer to a thickness of 10 nm. The thickness is measured by a crystal monitor.
- Increase the substrate temperature to 140°C.
- Evaporate K layer to 20 nm while monitoring the photocurrent change. Stop evaporation when photocurrent reaches maximum amplitude.
- Decrease the temperature.
- Evaporate Cs when temperature goes to 130° C, while monitoring photocurrent. Cs evaporation is stopped when the QE plateaus.

SELECTION OF CATHODE SUBSTRATE

In the first gun tests with electron beam, we will use K_2CsSb photocathode grown on the copper stalk. Because copper atoms easily diffuse into K_2CsSb crystal, the QE of a single layer cathode is usually lower than pure K_2CsSb crystal. Typically, the QE of K_2CsSb on copper cathode would be around 0.1% to 0.2% following the standard growth procedure. We have grown a single K_2CsSb layer on the copper substrate in this deposition system several times. The best QE was 0.2%. Additional K_2CsSb layers reduce the probability of copper atoms diffusing into emission surface, thereby increasing the overall QE But the thicker layer may result in flaking of the cathode material, which is detrimental to SRF operation. It is shown that high QE K_2CsSb cathode can be grown on Si [2], however, the large dielectric loss of Si in CW SRF environment precludes its use in an SRF gun. To find the suitable metal substrate for the 704 MHz gun, we compared the performance of the cathode on two substrates, Mo and Ta, chosen for compatibility of their mechanical, thermal and electrical properties with the SRF gun. Both samples were from Goodfellow with better than 99.9% purity. The samples' thickness is 0.5 mm. The Mo sample has an optical quality surface finish. The Ta samples with different surface finishes were tested for QE. One Ta sample was polished by 9 um polishing compound with Metadi No 40-6543 diamond suspension from Beuhler. Another identical Ta sample was not polished. No *in situ* cleaning was performed on any of these samples and *ex situ* cleaning consists of only typical ultrasonic cleaning and rinsing with acetone prior to insertion in the vacuum chamber. We found the cathodes on polished and unpolished Ta substrates to have nearly the same spectral response. Also, QE of both cathodes is similar with a value of 2.53%. Then, with the same procedure, we obtained a 3% QE with Mo substrate. The operating life time of the cathodes on all these substrates, measured using a low power 532 nm laser beam was comparable. Therefore, both Mo and Ta are suitable substrates for growing K_2CsSb cathode. The next

Copyright © 2013 CC-BY-3.0 and by the respective authors

step was incorporating the substrate material in our pre-existing cathode stalk, to be inserted into SRF gun. We sputtered a Mo layer with different thicknesses onto a 1 inch diameter polished copper stalk. However, none of the Mo layers adhere to the copper well and easily flaked off raising concerns over its operation in SRF gun. Then, AES, Inc. brazed a 0.006" thick Ta foil on the copper stalk. The braze material is under the entire surface of the Ta foil. The Ta attached to the stalk well, as shown on the left hand side of Figure 3. We measured the particles generation and electrical contact for the Ta-Cu brazed sample before and after cooling down to LN_2 temperature. Four-point resistance measurement shows that the resistance between Ta and Cu did not change after the cool down cycle. In a class 100 clean room, we immersed a particulate free Ta-Cu brazed sample into LN_2 and after cooling cycle, we compared the particle count with another identical sample which did not undergo the thermal cycling. We found the particle counts of both samples are comparable. There was no fracture in either Ta or braze material after cooling cycle. Therefore, we chose the Ta-Cu brazed stalk for the 704 MHz SRF gun test. This stalk is currently under procurement.

Figure 3: Left – the dummy brazed Ta-Cu sample; Right – the polished copper cathode stalk with the choke joint section.

NON-THERMAL SUBSTRATE CLEANING AND CATHODE REMOVAL

While operating in an electron gun, the K_2CsSb cathodes have limited charge life time. Usually, new cathode layers are grown over the used layer. However, after a few evaporations, the collective layer becomes thick enough to flake and contaminate the gun environment. For an SRF gun, non superconducting material contaminations will lead to field quenching or field emission. Heating the substrate to 800˚C may remove the old layers but is not suitable for the 704 MHz gun stalk due to significant engineering problem associated with the design of the heavy cathode plug. We have demonstrated that 248 nm excimer laser can totally remove the K_2CsSb cathode and preserve the substrate roughness [3]. We grew a cathode following the standard procedure described above. The excimer laser beam size is 3.5 mm^2. A collinear green laser with spot size smaller than that of the UV laser was used to measure the change in QE. We found that with excimer laser energy density of 3.5 mJ/mm^2 and repetition rate higher than 30 Hz, the cathode photocurrent decreases to background within 10 seconds. Figure 4 shows the regions exposed to the excimer laser, appearing visibly different. We used EDX to measure the elements present on the surface. In the EDX spectrum, we found the Sb, K, Cs signals were completely eliminated in laser exposed areas.

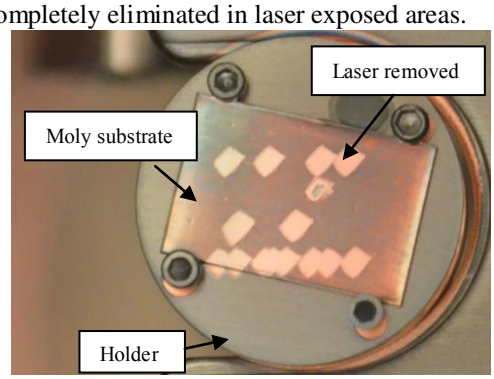

Figure 4: Excimer laser radiated K_2CsSb cathode sample. The rectangular regions are exposed to the laser. The cathode material in these regions is removed.

This technique can be used to address three issues associated with multi-alkali cathodes in high current photoinjectors. For instance, i) once the QE of the cathode decays below the design value, by irradiating it with the UV laser, we can clean substrate and remove the cathode simultaneously prior to fabricating the new cathode on the same substrate without any degradation of the UHV system. ii) Enhance the photoemission. We fabricated cathode with a stable 6% QE on a laser exposed Ta substrate. iii) In a photo-injector, by exposing the cathode to the UV laser, the cathode area could be exactly matched to the electron beam size, the halo electron beam generated either by the halo of the laser or the scattered laser beam can be completely eliminated, thereby improving the electron beam quality and reducing the beam loss induced pressure increase.

CONCLUSION

The cathode deposition system for the 704 MHz gun is ready for use. The photocathodes were grown on the copper cathode stalk a few times and a reasonable QE was obtained. The transport cart with the cathode stalk was pumped down to low 10^{-10} torr and tested in the SRF gun. We developed a new technique to remove the K_2CsSb cathode material by an excimer laser.

Abstract

Photocathodes remain the principal electron sources for many particle accelerators. With the increasing interest in the use of superconducting radiofrequency electron guns, it is important to understand how operation at cryogenic temperatures affects the performance of photocathodes. Here we report measurements of the quantum efficiency of copper and niobium under illumination with 266 nm light at temperatures between 85 K and 400 K. The quantum efficiency of copper was found to vary strongly over this range, while there was only a minimal change in the quantum efficiency of niobium.

INTRODUCTION

Superconducting radio-frequency (SRF) electron guns combine efficient CW operation with the excellent vacuum needed for high-quantum efficiency (QE) photocathodes and the high surface gradients needed to maintain the quality of high-charge bunches. However, they remain an immature technology, with a number of very different configurations currently being investigated [1]. One major concern has been how to best balance the tradeoffs associated with integrating photocathodes into these devices. As part of its research program on SRF guns [2,3,4,5], the Naval Postgraduate School has studied some of these issues, including the potential contamination from dispenser photocathodes [6,7] and cathode stalk cooling to mitigate thermal and RF losses [8]. Many SRF guns use a normal-conducting cathode which is mechanically isolated from the cavity to minimize heat leaks. But even without mechanical contact between the cavity and the cathode, the cathode will be radiatively cooled due to the surrounding 2 - 4 K environment. This raises the interesting question of how the cryogenic environment affects the performance of photocathodes. There have been many measurements of the QE of metal cathodes, including at cryogenic temperatures. However, comparing QE measurements from one experiment to the next is difficult because of differences in sample and testing conditions. Having a single experimental apparatus where the temperature of a cathode can be varied, while keeping other influences largely constant, aids in effectively isolating the dependence of QE on temperature. Accordingly, we modified the cathode stalk cooling experiment to serve as a temperature-controlled photoemission test stand, and used it to measure the QE of copper and niobium at temperatures from 85 K to 400 K with 266 nm light [9]. Our experimental apparatus and results are reported here.

EXPERIMENTAL APPARATUS

Figure 1 shows a schematic of the test stand. The cathode stalk (Fig. 2) was formed from a copper cylinder with a recess in the front surface to accept metal cathode samples, with the samples held in place by a copper retaining ring to provide good thermal and electrical contact between the samples and the stalk. Temperature control was provided by a liquid nitrogen line and a pair of resistive heaters in the back of the cylinder. The heaters were supplied from a variable autotransformer, while liquid nitrogen was supplied from a pressurized fill pot used for the experiments described in Ref. [8]. Temperature measurements were made with LakeShore DT-670-SD and DT-670-CU-HT diodes placed on the front and back faces of the cathode, respectively; these limited operation to temperatures at or below 400 K. The diodes were connected to a computer by a LakeShore 218 temperature monitor, and the data was recorded every 5 seconds by a LabView program.

The vacuum envelope was made from conventional UHV components, with an ion pump providing typical pressures of 3×10^{-8} - 4×10^{-7} Torr at room temperature during testing. In operation, the rate of cathode heating had to be limited to prevent vacuum pressure spikes. A ceramic break was placed around the cathode stalk, with the downstream end electrically isolated from the rest of the experiment to serve as the anode, and connected to a 10 kV Glassman high voltage supply. The floating end also contained a UV window and a small magnet to disperse the photoelectrons to prevent charging of the window. A Bergoz fast current transformer mounted outside the ceramic break provided a time-resolved measurement of the current flow on the stalk, and therefore served as a measure of emitted current.

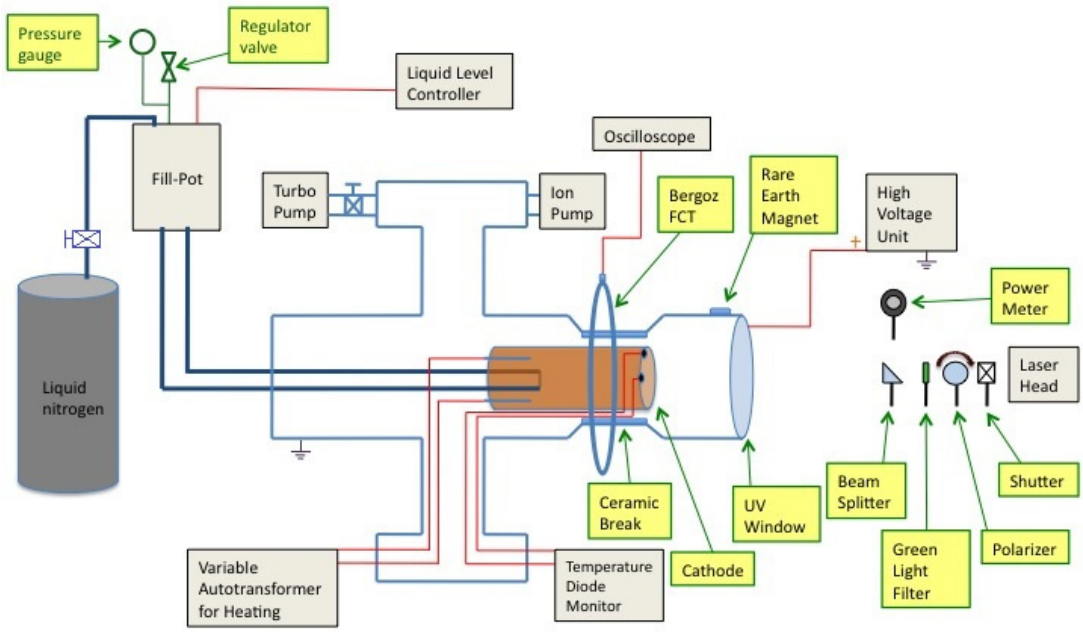

Figure 1: Schematic diagram of the temperature-controlled photoemission experiment [9].

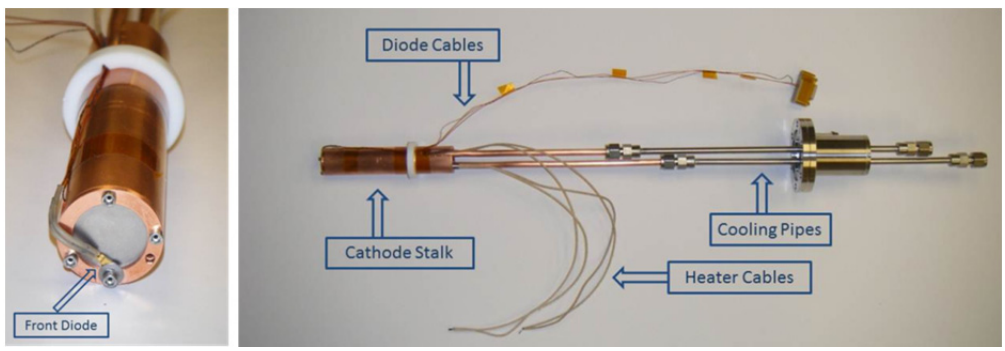

Figure 2: Photographs of the cathode stalk used in the temperature-controlled photoemission experiment, showing the niobium sample installed for testing [9].

Integrating under the transformer signal yielded the number of photoelectrons produced by each laser pulse.

This experiment used a frequency-quadrupled Continuum Minilite II Nd:YAG laser producing a 5 ns, 40 mW pulse of 266 nm light. A filter was used to block any light which was not fully converted to UV inside the laser, and a remote-controlled shutter and polarizer were used to control the laser power. Preliminary testing showed that at an anode voltage of 10 kV, the laser power on the cathode must be less than 4 mW to stay in an emission-limited, rather than space-charge-limited, regime. Conversely, our PM10 power meter required at least 5 mW to stay within its specified range and avoid a nonlinear response. To balance these requirements, 70% of the laser power was directed to the power meter using a beam splitter. The power meter measured the average power delivered to it by the laser; this was converted into the number of photons arriving at the cathode per shot using a conversion factor involving the measured UV window transmission coefficient, the nominal beam splitter power ratio, the laser repetition rate (10 Hz), and the energy per 266 nm photon.

RESULTS AND DISCUSSION

For this testing, a copper sample was machined from material already on hand, and a fine-grain niobium sample etched to 150 μm using buffered chemical polishing was provided by Cornell. Using the system described above, the sample temperatures were adjusted between 85 K and 400 K. At each temperature, the laser power was varied from the minimum power needed to avoid nonlinearity in the detector, to the maximum power that avoided the onset of space-charge-limited operation. The beam current data was integrated to determine the number of photoelectrons produced per laser pulse, and the power meter data was converted to find the number of photons arriving at the cathode per laser pulse. This data was plotted as shown in Fig. 3 and fit to a straight line, with the slope of that line giving the QE. Additional lines were used to conservatively bound the data, and the slopes of these lines set the upper and lower error estimates on the QE.

Copyright © 2013 CC-BY-3.0 and by the respective authors

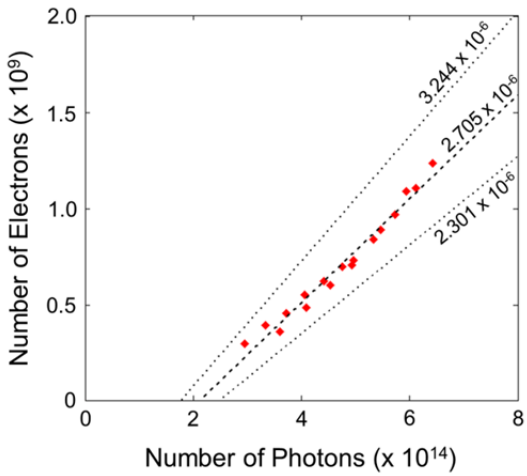

Figure 3: Data reduction for copper sample at 85 K, showing data, fitting line (dashed) and error bounding lines (dotted), with slopes (QE values) indicated.

Figure 4 summarizes the measured QE as a function of cathode temperature for the copper and niobium samples. Also shown are the measured vacuum pressures in the test stand at each temperature during the two sets of experiments. The measured QE of copper increased from 0.27 x 10^{-5} to 1.2 x 10^{-5} as the temperature increased from 85 K to 400 K. This represents a clear and statistically significant increase in QE by more than a factor of four. Over this range, the trend is well described by a quadratic fitting function (Fig. 5), except for the values at 200 K; the cause of this discrepancy is unknown. Vacuum pressure changed very little until the sample temperature exceeded about 350 K in these tests, suggesting that this does not explain the steady change in QE observed for copper.

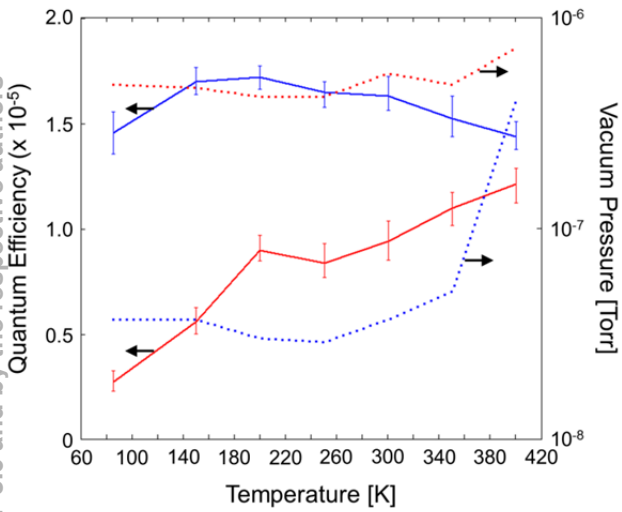

Figure 4: Measured QE (solid lines) and vacuum pressure (dotted lines) during experiments with copper (red) and niobium (blue) as a function of sample temperature.

By contrast, the observed dependence of QE on temperature for niobium is much weaker than for copper, with measured values varying from 1.4 to 1.7 x 10^{-5}.

This experiment found values of QE for copper and niobium that were generally in line with those reported in the literature [9], but the difference in the observed temperature dependence between copper and niobium is dramatic and unexplained. It is important to note that while the samples were handled and cleaned using standard vacuum procedures, the details of their surface conditions are unknown, and there was almost certainly some degree of oxidation present. However, this is representative of the likely surface conditions of these materials when used in actual accelerators.

Abstract

A high power CW, heavy ion linac will be the driver accelerator for the Facility for Rare Isotope Beams (FRIB) being designed at Michigan State University (MSU). The linac requires a Beam Position Monitoring (BPM) system with better than 100 micron resolution at 100 microamperes beam current. A low beam current test of the candidate technology, button pick-ups and direct digital down-conversion signal processing, was conducted in the ReA3 re-accelerated beam facility at Michigan State University. The test is described. Beam position and phase measurement results, demonstrating ~250 micron and ~1.5 degree resolution in a 45 kHz bandwidth for a 1.0 microampere beam current, are reported.

INTRODUCTION

The Facility for Rare Isotope Beams (FRIB) [1] will be a new accelerator-based user facility for research in nuclear physics. It will be located in the MSU campus and it is scheduled for completion in 2022. Its driver linac will accelerate ions as heavy as Uranium to energies higher than 200 MeV/u delivering up to 400 kW of beam power into a target. The desired Rare Isotope Beam (RIB) product of the reactions in the target will be transported to the different experimental areas after being selected in a fragment separator. Alternatively, the RIB can be thermalized, charge-bred and postaccelerated in the ReA re-accelerator [2] before being sent to an alternative experimental hall.

While the FRIB facility completion is scheduled for 2022, the first stage of the ReA re-accelerator was recently completed and connected to the Coupled Cyclotron facility (CCF) [2, 3]. During the measurements described in this paper, it has been used as a stand-alone accelerator to test the FRIB's prototype BPM system using a molecular Hydrogen beam produced by the off-line stable ion source.

DESCRIPTION OF REA3 AND THE BPMS

A Colutron-type ion source is used to produce several microamps of H_2^+ beam with an initial energy of 24 keV (defined by the 12 keV/u injection energy of the RFQ). The beam is then transported through an electrostatic transfer line and injected into a 4-rod 80.5 MHz RFQ after being bunched using a multiharmonic buncher. After the RFQ, the 600 keV/u beam is rebunched as it passes through a $\beta = 0.041$ SRF cavity operated at its zero-crossing phase (located in the first cryomodule (CM1) of the linac) and then accelerated to a few MeV/u when it passes through six more $\beta = 0.041$ SRF cavities located in the second cryomodule (CM2). Superconducting solenoids equipped with corrector coils inside the cryomodules are used to focus and steer the beam. During the tests, the two BPM sensors were installed in a drift space approximately 0.6 m down-stream of CM2 and separated by 2.08 m (Figure 1). Movable slits and Faraday cups in diagnostics stations before and after the BPMs were used to center and characterize the beam during the tests and beam attenuators and collimator slits were used to change the beam current.

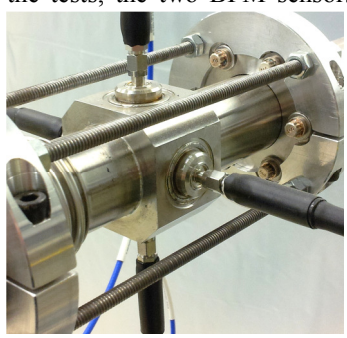

Figure 2: Prototype BPM as tested in ReA3.

The BPM system comprises two button-type BPM sensors (Figure 2, Table 1), signal amplifiers and digitizers that provide raw and processed data via EPICS channels to the control room. The button pickup has a design capacitance of 2 pF and impedance of 50 Ω. The

signals from the buttons are small (~ -80 dBm), requiring amplification before digitization. Each front-end channel has a low-noise amplifier with 80 dB gain and 14 MHz band width centered near the 2nd beam harmonic at 161MHz. The entire analog front-end is enclosed in a shielded box and connected to the bpm using solid copper shielded coax to further reduce noise from surrounding systems.

The signals are digitized and processed by an 8-channel digital receiver board developed at Fermilab. This board was initially used for the ATF damping ring BPMs [4]. The board consists of 125 MS/s 14 bit ADCs connected to a Cyclone III FPGA.

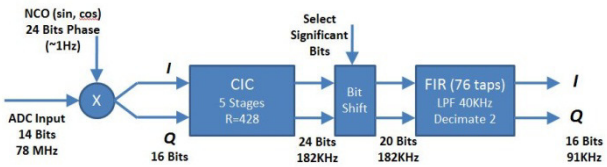

Figure 3: A block diagram of the DDC filter.

For the ReA3 system, an RF reference of 80.5 MHz is provided for the digitizer clock input. An internal PLL-based clock distribution chip sets the ADC clocks to operate at 32/33 of the RF clock. This undersamples the 161 MHz input signal producing an intermediate frequency (IF) of approximately 5 MHz. The IF signal is then processed by a Digital Down-Converter (DDC) circuit as shown in Figure 3. The output rate of the DDC is 91 kHz. The DDC yields the magnitude and relative phase of the input signal.

The 91 kHz output rate of the filter provides 2048 samples over a 22.5 ms window for each trigger. The beam pulse length was limited to approximately 25 ms for the tests. For each trigger, the front-end software reports the complete array of magnitude and phase data for the beam pulse as well as time-averaged values for positions, intensity and phase over the pulse.

Table 1: Characteristics of the BPMs

Parameter	Value
BPM aperture	1 3/8 in
Button diameter	20 mm
Signal frequency	161 MHz (2nd harmonic)
Trigger frequency	5 Hz

RESULTS OF THE TESTS

Several tests were conducted during 2012. The first tests confirmed the expected beam signal levels and uncovered an issue with electrical noise caused by the RFQ power amplifier. Electromagnetic shielding and filters were added to the BPM signal amplifiers in the following tests.

Beam Intensity Measurements

In an effort to understand the BPMs' performance at low currents and measure their response versus beam intensity changes, data were recorded while the beam current through the line was changed and measured in a Faraday cup located after the second BPM. The results of this measurement are shown in Figure 4 and demonstrate that the BPMs can be used with currents as low as 50 nA which is several orders of magnitude smaller than the anticipated 50 µA FRIB commissioning beam current. Their responses were linear over the range of available beam currents, which was limited by the ion source. The similarity in the results from the two BPMs indicates good reproducibility.

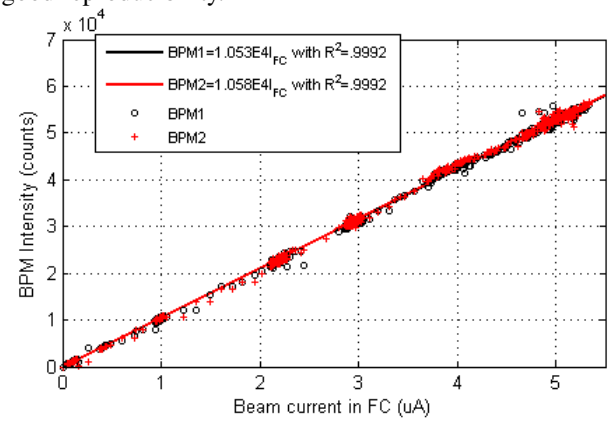

Figure 4: BPMs intensity signal vs. beam current. Currents as low as 50 nA could be measured.

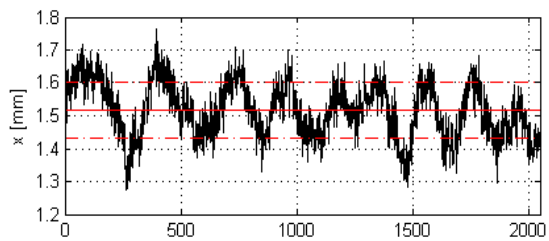

Figure 5: Typical measured beam position over 2048 consecutive samples (i.e. over 22.5 ms) for a 2 µA beam.

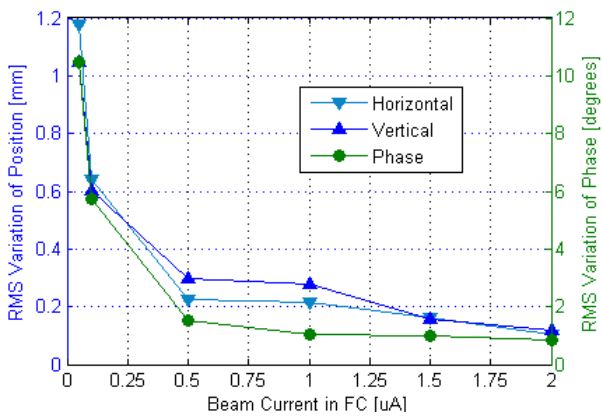

Figure 6: RMS variation of position and phase measurements as a function of beam current.

Variability of Position and Phase Measurements

Several experiments were conducted to characterize the resolution of the BPMs' position and phase measurements. Figure 5 shows the result of a typical

Copyright © 2013 CC-BY-3.0 and by the respective authors

measurement; Figure 6 shows a summary of the RMS distribution of position results as a function of current. Without an independent measurement of actual beam motion, this data merely sets an upper limit for the achieved measurement resolution.

The variability for currents lower than 0.5 µA seems to be defined by the BPM system itself; however, this may not be the case for higher currents. Figure 5 suggests that coherent beam motion might be dominant at the 2 µA current level. The resolution of the BPM system at currents between 1 and 2 µA might be a fraction of the ~100 µm shown in Figure 6.

Beam Position Measurements

To observe the BPM system response to changes in beam position, data was recorded while the beam was steered several millimetres horizontally and vertically using the last correctors in CM2. Inside the cryomodules, the corrector coils are embedded in the solenoids which explains the horizontal and vertical coupling apparent in Figure 7.

Currently the position and intensity is scaled linearly. A 3rd order two-dimensional polynomial is being implemented to linearize and decouple the positions and to correct the intensity. The polynomial compensates for non-linearity effects with good results over two thirds of the pickup aperture.

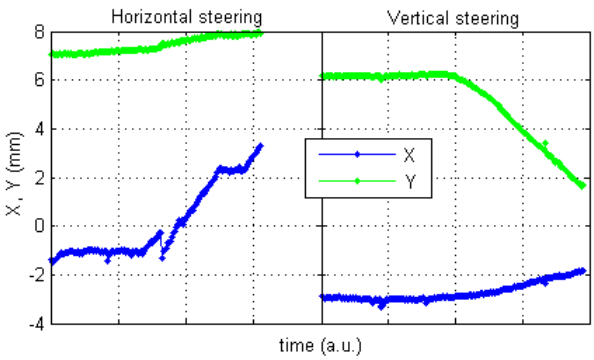

Figure 7: Beam position over time as it was steered horizontally (on the left) and vertically (on the right) during the test.

Phase Measurements

Simultaneous beam phase measurements enabled relative beam energy measurements by determining changes in time-of-flight. The beam phase at each of the two BPMs was observed as the beam energy was changed by scanning the RF phase of the last cavity in the second cryomodule.

Results show the expected sinusoidal-like phase variation between the two BPMs as a function of cavity phase setting (Figure 8). Measurement resolution was better than one degree of phase (17 picoseconds) in a 10 Hz bandwidth at 161 MHz for a 2 µA beam current.

The time-of-flight information provided by the BPMs has proven to be useful during the commissioning of the ReA3 linac. The time it takes to phase each cavity in the linac using the BPMs was reduced to a few minutes after automating the procedure, which is very important for FRIB given the number of cavities in the driver linac. More details on this procedure can be found in [5].

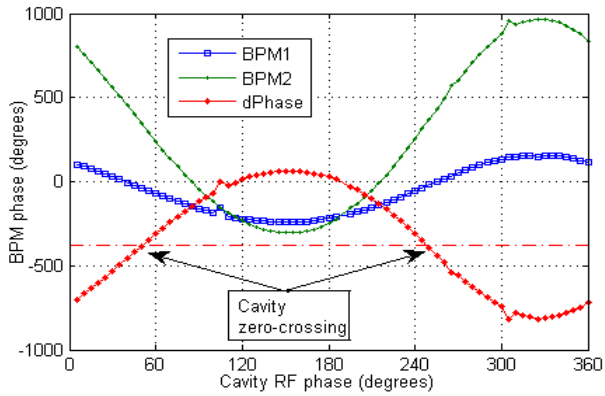

Figure 8: BPM phase measurements as the phase in the last cavity of CM2 is varied.

Signal to Noise Ratio Measurements

A spectrum analyser was used to measure noise with the amplifier located at the bpm and then at the digital receiver 18 m away. The noise power spectral density referenced to the amplifier input measured -167.4 dbm/Hz for both locations. No degradation in BPM signal quality was observed. This is relevant for FRIB because it is highly desirable that the amplifiers be located outside the tunnel to be shielded from ionizing radiation and accessible for maintenance.

CONCLUSION

The BPM experiments in the ReA3 facility have successfully demonstrated that high resolution for position and phase measurements with microampere beams can be achieved using button-type BPMs and 2nd harmonic signal processing. Scaling the ReA3 results to FRIB suggests a resolution 7 times better than the 100um at 100uAmp requirement. While work remains to assure this performance is achieved in the real FRIB accelerator environment, these tests provide a basis for proceeding with a FRIB BPM system design based on button-type pickups and a direct digital down conversion receiver.

LIFETIME STUDY OF TUNGSTEN FILAMENTS IN AN H- SURFACE CONVERTER ION SOURCE*

I.N. Draganic#, J. F. O'Hara, and L. Rybarcyk, LANL, Los Alamos, NM 87545, USA

Abstract

The tungsten filaments are critical components that limit the lifetime of the H- surface converter ion source. Their finite lifetime has a huge impact on the maintenance schedules and overall availability of an accelerator facility. We present in this work a simple analytical filament lifetime model and 3D thermal simulation explaining basic phenomena of filament erosion and electrical resistance changes during a normal run of an H- production ion source at the Los Alamos Neutron Science Center (LANSCE). The calculation of filament longitudinal temperature profile takes into consideration the effects of ohmic heating, thermal conductivity and total emissivity for tungsten wires in high vacuum. The simulation includes the DC voltage operation of the filament with and without pulsed arc discharge current and gives the differential filament resistance changes, metal evaporation rates and theoretical electron emission currents. The results of the computation are compared with observed experimental data recorded using the EPICS control system during a normal LANSCE production cycle of 28 days with pulse repetition of 60 Hz and duty factor of 5%.

H- ION SOURCE LIFETIME

H- surface converter ion sources are well described elsewhere [1-4]. Three nearly-identical H- radial extraction converter ion sources (see Fig. 1A) have been utilized for proton beam production at LANSCE for more than 25 years. These H- sources deliver typical beam current up to 18 mA into an 80-kV electrostatic column and have operational lifetimes more than four weeks between accelerators maintains periods at a repetition rate of 60 Hz and duty factor of 5 %. Typical EPICS-recorded data of the extracted H- ion beams and an evolution of each filament's relative differential resistance during an entire cycle are presented in Figure 2. The negative-ion source consists of a filament driven arc discharge in a permanent-magnet, multi-cusp vacuum chamber for plasma confinement and a negatively biased converter electrode for H- beam production. The source uses two filaments made of high purity tungsten wires (99.99%), bent in a characteristic shape (see Figure 1B) with length of 297 mm, 1.6 mm thick diameter, weight of ~12 g and resistance of 7.8 mΩ at 295 K. Nominal filament currents of 100 to 106 A are driven by DC constant voltage power supplies (11 - 12V) bringing the wires to working temperature range of 2600 to 2700 K. The increase of filament temperature for higher electron output (plasma discharge) or more intense H- current is limited by the increasing of evaporation of filament material, which

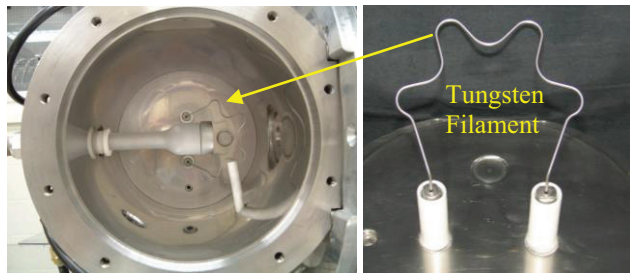

Figure 1: An internal side view of the LANSCE H- ion source is shown (A). New tungsten wire mounted on the water cooled ports (B).

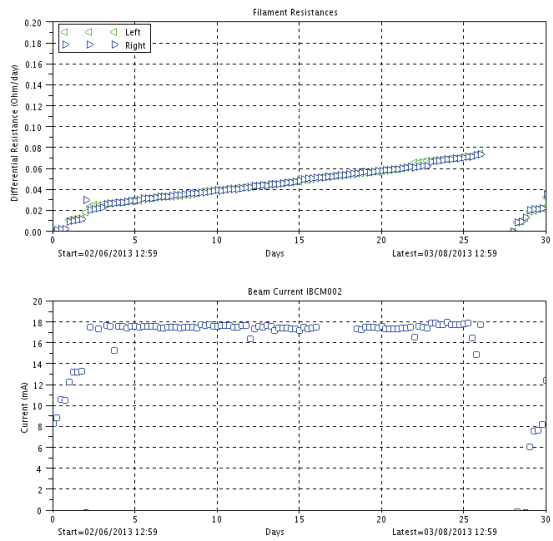

Figure 2: An EPICS application plots for operation monitoring purposes the filament relative differential resistances and the 80 keV extracted beam currents during a LANSCE beam production cycle (points every 6 hours).

decreases the lifetimes of the filaments, and ultimately limits the ion source operating period before replacement. The characteristics of tungsten filaments in vacuum at various high temperatures were studied in detail for incandescent lamps, radio tubes and in other scientific and engineering investigations [5-12]. There are two empirical criteria for critical differential resistance that predict the onset of filament failure: a) 12% of total increase in filament resistance or decrease in mass weight [5, 6] and b) 19 % of total increase in filament resistance or 10% of reduction in wire diameter [4, 8-12].

FILAMENT RELATIVE DIFFERENTIAL RESISTANCE

The LANSCE EPICS control system continuously records (a sample per minute) the filament currents and voltages, as well as the arc discharge peak currents and voltages. The filament resistances, based on U/I

measurements, change in the range from 100 to 115 mΩ (Figure 3A). The hot wire resistance increases over 140 times from the room temperature resistance. Differential resistance is calculated using a simple formula:

$$\frac{\Delta R}{R}=\frac{R_2-R_1}{R_1}=\frac{R_2}{R_1}-1=\frac{U_2 I_1}{U_1 I_2}-1 \quad (1)$$

where R_1 is the filament resistance at beginning of run (t_1=0) and R_2 is resistance recorded later during the cycle ($t_2 \neq t_1$). A characteristic relative differential resistance increase of 7.5% is shown in Figure 3B staying well below the 12% criteria. Digitized resistance data (40,000 points over 28 days) obtained using EPICS, enables easy data access and manipulation. The new filaments were weighed prior to installation and refurbishment to determine their mass, and later, after the production cycle and filament disassembly. The mass measurements are presented in Table 1. An average tungsten evaporation rate of 27 mg/day was observed. Measured relative mass changes were 2% less than the recorded differential resistances. Even after a correction for the inserted wire length into holder/ports, the discrepancy between mass and relative resistance measurements was considerable. Step-wise changes in both differential resistance graphs were observed during adjusting of the DC heating currents and source optimization. Systematic errors in differential resistances due to the long connection cables, shunts and voltage readings are being neglected.

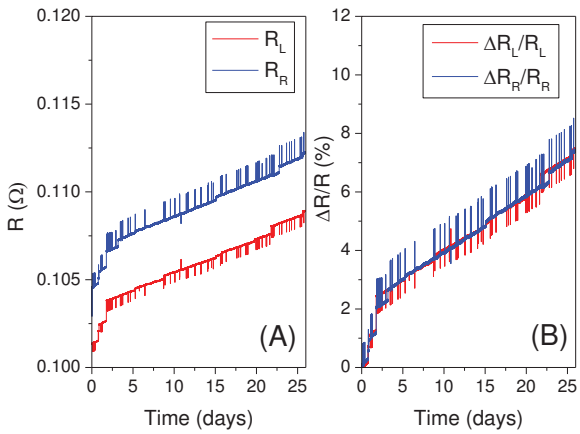

Figure 3: Characteristic filament resistances and relative differential resistances calculated using EPICS recorded U/I measurement data for both filaments.

Table 1: Mass Measurements and Recorded Differential Resistances from the EPICS Data are Listed. $\Delta M/\overset{*}{M}$ is a Length Corrected Evaporated Mass (k=1.072).

Filament	Left (#1)	Right (#1)
M1 (g) (before)	11.808	11.737
M1 (g) (after)	11.134	11.020
ΔM (g)	0.674	0.717
ΔM/M (%)	5.71	6.12
$\Delta M/M^*$ (%)	6.12	6.56
ΔR/R (%)	7.5	7.44

FILAMENT RESISTANCE MODEL

A simple analytical filament resistance model is needed to explain the wire erosion and recorded differential resistance behavior. The model has the following assumptions: a) an ideal wire is considered; it has a constant position/shape (no plastic deformation, sagging etc.), b) the filament temperature is constant across the wire length, c) thermal expansion is negligible, d) the mass evaporation is uniform over the wire surface and is a function of temperature, e) the total emissivity for tungsten wire varies only with temperature, f) the filament current is a sum of DC heating current and peak arc discharge current averaged by the duty factor, g) plasma sputtering is not taken into account, and h) microscopic effects like a recrystallization, grain growth, impurity content, electro-migration (Soret's effect) are not included [12]. The tungsten wire resistance is described using dimensional formula $R_i=\rho_i L_i/S_i$, for i=1(t_1=0), i=2 ($t_2 \neq t_1$); L and S are the wire length and cross section respectively. Because the filaments have very small thermal expansion differences ($L_1 \approx L_2$), equation (1) can be simplified:

$$\frac{\Delta R}{R}=\frac{\rho_1}{\rho_2}\frac{S_2}{S_1}\frac{L_1}{L_2}-1 \cong \frac{\rho_1}{\rho_2}\frac{S_2}{S_1}-1 \quad (2)$$

In our model, the specific electrical resistance is a linear function of temperature ($\rho_i=a+bT_i$). The time averaged mass evaporation is defined by the equation $\Gamma=\Delta M/A_e\Delta t$ or $\Gamma=(\rho_m L\Delta S)/(A_e\Delta t)$, where Γ(g/cm^3/s) is an evaporation rate [6. 11], A_e is the wire evaporation surface area, ΔM and Δt are evaporated mass and evaporation time, ΔS is a reduction in wire cross section and ρ_m is tungsten mass density (19.25 g/cm^3) [13]. Equation (2) can then be rewritten in the form:

$$\frac{\Delta R}{R}=\frac{b(T_2-T_1)}{\rho_1}+\frac{\Gamma(T_1)A_e\Delta t}{S_1\rho_m L}=\frac{b\Delta T}{\rho_1}+\frac{\Delta M}{M_1} \quad (3)$$

Equation (3) has two components. The first term takes into account material electrical characteristics and changes in filament temperature with filament current. This term represents "fast" processes and is independent of time, describes the tuning processes. The second term describes the "slow" processes including filament evaporation and steady state changes in filament mass and cross section. This time dependent term is a useful monitoring tool for the filament and source lifetime.

The filament temperature in our model is determined from the graphs presented in Ref. [6]. The temperature is defined by the heating current though filament, I, and the wire diameter d. For our model, we have created a two dimension polynomial fit to the data [6]: (surface function $T(K)=A_0+A_1 d+A_2 I+A_3 d^2+A_4 I^2+A_5 Id$).

The filament resistance model was applied to simulate the experimentally recoded data in Figure 2. Using estimated wire diameter after processing of H-source and recording total current for the left filament, calculation of the temperature was possible. Results of mass losses integrated over the run cycle and ΔR/R step changes are presented in Figure 4 and Table 2 showing a reasonable agreement with recorded data.

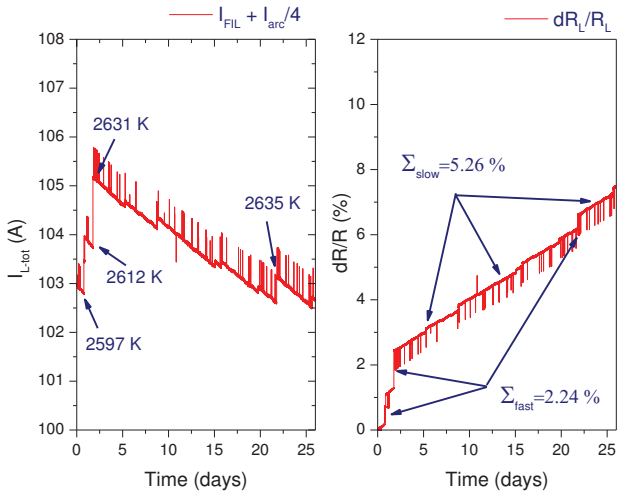

Figure 4: (A) Measured total left-filament current as a function of days during the run cycle. Also shown are associated changes in wire temperature after each source adjustment. (B) Measured left-filament differential resistance. Percent changes in differential resistances due "fast" and "slow" processes are shown.

Table 2: Measured Left Filament Differential Resistance Compared with Filament Model Calculation

Filament	Total (%)	Fast (%)	Slow (%)
EPICS data	7.50	2.24	5.26
Model	7.11	1.76	5.35

THERMAL FINITE ELEMENT ANALYSIS

A thermal finite element analysis was also performed to determine a steady state temperature profile. A 3D model of the tungsten filament was created. Included in the filament thermal simulations are the tungsten physical properties, ohmic heating, thermal conductivity and thermal emissivity in high vacuum [13]. A constant heating current of 103.5 A is applied to the filament. Arc current ranging from 0.75 A to zero is assumed to be decreasing linearly from one end of the filament to the other (discretized in 10 steps). Radiation and temperature boundary conditions across all wire segments are applied for 294 K at each end (due to water cooling loops). The total emissivity varies as a function of wire segment temperature. A peak filament temperature of 2684 K was calculated. The peak temperature moves from the center of the filament towards the higher-arc-current side (Fig. 5A). As the filament evaporates in a localized area close to the peak temperature location, the cross section of the filament decreases in that area. This decrease in cross sectional area causes an increase in resistance, which results in an even higher temperature for the same applied currents. This creates a runaway situation of decreasing wire cross section, increasing temperature and high evaporation rate that leads to creation of a localized hot spot that can cause catastrophic failure of the filament [7]. This typical filament failure mode is shown in Figure 5B.

We propose changing the polarity of the DC filament and arc voltages at least once per week in order to avoid hot spots created by this asymmetric ohmic heating.

PIN DIODE DETECTORS AT DARHT II*

Jeffrey B. Johnson, LANL, Los Alamos, NM 87544, USA

Abstract

PIN diode detectors are a useful diagnostic tool for accelerator operations. The DARHT Axis II electron beam accelerator utilizes an array of twelve PIN diodes to detect the location of high voltage column electron emissions during abnormal injector events. The PIN diodes are located outside the injector vacuum vessel and detect the x-rays that are produced when the -2 MeV column electrons strike the vacuum vessel wall. This paper describes the PIN diode selection, calibration and use on the accelerator.

INTRODUCTION

An array of twelve PIN diode detectors is used on the DARHT Axis II accelerator injector to monitor for abnormal high voltage events. The injector consists of a Marx bank pulse generator, high voltage column, thermionic cathode and a vacuum vessel as shown in Figure 1.

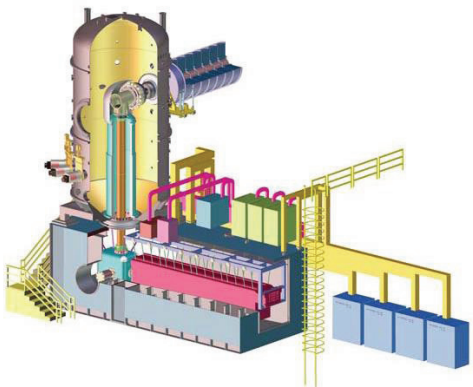

Figure 1: DARHT Axis II Injector.

During operation of the injector, abnormal events may occur. These include explosive electron emissions from the cathode and injector voltage droops from high voltage breakdowns of the cathode region or column. To help identify the precise location of such events, a PIN diode detector system was developed and installed on the injector. The PIN diodes detect the Bremsstrahlung radiation created when high energy electrons emitted during an abnormal event intercept the vacuum vessel wall. The array of twelve detectors is evenly spaced around the outside of the vacuum vessel.

PIN DIODE SELECTION

The sensitivity required for the PIN diodes was determined experimentally. A PIN diode detector assembly made by Emerge Semiconductors (100-PIN-250-HN-BG) was initially used as a single channel monitor for abnormal events. Data collected during a few abnormal events showed that this diode had the appropriate sensitivity to make the measurements. Unfortunately, the Emerge PIN diode assemblies are no longer available. An equivalent PIN diode assembly needed to be identified or built in order to construct the detector array. A market survey was conducted for a silicon PIN diode assembly similar to the Emerge detector and none could be found. This lead to the development a LANL designed detector assembly which uses a low cost commercial PIN diode chip and a custom made housing shown in Figure 2. The PIN diode chip selected was the OSI Optoelectronics PIN-RD-100. This chip has similar geometry (area and Si depth) compared to the Emerge diode. A steel housing was designed to hold the chip and provide some degree of collimation and shielding.

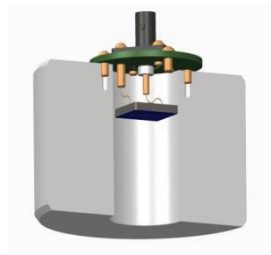

Figure 2: LANL PIN diode assembly.

CALIBRATION

The LANL PIN Diode detector assembly was calibrated against the Emerge detector using the DARHT Axis II accelerator Beam Clean up Zone (BCUZ) [1] as a radiation source. The BCUZ, shown in Figure 3, is an energy filter which absorbs beam energies below 3 MeV which occur during the rising and falling edges of the accelerator beam pulse.

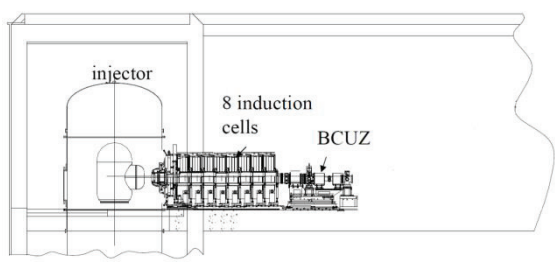

Figure 3: BCUZ region used for calibration.

The absorbed energy creates a pulse of broad band X-rays for the calibration. The central portion of the signal from the rising edge was used for the calibration. During calibration, the detectors were placed downstream from and just above the BCUZ. Detector reverse bias voltages

johnsojb@lanl.gov

Copyright © 2013 CC-BY-3.0 and by the respective authors

were 1000 volts for the Emerge detector and 100 volts for the LANL detector. Calibration data in Figure 4 shows that the LANL detectors are more sensitive to the middle of the calibration pulse than the Emerge detector. The LANL detector response is not as fast due to the lower reverse bias voltage [2]. The sensitivity for the LANL detectors is 1.53×10^{-7} A/(R/s) for the lower dose rates from the BCUZ X-ray source.

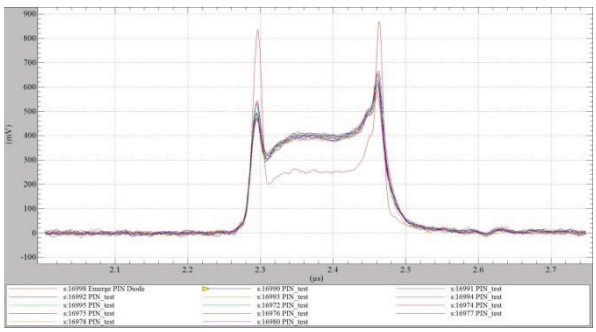

Figure 4: Calibration waveforms.

SYSTEM OPERATION

The PIN diode detectors must be operated with a reverse bias voltage applied across the P-I-N junction. To achieve this, a DC power supply is connected to the detector cable using a LANL designed bias tee as shown in Figure 5.

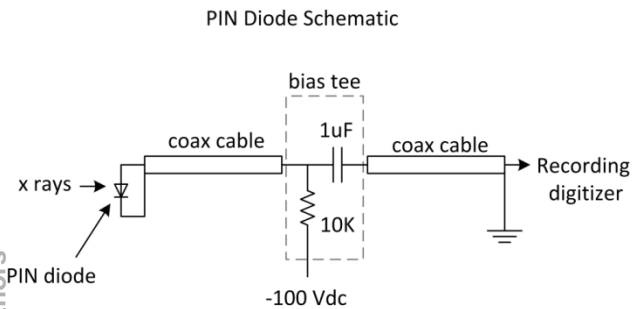

Figure 5: PIN diode schematic.

The bias tee can operate to 1000 VDC and has 1 microfarad of coupling capacitance. The large coupling capacitance provides extended low frequency response for slower signals produced during slower changing X-ray fluxes. There is one bias tee for each detector. A single DC power supply provides the bias voltage for all twelve detectors through a simple fan-out box. The detectors are operated with a 100 VDC reverse bias at DARHT to eliminate the electrical hazards associated with operation at greater voltage levels. Each detector output signal is recorded on its own high speed digitizer channel each time the injector is fired. The PIN diodes I layer is completely depleted at 80 volts reverse bias and the sensitivity will remain constant at any reverse bias greater than 80 volts as long as the output voltage stays less than half of the bias voltage. Increasing the reverse bias voltage increases the time response of the PIN diode.

RESULTS

On 9/25/2012, (shot 19274) an abnormal event occurred while operating the injector. The injector voltage pulse displayed a droop as shown in Figure 6. This occurred after the vacuum environment of cathode was accidently compromised which may have degraded the cathode surface leading to explosive electron emissions during pulsing. When this happens, it is likely that some of the emitted electrons do not enter the accelerator beam tube and instead impact the vacuum vessel wall.

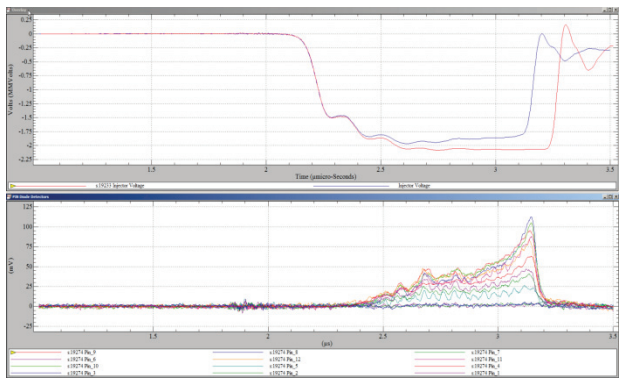

Figure 6: Injector voltage waveforms. Top waveform showing normal (red) and droop (blue) conditions. Bottom waveform shows PIN diode signals recorded during injector voltage droop.

A circular plot of the peak PIN diode signals shown in Figure 7 provides azimuthal information as to where electron emissions occurred inside the vacuum vessel.

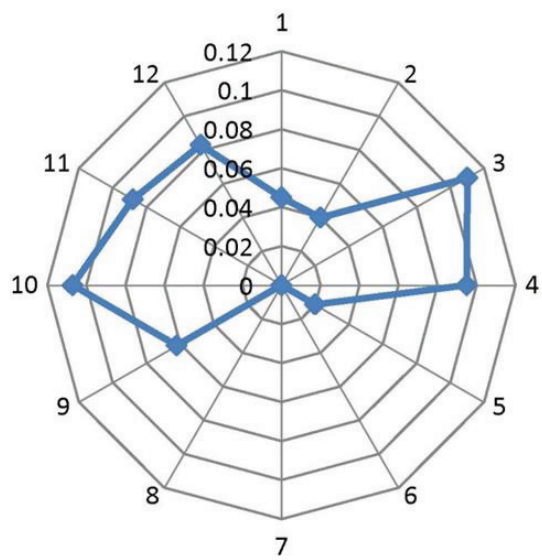

Figure 7: Circular plot of peak PIN diode signals during an abnormal injector event.

Copyright © 2013 CC-BY-3.0 and by the respective authors

CONCLUSIONS

A comparison of the PIN diode signal intensity shows that the LANL detectors are able to identify where electron emissions occur inside the vacuum vessel. The time response of detectors is limited by the low reverse bias voltage used with the system, but is adequate for the X-ray dose rates generated during abnormal injector events.

ACKNOWLEDGMENT

I would like to acknowledge C.Y. Tom of NS Tec for helping with the data collection during the calibration of the detectors.

LANSCE-RM WIRE SCANNERS: SLIP-ENCODED SERIAL COMMUNICATION FOR MAINTENANCE DISPLAY AT THE INSTRUMENT*

J. Sedillo, J.D. Gilpatrick, LANL, Los Alamos 87545, USA

Abstract

The newest LANSCE-RM wire scanner control systems at Los Alamos National Laboratory's LANSCE particle accelerator facility utilize touch-panel displays for limited status and control at the instrument. Since the wire scanner control hardware utilizes a National Instruments CompactRIO embedded controller, no display may be interfaced to the CompactRIO via conventional means. Thus, in order to display information from the CompactRIO, a touch-panel display and computer combo unit has been added to each wire scanner control chassis with information being exchanged via a common, RS-232 interface. This paper describes the maintenance features available at the touch screen and the underlying SLIP communication scheme used for simple packetized transfer of data between the touch-panel display and the CompactRIO.

INTRODUCTION

The control system outlined in figure 1 represents the solution developed by LANSCE staff for wire scanner actuator control and data acquisition [1]. Among its assortment of features is the control system's chassis-mounted, touch-panel PC (TPC) for localized control and diagnostics of the wire scanner system.

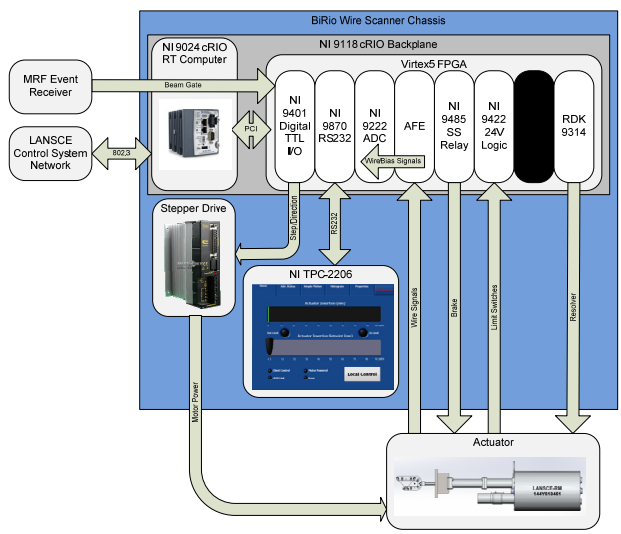

Figure 1: LANSCE-RM Wire Scanner Controller.

Although the touch panel PC offers a variety of high-bitrate interfaces (e.g. Ethernet and USB), the touch panel's RS-232, null-modem interface was chosen due to its ease of use and its common and direct interface to the compactRIO (cRIO) controller's FPGA (via the FPGA's NI 9870 RS-232 c-series module).

*Work supported by the U.S. Department of Energy.

MOTIVATION

RS-232 null-modem links offer a great deal of flexibility with how data is communicated since the hardware does not inherently provide the means to organize data meaningfully other than its FIFO approach. If context of the data may be derived from each individual byte communicated, then no expanded form of data encapsulation may be necessary. However, for more common situations where the data varies in content (e.g. varying data structures) and size (the size of the data structure in bytes), the implementation of a data encapsulation scheme will assist the receiver with making a clear determination of data boundaries by placing the data in "packets".

Data encapsulation schemes are fundamental to many familiar hardware communication systems, the most prevalent of which is 802.3 ethernet. Common encapsulation schemes leveraged on 802.3 networks include the familiar IP, TCP, UDP, etc. Given the successful standardization and implementation of these protocols, almost any one of them may be utilized for serial links implemented on hardware other than 802.3, depending on the application. Since the wire scanner's cRIO transmits a variety of data structures to the TPC and since the data can arrive in an unpredictable order, a data encapsulation method was required to assist both the TPC and cRIO to 1: understand the where a packetized data structure begins and ends, and 2: to determine how to direct the data to the proper methods for processing.

SLIP

IETF de-facto standard RFC1055, otherwise known as SLIP, was deemed the most suitable protocol for data encapsulation [3]. SLIP is an acronym for Serial-Line Internet Protocol and is a data-link layer protocol in the OSI conceptual model. SLIP was developed as a simple means of transmitting TCP/IP datagrams over serial lines when no standard yet existed and has since been replaced by PPP (Point-to-Point Protocol, RFC1661) in most applications. SLIP focuses only on packet framing, and therefore does not inherently provide a means for addressing, packet type identification, error detection/correction, or compression [2].

SLIP's simplicity made it an attractive choice for this application since encoding and decoding methods of more complex protocols would have been needlessly difficult to develop for the cRIO FPGA. Furthermore, the limitations of the SLIP protocol were of little concern since the wire scanner controller can operate without proper operation the TPC; and because the414-6541 link was short (<1 ft),

Copyright © 2013 CC-BY-3.0 and by the respective authors

low-speed (56kbps), and directly linked. These qualities ensure low probability of data corruption.

SLIP Encoding

The SLIP encoding method is generally simple to implement. Given a data structure that has been flattened into a 1-D array of bytes, the SLIP encoding method simply appends hexadecimal byte 0xC0 to the beginning and end of the array. These bytes encapsulate the data and form the boundaries of the SLIP packet (figure 2).

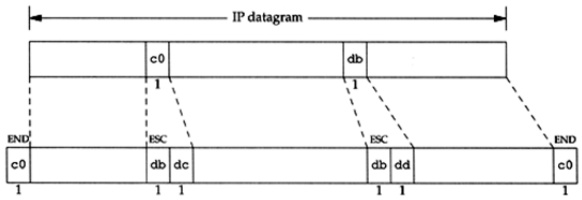

Figure 2: Slip packet layout [3].

If the 1-D array of data contains the value 0xC0, that value is replaced by 0xDBDC (two bytes). If 0xDB is encountered, it is replaced by 0xDBDD (two bytes). Through this method, special SLIP encapsulation characters and data cannot be mistaken by the SLIP decoder.

SLIP Decoding

SLIP decoding is slightly more complicated than encoding. In the ideal case, 0xC0 is the first byte a SLIP decoder encounters upon first receipt of SLIP-encoded serial data. The decoder must simply accumulate the bytes after the 0xC0 header until encountering 0xC0 again. In the not uncommon circumstance where the SLIP encoder utilized special byte patterns 0xDBDC and 0xDBDD, the SLIP decoder will replace 0xDBDC by 0xC0, and 0xDBDD by 0xDB. The data enclosed with the 0xC0 characters may then be passed to other routines for its appropriate use. In the event that a receiving system comes online after data transmission has progressed, the receiving system will simply disregard all data received until it encounters the next SLIP packet's 0xC0 header.

UTILIZATION

After implementing the SLIP encoding and decoding methods for the cRIO and TPC, a custom data encapsulation scheme was developed for incorporation within the SLIP packets. This was necessary to overcome SLIP's lack of a provision for identifying packet types.

Tag Length (1 byte)	Payload Length (2 bytes)	Tag (1-255 bytes)	Payload (1-65,535 bytes)

Figure 3: Custom packet structure.

The custom packet (Figure 3) specifies a 3-byte header and a variable-length payload. The first header byte represents a tag length in bytes. The remaining two header bytes represent the data payload length in bytes. The header is then followed by the tag and the data payload. The tag allows the receiving system to identify the data packet and direct its contents to the correct methods for proper use.

Three communication channels operate within the single, RS-232 link between the cRIO and TPC. The operational flow is shown in figure 4 and described in the sections that follow.

CompactRIO FPGA to TPC Channel

The wire scanner's CompactRIO FPGA sends wire scanner status information to the TPC. This status information includes: actuator position, limit status, sense wire continuity, remote operation status, the general error condition, network ID, beam gate, FPGA state, and the cRIO C-series module status.

The cRIO FPGA accumulates the data from its internal processes, encapsulates the data within "custom" packets with unique tags representative of the data, and then directs the custom packets through a SLIP encoding process. The SLIP packets that result are then directed to the RS-232 FIFO for transmission to the TPC. The FPGA has the least flexibility with regard to packet size since arrays dedicated to the transmission and reception of the packets must be of a fixed size prior to FPGA compilation. The corollary to this is that all packets transmitted to the FPGA from external systems must also fit within the FPGA's array size constraints.

TPC to CompactRIO FPGA Channel

The TPC sends commands to the cRIO FPGA for minimal control of the wire scanner actuator. Command information includes the actuator position setpoint and actuator operational envelope scan. These data allow for some localized control of the wire scanner actuator mechanism.

Data transmitted from the TPC to the cRIO FPGA occurs in a similar way to the "CompactRIO FPGA to TPC Channel" process. Although the TPC can dynamically allocate memory for substantially large SLIP packets, the size of the packets it transmits are of a size that are compatible with the maximum allocated array size of the cRIO FPGA's receive array.

CompactRIO RT to Touch Panel PC Channel

The cRIO RT system sends wire scanner configuration data to the TPC through the cRIO FPGA's RS-232 link. Configuration data includes:

- Actuator configuration: leadscrew pitch, stepper motor resolution, sense wire center positions, and mount angle.
- Motion control configuration: closed-loop control constants, position deadband, and stepper motor settings.
- Beam data acquisition configuration: AFE (Analog Front End) transimpedance values, ADC sampling rate, pre and post trigger samples, and macropulse waveform cumulative average count.

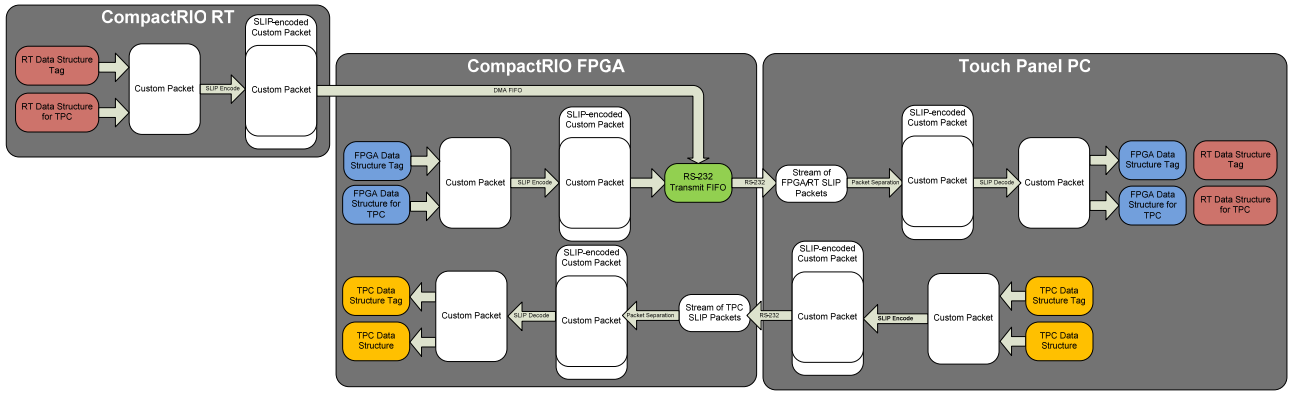

Figure 4: Overview of cRIO/TPC Communication flow.

The relatively large amount of data transmitted by the cRIO RT system to the TPC made it essential that data packets produced by the cRIO RT avoid the cRIO FPGA's bottlenecks. To do this, the cRIO RT encodes its data before transmitting the resulting data stream to a DMA FIFO read by the FPGA. Once the FPGA has completed sending its own packet stream to the TPC, it checks the DMA FIFO for data content. If data exists, the FPGA simply directs the data directly into the RS-232 FIFO for transmission to the TPC.

IMPROVEMENTS

SLIP is simply one of many methods for data encapsulation over serial streams. Again, SLIP does not inherently provide a means for addressing, packet type identification, error detection/correction, or compression. This work has compensated for SLIP's lack of packet type identification and required minimal error correction since a high-fidelity data link was utilized. More demanding applications may require more features from a SLIP implementation. In such cases, other protocols that possess the necessary features may be encapsulated within the SLIP packet or used outright, depending on the protocol and its compatibility with the application.

LANSCE-RM WIRE SCANNER PROJECT UPDATE

Six new LANSCE-RM wire scanner systems have been deployed throughout the LANSCE facility: two in the 201 DTL, Three in the 805 linac, and one in the switchyard. Integration of these systems is complete with all systems fully utilizable by LANSCE's central control room. Figure 5 shows a beam profile obtained by one of the wire scanners deployed in the 805 linac. Additional systems are planned for installation as resources become available.

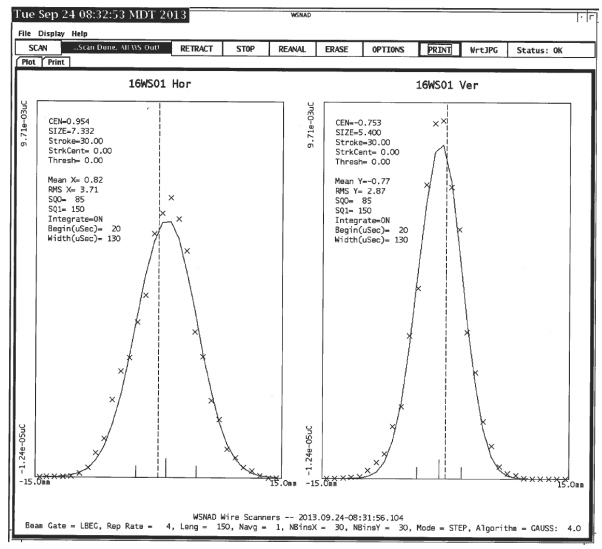

Figure 5: LANSCE Control Room view of wire scanner-acquired beam profiles.

ANALOG FRONT END DESIGN FOR HIGH SPEED DIGITIZING OF BEAM POSITION AND PHASE MEASUREMENTS AT LANSCE*

H. Watkins#, J.D. Gilpatrick, R. McCrady, LANL, Los Alamos, NM 87544, USA

Abstract

The Los Alamos Neutron Science Center (LANSCE) is currently developing beam position and phase measurements for its 805-MHz linac as part of the LANSCE risk mitigation project. Beam position and phase monitors (BPPMs) with four shorted strip lines have been installed throughout the linac. The BPPM electronics will sample each strip line at 240 MSPS and use a field programmable gate array (FPGA) to calculate position and phase of the beam relative to the linac reference. The beam micro-pulses from each electrode must be filtered and amplified to provide the correct frequency and amplitude level to the digitizer. This paper describes the signal conditioning required to interface LANSCE BPPMs to high speed digitizers, the diagnostic capabilities of the analog front end (AFE) module, digital control of the AFE module and design considerations to meet these objectives.

INTRODUCTION

Today's analog to digital converters (ADCs) are supporting higher sample rates and signal bandwidths allowing for direct sampling of RF signals that once required analog down conversion. The TI ADS62P49 14-bit ADC is being used at LANSCE to sample beam position and phase monitor (BPPM) signals. These signals are down converted digitally in a field programmable gate array (FPGA) to in-phase and quadrature-phase (I & Q) signals that are used to calculate position and phase of the beam centroid.

To take advantage of high speed digitizing and digital down conversion the micro-pulses from the BPPM's must be conditioned in frequency and amplitude to match the input range of the ADC. The analog front end (AFE) module was designed to interface between the BPPM and the digitizer to provide optimal signals for position and phase measurements.

This BPPM system is being developed as a replacement for LANSCE's legacy Δt system used for phase and amplitude adjustment of RF accelerating fields in the 805-MHz linac with the addition of measuring transverse beam position [1].

ARCHITECTURE

The hardware architecture for the system includes a 4-port BPPM, an AFE module, a 5-channel digitizer module and a Stratix 4 FPGA carrier board shown in Figure 1. The electronics system is housed in a VPX chassis that conforms to the ANSI/VITA 46.0-2007 standard [2].

The AFE module's printed circuit board design will conform to the VPX standard for size and backplane connections. Its power and control signals will come through the VPX backplane from the FPGA.

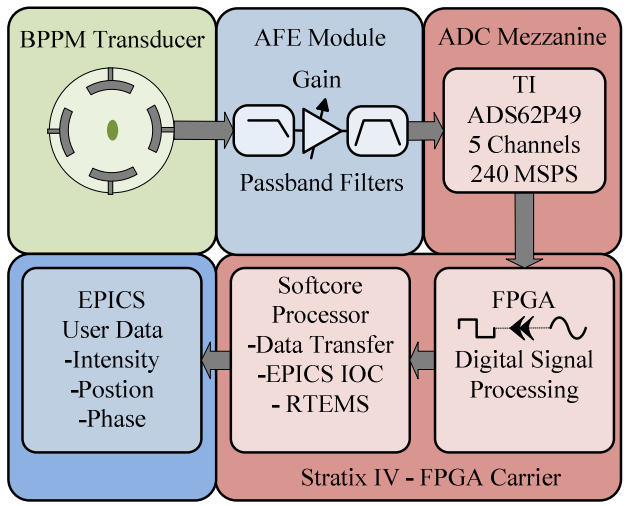

Figure 1: System Diagram

AFE DESIGN REQUIREMENTS

The following lists the design requirements for the AFE module to interface to the ADC. [1]

- Filter the micro-pulse signal to a fundamental frequency of 201.25MHz for sampling by the ADC while preserving pulse information.
- Increase the signal amplitude to match the dynamic range of the ADC without exceeding the 2Vp-p full scale range of the ADC.
- Provide a method of self calibration and signal integrity checks without beam present.
- Protect the digitizer from overdrive events.
- Provide conditioning for single micro-pulse position measurements.
- Provide remote control of the AFE gain and switching.

SIGNAL CONDITIONING

The AFE is designed to provide the filtering and gain to convert a micro-pulse from the BPPM to a sine wave that can be sampled by the ADC and analyzed by the FPGA.

Selectivity and Filtering

The beam doublets produced by the BPPM transducers are narrow micro-pulses occurring at the fundamental accelerating frequency (201.25MHz) with a pulse width of approximately one nanosecond. The ADC can only sample every four nanoseconds so the bandwidth of the pulse must be limited to provide a signal slow enough for the ADC to capture frequency and phase information.

*Work supported by the U.S. Department of Energy
#hwatkins@lanl.gov

Copyright © 2013 CC-BY-3.0 and by the respective authors

Harmonic amplitudes from the transducer can be equal or above the amplitude of the fundamental frequency and will cause interference with position and phase measurements. Figure 2 shows how the AFE module filters out higher order harmonics of the beam doublet and passes the fundamental frequency.

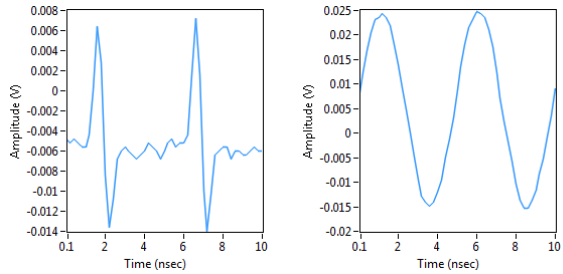

Figure 2: Transducer output and conditioned AFE signal

The harmonic selectivity requirement for the AFE is based on the ADC's spurious free dynamic range (SFDR) performance. The ADC's SFDR specification of -71dBFS [3] requires the AFE to provide rejection at least 10dB better (-81dB) at the harmonic frequencies.

The selectivity is provided by two filter stages in the AFE line-up. A low pass 5th order elliptical is used at the beginning of the line-up and a 3rd order band pass filter is used at the end to achieve the required selectivity.

The corner frequencies of the band-pass filter pass a 30MHz channel bandwidth. This channel bandwidth was selected based on the timing modulation of the beam. It is desirable for the system to analyze mini-pulses, short bursts of pulses (100nsec), at a 2.8MHz burst repetition rate. The bandwidth is intentionally larger than the repetition rate (10x) to maintain the pulse envelope for edge detection by the digital signal processor (DSP).

The low frequency corner of the band pass filter provides rejection of low frequency modulation components that occur from sources such as AC mains.

Gain and Noise

Due to space constraints in the accelerator, the BPPM transducers are shorter than a quarter wavelength of the fundamental frequency which results in reduced RF signal coupling. Two gain stages are added in the RF line-up to overcome losses from coupling, cabling and filtering.

The systems dynamic range requirement is 65dB minimum to provide optimal signal levels to the ADC over all beam conditions. This includes current settings, beam position, phase de-bunching and noise performance.

Measurements were done on BPPM's in the beam line to determine amplitude levels and a link budget analysis was performed to set the gain and noise figure of the line-up to levels that met the dynamic range requirement without exceeding the input range of the ADC. Table 1 shows the summary of the analysis.

Table 1: Link Budget Summary

RF Parameter	Link Budget	Requirement
Gain (dB)	20.2	20 typical
Noise Figure (dB)	11.8	23 maximum
Input Referred Noise (dBm)	-87.3	-76 maximum
Dynamic Range (dBFS)	77.1	65 minimum

The gain setting of the AFE is adjustable. Two fixed RF gain stages surround a digital step attenuator (DSA) which has 31dB of range in 1dB steps. A typical attenuator setting is 7dB to reach the typical gain setting but adjustment can be made to compensate for cable loss at different locations along the accelerator. The attenuator is digitally controlled by the FPGA. Support for automatic gain control by the FPGA is a future option.

SELF-DIAGNOSTIC

To support a method of self calibration and signal integrity checks the AFE module includes a switch matrix near the input connectors. The switch matrix allows the 201.25MHz reference to be injected upstream to the transducer or downstream through the AFE module for all four channels of the AFE. Figure 3 shows how the system can be tested in loopback mode for basic signal integrity or calibration mode to measure offsets in gain or phase internal to the AFE.

The switches selected are high-isolation terminated switches so the reference signal will not interfere with the desired signal during normal operation.

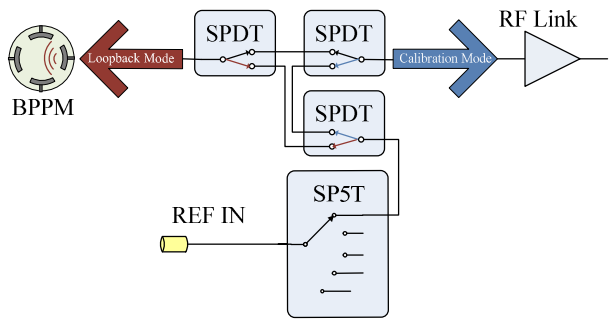

Figure 3: Single Channel Switch Matrix

Loopback mode

Injecting signals upstream of the AFE allows for loopback mode testing. This mode is intended for use when no beam is present. The reference signal can be injected from one channel of the AFE upstream to the transducer. Coupling occurs to the adjacent and opposite transducers in the BPPM. The coupled signal can then be analyzed by the three other channels of the AFE.

This mode allows the full system to be exercised. Problems with a particular signal path can be discovered by rotating the injection signal through all four paths of the BPPM. Imbalances in the signal paths can be analyzed and corrections applied to individual channels.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Calibration Mode

Injecting signals downstream through the AFE line-up enables calibration mode. In this mode the AFE has injection points that are phase matched at the input to each channel. The 201.25MHz reference is switched into the AFE input and analyzed by the FPGA. This mode shows the amplitude and phase differences between each of the four RF line-ups. Corrections can be made in the FPGA to improve the phase and amplitude offsets of the AFE signal paths.

OVERDRIVE PROTECTION

It is desirable to operate the ADC to within 1dB of full scale to maximize dynamic range without clipping the ADC. However, the flexibility of having remote gain control also poses an overdrive hazard when transducer signals are at high amplitudes. The maximum voltage level specification for the ADC is 3.6V or +15dBm rms [3].

The ADC is protected from overdrive events by a limiter diode placed prior to the output connector. This diode forward conducts when a power level of +10dBm is reached. This clip point keeps the ADC from receiving power levels that would exceed full scale operation.

SINGLE PULSE MEASUREMENTS

Certain target areas at LANSCE receive very short beam pulses called micro-pulses (~1 nanosecond). These micro-pulses occur as single pulses during a machine cycle and repeat at slow repetition rates. One of the BPPM requirements is to make transverse position measurements of these pulses. The signal must be transformed into a waveform that can be passed by the AFE to the digitizer.

A set of RF switches in the line-up provide the ability to change from a low pass filter at the front of the AFE to a narrow band filter (5 MHz). The pulse energy rings this narrow filter at its resonant frequency creating a sine wave within the channel bandwidth of the AFE as shown in Figure 4. This signal is passed through the RF lineup to the digitizer and analyzed by the FPGA to calculate beam position of the micro-pulse. Narrow band filter technologies such a surface acoustical wave (SAW) and lumped element filters are being evaluated for this application.

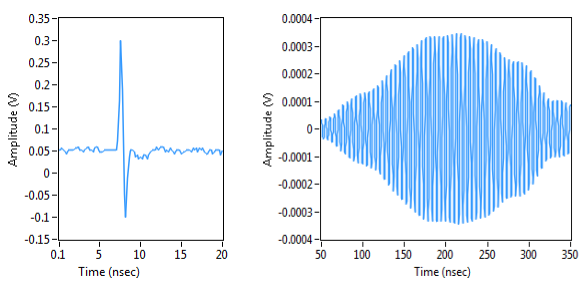

Figure 4: Single pulse to sine wave conversion

Measurements show that a trade-off exists between pulse length and amplitude level. Filters that ring for 200 nanoseconds have very small voltage level afterwards < 1 mV p-p. This low signal level will cause precision errors of up to 0.5mm for position measurements.

DIGITAL CONTROL

The AFE module has forty three digital control pins for selection of filters, gain and self diagnostic modes. The FPGA carrier card can only support eight lines of digital I/O since the majority of pins are assigned to the ADC channels. These control lines remain static the majority of the time making timing requirements fairly relaxed. In order to support the AFE module remotely through the FPGA a serial parallel interface (SPI) bus is used. The SPI bus requires four lines of communication (chip select, data in, data out and clock).

The SPI interface on the FPGA is connected to a general purpose I/O (GPIO) expander on the AFE module. Two GPIO expanders are used on the AFE module each supporting 28 pins of I/O. GPIO expanders can share data lines and clock but the chip select lines are separate to send instructions to each chip. This results in five digital control lines needed on the FPGA to support digital control of the AFE module.

CONCLUSION

The design phase is complete for the AFE module. Schematics have been created and the layout work for the printed circuit board is in process.

A two channel version of the system has been prototyped with evaluation boards so that the FPGA's DSP code could be evaluated. Final evaluation of the system and deployment are scheduled for 2014.

FABRICATION AND VALIDATION OF A NORMAL CONDUCTING RADIO FREQUENCY S-BAND DEFLECTING CAVITY FOR THE POHANG ACCELERATOR LABORATORY (PAL)

L. Faillace#, R. Agustsson, J. Hartzell, A. Murokh, S. Storms
RadiaBeam Technologies, 1717 Stewart St, Santa Monica CA, USA

Abstract

Radiabeam Technologies recently developed an S-Band normal-conducting Radio-Frequency (NCRF) deflecting cavity for the Pohang Accelerator Laboratory (PAL) in order to perform longitudinal characterization of the sub-picosecond ultra-relativistic electron beams. The device is optimized for the 135 MeV electron beam parameters. The 1m-long PAL deflector is designed to operate at 2.856 GHz and features short filling time and femtosecond resolution. RF design, fabrication, RF validation and tuning will be presented, as well as initial beam measurements.

INTRODUCTION

Some of the most compelling and demanding applications in high-energy electron beam-based physics, such as linear colliders [1], X-ray free-electron lasers [2], inverse Compton scattering (ICS) sources [3,4], and excitation of wakefields in plasma for future high energy physics accelerators [5,6] now require sub-picosecond pulses. Thus, improvement in resolution and capabilities of fast longitudinal diagnostics is needed.

RadiaBeam has recently developed and delivered an S-Band Traveling wave Deflecting mode cavity to be utilized for direct longitudinal phase space measurements of compressed electron beams at the Pohang Accelerator Laboratory X-ray SASE-FEL [7]. The PAL deflector takes advantage of the well-established cell machining in S-Band as well as our version of the SLAC-modified procedure for surface preparation for high RF power operation.

RF/THERMAL DESIGN

The initial 3D surface model used for RF simulations with HFSS [8] is shown in Figure 1. It is a disc-loaded traveling-wave (TW) structure operating in the TM_{110} mode at 2.856 GHz. Two coupler cells allow the input and output of the RF power provided by a standard WR284 metallic waveguide. The main deflecting cells, stacked in between the couplers, have a pillbox-like shape, each with holes located perpendicular to the deflection plane for the separation of the two dipole-mode field polarizations.

#faillace@radiabeam.com

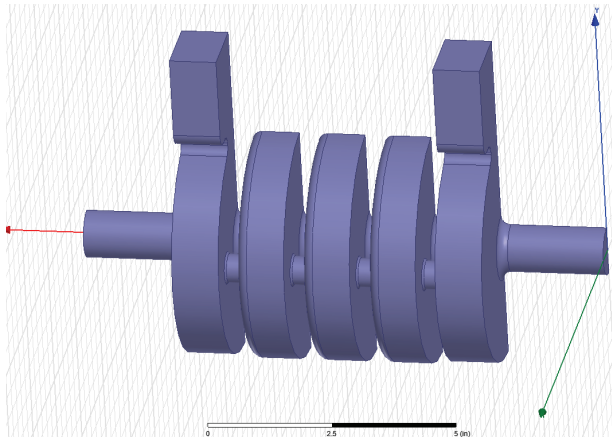

Figure 1: 3D surface model used for RF simulations in HFSS.

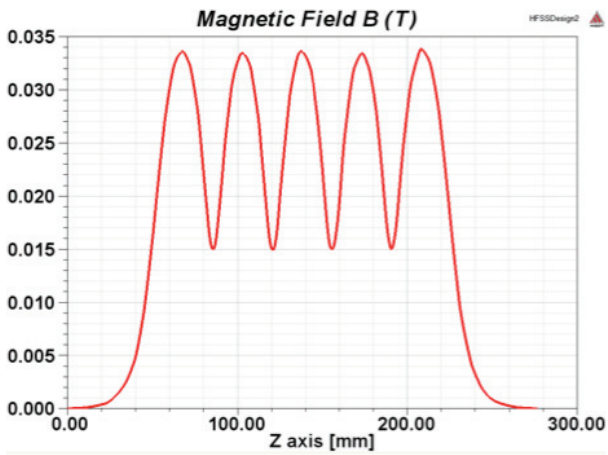

Figure 3: On-axis deflecting magnetic field profile.

The plot on the resulting on-axis deflecting magnetic field is given in Figure 2. The cell-to-cell phase shift is 120 degrees. The final full PAL deflector consists of an overall number (couplers plus main cells) of 28 cells. The main RF parameters for the L=1m long PAL deflector is listed in Table 1. The total deflecting voltage is equal to 8.5 MV, assuming an input RF power value of 10MW. Very good agreement was found between the simulated and the measured values.

Table 1: PAL Deflector RF Parameters

RF Parameter	Value
2π/3-mode frequency f	2.856 GHz
Transverse Shunt Impedance r_T	28.7 MΩ/m
Unloaded Q	13,400
Attenuation α	0.15 m^{-1}
Group Velocity v_g	0.014 c
Kick/√Power	2.7 MeV/√MW
Length L	1 m

Thermal simulations were carried out with Ansys [9]. We only inserted a cooling channels system, very compact, for frequency/temperature stabilization. The result shown in Figure 3 refers to the case of an average RF power of 1kW. Due to the low temperature gradient (<3deg) across the structure, no internal channels were necessary.

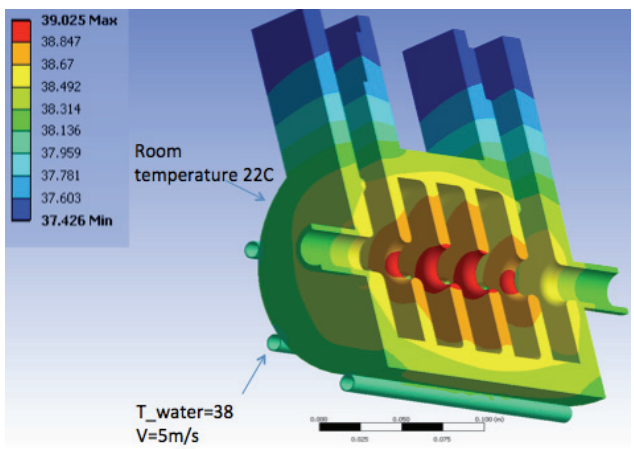

Figure 3: Thermal simulation of the PAL deflector model for 1kW average RF power.

THE PAL DEFLECTOR: TUNING AND INITIAL BEAM MEASUREMENTS

Figure 4: Picture of the PAL deflector after the final brazing and before installation.

The PAL deflector after final brazing and before installation is shown in Figure 4.

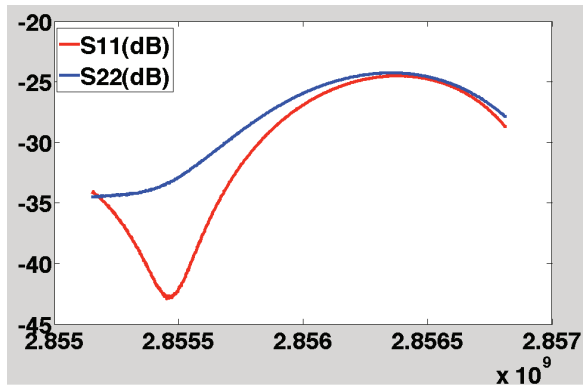

Figure 5: reflection coefficients at port1 and port2 (S11 and S22).

We measured the coupling coefficients at both ports, S11= -40dB (RF input port) and S22= -32dB with a SWR<1.05 for both ports.

The deflector cells were tuned to the spec (<±2°), at 22C and under nitrogen flow, by using the nodal shift procedure (plunger method).

From bead-pull measurements, we obtained the "flower"-like manifold that is plotted in Figure 6 showing a perfectly tuned 2π/3 operating mode.

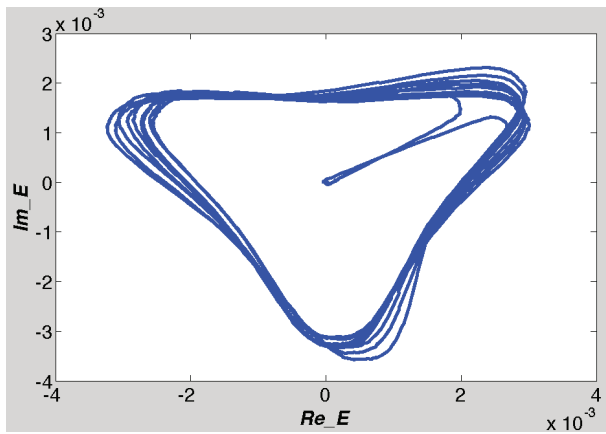

Figure 6: Polar plot of the on-axis electric field.

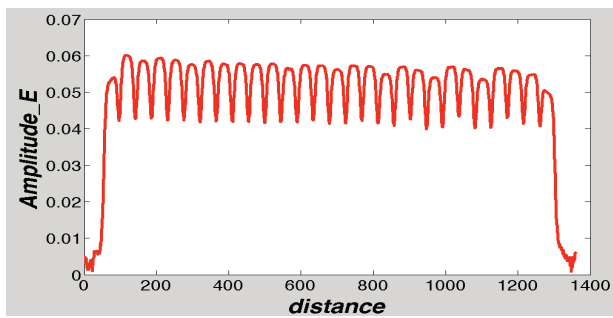
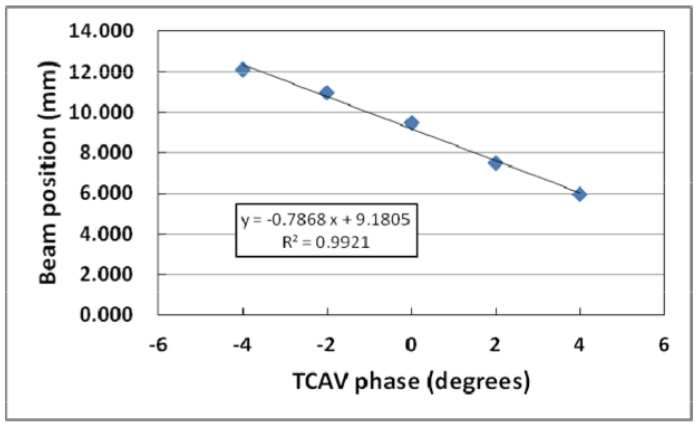
The bead-pull measurement (off-axis) of the electric field profile after final tuning is given in Figure 7.





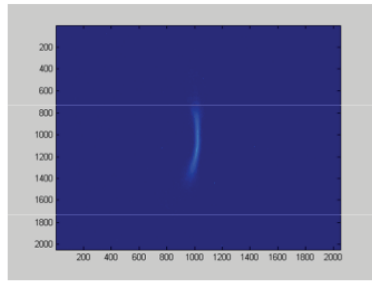


Figure 7: Off-axis electric field measurement (bead-pull).

Figure 8: Low-power initial beam diagnostics at PAL by using the deflector delivered by RadiaBeam.

The S-Band deflector was delivered to PAL in May 2013. After RF conditioning, initial beam length measurements were performed in August (see Figure 8). Only a fraction of MW of RF power was required at the moment for the resolution of their 200pC, 85.6 MeV beam.

CONCLUSIONS

RadiaBeam Technologies has successfully completed design, fabrication, brazing and validation of an S-Band deflector for the Pohang Accelerator Laboratory (PAL) X-FEL. Upon delivery to PAL and EF conditioning, promising and satisfactory initial beam length measurements were carried out.

TRANSVERSE BEAM PROFILE DIAGNOSTIC USING FIBER OPTIC ARRAY*

S. Wu#, G. Andonian, T. Campese, A. Murokh, R. Agustsson,
RadiaBeam Technologies, Santa Monica, CA 90404, USA
R.K. Li, UCLA, Los Angeles, CA 90095, USA

Brookhaven National Laboratory, NY 11961, USA

Abstract

The fiber-mesh diagnostic (FMD) is a transverse beam profile diagnostic based on the emission and detection of Cherenkov radiation produced as a relativistic electron beam traverses through an ordered bundle of fiber optics (SiO_2), arranged in a hexagonal close-pack configuration. Sub-10μm transverse beam profile resolution is attainable due to fiber optic core concentricity. Adequate SNR is achieved using a standard CCD sensor. A fiber optic taper input maximizes light collection efficiency by coupling each output channel to approximately single-pixel pitch. A v-groove holder and assembly process was developed to hold many fiber layers in the desired configuration. In this paper, we present results from a fully functional FMD prototype evaluated at the BNL ATF facility that demonstrates the efficacy of this diagnostic.

INTRODUCTION

The FMD was developed to address the need for higher resolution transverse profiling in low emittance electron beams. Standard techniques to measure the transverse extent of beams include fluorescent screens (such as YAG), observation of optical transition radiation, wire scanners and others. The resolution limit of these diagnostics hovers around >20μm. In the FMD, Cherenkov radiation is generated when a charged particle strikes a dielectric fiber that is placed at the Cherenkov angle. The device collects incoherent Cherenkov radiation, so the spatial profile is an accurate representation of the beam transverse charge distribution.

For a relativistic beam striking a dielectric, the Cherenkov angle, θ_C, is:

$$\theta_C = \cos^{-1}\frac{1}{n} \cong 46.5° \quad (1)$$

where n is refractive index of the fiber.

The approximate photons generated in each fiber are:

$$N_{photons} \approx \frac{2\alpha}{\sqrt{\pi}} N_e \left[\frac{d^2}{\lambda\sigma_x}\right]\left(\frac{\Delta\omega}{\omega}\right) NA \quad (2)$$

where α is the fine structure constant, d is the fiber core diameter, λ is the wavelength of light, N_e is the number of electrons, σ_x is electron beam RMS width, and Δω/ω is the fiber bandwidth.

A proof-of-concept experiment was executed at the UCLA Pegasus lab to demonstrate adequate photon yield for a single fiber [1]. The experiment results and theory were scaled for Brookhaven ATF parameters (Table 1). These results proved the feasibility to build a functioning prototype.

Table 1: Electron Beam Test Parameters

Facility	Energy (MeV)	Charge (pC)	Expected Photon Yield
UCLA Pegasus	2.5	25	10^4
Brookhaven ATF	57.6	100-1000	10^5-10^6

SYSTEM DESCRIPTION

The interaction point consists of an ordered array of single mode fiber optics (Fluorine-doped SiO_2, 6.8μm MFD, 245μm OD), which are also used at CERN for their radiation resistant qualities [2], to obtain multiple measurements in one instance. Cherenkov radiation is generated within the fibers, which also guide the radiation to an external CCD detector. Custom algorithms convert the multiple-fiber signals to a transverse profile charge distribution on a shot-to-shot basis.

The system consists of three key components:

(1) The fiber array at the interaction point
(2) The CCD acquires the Cherenkov signal
(3) DAQ logic converts signals to beam profile

Fiber Holder Fabrication and Assembly

The fibers are bundled in a hexagonal configuration so that each core position is set. They are held together with a v-groove clamping method:

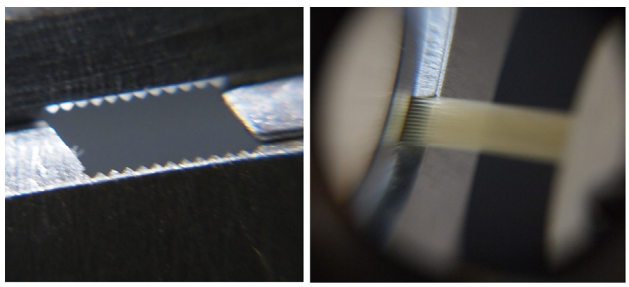

Figure 2: Photograph of fiber array. Fibers are clamped with v-grooves (Left). Fibers Assembled to holder (Right).

In order to correctly arrange fibers to the holder, fibers are initially bundled to single rows of 12. The first row settles into the v-grooves, and remaining bundles are laid onto the grooves of the previous layer. The tooling holds each layer taut during this process:

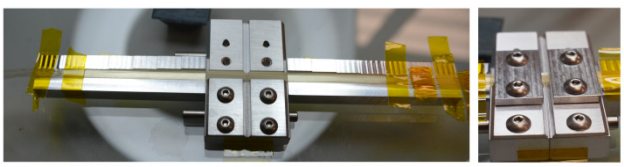

Figure 3: Tooling for holder assembly.

After the fibers are clamped to the holder, the holder arms are pulled apart, and fastened to the insertion rod:

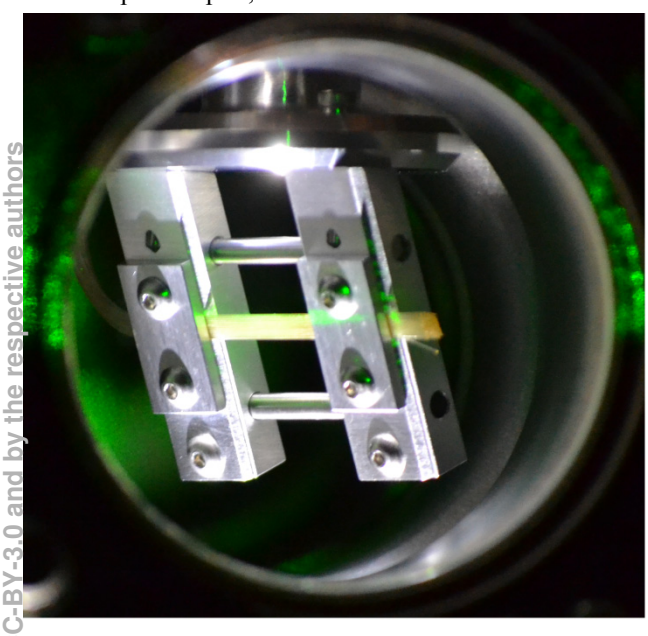

Figure 4: Fiber holder assembly in situ.

Camera Design

To maximize light collection efficiency, the fiber ends are mounted to a fiber optic taper input bonded directly to the CCD, providing a robust mounting surface. The result is focused light achieving almost single-pixel coupling, which optimizes the system's detection limit.

12-bit digital output is sent to the computer via Ethernet, enabling long distance data transmission needed from the experimental hall to the control room.

Data Acquisition

Prior to operation, fiber positions on the camera input are located by illuminating the fibers pointing to the camera. The sum of a 5x5 pixel region-of-interest for each location is ordered so that it represents the transverse position of each fiber core.

MATLAB interfaces with the camera. A TTL signal triggers the camera to capture an image, which is real-time processed to display the updated transverse profile. Background is subtracted from the profile, and the mean and RMS are calculated (See Fig. 5).

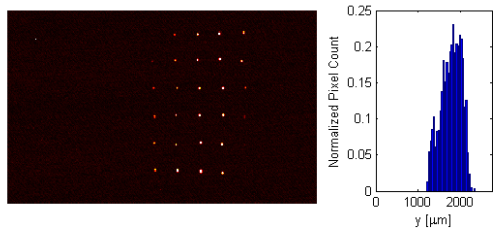

Figure 5: Raw image (Left), Single shot profile (Right).

RESULTS

The experiment was executed at Brookhaven ATF. YAG screens located on both sides of the FMD were used to benchmark the device under test.

Beam Width Measurements

YAG-based profile monitors along the beamline were used to tune the beam and for comparative studies with the FMD. A parabolic fit to the YAG-profile measurements was applied to calculate the expected beam width at the FMD location. Three beam widths were measured at 500pC and compared to the FMD measurements. The results are displayed in Figure 6, and shown in Table 2.

Table 2: Beam Width Comparisons at FMD Location

Calculated Width [μm] (YAG-profile monitors)	Measured Width [μm] (FMD)
171	139
341	365
448	449

Copyright © 2013 CC-BY-3.0 and by the respective authors

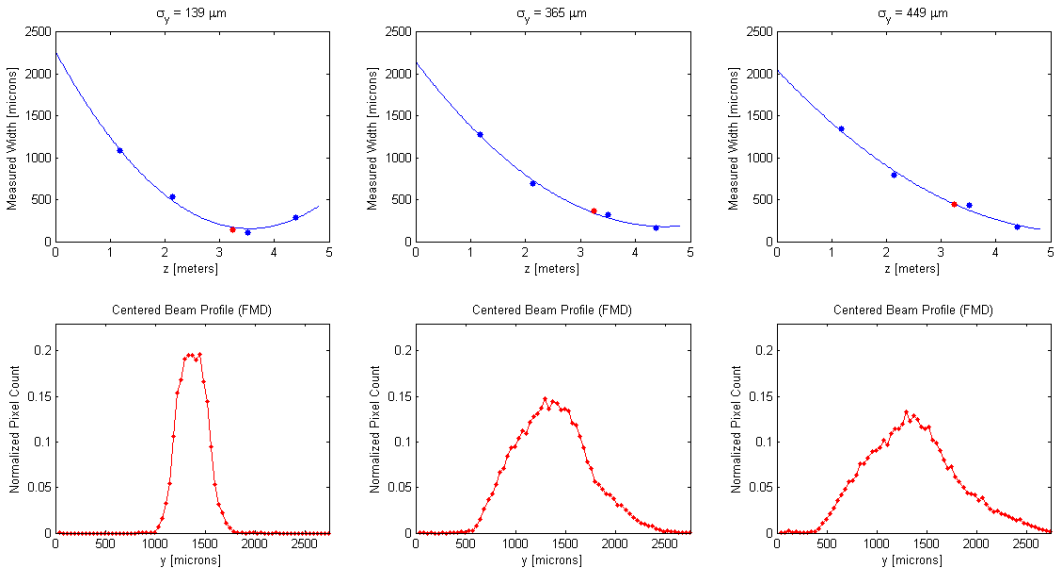

Figure 6: Top Row –Beam widths measured with YAG screens along the beamline (blue). Beam width measured with FMD plotted at the measured z- distance (red). Bottom Row – The averaged beam profile as measured with FMD.

The beam was also intentionally detuned to record a "non-Gaussian" profile with the FMD at 500pC (See Fig. 7) to observe profile features on the ~10μm scale.

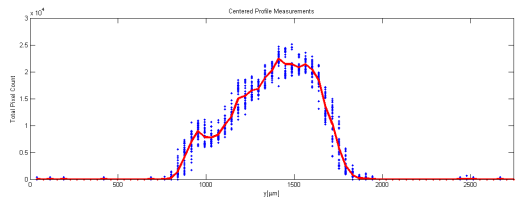

Figure 7: Each shot is centered (blue), and the averaged profile is calculated (red).

Quadrupole Scans

The current in an upstream quadrupole magnet was varied and the beam widths were recorded with FMD and a YAG-based profile monitor. The beam charge was 80pC. The emittance is calculated for both diagnostics and shows reasonable agreement (see Table 2).

Table 2: Comparison of Calculated Emittance

Diagnostic	Quad Distance [meters]	ϵ_n [mm-mrad]
YAG	2.58	4.2E-06
FMD	2.32	3.9E-06

CONCLUSION

The Fiber Mesh Diagnostic uses beam-generated Cherenkov radiation within a fiber optic array to characterize the beam transverse profile. The prototype was tested at the BNL ATF and its accuracy was compared to the YAG-profile monitors. The results were successful and demonstrated the viability of this diagnostic for high-precision transverse beam profile characterization. Future tests will address issues of fiber lifetime in high-radiation environments and an upgraded user-interface.

SCINTILLATOR DIAGNOSTICS FOR THE DETECTION OF LASER ACCELERATED ION BEAMS *

N. Cook†, R. Lefferts, Stony Brook University, Stony Brook, NY 11790 USA
O. Tresca, BNL, Upton, NY 11973, USA
V. Yakimenko, SLAC, Menlo Park, CA 94025, USA

Abstract

Radiation pressure acceleration with ultraintense laser pulses presents an exciting new scheme for accelerating ions. One of the advantages conferred by using a gaseous laser and target is the potential for a fast (several Hz) repetition rate. This requires diagnostics which are not only comprehensive for a single shot, but also capable of repeated use. We consider several scintillators as candidates for an imaging diagnostic for protons accelerated to MeV energies by a CO_2 laser focused on a gas jet target. We have measured the response of chromium-doped alumina (Chromox), CsI:Tl, and polyvinyl toluene (PVT) screens to protons in the $2-8$ MeV range using a CCD camera. We have calibrated the luminescent yield in terms of photons emitted per incident proton for each scintillator. We also discuss how light scattering and material properties affect detector resolution. Furthermore, we consider material damage and the presence of an afterglow under intense exposures. Our analysis reveals a near order of magnitude greater yield from Chromox in response to proton beams at >5 MeV energies, while scattering effects favor PVT at lower energies.

INTRODUCTION

Acceleration of protons by intense laser pulses has become an increasingly active area of study amongst nuclear, plasma, and accelerator physicists. Recent experiments with intense CO_2 laser pulses have produced collimated bunches of protons with energies greater than 1 MeV and narrow energy spread with the potential to do so at repetition rates on the order of $1-10$ Hz [1] [2]. The evolving nature of this field necessitates flexible diagnostic techniques suited to measure a myriad of experimental outputs.

Film and resin diagnostics offer single particle sensitivity but require weeks of analysis. MCPs offer a controlled gain curve and excellent resolution but are extremely delicate and ill-suited to high energy radiation. The use of scintillators has emerged as a flexible diagnostic as they may exhibit strong luminescence in response to an array of radiation types and energies; nonetheless their use necessitates precise calibration and their specific responses may vary by orders of magnitude [3]. The goal of these tests was to find a material which produces an adequate and consistent light yield under expected conditions (10^4-10^6 protons with energies $\sim 1-20$ MeV). The material should have sufficient resolution to determine bunch size, and should be relatively inexpensive and robust when exposed to high radiation flux at a repetition rate near 1 Hz.

EXPERIMENTAL METHOD

We narrowed our potential candidates to three scintillators: Chromox, CsI:Tl, and PVT. Chromox (Al_2O_3 : Cr_2O_3) is a ceramic phosphor designed to be durable under high radiation exposure and is responsive to ions in the MeV range [4] [5]. Chromox emits at ~693 nm. CsI:Tl is an inorganic crystal scintillator which emits at 550 nm. Though designed for photon detection, it's high-Z composition improves proton stopping power and makes it a high yield candidate. PVT is a low Z organic compound comprised of covalently bonded vinyl toluene chains, and as such it is easily damaged by high linear energy transfer (LET) radiation [6] [7]. BC-416 is the specific PVT variant tested, featuring added fluorophores as solvents to adjust the emission spectrum. It emits light through several channels, due to the presence of several solvents; the maximum of its emission spectrum occurs at 434nm, and its stated decay time is 4 ns.

We obtained a 1 inch diameter, 0.82 mm thick Chromox disc from Morgan Advanced Ceramics. We evaporated a 225 nm thick aluminium coating on the disc to diminish noise from electrons and X-rays. An uncoated 25 mm diameter by 1 mm thick CsI:Tl disc was purchased from Marketech International Ltd. The plastic scintillator is a 2" $\times$ 2" square, 1 mm thick, with a 50 μm Al coat, and has been used for previous proton experiments at the Accelerator Test Facility at BNL.

Experiments were performed at Stony Brook University using the Stony Brook Tandem Van de Graaff. Protons may be accelerated to total energies of $2-12$ MeV with 0.01% accuracy. Beam currents are flexible from 200 pA to 8.0 nA. Current regulation limits instantaneous uncertainties to no less than 10% regardless of beam parameters.

We used a Basler scA1400-17gm monochrome CCD camera to image the scintillator output. It features a 58% quantum efficiency at 545 nm, 12-bit image depth, and a 1392×1040 pixels sensor with 6.45μm $\times$ 6.45μm pixel size. The camera is paired with 75 mm $f\#/1.4$ tv-lens which corresponds to a maximum aperture of 0.414 sr.

RESULTS AND ANALYSIS

Captured images are analyzed following the European Machine Vision Association (EMVA) Model 1288 [8]. 300

images were taken for each camera setting after specifying a 200x200 pixel A.O.I, from which an average background subtracted grey value was obtained, correlating the luminescence due to scintillation for given beam parameters. An average yield was then calculated using the EMVA Model given the optical parameters of our setup. A Lambertian falloff of light intensity versus the angle, θ, between the scintillator surface and the camera is assumed. This contributes a factor of $\cos\theta$ to the model. We define the yield according to

$$Y = \frac{\mu_\gamma}{f_\gamma N_p} \quad (1)$$

$$\text{and} \qquad f_\gamma = \frac{\Omega}{4\pi} T_w \cos\theta$$

where f_γ is the fraction of photons collected by the camera, which is a function of solid angle,Ω, weighted transparency of insertion devices, T_w, and θ. The yield Y then depends on $f\gamma$, N_p the number of protons, and μ_γ, the number of photons collected per pixel by the camera.

Table 1: Raw Photon Yields for Tests Done in Transmission for each Scintillator (All Uncertainties $\pm 5\%$)

Material	2 MeV	4 MeV	6 MeV	8 MeV
Chromox	75.5	216	393	728
PVT	51.9	80.3	174	256
CsI:Tl	0.812	2.32	3.15	4.75

Table 1 shows the measured yield-energy data accumulated during our tests. Tests were limited to 8 MeV due to proton penetration depth limitations. Uncertainties are dominated by current regulation instability on the order of $\pm$ 5%.

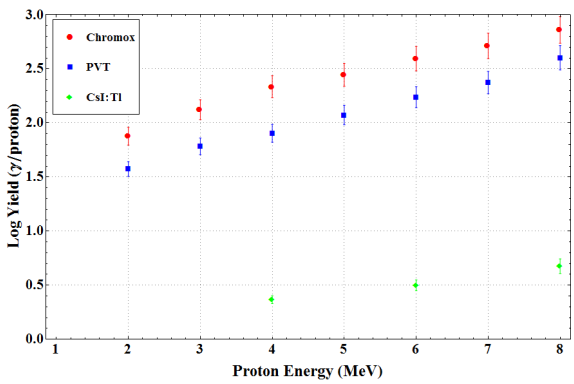

Figure 1: A comparison plot of $Log(Y(E))$ for each scintillator in transmission.

Chromox Transparency

Assuming a simple model of scintillation, light yield scales linearly with beam energy in absence of strong quenching. However, both Chromox and PVT yields do not correspond to a linear relationship. We consider the role of transparency in introducing nonlinearities in the yield. Chromox is constructed of granules of approximate size $w_g = 10 - 15\,\mu m$. Photons passing through the material may be scattered or reflected at each of the grain boundaries, such that the transmission coefficient through a granule is T_g. Assuming that $\frac{w_g}{w_c} \ll 1$ and $(1 - T_g) \ll 1$, we conclude that photon yield is a linear function of distance travelled through the material. Thus, we may use the range of protons in the scintillator, $r(E)$ as a linear transparency metric. We have

$$Y_A(E) = Y(E) * w_c(1 - r(E)) \quad (2)$$

where Y_A is the transparency-adjusted yield. Figure 2 demonstrates that Y_A scales linearly with proton energy. We then work backwards to make an "expected yield" fit.

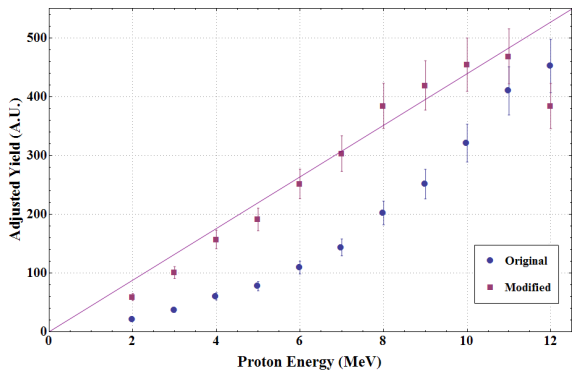

Figure 2: Chromox yield is shown with a penetration distance adjusment and corresponding linear fit. The raw yield is scaled down for comparison.

PVT Transparency and Damage

We performed a similar adjustment to the PVT yield, and after accounting for the Al coating, we achieve an improved fit. However, we observe a sharp discrepancy in the fit above 6 MeV. We believe this can be explained by non-radiative dissipation of deposited energy in the scintillator resulting in damage and a diminished yield for high incident flux [6]. To investigate, we placed the PVT under a continuous 8 MeV beam at 1 nA and examined the yield over time; we recorded a 31.6 % decline in mean intensity during 2 minutes of exposure. Afterwards, beam was blocked for 5 minutes, at which point the average yield was found to be consistent with the two minute value. As no significant afterglow was present, we conclude that there is a long term reduction in yield which corresponds to damage to the scintillator [9].

Resolution Analysis

For use in transmission, we performed comparative tests by imaging a pinhole with a 6 MeV CW beam. We imaged the output from each scintillator under these conditions, and the resulting images can be seen in figure 3. We then calculated the normalized intensity falloff from the edge of

Copyright © 2013 CC-BY-3.0 and by the respective authors

the pinhole along a fixed vertical axis, averaged over 300 images.

These tests demonstrate a significantly lower scattering in CsI:Tl, leading to a 20% falloff length of 0.31mm. For Chromox, we found a 0.79 mm falloff length, while PVT displayed the greatest scattering with a falloff length of 1.15 mm. We also observe greater fluctuations in the scattering properties of the PVT than the Chromox, suggesting further evidence of damage to the scintillator.

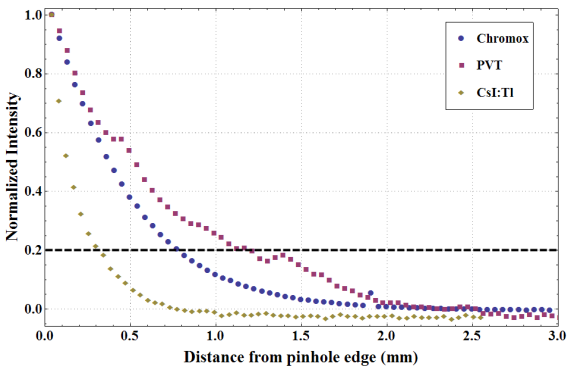

Figure 3: Intensity falloff from pinhole edge compared across three scintillator candidates.

Afterglow Analysis

Though boasting impressive scintillation response to ions and high $\frac{dE}{dx}$ particles, Chromox demonstrates an afterglow effect, only in part due to natural quenching. The granules introduces more lattice defects at grain boundaries, increasing the probability that photons are trapped away from an activator site thus enhancing afterglow. This effect has been measured in our Chromox sample both under continuous and pulsed beam conditions.

We generated a beam of 6 MeV protons at a current of 500 pA, and imaged the disc in reflection. The beam was shut off after an incidence period of several minutes, and the camera set to take pictures continuously at a 1 ms exposure time at approximately a 1 Hz rep rate. We found that there is significant afterglow for more than a minute after the beam is shut off. The sample exhibited a strong immediate afterglow, 28% of the value under beam exposure 1 s after beam shutoff. After 10 s, the afterglow intensity was less than 10% of the intensity under exposure. Even after 90 s, an afterglow of approximately 1.5% of the intensity under incidence was observed.

As laser acceleration produces sub-ns pulses, it is sensible to examine the afterglow under pulsed beam conditions as well. Though we cannot replicate experimental conditions with the tandem, pulsed beam was run at 3 Hz with 25 ms pulse lengths. A baseline response to the pulses was measured before blocking the beam to measure afterglow. Image intensity is plotted versus time in figure 4. It can be seen that in the case of pulsed beam, the light output falls much more quickly, reaching less than 3% of its nominal value after 0.1 s. Moreover, in this case, a stretched exponential of the form $e^{-(\frac{t}{\tau})^{\beta}}$ provides a strong fit candidate, with $\tau = 0.18$ms, and $\beta = 0.20$. This fit is characteristic of phosphorescence and suggests that Chromox is suitable for pulsed use at Hz-scale rep. rates.

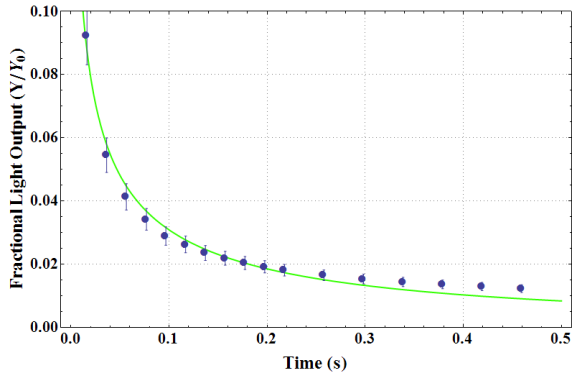

Figure 4: Chromox afterglow measured after a 5nA proton beam is pulsed for 25ms on, 325ms off.

CONCLUSION

We have measured the response of several candidate scintillators for use in a high rep rate laser acceleration experiment. Our findings suggest that Chromox has the strongest response to protons in the 2-10 MeV range. Resolution findings are worse than a single crystal scintillator like CsI:Tl, but acceptable for use with a Thomson spectrometer. Moreover, the afterglow in response to a pulsed beam is not significant on a 1s time scale, similar to the current maximum laser rep rate at ATF. Transparency remains a concern as it significantly reduces yield, depending on the geometry of the scintillator. Likewise, quenching remains a concern at high energies, but Chromox demonstrated the best radiation hardness among candidates. However, at low energies, photon scattering at grain boundaries reduces both yield and resolution for Chromox. Assuming comparable disc thickness, at energies < 4 MeV, a PVT based scintillator provides a superior response.

Abstract

Diamond as a large band gap material can be easily made to have negative electron affinity (NEA) surface. Using a few keV primary electrons as input and a few kV bias, the NEA diamond will emit cold electrons into vacuum with a large gain. We had tested and reported the performance of the diamond amplifier in our DC system. The best amplification achieved so far was above 170. Next step of the experiment is to test the diamond amplifier in a 112 MHz superconducting RF electron gun. In this report we describe the design of the amplifier containing a DC primary gun and light optics, to be tested in our SRF gun and relevant simulations. We also provide preliminary test results of the laser and electron beam transport.

INTRODUCTION

In previous papers, works on hydrogenation of CVD diamond and on measurements of secondary electron gain in a DC system at Brookhaven National Lab were reported [1-3]. The next step will be testing the diamond amplifier in a Superconducting RF (SRF) gun. For this purpose a specially designed cathode stalk is needed to work as a transporter/holder of a diamond in the gun. Besides that, we also designed a subsystem, which will be inserted into the cathode stalk and act as the DC stage of the amplifier.

DIAMOND AMPLIFIER

A basic diagram of a diamond amplifier is shown in Figure 1. A primary beam, with a few keV energy, hits the Pt coated back of the diamond and generates a cloud of electron/hole pairs inside the diamond. This entrance surface of the diamond is negatively biased hence the electrons separate from the cloud and drift across the bulk of diamond to the opposite, hydrogenated NEA emission surface. An anode is placed 200 μm away from the emission surface so that the electric field will extract the secondary electrons from the NEA surface of diamond into vacuum.

Design of Amplifier for SRF Gun Test

For the test of the Diamond Amplifier in an SRF gun, we need a special stalk to position the diamond in right location in the cavity and hold it there. The detailed description of the stalk can be found in previous papers [4, 5]. As for the source of primary electrons, we decided to use a newly designed DC assembly with a UV driven copper cathode. A CAD model and a photo of this system, which will hereby be called Amplifier, is shown in Figure 2.

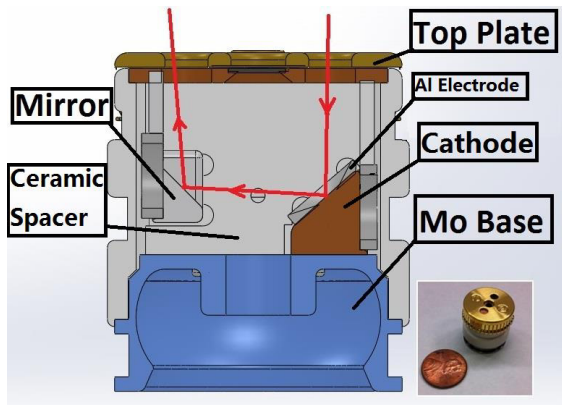

Figure 2: Section view of the Amplifier: red lines show the path of UV light. Smal insert is a photo of the first prototype Amplifier with a penny on the side as size reference.

This is the first prototype amplifier we made for SRF test. There are four major pieces. A gold plated copper top plate is used to hold the diamond and ground it to the cavity. A ceramic spacer serves as an insulator between the grounded top plate and biased molybdenum base. It also acts as a holder for the cathode and mirror and defines the crucial distance between the cathode and diamond. The third part is the cathode/mirror pair that will provide electron beam and guide the laser beam out of the cavity. The fourth part is the molybdenum base that works as the connection between the Amplifier and the transport arm.

Laser will come in through a hole in the top plate and illuminate the cathode. There is an aluminium electrode surrounding the cathode optimized for beam focusing. After the laser bounces off the mirror-finished cathode, it will hit a metal-coated mirror on the other side, which will redirect the laser out of the amplifier through an exit hole in the top plate. Figure 3 shows how the amplifier will be positioned in the stalk and cavity as well as depicts the paths of laser and electron beams. The angles of the cathode and mirror are chosen to meet two conditions. The first one allows the laser beam to escape the cavity with no obstacles. And the second condition is that the electron beam must hit the center of the diamond so that we do not

Copyright © 2013 CC-BY-3.0 and by the respective authors

have to worry about charging up of ceramic spacers. The cathode will be negatively biased by a DC power supply to -5 kV. The top plate will be grounded to the cavity though the gold plated fingers.

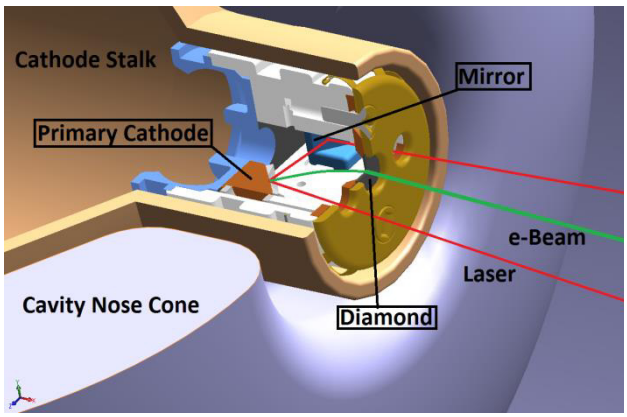

Figure 3: Diagram of laser and electron beam paths.

Simulation Result of Amplifier

In order to find the optimal orientation of the cathode, we used CST Particle Studio to simulate the trajectory of electron beam after it leaves the cathode. Table 1 shows parameters we used in the simulation.

Table 1: Parameters for simulation

Parameters	Value
High Voltage	-5 kV
Average Current	5 nA
Pulse width	1 nS
Repetition rate	80 kHz

After a few iterations the angle between the normal direction of cathode and axis of cavity is chosen to be 42 degrees. The distance between centers of the cathode and the diamond is optimized to 6.6 mm. Figure 4 shows the potential distribution inside the amplifier and the electron beam trajectory. We were able to guide the primary beam onto the center of Pt coating layer on back of the diamond. The distance between the center of the beam spot and the center of the diamond was eventually brought down to 180 μm. RF field leakage through the holes in top plate was taken into consideration and it was found that the field is low enough that there is no observable effect on the beam energy and position.

Prototype Testing Result

We built a prototype Amplifier this year and made some preliminary measurement on it to demonstrate the feasibility of our design in terms of laser and electron beam paths.

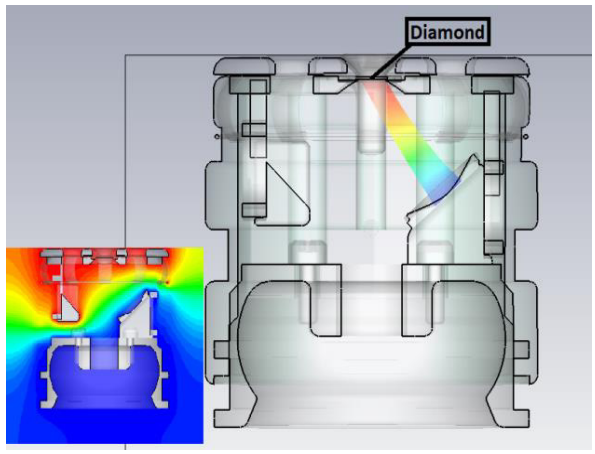

Figure 4: Trajectory of electron beam between primary cathode and diamond. Smaller picture shows the potential distribution inside the Amplifier.

Figure 5 shows the test with a green alignment laser. Incoming laser goes through the half pass Kapton film then illuminates the copper cathode. After two reflections it comes out of the exit hole on the other side of the top plate. The reflected laser beam was captured by the half pass film and indicated as a weaker spot.

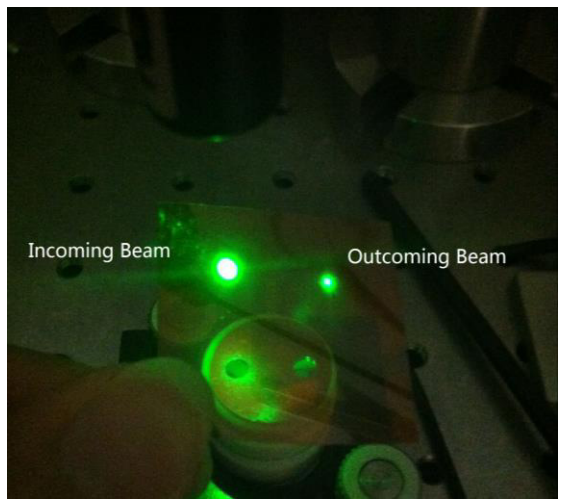

Figure 5: Demonstration of the laser beam passage.

We also measured the percentage of electrons that we were able to capture with a dummy electrode, which is acting in place of diamond. In this measurement we successfully applied -5 kV bias to the cathode. Then a 220 nm UV light was introduced to the amplifier. A deuterium lamp/monochromator system was used to generate the required UV light.

We recorded the current leaving the cathode and the current intercepted by an isolated dummy electrode under different bias voltages. The result of the measurement is shown in Figure 6.

Copyright © 2013 CC-BY-3.0 and by the respective authors

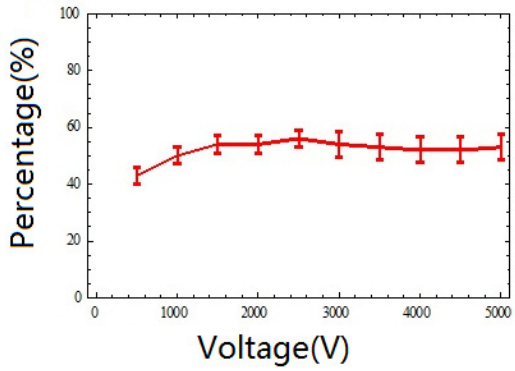

Figure 6: Percentage of electrons reaching dummy electrode over electrons leaving cathode.

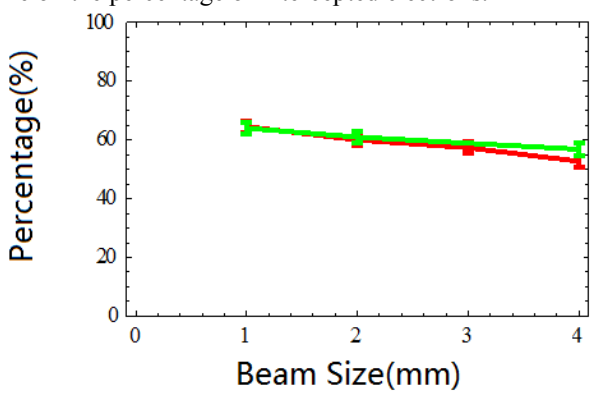
One can see that about half of the electrons that left the primary cathode didn't make it to the dummy electrode. This can be result of stray light illuminating the cone shaped electrode sitting on top of the cathode. Since the spot size of UV light from lamp could not be reduced to exactly match the size of the copper cathode, we are expecting certain amount of electrons from the aluminium electrode. Figure 7 shows the effect of changing light spot size on the percentage of intercepted electrons.



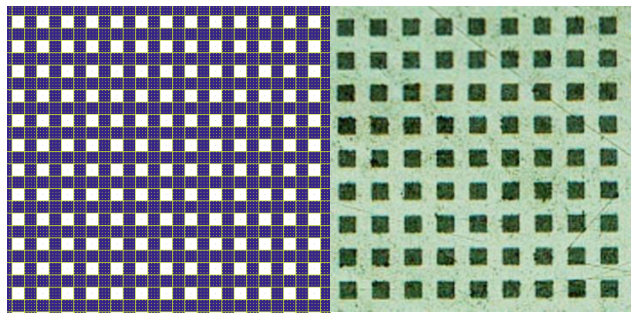


Figure 7: Percentage of electron intercepted by dummy electrode *vs.* UV light spot size.

Considering the total area of the electrode and the QE of the aluminium, it is possible that nearly half of the signal in the measurement of current leaving cathode was due to the photoemission from aluminium. In future tests the light source will be changed to a UV laser and the spot light will be sufficiently reduced to minimize the number of electrons caused by stray light.

Future Modification

We are planning to change the previous one hundred percent coverage metal coating to a lithographical patterned grid coating. Because the metal layer will reduce the energy of primary electrons, less coverage means larger effective impact energy from primary beam. Hence the total number of secondary electron product in each pulse will be increased according. The trade off is that the weaker electric field established by grid coating inside diamond will drag less secondary electrons to the emission surface. Figure 8 shows the pattern we are planning to use and the coating made from it.

a b

Figure 8: (a) Mask used for lithography; (b) Picture of back electrode made with patterned mask. The grid spacing is 50 μm.

CONCLUSION

For future tests of the Diamond Amplifier in a Superconducting RF gun, a DC subsystem was designed to provide primary electron beam inside the RF cavity. The system includes the following parts: a primary photocathode made of copper; an aluminium electrode for beam regulation; a metal-coated dielectric mirror to guide the laser out of the cavity; a holding mechanism to hold the diamond in position and ground it to the cavity; and a molybdenum base part to connect the amplifier to the transport arm. Simulation result from CST Particle Studio shows good aiming of electron beam onto the center of the diamond and acceptable DC field strength near the dangerous region. Experimental result verified the design of the optics for the laser beam and showed a reasonable capture ratio of electrons by the diamond. We are still working on improving the Amplifier in order to make it more compatible with our SRF electron gun.

Abstract

The 112 MHz quarter wave superconducting electron gun was designed and built as an injector for the coherent electron cooling experiment. Besides that, the gun is suitable for testing various types of photocathodes thanks to its specially designed cathode holder. In recent RF tests of the gun at 4 K, the accelerating voltage reached 0.9 MV CW and more than 1 MV in pulsed mode. During this testing, we observed several multipacting barriers at low electromagnetic field levels. Since the final setup of the gun will be different from the cool down test configuration, we want to understand the exact location of the multipacting sites. We used Track3P to simulate multipacting. The results show several resonant trajectories that might be responsible for the observed barriers, but fortunately no strong multipacting barriers have been found in the cavity.

INTRODUCTION

The fabrication of the 112 MHz SRF quarter wave cavity as well as the cryomodule has been finished and the cold test was successfully conducted early this year. The gap voltage had reached 0.9 MV in CW mode test and 1 MV in pulsed mode. Further increase in gap voltage was limited by radiation. During the conditioning process we encountered several multipacting barriers. The purpose of study shown in this paper is to investigate the relative strength of the known barriers to the ones that are predicted by the simulation under higher field level with different FPC and cathode stalk for future test so that the difficulty of future conditioning can be estimated.

EXPERIMENTAL ASPECTS

General Layout

The cavity and a new cryomodule were built and assembled at Niowave. The layout of the cavity, fundamental power coupler (FPC) and pickup antenna is shown in Figure 1. The FPC antenna was designed with an adjustment range allowing critical coupling at different levels of RF losses in the cavity. Special precaution was taken during the cool down to avoid the accumulation of residual gas on the outer conductor of the FPC. We suspected that changing of surface condition might explain multipacting in a previous cold test. Also a standing wave structure was introduced between the RF amplifier and the feed through of the FPC to further enhance the coupling in case stronger coupling is needed to condition a multipacting barrier. The design parameters of the 112 MHz electron gun are shown in Table 1.

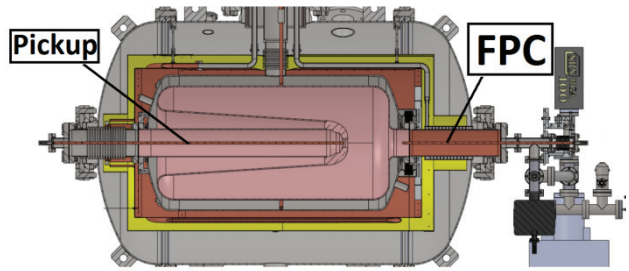

Figure 1: Layout of the 112 MHz SRF cavity horizontal test. The coaxial FPC approaches from the exit of the cavity and the pickup antenna goes through the nose cone part of the cavity and positioned 2 cm behind the entrance of the cavity.

Table 1: Design Parameters of the 112 MHz Electron Gun

Parameters	Value
Frequency	112 MHz
Charge per Bunch	1~3 nC
Repetition Rate	78 kHz
Acceleration Voltage	1~2 MV
Cavity Q_0	1.8e8
R/Q	122 Ω

Experimental Results

The cool down took about 4 hours to bring the cavity to superconducting status. To avoid condensation of residual gas on the FPC, the thermal shield was not cooled until later in the process.

Soon after the superconducting status was reached, the multipacting barriers were observed at relatively low field level. The corresponding gap voltage was estimated to be below 50 kV and the more accurate value was later confirmed to be in the range of 30 kV to 40 kV by Track3P simulation.

After overcoming the multipacting barriers, the cavity Q *vs.* accelerating voltage Vc was measured. Figure 2 shows the result of the measurement.

*This work was carried out at Brookhaven Science Associates, LLC under Contracts No. DE-AC02-98CH10886 and at Stony Brook University under grant DE-SC0005713 with the U.S. DOE.

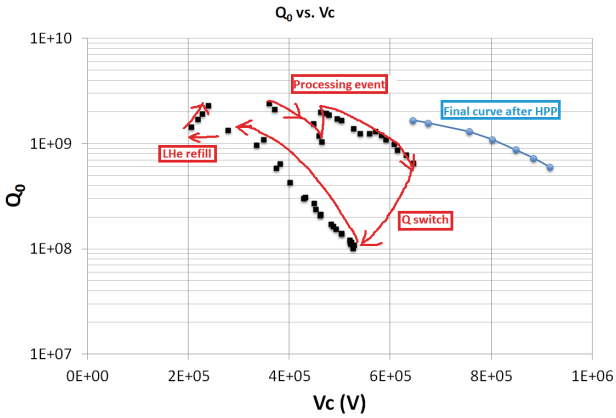

Figure 2: Q_0 *vs.* V_c during the 112 MHz SRF cavity cold test. The black squares show the process of conditioning and the blue dots show the final measurement after the high power pulse processing.

Black squares show the processing which includes the activation of emitter and the consequent Q switch. Blue dots show the final Q_0 *vs.* Vc curve after the high power pulse process. As we can see under CW mode the gap voltage reached 0.9 MV, only limited by the radiation concern at Niowave test facility.

MULTIPACTING SIMULATION

The multipacting barriers we encounter in this cold test were relatively easy to overcome as soon as we improved the FPC coupling. However, in a future test of the gun at Brookhaven National Lab, there will be a different fundamental power coupler. In addition, a cathode stalk, which is specially designed to transport and support the photocathode in the gun, will take the place of the pickup antenna [1, 2]. All these differences might introduce different multipacting barriers and we want to see the relative strength between the known one and the barriers predicted by simulations.

Secondary Electron Yield Curve

For the Secondary Electron Yield (SEY) curve, we chose Furman's model [3]. The SEY curves of the materials we encounter in our gun are shown in Figure 3. The parameters used to generate these curves are shown in Table 2. The formulae for three different type of secondary emission are shown bellow.

True secondary:

$$\delta_{ts} = \frac{s\times\frac{E_0}{E_{max}}}{s-1+\left(\frac{E_0}{E_{max}}\right)^s} \quad (1)$$

Elastic backscattering:

$$\delta_e = P_{1,e}(\infty) + \left(\hat{P}_{1,e} - P_{1,e}(\infty)\right) EXP\left[-\frac{\left(\frac{E_0}{W}\right)^p}{P}\right] \quad (2)$$

Rediffused electrons:

$$\delta_r = P_{1,r}(\infty)\left\{1 - EXP\left[-\left(\frac{E_0}{E_r}\right)^r\right]\right\} \quad (3)$$

Total SEY:

$$\delta = \delta_{ts} + \delta_e + \delta_r \quad (4)$$

The cavity and part of the beam pipe is made of niobium. For Niowave test, the center conductor of the FPC and pickup were copper.

Table 2: Parameters used to Generate SEY Curves

	Niobium	Copper
True secondary		
δ_{max}	1.36	1.88
E_{max}(eV)	300	276e
s	1.3	1.54
Elastic backscattering		
$P_{1,e}(\infty)$	0.001	0.02
$\hat{P}_{1,e}$	0.002	0.496
W	100	60.86
P	0.9	1
Rediffused		
$P_{1,r}(\infty)$	0.001	0.2
E_r	40	0.041
r	1	0.104

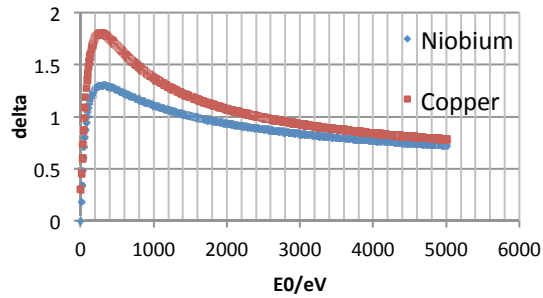

Figure 3: SEY curves of niobium (blue diamonds) and copper (red squares).

Simulation Result for Niowave Test

Figure 4 shows the electric field and magnetic field simulated by Omega3p. This field distribution was used as the input for Track3p simulation. The primary electrons were generated from the inner surface of the whole assembly near the vertical symmetry plane. Then the electrons would be tracked under the force exerted by the RF field. After each impact the phase of the field will be evaluated, if the direction of the field favours the emission of the secondary electron, the impact energy and the location of the electron will be recorded. If the field on impact phase doesn't allow the emission of secondary electron then the particle is removed from simulation. After 50 RF cycles, only the survived particle would be recorded and marked as resonance particle [4]. The total enhanced counter function of these particles will be calculated based on the impact energies and the SEY curve of the impact surface. By looking at the relative height and width of the Enhanced Counter Function peaks we can get the idea of the difficulties in overcoming those barriers.

Copyright © 2013 CC-BY-3.0 and by the respective authors

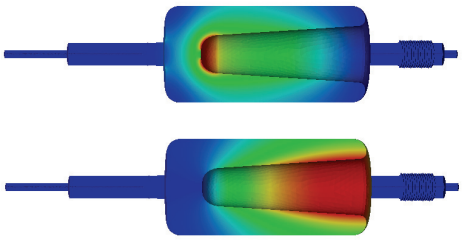

Figure 4: Electric (upper) and magnetic field (lower) simulated by Omega3p for the 112 MHz SRF cavity in the Niowave test configuration.

The simulation gives two potential bands of multipacting. Figure 5 shows the longitudinal location of resonance particles versus impact energy. Since the SEY curve of niobium surpass unity between 100 eV and 1300 eV, we only have to pay special attention to the particles that have impact energy fall into this range.

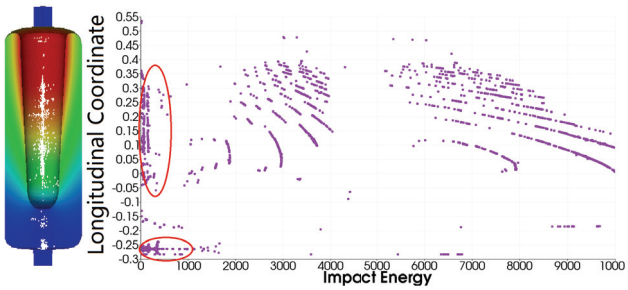

Figure 5: The diagram on the right hand side shows longitudinal location of potential multipacting sites. Picture on left hand side shows the locations (white dots) of those sites inside the cavity. The longitudinal Coordinate axis is mutually applicable to both pictures. The gap voltage was scanned between 100 V to 100 kV.

Post processing of Track3P data shows two multipacting barriers near 30 and 40 kV gap voltage, which is consistent with the observation during the Niowave cold test. Figure 6 shows the Enhanced Counter Function versus the gap voltage of the cavity. One site is located near the gap of the cavity and the other one is located near the high magnetic field region. Both of them survived 50 impacts in RF cycles.

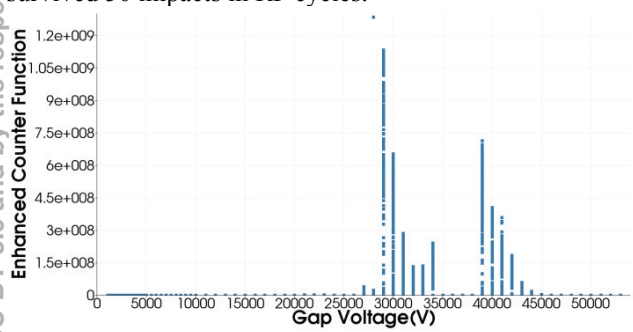

Figure 6: Enhanced Counter Function versus gap voltage of the cavity.

After identifying the field level of two multipacting barriers, we performed the single field mapping with Track3P and extracted two typical trajectories of the potential multipacting electrons. Figure 7 shows the trajectories of two suspicious multipactors. The one that is close to the gap of the cavity is a 1st order multipacting and the one located in the high magnetic field region is a 2nd order multipacting.

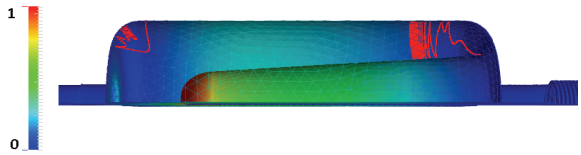

Figure 7: Trajectories of electrons at two multipacting sites (red lines). The left one is under 29 kV gap voltage and the right one appears at 40 kV gap voltage. The color scale indicates the relative strength of electric field.

CONCLUSION

The successful cold test at Niowave gave us a good opportunity to compare the experimental result with the simulation result of the multipacting barriers in the 112 MHz cavity. Two major sites of potential multipacting in the cavity were captured by the simulation of Track3p and also observed during the conditioning process. The multipacting barriers were relatively easy to overcome. This gives us more confidence in future test at BNL since the strength of the suspected multipacting barriers given by previous simulation in the FPC and cathode stalk are much lower than what we found from this run.

Abstract

RadiaBeam Technologies is in the process of developing bulk textured dysprosium as a potential replacement for CoFe steel as undulator poles. For cryogenic undulators that can be cooled below the ferromagnetic transition of dysprosium, textured dysprosium offers potential increase in the peak field of the undulator. Here we report on the progress of the project, including magnetization curves for the material.

INTRODUCTION

The operation of cryogenic permanent magnet undulators (CPMUs) at temperatures below the Curie transition of rare-earth metals offers the opportunity to develop new pole materials that take advantage of the existing cryogenic conditions to potentially produce higher peak field undulators. To this end, RadiaBeam Technologies has been investigating the use of dysprosium and gadolinium to replace the cobalt-iron (CoFe) typically used in high field hybrid undulators. CoFe is the pole material of choice for high field undulators because of its large saturation magnetization (2.35 T), very large initial permeability ($\mu_i \sim 10^4$) and small non-linear knee region which is the transition between the two regions. In single crystal form, dysprosium demonstrates much higher magnetic moment (>3 T [1]) at low applied field and cryogenic temperatures than CoFe [2]. However, single crystals of these materials are difficult and expensive to produce at the dimensions and scale required for undulator fabrication and polycrystalline versions of the materials are not useful for undulator applications because of low initial permeability.

A compromise between the single crystal and polycrystalline forms can be reached through a processing technique that generates so-called texture in the material. This technique takes advantage of a favorable energy difference between crystallographic orientations during a rolling and annealing cycle [3]. Briefly, the polycrystalline material is rolled out and then annealed near the melting point. For dysprosium, which has an *hcp* structure, grains within the foil that are oriented with the hardest axis within the plane of the foil are taken over by grains that have the hardest axis pointed normal to the plane of the foil in a process known as secondary re-crystallization. This process dramatically increases the permeability within the plane of the foil [1]. The foils can then be annealed together in stacks to produce a macroscopic piece for further machining.

MATERIAL DEVELOPMENT

We have previously reported the results of magnetic measurement of the textured dysprosium [2]. Those results showed that the textured dysprosium, made up of 100 μm thick foils, used in the initial 2-period prototype would not produce an improvement in peak field over CoFe poles. In that publication we suggested several changes that might increase the performance of the the textured dysprosium poles: operate the undulator at lower temperature, use thinner foils in the poles, and increase the complexity of the design of the undulator by installing backing magnets on the side of the poles opposite the magnetic gap. Because of those observations, all foils created subsequently have been 25 μm thick. Since that previous publication we have found evidence of another feature of the textured dysprosium that will influence future magnetic designs, namely that the direction of rolling affects the orientation of the easy axes of magnetization. Unfortunately, because cryogenic magnetic measurement techniques below 77 K require the use of liquid helium, we have had difficultly finding facilities willing to perform these measurements until recently.

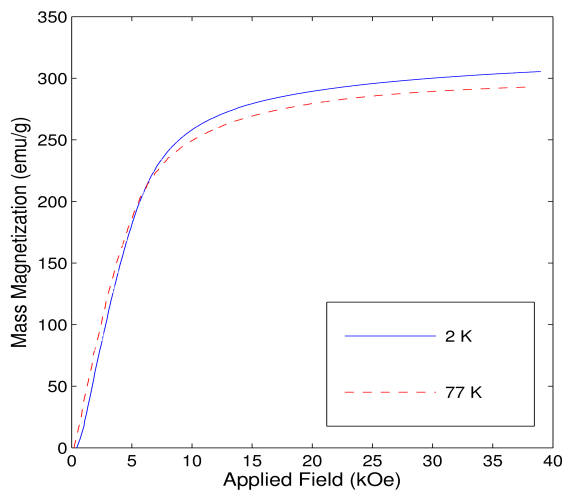

Figure 1: Comparison of the magnetic performance of textured dysprosium at 2 K and 77 K. The sample was cut such that the direction of measurement was within the rolling plane.

Temperature Effects

The first suggested solutions is to decrease the temperature of the device. A colder undulator would have both higher remanent magnetic field of the PrFeB magnets [4, 5] and higher initial permeability in the textured dysprosium poles. The former results in larger applied fields while the latter results in greater pole tip field per unit of applied field, both critical to attaining large on-axis magnetic fields [6]. Figure 1 shows a comparison between the magnetization of textured dysprosium at 2 K and 77 K. The two features of note are that above 5 kOe applied field, the colder textured dysprosium is more strongly magnetized and below 5 kOe, the warmer sample is more strongly magnetized. We would expect that as the material is cooled, it is more easily magnetized because the thermal energy that allows the individual dipoles to resist the torque of the applied field is reduced [7]. That appears to be the case at larger applied field (>10 kOe), but not lower applied field.

The shape of the measured sample in Fig. 1 was modified from the original shape to fit into the measurement device. The modification resulted in a large demagnetizing factor [8]. Because of this we hypothesize that the unexpected reversal of performance below 5 kOe can be explained by the effect of the large demagnetizing factor. At low applied field, we would expect that the actual applied field would be lower than the observed applied field, which is the abscissa of Fig. 1, in the case of stronger magnetization because the two are related as $H_{actual} = H_{observed} - NM$, where N is the demagnetizing factor and M is the magnetization of the sample.

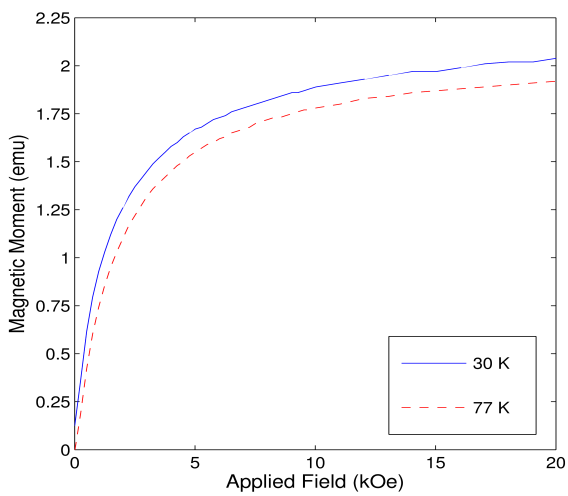

Figure 2: Comparison of the magnetic performance of textured dysprosium at 30 K and 77 K. The sample was cut such that the direction of measurement was within the rolling plane. Note the different ordinate as compared to Fig. 1.

To test this hypothesis, a different sample, manufactured identically and of smaller demagnetizing factor, was measured in a different measurement setup at a different location. The results of the measurements at 30 K and 77K, after correction for the demagnetizing factor, are shown in Fig. 2. It can be seen that the lower temperature magnetization curve always shows higher magnetization than the higher temperature curve, consistent with the hypothesis of a large demagnetizing factor in the measurement shown in Fig. 1 We chose to perform the second measurement at 30 K, instead of the previous 2 K, because that temperature can be maintained by a closed loop cold head, reducing future experimental complexity. 30 K is also the approximate temperature of maximum thermal conductivity of copper [9].

Orientation Effects

In previous simulation work, we have treated textured dysprosium as an anisotropic material with one hard axis, [0001], and two easy axes, $<10\bar{1}0>$ and $<11\bar{2}0>$. This is because the available simulation packages can only handle anisotropy of this 2+1 form [10]. The assumption is that there is an equal mixture of the two easy domains in the plane of the foil (the basal plane). However, the two easy axes are not equivalent, the $<10\bar{1}0>$ axis is actually harder than the $<11\bar{2}0>$ axis, even though both are much softer than the [0001] direction [11, 12]. Therefore, if the process that generates texture produces a preference for grain orientation, there will be a preferred direction for cutting the poles out of the bulk laminated material. The highest on-axis magnetic field will be obtained if the pole is manufactured such that the $<11\bar{2}0>$ axis is normal to the undulator mid-plane. This is, of course, a statement of the average direction in which each axis points.

Previous work studying textured dysprosium has observed that the texture develops such that the $<10\bar{1}0>$ axis is preferentially aligned with the direction of rolling [13]. We should, therefore, be able to detect this difference in measurements made on samples cut from the two different orientations. To measure the difference in magnetization, two samples were cut from the same piece of bulk laminated pole, called sample A and sample B. Sample A was measured along the direction of rolling and sample B was measured along the direction perpendicular to the rolling direction and the foil normal. As can be seen in Fig. 3, sample A is clearly magnetically harder than sample B, consistent with previous observations showing a preference for the texture to develop with the $<10\bar{1}0>$ axis along the direction of rolling. Both samples are more easily magnetized at lower temperature and the benefits of cooling the textured dysprosium to 30 K are almost entirely erased by non-optimal orientation of the texture relative to the undulator mid-plane.

Simulation has shown that, in a hybrid undulator design of 7-9 mm period length, the applied field at the pole tips is approximately 0.15 T. At this applied field, the remanent field of the textured dysprosium is 25% larger for a pole cooled to 30 K and cut such that the $<11\bar{2}0>$ axis is optimally oriented, as compared to a pole cooled to 77

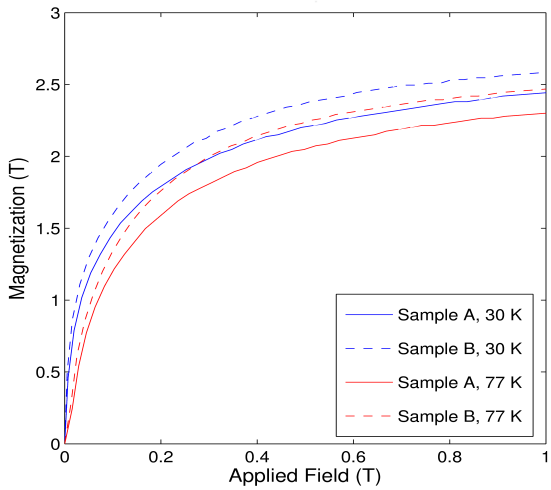

Figure 3: Comparison of the magnetic performance of textured dysprosium as a function of measurement along the two axes of the basal plane, $<10\bar{1}0>$ (sample A) and $<11\bar{2}0>$ (sample B), at two different temperatures.

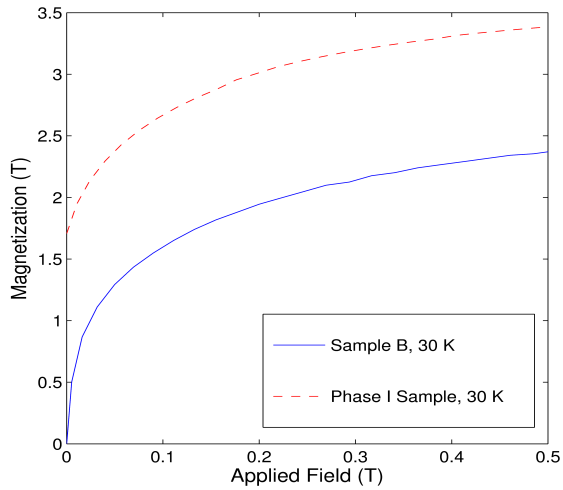

Figure 4: Comparison of the easy magnetization curves from the current sample B and the data presented in Ref. [2]. The decrease in magnetic performance is due to increased oxide formation in the updated procedure for making the bulk laminate.

K and cut such that the $<10\bar{1}0>$ axis is normal to the undulator mid-plane. In fact, this is a conservative estimate because the more easily magnetized material will apply a larger field at the pole tip.

Material Performance

It is clear from the preceding that the highest peak field will result from choosing sample B cooled to 30 K. By cutting the poles from the bulk laminate such that the $<11\bar{2}0>$ axis of the texture is oriented in the same direction as the dominant magnetic field. For example, in a vertically ($\hat{y}$) polarized planar undulator in which and electron in the mid-plane oscillates horizontally ($\hat{x}$) and the beam travels along the $\hat{z}$-direction, the texture of the dysprosium should be oriented such that ($\hat{x}$,$\hat{y}$,$\hat{z}$):([0001],$<11\bar{2}0>$,$<10\bar{1}0>$) for optimal performance. Previous simulation has shown that there is a small decrease in performance when the texture is oriented with the $\hat{x}$ and $\hat{z}$ directions switched, poles with this texture orientation are much easier to manufacture.

To more efficiently produce a large amount of bulk laminate textured dysprosium, we modified the processing technique that produced excellent magnetic results in earlier phases of the project. The principal modification was an intermediate annealing step during rolling to relieve strain from the rolling. Although x-ray 2θ scans of the material show good texture development [1], this additional step substantially increases the fraction of the bulk laminate that is made up of dysprosium oxide, reducing overall magnetic performance. This additional annealing step has been removed from the process and additional measurements are being performed at the time of publication.

ACKNOWLEDGMENT

We thank E. Mun and J. Betts at the National High Magnetic Field Laboratory at Los Alamos for the data used in Fig. 1 and T. Scrivnor for careful machining of the samples measured.

SURFACE PLASMON RESONANCE ENHANCED MULTIPHOTON EMISSION FROM METALLIC CATHODE*

H. To, R. Li, P. Musumeci, UCLA, Los Angeles, CA 90095, USA
G. Andonian, Radiabeam Technologies, Santa Monica, CA 90404, USA

Abstract

We investigate the use of surface plasmonic nanostructures in increasing the efficiency of copper photocathodes for high-brightness electron sources. A nanohole structure was fabricated, using focused ion beam milling, such that it exhibited a strong plasmonic response near 800 nm. The reflectivity of the nanostructured surface was significantly lower compared to that of a flat surface, due to plasmonic resonance effects. A previous experiment [1] demonstrated an increase in charge yield by over a factor of 100, using a slightly off-resonance structure. With this new near-resonant structure, the reflectivity is expected to be even lower and the charge yield enhancement factor even larger.

INTRODUCTION

Recently, progress has been made in using metal photocathodes to generate high brightness electron beams, as an alternative to using semiconductor cathodes [2]. Because of their prompt response, low vacuum requirements, robustness, and fabrication simplicity, metals are typically the preferred choice in high peak brightness photoguns [1]. However, metal cathodes are not without disadvantages, a significant one being that they are often highly reflective at optical and infrared wavelengths and in general offer lower QE than semiconductors [3].

We, at the UCLA Pegasus laboratory, have demonstrated the generation of electron beams through multiphoton emission using a copper photocathode with an 800 nm Ti:Sa incident laser [2]. At 800 nm, copper is ~95% reflective, and thus, most of the photons from the incident laser are wasted and do not participate in the multiphoton emission process [3]. To increase the efficiency of the cathode, an obvious solution would be to increase the absorptivity of copper at 800 nm. One way we propose to do this is to pattern a cathode surface with nanoscale features that take advantage of plasmonic effects.

THEORY

Recent advances in nano-plasmonics have enabled fine control of optical properties of metal surfaces by patterning them with sub-wavelength or nanoscale features [4]. Nanoscale features of the correct geometry can lead to surface plasmon resonance, or a resonant interaction between surface plasmons and incident photons [5]. This produces two major effects [4]: 1) significant reductions in metal reflectivity due to photons being absorbed by surface plasmons, and 2) large enhancements of local optical field intensity due to photon energy being stored in the surface plasmons. These nano-plasmonic phenomena could be applied to optimize the optical response of a cathode and obtain high efficiencies in photoemission charge yield.

Previously, we reported the first experimental results of the generation of relativistic electron beams from a nanostructured photocathode in a high gradient RF gun [2]. The aforementioned nanohole array structure exhibited a resonant response at ~810 nm. At 800 nm, the reflectivity of the nanopattern was ~60%, still producing a >100-fold enhancement in the multiphoton charge yield. With a nanopattern that is resonant closer to 800 nm, the charge yield can be expected to be greater.

SETUP

The geometry of the nanopatterns consist of rectangular arrays of nanoholes fabricated with focused ion beam (FIB) milling, as shown in Fig. 1. The patterns were milled onto a single crystal Cu(100) substrate to avoid pattern variation due to the random grain sizes and orientations associated with polycrystalline substrates.

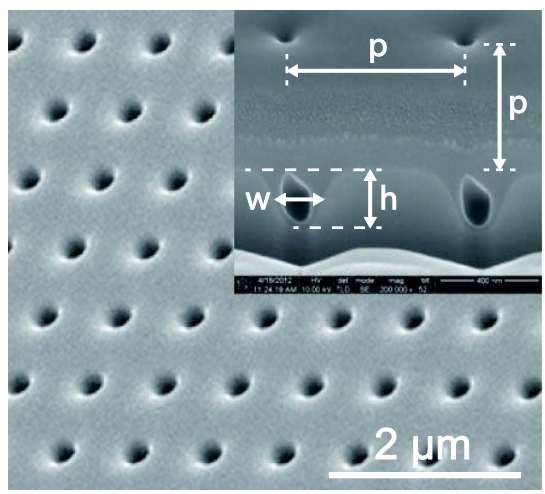

Figure 1 [1]: Scanning electron microscopy images of a nanohole array. Inset: Zoomed in profile view of nanoholes.

When using the nanohole array geometry, the resonant wavelength is much more sensitive to the spacing of the holes than to their depth, width, and even their shape [1]. Each nanohole has an approximately Gaussian profile, mainly due to the current density distribution of the milling ion beam. Finite Difference Time Domain (FDTD) simulations were performed to compare the

difference in resonant response between Gaussian-shaped holes and ideal rectangular holes, using the same depth, width, and spacing. We found that the resonant wavelength for these two profiles differed only by about 4 nm, as shown in Fig. 2. This finding is important in that it allows us to fine tune the resonant wavelength primarily by changing the hole spacing p, which is the most controllable and reproducible parameter in a FIB device.

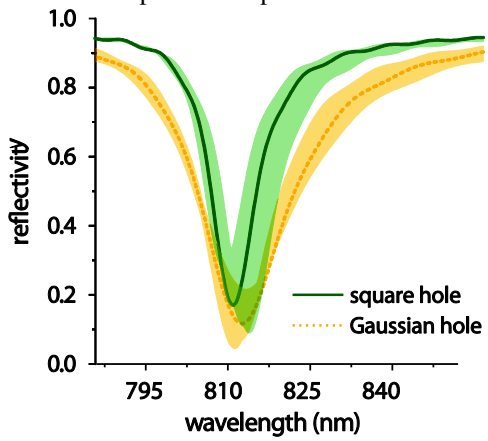

Figure 2 [1]: Simulated reflectivities at normal incidence of two types of nanohole pattern: square holes and Gaussian holes.

In this study, we fabricated nanopatterns with spacing p of 765 nm, shown in Fig. 3. The dimensions of the structure (spacing p, depth h, and FWHM width w of the holes) were optimized through finite difference time domain (FDTD) simulations. The values of h, w, and p are ~300 nm, ~200 nm, and ~765 nm respectively. The middle right pattern is the same as the top and middle left patterns, but rotated 90 degrees. This is to check the possibility of asymmetry in the nanoholes, i.e. the holes could be slightly elliptical rather than perfectly circular. Fig. 4 shows the reflectivity curves for the un-rotated and rotated patterns. When imaging the nanopattern at normal incidence using a 2 nm FWHM laser at the resonant wavelength, the incident light is strongly absorbed (Fig. 3).

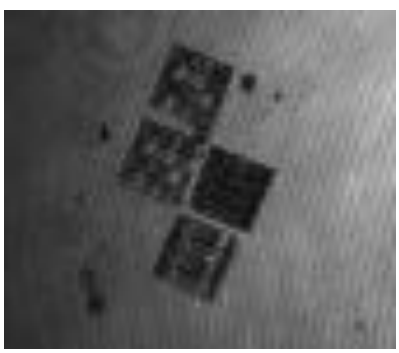

Figure 3: Nanopatterns with 200 nm FWHM width and 300 nm depth. Top left: 765 nm spacing. Middle left: 765 nm spacing. Middle right: 765 nm spacing, pattern rotated 90 degrees with respect to first two patterns. Bottom right: practice pattern. Pattern square sizes: ~ 100 μm by 100 μm.

When imaging the nanopattern at normal incidence using a 2 nm FWHM laser at the resonant wavelength, the incident light is strongly absorbed, as shown in Fig. 3. The measured resonant wavelength of this nanopattern is 795 nm with a bandwidth of 34 nm, and corresponds to a reflectivity of 12%. At 800 nm, the nanopattern exhibited a reflectivity of 23%.

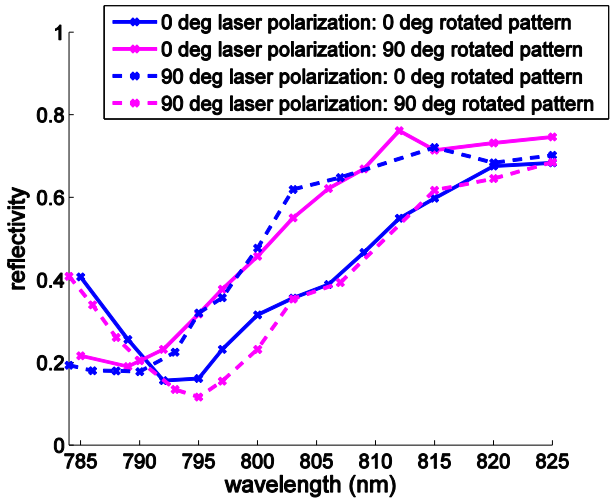

Figure 4: Reflectivity curves for most recent nanopatterns. Solid curves: 0 degree laser polarization. Dashed curves: 90 degree laser polarization. Blue curves: un-rotated pattern. Magenta curves: rotated pattern, 90 degrees with respect to un-rotated pattern.

ANALYSIS

The reflectivity curves in Fig. 4 indicate polarization dependence for the nanostructures. For a pattern, the un-rotated pattern for example, the resonant wavelength shifts when the laser polarization is changed by 90 degrees (blue curves). The rotated pattern exhibits the same behaviour, but in reverse (magenta curves). This suggests that the holes are indeed slightly elliptical in shape. The small shift (< 4 nm) in the plasmonic resonance peak can be explained due to some asymmetry in the FIB machine's focus in the x and y directions in agreement with the simulation prediction.

It is interesting to compare the potential increase in charge yield from the 795 nm resonance pattern to the previous 810 nm resonance pattern. In the previous experiment [1], IR laser pulses (150 fs FWHM) were focused to 120 μm rms and scanned around the nanopattern at near normal incidence (<1°) with a piezo-controlled mirror. The position of the laser spot on the cathode was monitored using a virtual cathode screen, and the generated beam charge was measured by a calibrated high efficiency beam profile camera. The maximum

Copyright © 2013 CC-BY-3.0 and by the respective authors

signal, obtained when the laser spot fully covered the nanopattern, was $Y_{exp} > 1.2 \times 10^2$ times greater than when the laser was hitting only a flat surface [1].

This large increase cannot by fully explained by just the change in IR reflectivity and absorption. The generalized Fowler-Dubridge theory [6] predicts an increase of $Y_{FD}=(1-R_p)^3/(1-R_f)^3=27$ times, where $R_p=64\%$ and $R_f=88\%$ are the measured reflectivities of the previous nanopattern and the flat cathode surface, respectively. The additional enhancement in charge emission can be attributed to the optical intensity enhancement due to surface plasmon resonance (Fig 5.).

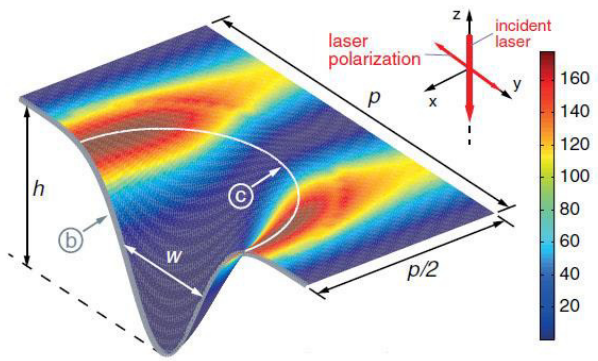

Figure 5 [1]: Intensity distribution on the nanohole surface.

It is estimated that a nanopatterned surface produces ~5 times more charge than a flat surface under equal absorbed intensity [1]. As mentioned, the more recent nanopattern exhibited a reflectivity of $R_p=23\%$. From a reflectivity standpoint alone, this corresponds to a charge enhancement factor of $Y_{FD}=(1-R_p)^3/(1-R_f)^3\sim250$ times. Taking into account the enhancement due to surface plasmon resonance, this suggests that the total enhancement factor could be at least 1000.

It is important to consider possible limitations to this large enhancement factor. It has been demonstrated that structural changes to a nanopatterned cathode surface occur when the absorbed fluence approaches 10 mJ/cm^2 [1]. The result is consistent with the 50 mJ/cm^2 limit reported for a flat copper surface [7] taking into account the ~5 times enhancement due to surface plasmonic effects. This sets an upper limit to incident laser power for nanopatterned surfaces that is lower than the limit for a flat surface, i.e. using an arbitrarily high laser power does not yield an arbitrarily high charge yield. In regards to an upper limit to charge yield, at present, it is unclear whether the localized emission of photoelectrons from a nanostructured cathode sets a different limit on the highest extractable charge density than a flat cathode case, but that should be an interesting topic for future studies.

CONCLUSION

In summary, this work demonstrated the potential to use plasmonic nanostructures to change the optical properties of a copper photocathode. In doing so, we were able to mitigate the inherent ~90% reflectivity of a flat copper surface. We showed a significant increase in charge yield from using a previous nanostructure that was 64% reflective at 800 nm, and thus, we can expect any even larger increase from the current nanostructure, which is 23% reflective. Our next steps include generating an electron beam with this nanostructured cathode and comparing its characteristics (charge yield, intrinsic emittance, and bunch length) to that of a beam from an ordinary flat cathode. We envision this work to be a promising step in a new direction of photocathode research.

BEAM DYNAMICS DRIVEN REQUIREMENTS ON THE ARIEL E-LINAC SRF SEPARATOR CAVITY*

Douglas W Storey[1,2†], Yu-Chiu Chao[2], Lia Merminga[2],
[1]University of Victoria, Victoria, B.C, Canada, [2]TRIUMF, Vancouver, B.C, Canada

Abstract

A possible future extension to TRIUMF's ARIEL e-linac is the addition of a recirculation path for an Energy Recovery Linac (ERL), which will drive an Infrared or THz Free Electron Laser (FEL). The ERL electron beam will be interleaved with the single-pass beam bound for Rare Isotope Beam (RIB) production in the ARIEL facilities, allowing for simultaneous beam delivery to both FEL and RIB users. A superconducting RF separator will separate the beams at the exit of the linac at a frequency of 650 MHz in CW mode. After a second pass through the linac, the energy recovered ERL beam will pass through the separator cavity out of phase with the deflecting fields, and at a much lower energy, before continuing to a beam dump. Using the General Particle Tracer software, three-dimensional simulations of the beam dynamics of the passing beams have been performed to determine the requirements on the SRF separator's deflecting field uniformity. Operation of the FEL requires minimal emittance dilution of the ERL beam from the separator. This contribution describes the results of these studies and the requirements imposed on the SRF beam separator.

INTRODUCTION

The ARIEL e-linac will produce a 50 MeV, 10mA CW electron beam as the photo-fission driver for the production of neutron rich Rare Isotope Beams (RIB). This complementary RIB source will expand TRIUMF's existing ISAC experimental program. The electron beam is accelerated through an injector cryomodule to an energy up to 10 MeV, and two accelerating cryomodules (ACM) up to an energy of 50 MeV in cavities operating at 1.3 GHz [1].

A future phase will be the addition of a recirculation loop to return the electrons for a second pass through the main linac. This may be configured as a recirculated linac (RLA), accelerating the beam up to 75 MeV before continuing on for RIB production, or as an Energy Recovery Linac (ERL) with a Free Electron Laser operating in the back leg of the recirculation loop and interleaved with the RIB beam in the main linac.

Successful operation of the FEL depends on a low emittance beam, requiring minimal emittance dilution imparted during the separation of the beams at the exit to the main linac.

† dstorey@uvic.ca

RF Separator Layout

Bunches bound for either RIB production or the ERL will have the same energy when reaching the separator section and will occupy alternating buckets of the 1.3 GHz accelerating RF. Separation of the bunches will then require RF separation at a frequency of 650 MHz at the exit of the main linac. Furthermore, the separator layout must also be compatible with the RLA operating mode, which will rely on the static magnetic separation of the two beams.

The basis of this separation scheme has been developed in [2] and comprises of an RF separator cavity imparting an initial differential transverse kick to the two beam types, followed by a steering dipole, a defocusing quadrupole to further enhance the separation, and finally a septum magnet to perform the final separation of the beams. This scheme is driven by rigid space constraints that require the full separation of the beams within a distance of about 3 m. The layout of the separation section of the e-linac is depicted in Fig. 1.

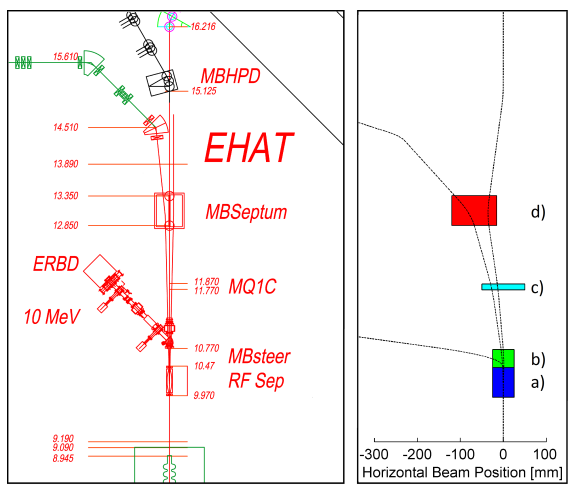

Figure 1: The layout of the ARIEL RF separator on the left with the beam deflections shown on the right. The elements shown are the a) RF separator cavity, b) dipole magnet, c) quadrupole, and d) septum.

In addition to the RIB and ERL beams, the decelerated beam after making its second pass through the ACM, will reach the RF separator with energy of 5 to 10 MeV and 90°out of phase with the cavities deflecting phase. It will therefore pass mostly unaffected through the separator cavity and receive a sharp deflection by the dipole magnet due to its low energy to be directed down a short transport line to a beam dump.

Copyright © 2013 CC-BY-3.0 and by the respective authors

An SRF cavity with RF Dipole geometry [3] is being considered for the RF separator. This cavity is compact in size and the transverse deflections are high with low peak electric and magnetic fields.

Beam Properties

The RF cavity will operate at 650 MHz to give opposing transverse momentum kicks to adjacent bunches from the main linac at $\pm 90°$. The required angular deflection imparted by the cavity is ± 4.5 mrad for beam energies of up to 66 MeV and currents up to 16 mA CW.

The incoming RIB and ERL beams will have normalized emittances of 5 mm-mrad in both x and y and the transverse RMS beam widths on entering the RF separator cavity are 0.68 mm and 0.42 mm respectively, as determined from the e-linac optics. The energy spread of the beam will be around 0.5%.

After deceleration in the main linac, the beam will have an energy of 5 to 10 MeV with a significant energy spread of about 5%. Additionally, the bunch length will be quite long, up to 6.5 mm RMS.

TRACKING SIMULATION

The simulations of the beam dynamics were performed using the General Particle Tracer (GPT) [4] to quantify the emittance growth of the beam primarily within the separator cavity. The fields in the separator cavity, as described in [5], were exported from the HFSS RF simulation tool on a grid with 1 mm spacing [6]. GPT in turn uses this field map in an 8-point bilinear interpolation to evaluate the field at a specific point in space.

Bunches of 100,000 macro-particles were initiated immediately before the RF cavity with Gaussian spatial distributions and divergences scaled to obtain 5 mm-mrad emittances. The macroparticles were given a uniform distribution of energy spread about the mean beam energy of 50 MeV for the ERL/RIB beams and 7 MeV for the decelerated beam.

The tracking simulation through the RF cavity was performed with varying incoming beam parameters, different momentum kick strengths, and different cavity geometries to determine the emittance growth imparted by the cavity.

RESULTS

For the nominal beam parameters, the emittance growth in the horizontal direction was found to be very minimal with well under a 1% increase. The emittance in the vertical direction was found to be mostly unaffected by the RF cavity within the parameter space studied.

Sensitivity Studies

To investigate the impact of the RF separator cavity under non-optimal beam properties, the transverse and longitudinal RMS sizes, energy spread, and transverse position of the beam were varied about their nominal values.

The horizontal emittance was found to be most sensitive to changes in the transverse beam sizes, particularly in x direction, as shown in Fig. 2. The emittance growth stays below 1% for beam widths under 2 mm but grows very quickly for larger beams.

The emittance showed very little dependence on both the energy spread of the beam and the transverse position.

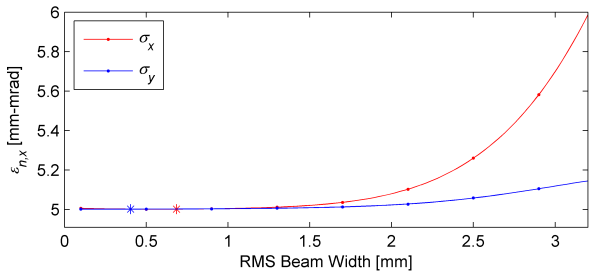

Figure 2: The normalized RMS transverse emittance, $\varepsilon_{n,x}$ at the exit to the RF separator cavity for different beam widths, for an RF voltage of 0.3 MV. The nominal beam widths are marked by the * symbol.

Increased Momentum Kick

Due to the limiting space within the TRIUMF E-Hall, a larger momentum kick imparted by the RF separator could achieve the separation of the beams in a shorter distance. This is desirable as it would loosen space requirements on the surrounding beam-line by allowing a shorter distance between the separator cavity and septum.

Increasing the transverse voltage of the RF cavity will amplify its effect on the emittance of the beam. This effect was studied with increasing deflecting voltages from the nominal 0.3 MV up to 1.7 MV for a 25 mrad angular deflection. This is nearing the upper limit of this cavity geometry with the peak fields approaching operational limits.

At the nominal beam parameters, minimal emittance growth is seen up to the maximum kick strengths studied, with the horizontal emittance increasing by less than 0.5%. Again, the emittance growth sees the largest correlation with the width in the x direction, as shown in Fig. 3. The emittance growth also shows a dependence on σ_y, bunch length, and shows a growing dependency on the y position of the beam.

Based on these results, the deflecting voltage of the cavity may be increased to approximately 0.7 MV, after which the emittance would become too sensitive to the beam width in the x direction. This corresponds to angular deflections after the separator cavity of up to around 10 mrad.

Field Uniformity

The main source of emittance dilution when passing through the separator cavity is the non-uniformity of the fields across the aperture, which causes beam particles to receive a different momentum depending on their transverse position. One way to achieve more uniform deflecting fields is to modify the geometry of the inner ridges of

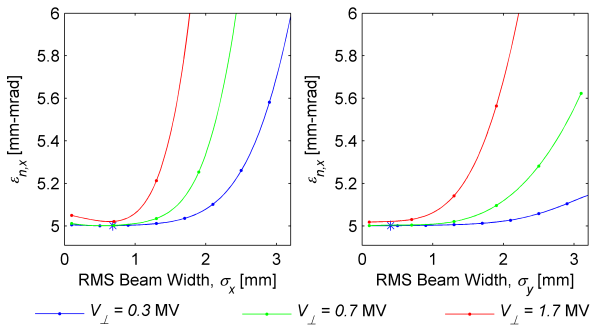

Figure 3: The normalized RMS transverse emittance, $\varepsilon_{n,x}$ at the exit to the RF separator cavity for different beam widths and varying momentum kick from 0.3 MV to 1.7 MV.

the RF dipole cavity to shape the fields in a more uniform way.

The cavity considered thus far has flat inner ridges, as shown in Fig. 4. By giving the inner ridges a slight outwards curvature, the field uniformity can be greatly increased with little effect on the RF properties of the cavity.

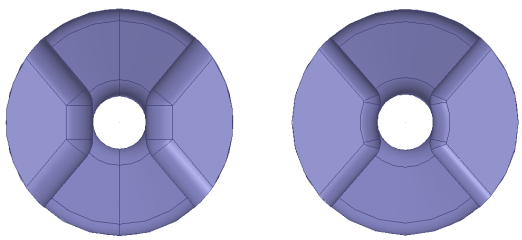

Figure 4: The cross section of the separator cavity with flat inner ridges on the left and curved ridges on the right.

In Fig. 5, the cavity with curved ridges contributes to the emittance growth similarly to the flat ridged cavity for RMS beam sizes less than 1.5mm, after which the curved ridge cavity results in lower emittance growths.

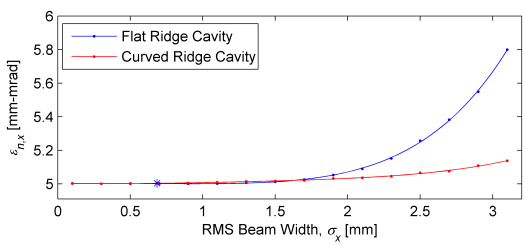

Figure 5: The normalized emittance, $\varepsilon_{n,x}$ at the exit to the RF separator cavity for the two different cavity geometries.

Decelerated ERL Beam

The decelerated beam passes through the RF separator cavity at the zero crossing, nominally with no deflections. However, as the bunch enters the cavity it sees the decreasing deflecting fields, imparting a small momentum to the bunch. While exiting, it sees the fields increasing again and receives an opposing kick. This results in a net zero angular deflection, but also a small horizontal deflection at the exit of the cavity. Additionally, since the bunch length of the decelerated beam is quite long, the head will see a small net angular deflection in the opposite direction as the tail, resulting in a small defocusing effect on the beam.

The scale of the horizontal deflection is approximately 0.5 mm for a 0.3 MV transverse deflecting voltage. This scales linearly with kick strength, resulting in a maximum offset of 2.5 mm for the highest kick strengths considered here, 1.7 MV. The defocusing effect was also found to be minimal.

Deflections of this size will not impede the safe passage of the decelerated beam through the separator cavity and dipole magnet without losing particles along the way. Quadrupoles located after the dipole along the dump beam line will ensure safe transport of the beam to the 10 MeV beam dump, located another 2 m past the separator cavity. The effect of the decelerated beam therefore does not impose any further requirements on the RF cavity.

CONCLUSION

These studies indicate that operating with nominal beam properties, the RF separator cavity will impart minimal emittance growth to the ERL and RIB bound beams. The beam width in the x direction contributes the largest to emittance dilution and for a cavity with flat inner ridges, RMS beam widths of under 2 mm will limit the emittance growth to less than 1%. Overall, the beam dynamics do not imply any stringent requirements on the RF separator cavity.

The upper limit to the deflecting voltage of the cavity is approximately 0.7 MV, after which with the emittance becomes very sensitive to the transverse beam width. This corresponds to a ± 10 mrad angular deflection by the RF cavity. This sensitivity may be decreased by using a cavity with better field uniformity such as one with curved inner ridges.

FEASIBILITY OF AN RF DIPOLE CAVITY FOR THE ARIEL E-LINAC SRF SEPARATOR*

Douglas W. Storey[1,2†], Robert Edward Laxdal[2], Lia Merminga[2], Vladimir Zvyagintsev[2]
[1]University of Victoria, Victoria, B.C, Canada, [2]TRIUMF, Vancouver, BC, Canada

Abstract

A megawatt class CW e-linac is being designed and constructed at TRIUMF with the main goal of producing neutron rich isotopes for TRIUMF's Rare Isotope Beam (RIB) program. A possible extension of the beam-line will allow recirculation of the beam for an Energy Recovery Linac (ERL) to operate in tandem with the RIB user program. A superconducting cavity with RF dipole geometry is being considered for separation of the ERL and RIB beams at the end of the linac to provide simultaneous beams to both the ERL and RIB programs. This contribution describes optimization studies performed on the RF dipole design to determine if this geometry will meet the requirements of the ARIEL e-linac. The resulting 650 MHz structure has compact cavity dimensions, low peak fields, and high transverse shunt impedance. Due to the large aperture beam-line and stringent requirement on preserving beam quality, extensive focus has been placed on transverse uniformity of the deflecting fields.

INTRODUCTION

A future extension to the ARIEL e-linac [1] will be the addition of a recirculation path to the beam-line for an Energy Recovery Linac (ERL), the driver for an Infrared or THz Free Electron Laser (FEL). The ERL electron beam will be interleaved with the single-pass beam bound for Rare Isotope Beam (RIB) production in the ARIEL facilities, allowing for simultaneous beam delivery to both FEL and RIB users.

Bunches of electrons bound for either the ERL or RIB will occupy alternating buckets of the 1.3 GHz accelerating RF. The separation of the beams will take place at the exit of the main linac. The basis of this separation scheme is introduced in [2], which describes the layout and deflections required by each element in the separation complex: an RF separator, steering dipole, defocusing quadrupole, and septum magnet. This scheme is driven by the rigid space constraints that require the separation of the beams within a distance of about 3 m.

After energy recovery in its second pass through the accelerating modules, the recirculated ERL beam will reach the RF separator with beam energy of approximately 5 to 10 MeV, and 90°out of phase with the deflecting phase of the cavity. It will therefore pass mostly unaffected through the separator cavity and receive a sharp deflection in the dipole magnet and be directed down a short beam-line to a beam dump.

The initial separation will take place in an RF separator cavity operating at a frequency of 650 MHz, imparting opposing transverse momentum kicks to the ERL and RIB bound beams and deflecting them by ±4.5 mrad in the horizontal direction. This deflection will be amplified by the quadrupole magnet with the final separation of the beams reaching $\sim$ 35 mm by the time they reach the septum. At this point, the ERL beam will be directed around the recirculation loop and the RIB beam back towards the main linac axis.

Additionally, the layout of the separator section of the linac is compatible with a two pass Recirculating Linac in which the beam is directed around the recirculation loop after its first pass to be accelerated a second time in the main linac before continuing on for RIB production. This mode would not employ the RF separator cavity, but would rely on the static magnetic separation of the beams with different energies in the dipole.

The maximum beam energy at the exit of the main linac will be 66 MeV. This translates to a 0.3 MV transverse momentum kick imparted by the RF separator cavity and transverse deflecting field of $E_\perp = 1.3$ MV/m for a single deflecting cavity.

SRF SEPARATOR CAVITY

The RF dipole deflecting cavity is being considered for use in the ARIEL separator complex. This cavity is compact in size and the transverse deflections are high with low peak electric and magnetic fields. Extensive scaling studies have been performed on this geometry [3], however detailed optimization is required to fully access the suitability of this cavity design for the ARIEL e-linac separator.

The geometry of the RF dipole separator cavity is shown in Fig. 1. The inner ridge length of the cavity will be of order $\beta\lambda/2 = 230$ mm at 650 MHz, and the aperture 50 mm, the same as along the rest of the length of the e-linac.

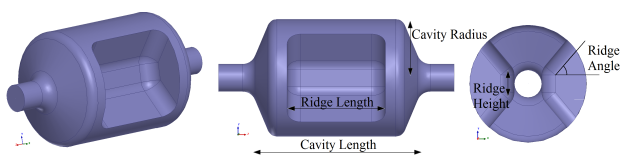

Figure 1: The RF dipole geometry showing the key parameters affecting the cavity performance.

In the deflecting mode, a transverse electric field is produced between the cavity ridges while the magnetic field circulates around them. The x component of the electric field provides the main contribution to the horizontal deflections while the y component of the magnetic field acts to decrease the deflection, by a relatively small amount. The deflecting mode of this cavity geometry is the lowest order mode of the cavity and the next higher order mode has a frequency far from the fundamental mode.

GEOMETRY STUDIES

The RF Dipole cavity behaviour has been studied using HFSS [4] to determine an optimal separator cavity geometry for the ARIEL separator specifications. The main goals of the optimization were to maximize the transverse shunt impedance while minimizing the peak electric and magnetic fields.

The parameters that have the most significant effect on the cavity behaviour are shown in Fig. 1. These are the height and length of the inner ridge, the angle of the ridge cut-out, and the length and radius of the cavity. For each change to the geometry, the cavity radius was adjusted such that the fundamental frequency of the cavity was held at 650 MHz.

The length of the inner ridge was varied, along with the cavity length, to determine the optimal ridge length. It was found that a ridge length of 0.6 times the cavity length consistently resulted in minimized electric fields, as seen in Fig. 2. The peak magnetic fields followed a similar trend. Increasing the overall cavity length also resulted in lower peak fields, and an increase in the transverse shunt impedance, $R_\perp$. For the remainder of the parameter search, the ridge length was set to 0.6 times the cavity length.

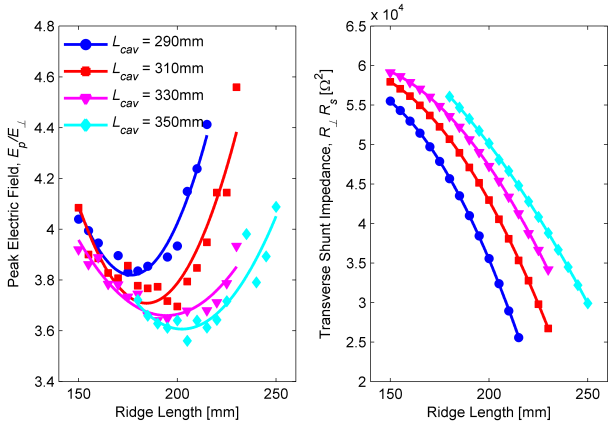

Figure 2: The peak electric fields on the left, and the transverse shunt impedance on the right for varying ridge and cavity lengths. For reference: $\beta\lambda/2 = 230$ mm at 650 MHz.

Next, the height and angle of the ridge were varied simultaneously for different cavity lengths. Again, the outer radius was adjusted to retain a cavity frequency of 650 MHz. The HFSS results show that the peak fields are lowest for larger ridge heights and larger ridge angles, as seen in Fig. 3. In each case, the electric field reaches a minimum value at a cavity length of approximately 380 mm. This corresponds to an inner ridge length of 230mm, precisely the value of $\beta\lambda/2$. The peak magnetic fields show a similar dependency on ridge length and angle.

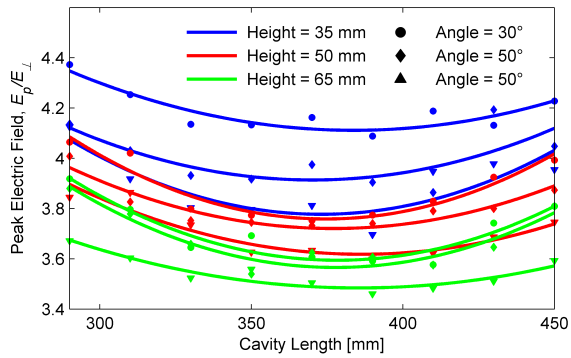

Figure 3: The peak electric fields for varying ridge height and angle and the cavity length. The colour of the line indicates the ridge height and the shape of the data point the angle of the ridge.

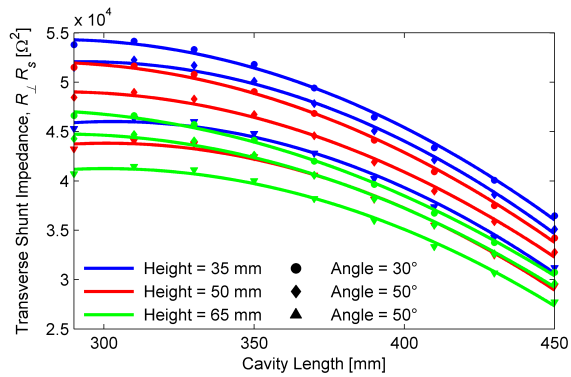

Figure 4: The transverse shunt impedance for varying ridge height and angle and the cavity length.

The transverse shunt impedance, Fig. 4, is seen to decrease with increasing cavity length as well as for larger ridge height and angle. This leads to conflict between the objective to minimize the peak fields while maximizing the shunt impedance.

A compromise of a ridge height of 50 mm and angle of 50°would provide reasonably high transverse shunt impedance while keeping the peak electric and magnetic fields below 5 MV/m and 10 mT for a transverse deflecting voltage of 0.3 MV. These are well below currently accepted upper limits for electric and magnetic fields in SRF cavities. Since the shunt impedance decreases with cavity length, a cavity length of $\sim$ 330 mm provides a compromise between minimizing the peak fields and maximizing the shunt impedance.

Field Uniformity

Successful operation of an FEL requires a beam with low emittance, and therefore minimal emittance dilution of the ERL beam as it passes through the RF separator. Non-uniformity of the fields across the cavity aperture is one of the main sources of emittance growth.

A larger ridge height and angle results in the most uniform fields within the central portion of the cavity, leading to lower emittance growth. However, as noted in the previous section, a large ridge height and angle would also result in a lower shunt impedance.

Another way to achieve more uniform deflecting fields is to modify the shape of the inner ridge in such a way that forces the uniformity of the fields between the ridges. Giving the inner faces of the ridges a slight curvature allows the bars to come slightly closer together while maintaining the 50 mm diameter aperture, as well as shaping the fields in a more uniform way. This geometry is shown in Fig. 5, along with the cavity geometry with flat inner ridges.

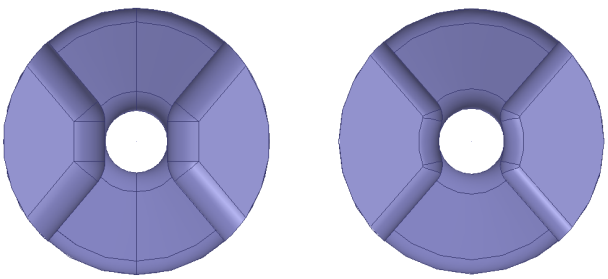

Figure 5: The cross section of the original RF dipole geometry, with flat inner ridges on the left and the modified separator cavity shape on the right, showing the curved faces of the inner ridge.

To quantify the field uniformity, the momentum gain in the x direction relative to the kick received by an on-axis particle was plotted across the aperture of the separator cavity, Fig. 6. The transverse radius within which the relative momentum kick is less than 2% of the on-axis kick strength was found to be 8.5 mm for the flat ridged cavity, compared to 12.5 mm for the curved ridge geometry. The shunt impedances of the two geometries are very similar and the peak electric and magnetic fields are slightly higher for the curved ridge cavity, but are still well below operational limits.

An in depth analysis of the beam dynamics has been performed to access the emittance growth of the ERL and RIB beams passing through the RF separator cavity [5]. It was found that under nominal beam conditions, the flat ridged cavity will contribute to acceptable emittance growth. For beams with larger RMS width or requiring stronger transverse momentum gain, the curved ridge may be useful to limit the emittance growth.

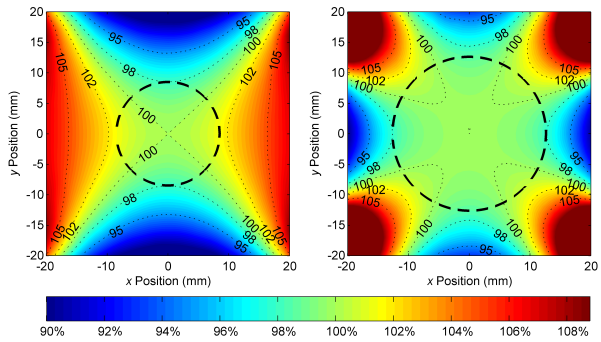

Figure 6: A comparison of the kick-uniformity for the RF dipole with flat ridge geometry on the left, and curved ridges on the right. The dashed circle shows the area in which the momentum kick is within 2% of the on axis kick strength.

CONCLUSION

The RF dipole cavity has been determined to be compatible with the requirements for the ARIEL e-linac RF separator. The main properties of the cavity with flat inner ridges are summarized in Table 1.

Table 1: Properties of the RF Dipole Separator Cavity Optimized for the ARIEL e-linac Requirements

Parameter	Value	Units
Frequency of the deflecting mode	650	MHz
Cavity length	330	mm
Cavity diameter	210	mm
Inner ridge length	198	mm
Transverse deflecting voltage, $V_\perp$	0.30	MV
Transverse deflecting field, $E_\perp$	1.30	MV/m
Geometry Factor, G	117	Ω
Transverse Shunt Impedance, $R_\perp/Q$	411	Ω
Peak electric field, E_p	4.5	MV/m
Peak magnetic field, B_p	7.8	mT

DESIGN, FABRICATION, MEASUREMENT, INSTALLATION AND ALIGNMENT OF 2 TYPES OF QUADRUPOLE-SEXTUPOLE COMBINED MAGNETS FOR THE UPGRADE OF THE 1.2 GEV BOOSTER SYNCHROTRON AT TOHOKU UNIVERSITY

W.Beeckman, S.Antoine, P.Bocher, F.Forest, P.Jehanno, P.Jivkov, M.J.Leray, L.Swinnen, S.Taillardat, , SIGMAPHI, Vannes, France
H.Hama, F.Hinode, Electron Light Science Centre, Tohoku University, Sendai, Japan

Abstract

The upgrade of the 1.2 GeV booster synchrotron is part of the recovery program from the March 11 2011, Great East Japan Earthquake. The replacement of standard quadrupoles by combined quadrupole-sextupole magnets will tame the head-tail instability by changing the chromaticity from the natural, negative, values to positive values, and prevent the unstable m=0 mode to develop.

In January 2012, Sigmaphi was awarded a contract for the design of 2 kinds of combined magnets and the fabrication of 8 magnets of each type, including rotating coil and Hall probe measurements of every unit. The contract also required disassembly of the old quadrupoles and installation of the new combined magnets, including disassembly/reassembly of the vacuum chambers and fitting with new UHV gaskets. Finally, all the booster magnets, namely 8 dipoles, 4 achromat quadrupoles and the 16 new combined function magnets were to be realigned within ±0.2 mm accuracy by mid-January 2013. The presentation outlines the main steps of the different operations and presents the achievements and results.

DESIGN

A general overview of the status of the project is given in [1] and we concentrate here on the magnets.

Table 1 presents the requirements for the new magnets.

Table 1: Magnet Requirements

Requirement	QSF	QSD
Quadrupole	k=2.01044 m^{-2}	k=2.21750 m^{-2}
Sextupole	2.4 times 4-pole m=4.825061 m^{-3}	3.8 times 4-pole m=8.426508 m^{-3}

Additional requirements are listed below

- Same geometry as old magnets including coil shape and electrical/water connections. Only the pole face may be changed.
- Magnetic centre at ±0.5 mm from mechanical centre in both transverse dimensions
- Alignment error may not be larger than ±0.2 mm
- 1 year from contract to end

All these requirements put together make a very demanding job with little freedom.

Many different designs of such combined magnets can be found in the literature. The extra function is added on top of the main multipole either through pole shaping [2][3], or by using extra coils that superimpose a second multipole [4][5]. By requirement, we must not only adopt the first scheme but we must also abide to the very strong constraint of keeping the magnetic circuit within the yoke shape of the existing magnets.

The pole profile [6] of such a combined function magnet is a superposition of the potentials, hence an equation $kxy+\frac{1}{6}m\left(3x^2y-y^3\right)=\frac{1}{2}kR^2+\frac{1}{6}mR^3$

The field components are summarized in table 2.

Table 2: Field Components

Field component	Bx	By
Quadrupole	ky	kx
Sextupole	mxy	$\frac{1}{2}m\left(x^2-y^2\right)$

Thus, the vertical component in the horizontal plane (y=0) is equal to $B_y = kx+\frac{1}{2}mx^2$

Starting from the above theoretical pole profile with a pole radius of 50 mm and maximum coil current of 700 A we can aim at designing a pole profile that satisfies the requirements. However, as shown below, incompatible symmetries generate differential saturations which prevent required fields to be achieved with the prescribed yoke thickness. The possible m/k ratio was redefined as m/k(QSF) ~ 1.0 (2.4) and m/k(QSD) ~ 1.8 (3.8)

The pink and green rectangles locate the 4 and 6-poles and the matching arrows the resulting field, adding on the right and subtracting on the left.

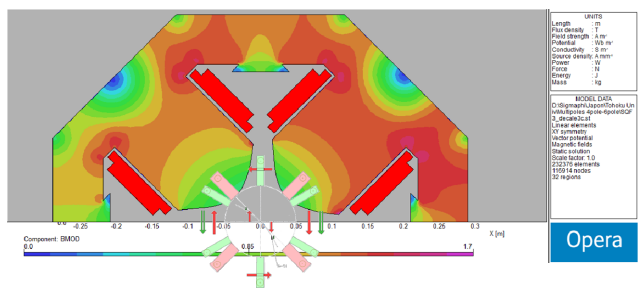

Figure 1: 2d cross-section of a combined magnet showing the strong differential yoke saturation.

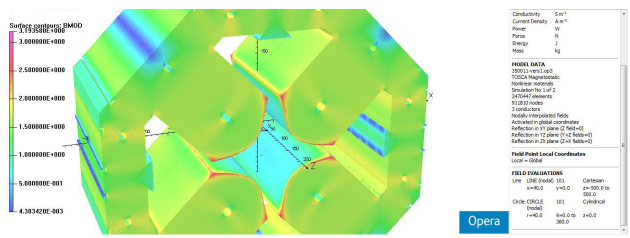

Figure 2: Opera3d model

Copyright © 2013 CC-BY-3.0 and by the respective authors

MEASUREMENTS

For pure multipoles, iso-modulus lines are concentric circles $|B^{(n)}| \propto r^{n-1}$ but for combined multipoles, the modulus $|B^{(2+3)}| = k^2 r^2 + \frac{1}{4} m^2 r^4 + \frac{1}{2} m x^3$ is not purely radial.

Hall probe measurements are therefore better suited than harmonic coils for some data.

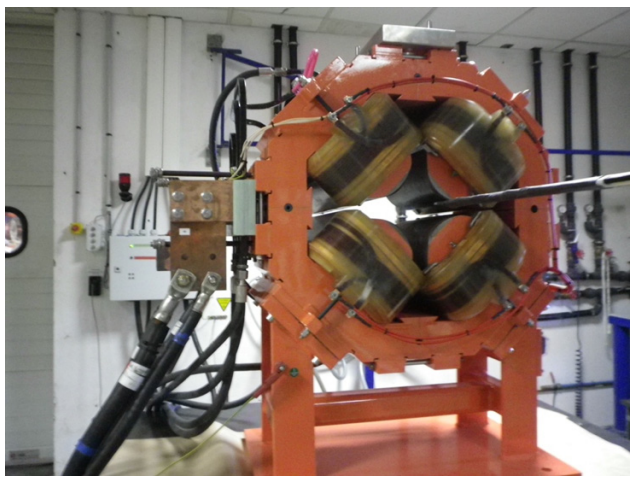

Figure 3: Hall probe median plane measurement.

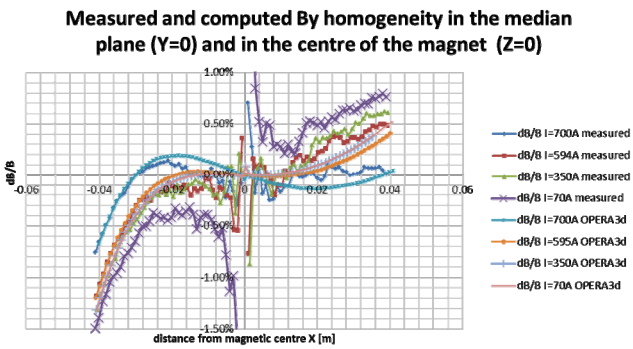

Figure 4: Homogeneity is computed from Hall probe data

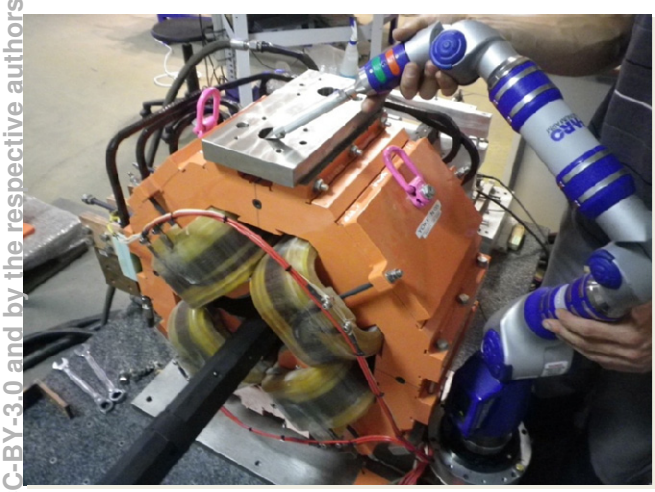

Figure 5: Faro arm fiducialization is performed on the harmonic coil measurement bench.

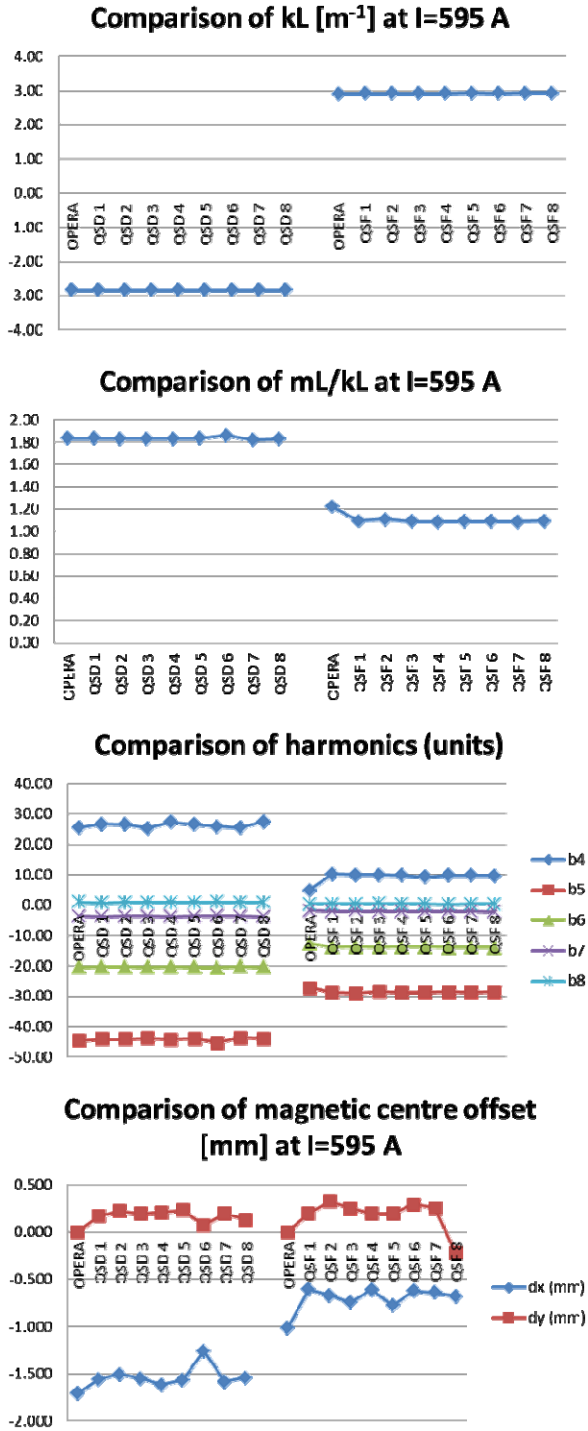

Figure 6: Some of the harmonic coil results showing a good reproducibility between magnets and a good agreement with the Opera3d models.

INSTALLATION AND ALIGNMENT

Replacing magnets in an existing facility is much more complex than installing new magnets in a newly built place since space is usually very crowded as shown in figures 7 below.

Disassembly and storage of the old magnets also required disassembly of the vacuum chambers and

Copyright © 2013 CC-BY-3.0 and by the respective authors

replacement of all UHV gaskets after installing the new magnets.

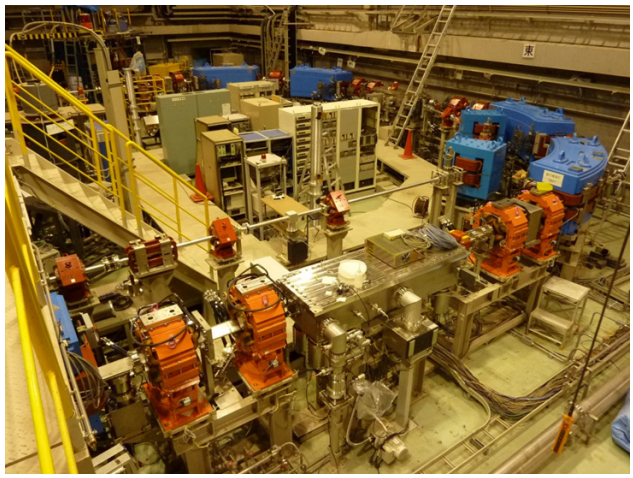

Figure 7: South and East sides with new magnets installed.

Alignment was performed using the following material.

- Tracker: Leica AT401
- Targets: Leica red-Ring Reflector 1.5”
- Monument holders: Hubbs 1.5 TSM M10
- Target holders: Hubbs 1.5 SMN 40mm 25mm outer diameter 46 mm.
- Software: Polyworks IMInspect Probing

Achieved accuracies are shown in figures 8 and 9.

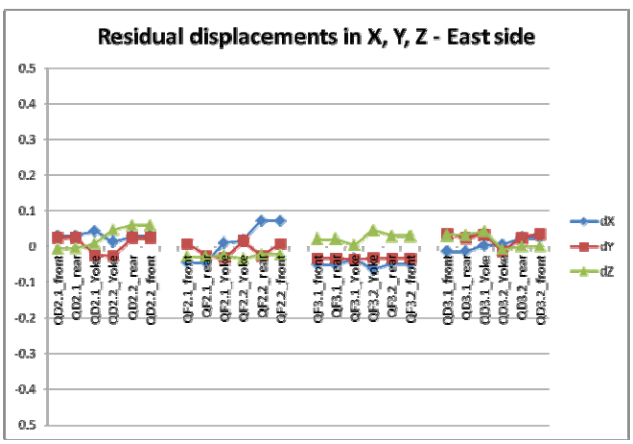

Figure 8: Alignment errors are much smaller than the required ±0.2 mm (East side).

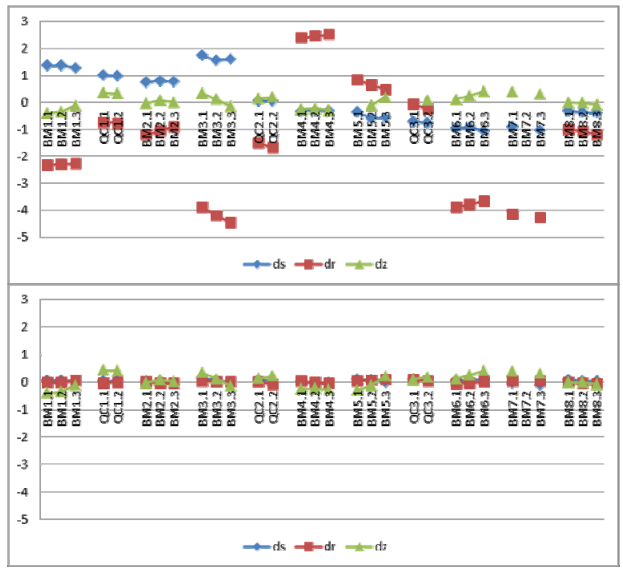

Figure 9: Dipoles and central quads positioning error before and after realignment (mm).

CONCLUSIONS

We have successfully designed, built, measured, installed and aligned 2 types of combined 4+6-poles.

All specifications were met but the integrated sextupole which is impossible to achieve with the prescribed geometry. A new set of possible m/k ratio was redefined.

Besides the 16 new magnets, the contract also included the removal of old quads, change of all UHV gaskets and realignment of all magnets including the 8 big dipoles.

Everything was finished by mid-January 2013, within the 1-year allotted time-schedule.

DESIGN AND CONSTRUCTION OF THE PROTO-TYPE QUADRUPOLE MAGNTS FOR THE SUPERKEKB INTERACTION REGION

N. Ohuchi#, Y. Arimoto, H. Yamaoka, Z. Zong, M. Tawada, K. Tsuchiya, H. Koiso, Y. Ohnishi, A. Morita, H. Sugimoto, K. Oide, KEK, Tsukuba, Japan

Abstract

Construction of the SuperKEKB accelerator started from 2010. The final focusing system in SuperKEKB was designed, and it consisted of 8 superconducting quadrupole magnets. As part of the R&D of the final focusing system, two prototype magnets were designed and constructed. The magnets were cooled to 4 K, and they were excited over the design current and the field measurements were performed.

INTRODUCTION

SuperKEKB [1] is the upgraded machine of KEKB, and the design luminosity is $8\times10^{35}\mathrm{cm}^{-2}\mathrm{s}^{-1}$, which is 40 times higher than that achieved at KEKB. SuperKEKB has a single interaction point, IP, to collide the 7 GeV e- beam and the 4 GeV e+ beam with a finite crossing angle of 83 mrad. The colliding energy is planned to be increased to 12 GeV. The design concept of SuperKEKB is based on the Nano-Beam Scheme, originally proposed by P. Raimondi for SuperB [2]. In order to focus the beam at IP with the vertical beam size of about 50 nm, a pair of the quadrupole doublet system for LER and HER [3, 4], respectively, was designed with 8 superconducting magnets. As the R&D of the final focusing system, the QC1P and QC1E prototype magnets were constructed and cold tested at 4K. In this paper, the magnet designs, constructions and test results are reported.

DESIGNS OF QC1P/QC1E MAGNETS

The QC1P and QC1E magnets were designed for the e+ and e- beams, respectively, and they are located at the closest position to IP on each beam line [3].

QC1P Magnet Design

The QC1P is the collared quadrupole magnet without iron yokes in order to make the solenoid field profile required from beam optics. The magnet cross section is shown in Fig. 1, and the parameters are summarized in Table 1. The magnet consists of two layers of the superconducting coil, and the thickness of the two-layers is 5.425 mm. Because the separation between two beams at the front end of the QC1P magnet is only 61 mm, the outer radius of the magnet was designed to be 30.425 mm while the coil inner radius was 25 mm. The field gradient of the magnet was 76.17 T/m at the design current, I_d=1800 A, and the magnetic length was 0.3372 m. I_d was for the colliding energy of 12 GeV, and the magnet current for 11 GeV was 1624 A. For this magnet, the small Rutherford cable, which consisted of 10 strands, was developed. The cable size was 0.93 mm in mid-thickness × 2.5 mm in height, and the key stone angle of the cable was 2.09 degree because the coil inner radius was 25 mm. I_d is 60 % of the critical current of the cable, I_c, at 4.7 K. The cable parameters are listed in Table 2.

The magnetic field of the QC1P magnet was calculated with the magnet cross section model and with the whole magnet model including the lead end and the non-lead end. They are summarized in Table 3. The each coil was designed with three coil blocks, and b_6 and b_{10} of two layer coils were optimized to be 0.16 units and -0.02 units in the cross section, and -0.11 units and -0.05 units in the whole magnet, respectively, at the reference radius of R_{ref}=10mm.

QC1E Magnet Design

The QC1E magnet was located behind the QC1P magnet from the IP. The prototype magnet was designed with iron yokes, and the yoke outer radius was 70 mm. The magnet consisted of two layer coils, and the inner radius was 33 mm. The superconducting cable had same parameters as those for the QC1P magnet except for the cable keystone angle of 1.59 degree. The QC1E was designed to generate the field gradient of 91.73 T/m at I_d=2000 A, and the magnetic length was 0.3774m. The magnet current for 11 GeV was 1577 A. The magnet cross section was optimized with three coil blocks of each layer as same as the QC1P magnet, for b_6 and b_{10} to be -0.04 units and -0.08 units at R_{ref}=15mm, respectively. In the whole magnet, b_6 and b_{10} were optimized to be -0.17 units and -0.20 units, respectively.

CONSTRUCTION OF MAGNETS

The QC1P and QC1E prototype magnets were constructed in KEK. Since the cable was the small size of 0.93 mm × 2.5 mm, the cable tension during winding coil was carefully controlled. The tension was decreased from 130 N to 60 N as function of turn number. After winding coil, the coil was cured in the form block at the temperature of 130 degrees C. Figure 2 shows the cured coils of QC1P and QC1E. The average lengths of QC1P and QC1E coils were 384.14 mm and 430.31 mm to the design values of 384 mm and 430 mm, respectively.

The four coils were assembled together, surrounding a support bobbin in the vertical position. The coils were covered with multiple ground plane insulation layers. The 2-split High-Mn collars were assembled around the coils with 90 degree rotation every set of collars. Assembled collars were squeezed and keyed from the four directions at once with a hydraulic press. Until these assembly processes, the QC1P magnet was completed. Yoking process for the QC1E magnet was performed with the same collaring tool. The half–split iron yokes of 3 mm thickness were assembled around the collars with 90 degree rotation every set of yokes. Yokes were fitted to collars by the collaring press. Figures 3 and 4 show the completed QC1P and QC1E prototype magnets.

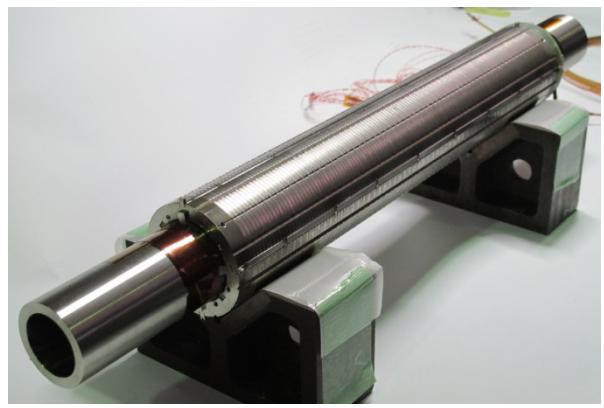

Figure 3: QC1P prototype magnet.

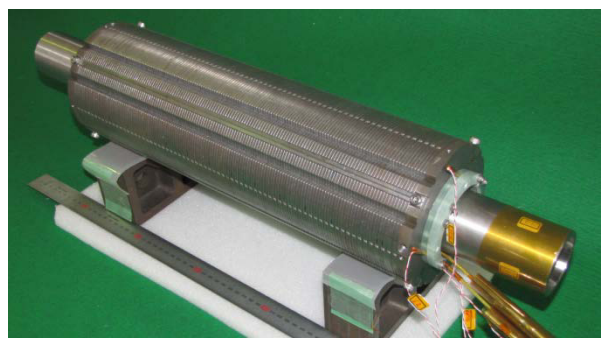

Figure 4: QC1E prototype magnet.

EXCITATION TESTS

Two magnets were installed into the vertical cryostat, individually, and they were cooled by liquid helium. The QC1P and QC1E prototype magnets were excited to 2100 A and 2157 A without quench, respectively. The maximum currents were limited by the power supply. The current of 2100 A of the QC1P magnet corresponded to 70 % of I_c on the load line at 4.7 K. The current of 2157 A of the QC1E magnet was 87 % of I_c.

MAGNETIC FIELD MEASUREMENTS

Magnetic field measurements were performed with the harmonic coils. Two coils of 600 mm and 40 mm long were used for measuring the integral field and the field profile, respectively.

Integral Field Measurements

The integral field was measured with the 600 mm long harmonic coil. The coil radius was 9.55 mm. At the magnet currents of 1701.7 A for QC1P and 1561.7 A for QC1E, the measured integral field gradients were 24.32 T and 26.22 T, respectively. For comparison, the calculated integral field gradients of the QC1P and QC1E magnets at these currents are 24.28 T and 27.03 T, respectively.

The measured error field components at R=9.55 mm are shown in Table 4. From the result, the both magnets had large sextupole field components. The components can be converted at the reference radius of each magnet. a_3 and b_3 for QC1P are 2.95 units and 3.83 units at R_{ref}=10mm, and a_3 and b_3 for QC1E are 1.79 units and 8.64 units at R_{ref} =15mm, respectively. The beam optics simulation showed these sextupole components remarkably degraded the Touschek beam life time.

Table 4: Measured Error Field of Prototypes in Units

	QC1P		QC1E	
n	a_n	b_n	a_n	b_n
2	0	10000	0	10000
3	2.82	3.66	1.14	5.50
4	2.08	0.24	0.18	-0.28
5	0.35	0.23	0.06	-0.48
6	0.03	-0.56	-0.06	-0.31
7	0.07	0.13	-0.01	0.01
8	0.03	0.01	0.05	-0.00
9	-0.08	0.05	0.02	-0.00
10	0.02	0.01	-0.00	-0.02

Field Profile Measurements

The field profiles of the prototype magnets were measured with the 40 mm long harmonic coil. The coil radius was 9.74 mm. Figures 5 and 6 show the profiles of the field gradient, a_3 and b_3 along the axes of the QC1P and QC1E magnets, respectively.

From Fig. 5, a_3 and b_3 in the QC1P magnet straight section (-100mm<position<100mm) are in the range from -2 units to 2 units. On the other hand, in the QC1E magnet, b_3 is from 5 units to 8 units while a_3 is within plus or minus 1 unit.

For the QC1E magnet, the error field due to the coil deformation was calculated. The b_3 and a_3 components were produced by the dipole deformation of 4 quadrant coils. The coil movements in the radial direction by the measured b_3 component were calculated to be plus and minus 30 μm for the two coils in the left and right sides of the magnet cross section, respectively. For the QC1P magnet, the b_3 and a_3 of 3 units was produced by the dipole deformation of 10 μm.

As the results of the field measurements, the b_3 and a_3 correctors has been decided to be installed in the final focusing system in order to attain the acceptable Touschek beam life time of 600 seconds.

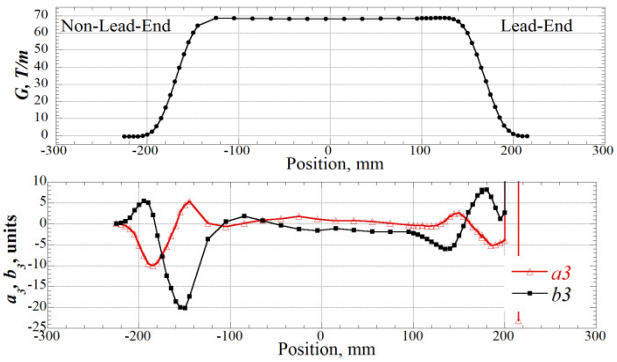

Figure 5: QC1P field profile measurement. I=1627 A.

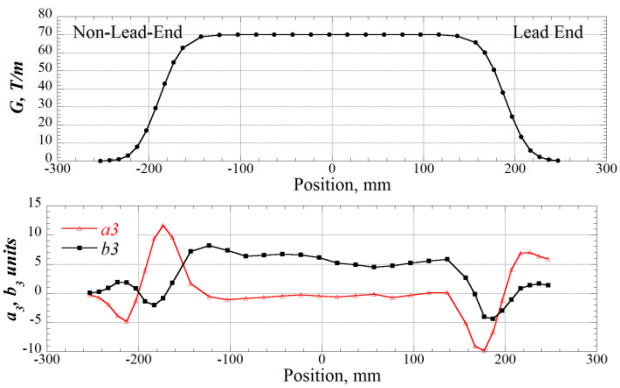

Figure 6: QC1E field profile measurement. I=1561 A.

SUMMARY

As the R&D of the SuperKEKB final focusing system, the prototype magnets of QC1P and QC1E were constructed and tested at 4K. The magnets were excited over the design current without any quenches. From the field measurements, the b_3 and a_3 correctors were decided to be installed in the final focusing superconducting magnet system.

MULTIPOLE MAGNETIC MEASUREMENTS USING A LOCK-IN AMPLIFIER TECHNIQUE*

C. Doose, M. Kasa, ANL, Argonne, IL 60439, USA

Abstract

Magnetic measurement systems for accelerator magnets typically use relatively complicated rigid rotating coils and digital integrators to capture the integrated coil signal as a function of angular position of the coil. This technique has proven to be reliable and accurate for measuring the field quality of conventional multipole magnets; however, the design and construction of the rotating coils ultimately determine the accuracy of the measurement system. A different concept and implementation of a simple stretched-wire rotating coil will be described. This system utilizes a single-turn radial coil continuously rotating at a fixed angular velocity. The coil signal and a reference pulse are sampled with a 24-bit ADC. A lock-in technique or an FFT can be used to determine the harmonic content of the signal and thus calculate the main field strength and angle, multipole coefficients, and magnetic center offsets. The main advantages of such a system are ease of coil manufacturing and simple mechanical system design.

INTRODUCTION

Motivation for this project was prompted by the need to quickly measure modified multipole magnets for the APS storage ring. Existing six-pole horizontal/vertical dipole corrector magnets were modified to become horizontal correctors and skew quadrupoles. A need to measure the multipole components and magnetic center of these new combination magnets prompted the design of a new, relatively simple multipole magnet measurement system.

The previous APS multipole magnetic measurement system used G-10 and ceramic Morgan coils that were supported in air bearings and driven by a DC motor. A 16-bit absolute encoder was used to trigger an integrator based on rotary position. This system had not been used in many years and the quality of the coil assemblies was questionable. We had recently completed magnetic measurements of a superconducting undulator (SCU) and had used a single-turn stretched coil to measure the integrated dipole components. Since we already had much of the hardware required, we decided to use a single-turn radial coil for harmonic field measurements of multipole magnets.

SYSTEM OVERVIEW

The following is a list of some of the features of the new multipole measurement system:

- Continuous coil rotation without slip rings
- Quasi-real-time measurements of individual multipole components using a lock-in amplifier (LIA)
- Measurement of the integrated magnetic field strength, multipole coefficients, magnetic-center offsets, and magnetic angle
- Automatic alignment of quadrupole and sextupole magnet positions relative to the center of rotation of the coil

The key components for the multipole measurement system were two Newport RGV100BL precision rotary stages. The precise control of position, velocity, and simultaneous timing allowed synchronous operation of both stages as if the coil wires were rigidly linked.

The system utilized a single-turn stretched coil in a radial configuration, as shown in Fig. 1. The coil-wire was 100-µm-diameter CuBe. The coil-wire ends were held in place with plastic fixtures connected to the rotary stages, as shown in Fig. 2. Coil fixtures can easily be made overnight on a 3D printer, so changing the radius of the coil would be a simple matter of changing the fixture radius. The coil was tensioned by moving the signal-end rotary stage in the longitudinal direction until the sag was minimized. The coil-wire sag was typically less than 200 µm when using a 1.5-m-long coil. Optical alignment telescopes were used to confirm the coil dimensions and alignment to approximately 50-µm accuracy.

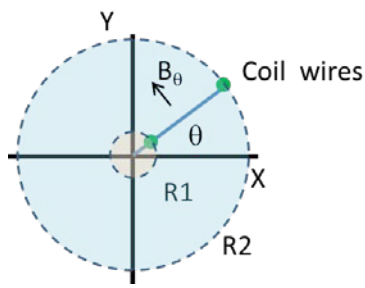

Figure 1: Radial coil configuration is sensitive to the radial component of the B field.

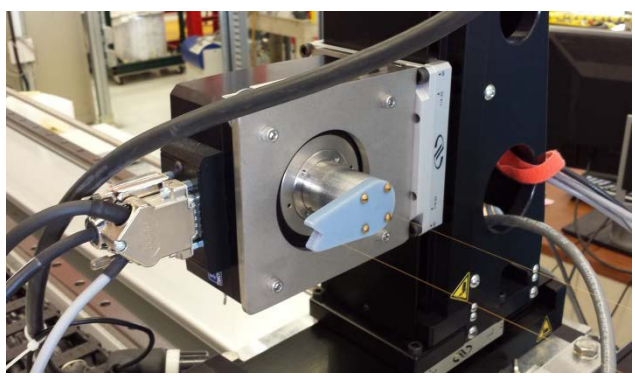

Figure 2: Signal-end rotary stage looking at the plastic coil positioning fixture.

The non-signal-end rotary stage was located at a fixed position; the signal-end rotary stage could be moved in all axes for alignment purposes. The signal-end rotary stage contained a sealed mercury-filled rotary connector from Mercotac. The rotary connector provided a means of coupling a low-noise signal from the rotating coil to the fixed signal cable. This rotary stage also utilized an opto-interrupter, which provided a trigger pulse for angular reference of the coil signal, as shown in Fig. 3.

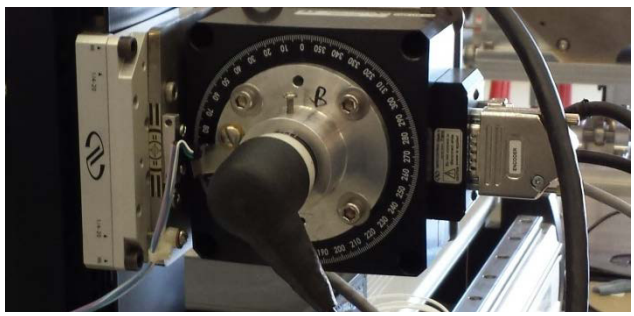

Figure 3: Signal-end rotary stage looking at the rotatable connector and opto-interrupter (left of stage scale), which provided a pulse for phase reference.

The two rotary stages were aligned to be co-linear, level, and parallel, and rotate in unison with a constant velocity of 1 rps. The coil signal could be amplified with gains of 10, 100, or 1000 before being digitized by a National Instruments dynamic signal analyzer (DSA) module.

LOCK-IN-AMPLIFIER

The integrated harmonic field components could each be separately measured using the rotating coil and a lock-in amplifier. Using National Instruments hardware and a LabVIEW software module downloaded from National Instruments, the LIA was easily implemented at very little cost. The software required two input signals, a reference and a measured signal, which were measured with the 24-bit analog-to-digital inputs of a PXI-4462 DSA module. The sampling rate of the DSA was 200 kHz and 25600 samples were recorded per coil revolution. This gave an angular resolution of 0.25 mRad between samples. The reference signal was provided by the opto-interrupter pulse, which occurred once per revolution.

The reference and measured signals were processed with LabVIEW software and the integrated field components were derived. The vertical and horizontal components were derived simultaneously and the individual harmonic number to be measured could be chosen through a user selectable software option. The software used the measured frequency and phase of the reference signal to create a new sine wave reference that was mixed with the measured signal [1]. The result of mixing the two signals was a DC signal and an AC signal with twice the reference frequency. The DC level was proportional to the measured signal at the reference frequency and was used to calculate the magnitude of the integrated field components. The LIA software also returned the phase of the measured signal relative to the reference signal.

The LIA measurement technique was convenient for initial magnet alignment or studying the effects of magnet coil current changes. The results can be observed in quasi-real time after a short settling time. The disadvantage of the LIA was that an individual measurement for each desired harmonic was required to fully characterize a particular magnet.

MULTIPOLE MEASUREMENTS

A multipole measurement (MM) technique was developed whereby ten rotations of the coil voltage signal were digitized and time averaged to create an averaged single-rotation time record. The time record harmonic content was then processed by a built-in LabVIEW FFT routine. The magnet main field strength, angle, and all harmonics were then calculated. Total time per measurement was approximately 15 seconds.

The rotating coil voltage waveforms of three different magnetic fields are shown in Fig. 4. The dipole and skew quad waveforms were generated by a six-pole combination dipole and skew quadrupole magnet. The SR quad waveform was from an APS 0.5-m storage ring quadrupole. The dipole and skew quadrupole signals had visibly large harmonic content. The skew octupole (a_4) is especially large at -344.3×10^{-4}. The relative normal and skew harmonic coefficients for each magnetic field from Fig. 4 are listed in Table 1. The b_2 and a_2 components represent the normal and skew quadrupole components, respectively. The components are relative to the main field for each case, and all are calculated at a specification radius of 10 mm.

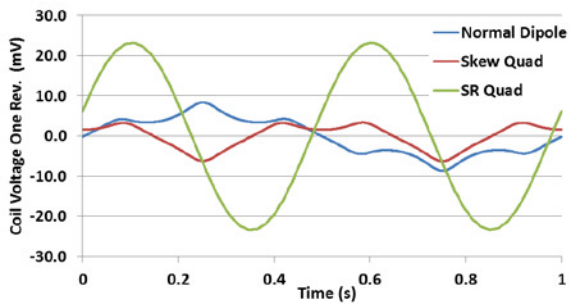

Figure 4: Digitized coil voltage waveforms for three different magnetic fields. “Normal Dipole” and “Skew Quad” are two configurations of the same six-pole magnet structure. The “SR Quad” is a 0.5-m-long APS storage ring quadrupole magnet.

Table 1: Relative Multipole Coefficients (10^{-4} units) at 10-mm Specification Radius (b_2, a_2 are quadrupole)

Harmonics	Normal Dipole	Skew Quadrupole	Normal Quadrupole
b_2, a_2	-7.4, -2.1	0, 10000	10000, 0
b_3, a3	2.8, 0.2	-16.9, 11.0	-1.0, -0.5
b_4, a_4	-0.5, -0.5	1.2, -344.3	-0.2, 0.1

Ambient Field and Magnet Alignment

The typical measurement sequence for a quadrupole magnet began with recording the ambient field with the magnet under test fully degaussed. The dipole components, due to the Earth's field, were then subtracted from subsequent measurement of the dipole components. This was most important for accurate measurement of the magnetic offset and alignment of quadrupole magnets since a quadrupole magnet is aligned to minimize the integrated dipole field. After the ambient measurement, the magnetic offsets and angle were measured and the magnet was aligned with a motorized magnet support table. Multipole measurements were then performed at the prescribed coil currents.

Measurement Repeatability and Resolution

A series of 16 measurements were performed over the course of 10 minutes using a storage ring 0.5-m quadrupole magnet. The results of the repeatability of the magnetic offsets and magnet angle are shown in Fig. 5. The coil radius for these measurements was 38.14 mm.

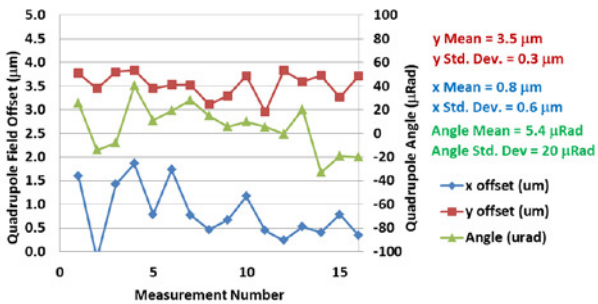

Figure 5: Plots of the measured magnetic offsets in x and y from the coil rotation center and the magnetic angle relative to gravity. The standard deviation of the offsets and angle were less than 1 µm and 25 µRad, respectively.

HARMONIC CALCULATIONS

The theory of harmonic magnetic measurements has been well known for many years [1], but can be confusing due to differences in notation and conventions. Two invaluable references used by the authors were by A. Jain [2] and L. Walckiers [3].

The instantaneous single-turn coil voltage can be described by:

$$V(t) = \sum_{n=1}^{\infty} K_n \left[C_n e^{-in(\omega t+\delta)}\right], \quad (1)$$

where

$$K_n = L\omega \left[\frac{R_2^n - R_1^n}{R_{spec}^{n-1}}\right]. \quad (2)$$

The complex Fourier components are

$$\mathbf{V_n} = K_n \mathbf{C_n} = K_n(B_n + iA_n), \quad (3)$$

where L is the magnet length; R_2 and R_1 are the coil major and minor radii, respectively; δ is the reference phase angle; R_{spec} is the specification radius; and B_n and A_n are the normal and skew integrated multipole coefficients, respectively. The relative multipole coefficients listed in Table 1—b_n and a_n—are B_n and A_n normalized to the main field components.

CONCLUSION

The implementation of a single-turn CuBe radial coil has proven to be an effective means to measure the harmonic content of accelerator magnets. By combining very accurately controlled rotary stages, a rotatable signal coupler, and a 24-bit DSA module, measurements of the main and harmonic field errors were possible with a simple radial coil design. Continuous measurements of an individual harmonic could be performed using the LIA technique, or when complete harmonic components were desired, the MM technique was chosen.

Repeatability, as shown in Fig. 5, was quite good. The absolute accuracy was dependent on how well the dimensions of the coil could be measured; typically it was on the order of 0.5% for a 38-mm coil radius. Presently the repeatability of the magnetic center measurements of the new system is approximately an order of magnitude better than the previous APS measurement system. Further testing of the system will be performed on calibration magnets and compared to previous APS multipole measurements performed over 20 years ago.

ACKNOWLEDGMENTS

The authors would like to thank S. H. Kim for his thoughtful insight with the details of the harmonic coefficient calculations. We also thank D. Pasholk for his quick modeling and printing of the coil-holding fixtures.

MAGNETIC MEASUREMENTS OF THE FIRST SUPERCONDUCTING UNDULATOR AT THE ADVANCED PHOTON SOURCE*

C. Doose, M. Kasa, ANL, Argonne, IL 60439, USA

Abstract

A superconducting (SC) undulator prototype designated SCU0 was installed in the APS storage ring in December, 2012, and is providing users with photons in the energy range of 80-100 keV. This device was assembled and tested during the majority of 2012. Detailed tests were performed related to cryogenics, vacuum, mechanical motion due to thermal contraction, and magnetic performance. Magnetic measurements have been performed using a horizontal measurement system, which utilizes Hall probes and an integral coil. The measurement system was configured without interfering with the cryogenic or vacuum systems of the SCU0 cryomodule. Some of the magnetic measurement results will be presented for local and integrated field measurements, integrated field uniformity, and integrated fields during a quench. The measured rms phase errors were typically less than two degrees. The measured change in the integrated field during an intentional quench was less than 35 G-cm. The magnetic performance of SCU0 has proven to be within design tolerance for field quality and quench characteristics. Beam-based integral measurements agree well with the magnetic measurements.

SCU0 BACKGROUND

SCU0 is a prototype superconducting undulator (SCU) that was installed in the APS storage ring during December 2012, and is presently operating successfully at the APS sector 6 beamline [1,2].

Table 1: SCU0 Magnetic Specifications

Period	16 mm
Magnetic gap	9.5 mm
Magnet length	331 mm
Design peak field	0.4 - 0.65 T
Design Current	200 - 500 A
Maximum achieved peak field	0.82 T
Maximum achieved current	740 A

Table 2: APS Undulator Error Tolerance

1st Horizontal Field Integral	50 G*cm
1st Vert. Field Integral during quench	2100 G*cm
2nd Horz. And Vert. Integrals	1×10^{-5} G*cm^2
Normal and Skew Integrated Quadrupole	50 G

*Work supported by the U.S. Department of Energy, Office of Science, under Contract No. DE-AC02-06CH11357

The assembly of the SCU0 cryomodule began in January, 2012; the first magnetic measurements of the assembled device began in June 2012 and were completed in August. A second set of magnetic measurements was done in November and December of 2012. The first set of measurements was performed with the original pair of SC magnetic structures. From September to October, the SCU0 was disassembled to replace the Al beam chamber with a new design. In the process of disassembly one of the SC wires was possibly damaged. A spare magnet structure was available so it was installed rather than risk a failure of the suspect SC wire.

HALL PROBE MEASUREMENT RESULTS

The following section describes some of the typical measurement results while using a room temperature Hall probe to measure the local fields along the longitudinal axis (z). The measurement system utilizes a room-temperature Ti tubing, "warm-bore," as a guide tube for the carbon fiber Hall probe assembly. The Ti tubing is tensioned inside but isolated from the cold (~10 K) Al beam chamber. A similar concept is used by the Budker Institiute for SC wiggler magnetic measurements.

An overview of the measurement system is shown in Fig. 1. The 3.5-m-long stage is used to drive a carbon fiber Hall probe assembly through the Ti guide tube. Stages mounted to the ends of the SCU0 cryomodule provide support and tension for the Ti guide tube and horizontal transverse motion (x) for measuring up to ±10 mm from the central axis.

Figure 1: SCU horizontal magnetic measurement system with 3.5-m linear stage for Hall probe scans. SCU0 cryomodule is on the left.

1st and 2nd Field Integrals and Phase Errors

The measured 1st and 2nd vertical field (B_y) integrals from the measurements performed in August and December of 2012 are shown in Fig. 2 and Fig. 3. The final 1st integral values were +31 and -87 G*cm in August and December, respectively. The August measurements of

Copyright © 2013 CC-BY-3.0 and by the respective authors

the 1st integrals, with the original magnet structures, typically showed values below 35 G*cm when using the Hall probe system. With the replacement magnet structure, a current-dependent 1st integral was introduced. The current-dependent 1st field integrals from the December measurements are most likely due to stray fields from the configuration of the SC leads from the magnet structure to the terminals on the cryocoolers. The stray field appears to have been adversely affected after the replacement of the suspect magnet structure.

There is no provision for adjustment of the final 1st field integral value, but the 2nd integral is adjusted via end correction coils that are located on the ends of the magnet structures [3]. These end correction coils can be energized symmetrically or differentially with respect to each other. When adjusted differentially, a varying (along the length of the device) vertical dipole component is created, which affects the straightness of the 2nd field integral. Figure 3 depicts the 2nd field integrals with symmetrical and differential end-field correction currents measured in December and the original measurement in August. By adjusting the average and differential end correction currents, both the slope and straightness of the 2nd field integral (trajectory) can be optimized.

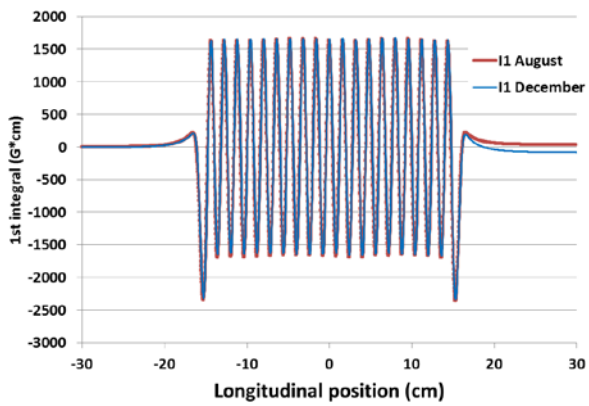

Figure 2: Plots of the SCU0 1st B_y field integrals at the design current of 500 A from August and December data. The final 1st integral values were +31 and -87 G*cm in August and December, respectively.

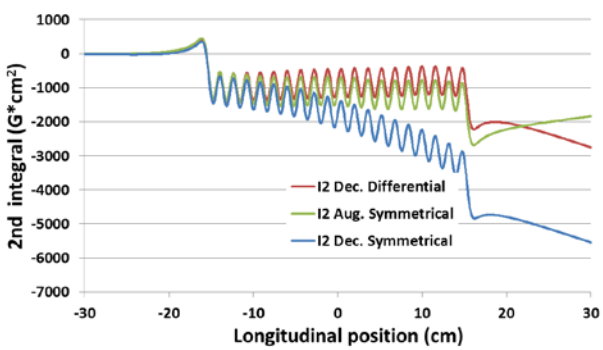

Figure 3: Plots of the SCU0 2nd B_y field integrals at the design current of 500 A from August and December data. The end correction coil currents were optimized using a 0.4% differential for the "Dec. Differential" case.

The measurements performed in August did not require any differential correction due to the fact that the 1st field integrals were naturally small and the 2nd field integrals were quite straight. Careful attention to SC lead dress was done during the initial assembly, but some compromises were made during the installation of the spare magnetic structure, which may have caused the increased stray field.

The data shown in this paper typically represents operation with optimized end correction coil currents set to minimize the 2nd field integrals using only symmetrical end correction currents. The measured K values from December and the phase errors from both the August and December measurements are depicted in Fig. 4.

The increased phase errors for the December measurements are due to a dipole component (from the SC stray field) that also affected the 1st field integrals, as shown in Fig. 2. If differential correction current was implemented, the phase errors during the December measurements could have been reduced to below 2 degrees and much closer to the August value of about 1 degree at 500 A.

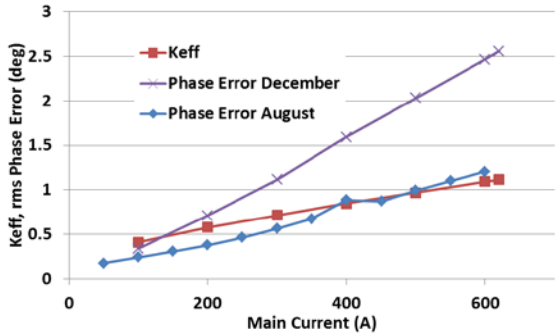

Figure 4: Plots of the SCU0 effective K value (K_{eff}) and phase errors as a function of current from the August and December Hall probe measurements.

INTEGRAL COIL RESULTS

A 4-mm-wide, 3.5-meter-long, single-turn stretched integral coil was used for measuring the static and dynamic 1st and 2nd field integrals as well as the multipole coefficients. The coil was rotated at 1 rps for the static field measurements and was fixed for measurements of the dynamic field integrals during a quench. The wire used for the coil was 100-μm-diameter CuBe stretched between two 4-mm-wide ceramic fixtures.

Static Integrated Field Measurements

The data in Fig. 5, labeled "I1 August" and "I1 December," were taken at fixed main coil currents. The data were recorded in the laboratory using the rotating coil system and using the storage ring with a beam-based integral measurement technique. The sign of the rotating coil field integral data was negated to agree with the beam-based data polarity. The data show that the change in the integrated field from 200 A to 500 A (the design operating range) was about 60 G*cm, which is within the APS tolerance of 100 G*cm.

Copyright © 2013 CC-BY-3.0 and by the respective authors

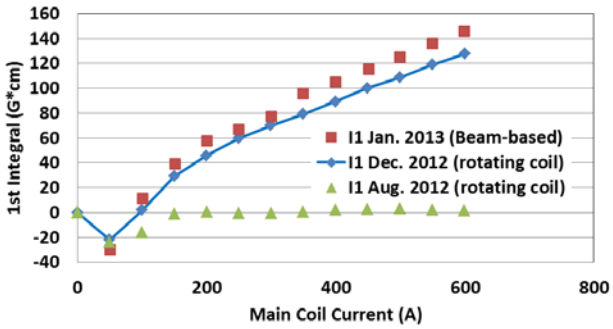

Figure 5: Plots of the SCU0 1st B_y field integrals as a function of current. These data were measured with a rotating coil in August and December, 2012, and using a beam-based technique with the APS storage ring in January, 2013.

Multipole Measurements

The rotating coil was also used to measure the integrated field uniformity over a horizontal range of ±4 mm. The curves in Fig. 6 show the integrated B_y (I1y) and B_x (I1x) along the x axis. It was discovered for the first time in August that a skew quadrupole component, which is larger than the APS undulator error tolerance, was present. It was decided to install the SCU0 as-is and use a feed-forward technique to adjust the beam coupling, if needed. This has proven successful in operation.

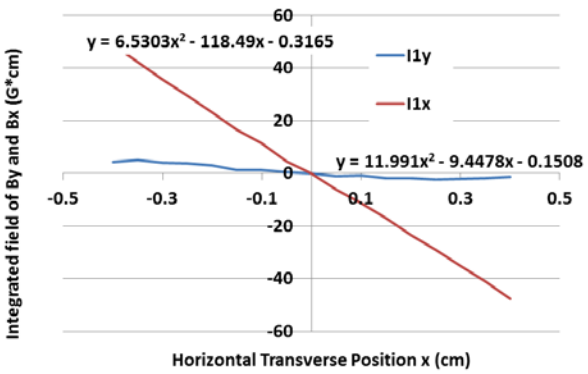

Figure 6: Plots of the SCU0 B_y (I1y) and B_x (I1x) 1st field integrals as a function of x position at a main coil current of 500 A. The normal and skew quadrupole components were -9.4 G and -118.5 G, respectively. The APS error tolerance is 50 G.

Dynamic Field Integral During a Quench

Measurements of the integrated field during quenches were done using a fixed coil. The data shown in Fig. 7 were taken during a forced heater-quench at 500 A. The 1st B_y integral curve was 35 G*cm p-p, which is 60 times less than the requirement of 2100 G*cm This low integral value is achieved by having the end correction coil currents slaved to the main current with an optimized look-up table. The look-up table was generated experimentally by optimizing the 2nd field integral (by adjusting the end correction current) at many fixed main coil currents.

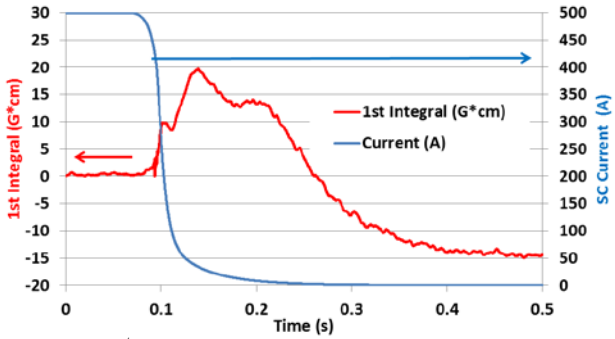

Figure 7: 1st B_y field integral and the main coil current as a function of time during a forced quench at 500 A.

CONCLUSIONS

The SCU0 magnetic measurements confirmed that all design parameters were within the APS error tolerances except for the integrated skew quadrupole component being slightly more than twice the 50-G tolerance. Measured phase errors were typically less than 2 degrees rms. The integrated field during a quench does not cause a beam dump; in fact it only causes a 60-µm beam motion. Comparing the August and December measurement results, it was found that initially the 1st field integral was very low and not current dependent, but after replacing one of the magnet structures, the 1st field integral was proportional to current but still within the error tolerance.

A new coil winding technique has been developed and will be implemented in the next SCU device. This new design was developed in order to minimize the skew quadrupole component, reduce machining cost, and improve the epoxy potting of the SC magnet structures.

The users in sector 6 have been routinely using the SCU0 at 685 A, 185 A above the design of 500 A.

ACKNOWLEDGMENTS

The authors would like to thank N. Mezentsev and V. Syrovatin from the Budker Institute for their collaboration with the "warm-bore" SCU measurement concept.

Abstract

SuperKEKB is an upgrade project underway at KEK, to increase the KEKB b-factory luminosity 40-fold by using nanobeam Interaction Region (IR) focusing optics [1] for which the production of new superconducting IR magnets and correctors is critical [2]. SuperKEKB corrector design and production is challenging since many different coils are needed for precise control of IR magnetic fields, in order to ensure good beam lifetime and there is very little space for them. SuperKEKB corrector production is about half completed and we report here on new techniques recently developed to address production challenges.

INTRODUCTION

The SuperKEKB IR magnet layout in the left-side and right-side cryostats is shown in Fig. 1. The SuperKEKB design has 83 mrad total crossing angle to separate the e^- (E) High Energy Ring (HER) and e^+ (P) Low Energy Ring (LER) beam lines in independent non-cryogenic vacuum apertures. A few millimetres of radial space is available for corrector coils atop support bobbins that serve as the inner cold mass containment wall and the main quadrupole coils' inner surface. The corrector requirements, presented in Table 1, evolved in response to results from optics optimization and tracking studies and differ from those available before production started [3].

Left-side corrector production commenced first using preliminary specifications provided before the right-side requirements were set. Later optics studies found that sextupole coils, b_3 and a_3, not in the original design, are needed; so these coils are added to the right-side layout. The majority of the corrector coils are located inside a main quadrupole coil; however, with insufficient space inside the first IR quadrupoles, QC1LP/RP, their b_4 correctors are wound on bobbins placed just outside the

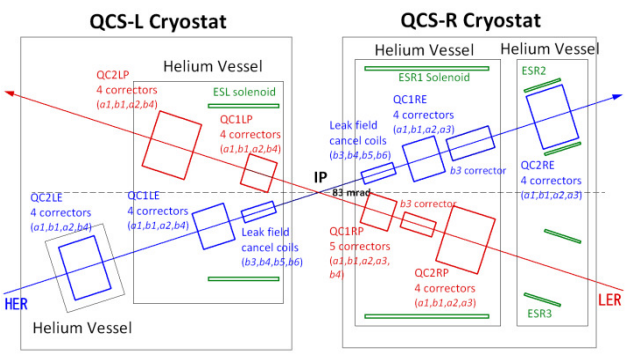

Figure 1: SuperKEKB IR magnet layout schematic.

Table 1: Corrector Integral Field Strength Requirements. Here R/L denote left- and right-side magnets and P/E denote the LER and HER beam lines. The right-side b_3 coils are placed between main magnets. The external field cancel coils for the HER are not included in this table.

Magnet	R_r	A_1	B_1	A_2	A_3	B_3	B_4
	mm	T•m	T•m	T	T/m	T/m	T/m^2
QC1RP	10	0.016	0.016	0.64	7.6	17.2	60
QC2RP	30	0.03	0.03	0.31	1.36		-
QC1RE	15	0.027	0.046	0.75	7	27	-
QC2RE	35	0.015	0.015	0.37	1.5		-
QC1LP	10	0.016	0.016	0.64	-	-	60
QC2LP	30	0.03	0.03	0.31	-	-	60
QC1LE	15	0.027	0.046	0.75	-	-	60
QC2LE	35	0.015	0.015	0.37	-	-	60

main coil (along with an a_3 corrector only for QC1RP). Because these first LER quadrupoles have insufficient space for magnetic flux return yokes between their coils and the nearby HER beam, there is significant external field leakage that must be dealt with so as not to adversely impact the HER optics. Requirements for these additional external field cancel coils for the HER are discussed later.

Both the corrector and cancel coils are attached to support bobbins via the BNL Direct Wind technique [4] using 0.35 mm diameter, single-strand superconducting round wire from Furukawa with a 1:1 Cu:NbTi ratio and critical current at 4.2K greater than 130 amps in a 5 T background field [5]. The wire is Kapton® overwrap insulated and adhesive coated to be compatible for use with BNL Direct Wind ultrasonic bonding technology.

CORRECTION COIL PRODUCTION

The SuperKEKB corrector requirements span a broad range of field harmonics and focusing strengths and are manufactured in many radius and length combinations. In order to make the best use of the available space attention to detail is needed regarding the careful nesting of coil layers. The QC2LE multi-layer arrangement shown in Fig. 2 offers an example of how lead management is an important consideration. At the bottom of the QC2LE coil stack is a single layer planar pattern [6] dipole winding over which skew dipole and then skew quadrupole planar coils are wound. The skew quadrupole is topmost because its ends, with fewer turns, are naturally shorter than those of the layers below and its four pole regions line up with

#parker@bnl.gov

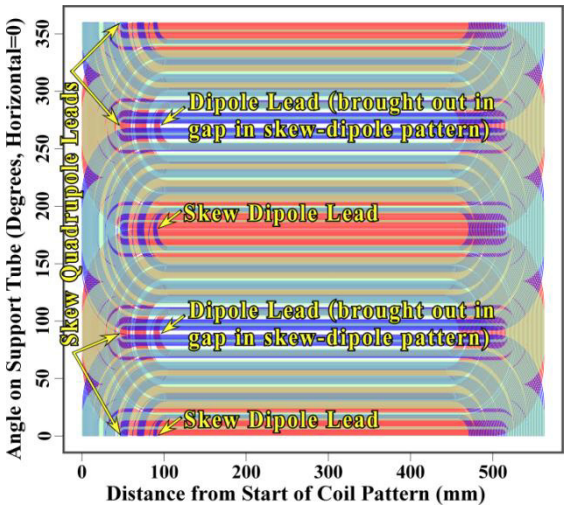

Figure 2: Multi-layer corrector coil winding example.

the lower pole regions. Thus it is possible to "see" the other current leads under the skew quadrupole pattern to bring them out over the top of the final coil package. But with this lead arrangement the dipole leads would be blocked by the skew dipole coil pack if we did not also open the mid-plane gap shown in the skew dipole pattern.

SuperKEKB beam lifetime is fairly sensitive to IR local field errors; so we use several field tuning spacers, in both the coil body and ends, to try to limit local field harmonic design errors to the level of a few gauss. For clarity a final b_4 coil winding is omitted from Fig. 2. The QC2LE b_4 integrated strength requirement is sufficiently small that we can use a short b_4 pattern that does not extend over the region of the previously wound coil leads

For some coils, such as the b_1, of QC1LE/RE, the current to reach the Table 1 value would be excessive with only a single coil layer. In this case we wind a_1 and a_2 layers first and move the b_1, coil out where we can use a shortened two-layer Serpentine style coil pattern [7] that does not block the a_1 and a_2 leads. The Serpentine pattern lets the b_1 leads exit cleanly even with a b_4 pattern of the same length wound on top of it [6].

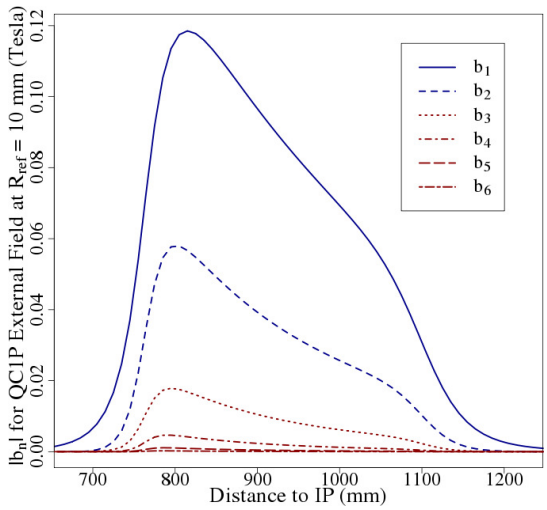

Figure 3: Decomposition into magnetic multipoles for QC1P external field plotted as a function of distance to the IP, for 10 mm reference radius, at the HER beam line.

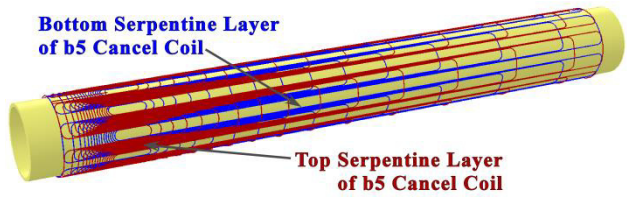

Figure 4: Final twisted b5 cancel coil winding used to generate the b5 and a5 fields shown in Fig.5. This pattern is a dual-layer Serpentine style coil winding with end turn spacing adjusted in both layers to achieve the desired field falloff with distance to the IP. Note that there are a large number of different sized coil end spacer gaps that must be filled with custom sized Nomex paper inserts.

CANCEL COIL PRODUCTION

External field leaking from the first LER quadrupoles, QC1LP\RP into the HER aperture, decomposed as a field multipole expansion, is plotted in Fig. 3. The linear, b_1, b_2, external field components are not of concern as they are easily included in the SuperKEKB IR optics; however, the non-linear fields shown in Fig. 3 would adversely impact HER beam lifetime. Via iterative adjustment of coil end turn spacing, four independent cancel coil windings, b_3, b_4, b_5 and b_6, are tailored to match the different external field profiles plotted in Fig. 3 that arise as the beam separation increases away from the IP.

We find that dual-layer Serpentine patterns, such as that shown in Fig. 4, are especially suited for use as cancel coils because they exhibit a simple, direct relationship between the straight section "body fields" and the end fields. At 10 mm reference radius the cancel coil's main harmonic dominates the total field until close to each coil end; so we developed fast codes that approximate the cancel coil field shape based on scanning at a single

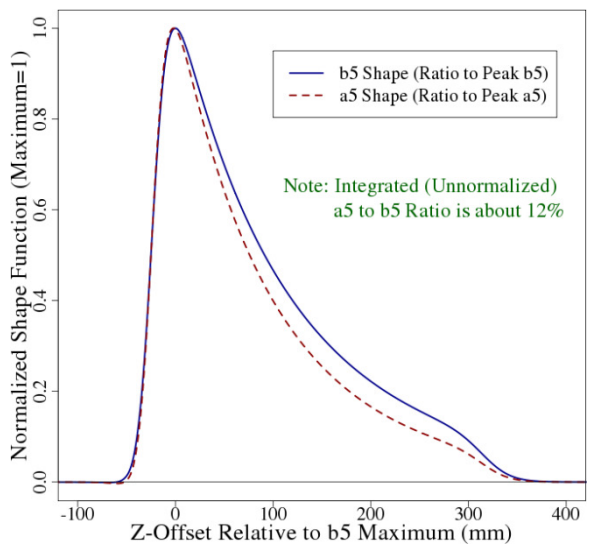

Figure 5: Normal and Skew Field Falloff Comparison. We plot b5 and a5 external field multipoles, with common peak normalization, to highlight their different shapes. A simple coil rotation cannot generate the correct a5 distribution from a pure b5; thus we must "twist" the coil pattern as a function of length along the coil support tube.

Copyright © 2013 CC-BY-3.0 and by the respective authors

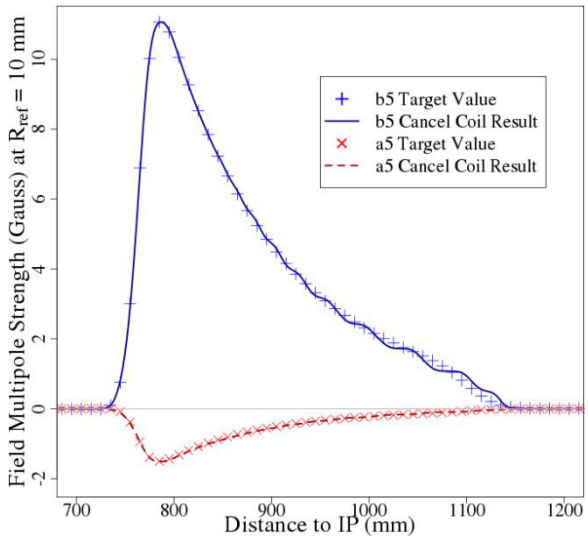

Figure 6: The b5 and a5 field multipole distributions generated by the b5 cancel coil with an applied twist transformation are compared here to the target goals set for perfect QC1P external field cancellation.

azimuthal angle rather than having to do a much more calculationally intensive full-angle range z-scan.

With an end turn spacing parameterization versus turn number that maps to specific shape features (e.g. regions of constant slope, a peak or a shoulder falloff), we can vary the end spacing in a smooth manner and after a few iterations come close to the desired external field target shape. With this candidate solution in hand we do a full harmonic z-scan to verify that unwanted higher-order end field harmonics are sufficiently small. A typical target normal-harmonic field shape curve, b_5, is plotted in Fig. 5. Note that in addition to b_5 there is a second a_5 curve shown that has a different falloff with distance from the IP. A similar shape difference between normal and skew occurs for all of the QC1P external field multipoles and this presented an unexpected design challenge.

The SuperKEKB quadrupoles experience a combined background field from the detector and compensation solenoids and are rotated in order to achieve the desired optics for the beam eigenplanes; the corrector magnets are rotated the same amount. A naive expectation was that the cancel coils could also be similarly rotated to provide the proper mix of normal and skew cancel fields; however, the SuperKEKB IR layout has some HER and LER quadrupoles at different vertical offsets to reduce needed corrector strengths. Unfortunately this combined rotation and offset results in our having to match different normal and skew external field target shape curves.

To alter the skew/normal field ratio we must rotate different sections of the coil pattern by different amounts, i.e. we have to twist the coil pattern. A uniform twisting of a pure b_5 coil pattern produces the required a_5 field profile as illustrated in Fig. 6. The most obvious field deviations from target values are the small constant field "shoulders" that result from the limited number of b_5 end turns available to optimize. The b_3 and b_4 cancel coils have more turns and smoother field profiles while the b_5 and b_6 coils, with fewer turns, have the largest relative tail deviations. Still the target b_5 and b_6 fields are already so small that these errors really do not matter.

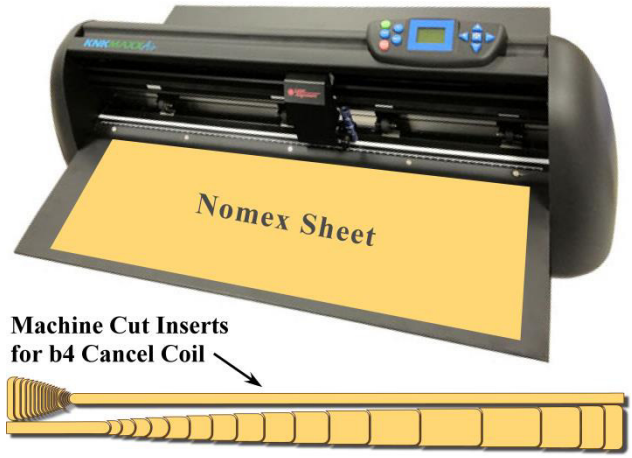

Figure 7: This machine automatically cuts coil end spacer inserts from Nomex sheets using information derived from a computer winding file. The pattern for a single b4 pole is also shown. The cut outs have tab connections to keep inserts in place until needed and avoid hand sorting.

While it is convenient for optimizing a magnetic design to use the large number of spacers shown in the patterns of Fig. 2 and Fig. 4, it is also a production nightmare to ask technicians to cut so many tiny fill pieces by hand. For SuperKEKB production we developed an automated procedure where the coordinates of the coil pattern are fed into Pro-Engineer software [7] that follows the coil path in 3 dimensions and then unwraps it to a flat pattern. To have a proper gap between the fill spacers and coil, this flattened path is thickened to simulate wire thickness and offset by a small amount. Additional processing removes extraneous lines and leaves only the shapes to be cut. That file is then read by the computer controlled flat pattern cutter shown in Fig. 7 that uses a small steel blade to cut the pattern from a sheet of Nomex [8].

PARTIAL RETURN YOKE FOR MICE – ENGINEERING DESIGN*

H. Witte†, S. Plate, Brookhaven National Laboratory, Upton, NY, USA
J. Tarrant, STFC Rutherford Appleton Laboratory, Didcot, UK
A. Bross, Fermilab, Batavia, IL, USA

Abstract

MICE, which is an acronym for Muon Ionization Cooling Experiment, is a technology demonstration which is presently assembled at the Rutherford Appleton Laboratory in Didcot, UK. MICE aims to demonstrate ionization cooling experimentally, which is an essential technology for potential future accelerators such as a muon collider.

The MICE channel consists of up to 18 large bore superconducting solenoids, which produce a substantial stray field. This stray field can jeopardize the operation of electrical and electronic equipment in the MICE hall.

The concept of a partial flux return yoke has been developed, which reduces the stray field in the MICE hall to a safe level. This paper discusses the engineering design of the partial return yoke.

INTRODUCTION

MICE will be assembled in several steps [1]. At the time of writing it is aimed to finish construction of Step IV by summer/autumn 2014. MICE Step IV consists of 12 large bore superconducting solenoids (18 for Step VI). The MICE solenoids produce a substantial amount of stray field, which is a concern as some of the technical equipment in the MICE hall may not work.

This paper discusses the engineering aspects of a partial return yoke (PRY) for the MICE solenoids for Step IV; the partial enclosure is sufficient to reduce the stray fields to an acceptable level.

Details on the general design approach, the coil configuration of Step IV, expected shielding performance and effect on the performance of MICE are given in [2, 3].

ENGINEERING CONCEPT

The evolution of the PRY geometries is shown in Fig. 1. It is important to note that in general all shown geometries have a similar shielding performance. The vertical extensions (middle plot) have been found to further reduce the stray field behind the PRY by preventing flux leakage from the unshielded part. The final geometry, shown on the right, was chosen because of engineering considerations.

The MICE PRY will consist of in total eight shielding plates, each of which is about 4 m long and 1.5 m wide. The thickness of each shielding plate is 10 cm or 12 cm depending on the desired shielding performance. The weight

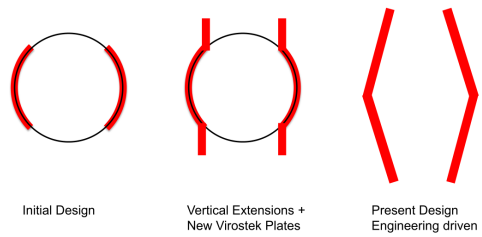

Figure 1: Evolution of the PRY geometry.

of a 10 cm thick shielding plate is about 4.8 tons, which is less than the limit of the lifting crane in the MICE hall.

To avoid field leakage (see section 'Vertical Gaps') two backing plates are installed on the inside and outside of the PRY covering the vertical joint. The thickness of each backing plate is half that of the PRY.

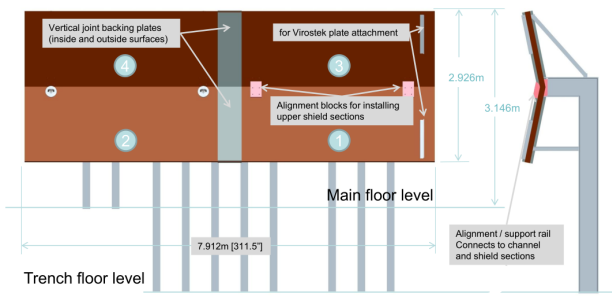

Figure 2: MICE partial return yoke.

SUPPORT STRUCTURE

The support structure has been designed to cope with the dead weight of the PRY as well as magnetic forces. The magnetic forces on the structure were evaluated using the Maxwell stress tensor. The forces were evaluated for each of the shielding plates separately. The main force component is in horizontal direction, directed such that the shielding plates want to move towards the MICE experiment. The maximum force is equivalent to 34 tons for half of the PRY (four shielding plates) and occurs for the 240 MeV flip mode. There is no net longitudinal or vertical magnetic force on the PRY due to symmetry reasons.

The support structure, as shown in Fig. 2, consists of several S-beams which are anchored in the floor of the MICE hall. An ANSYS study was carried out to evaluate peak stresses and deflections. While the stresses are not a concern (123 MPa) a maximum deflection of 5 mm was ob-

served at the top corner of the PRY. To avoid this eight horizontal support straps will be installed to transfer forces between the two PRY halfs. This reduces the deflection to 0.28 mm.

PENETRATIONS

Vertical Gaps

Vertical gaps in the PRY occur between two adjacent shielding panels. Initial investigations showed that vertical gaps in the PRY are detrimental for the shielding performance. Figure 3 shows the position of a vertical gap in the PRY near the tracker region. The simulation result of the stray magnetic flux behind the PRY at a radius of 1.5 m and beam height is shown in Fig. 4. The figure shows that depending on the width of the gap the stray field behind the PRY increases substantially.

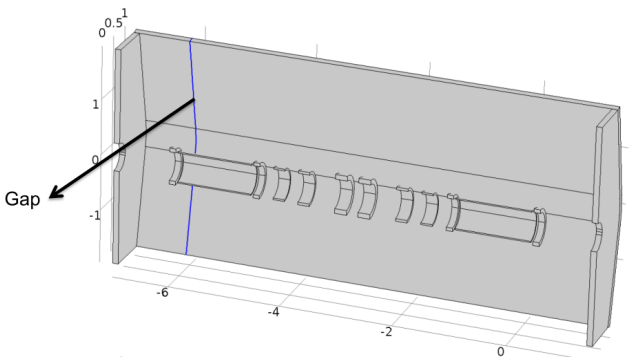

Figure 3: Geometry: Vertical gap in shield.

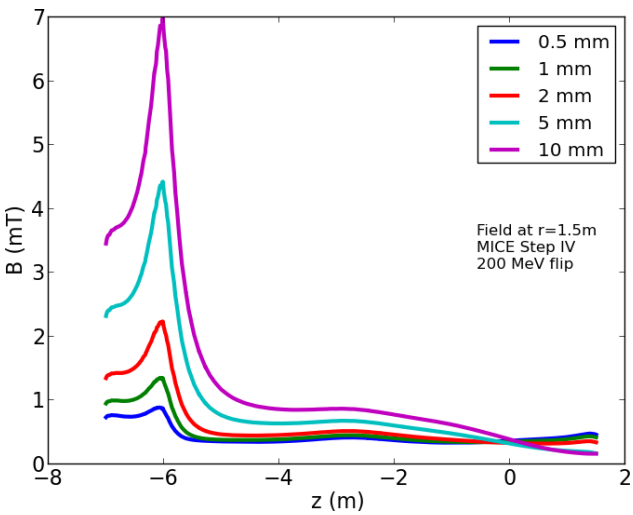

Figure 4: Modulus of the magnetic flux density at a radius of 1.5 m for 200 MeV flip mode assuming a vertical gap at $z = -6$ m.

To avoid performance impacts several potential solutions were studied. An adequate and easy to implement strategy is to double-up the PRY at the position of a vertical gap; Figure 5 illustrates the concept. Each of the two backing plates is required to be half the thickness of the shield. The width of each backing plate is 0.4 m. The backing plates work by forming a low magnetic reluctance joint between neighbouring PRY sections; at the joint the magnetic flux is redirected into the backing plates, thus avoiding the vertical gap.

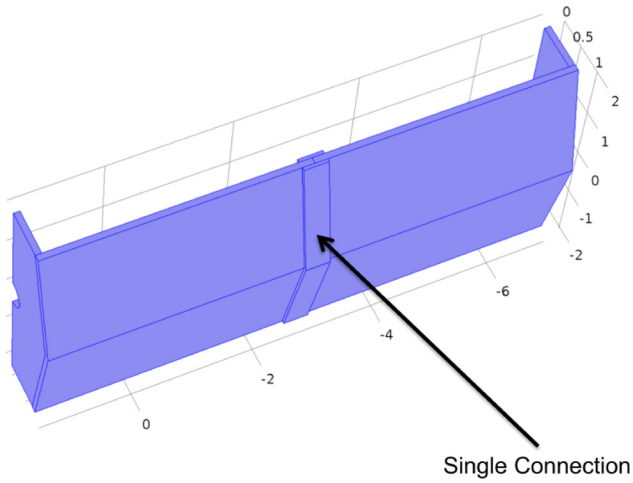

Figure 5: Concept of doubling up a vertical gap.

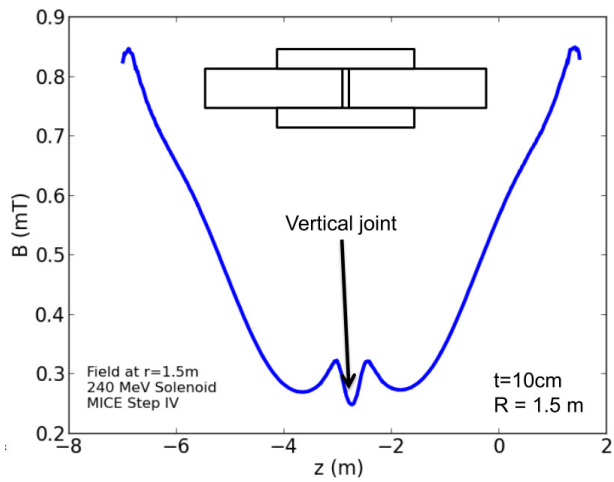

Figure 6: Modulus of the residual stray field at a radius of 1.5 m (beam height) for 200 MeV flip mode. The vertical gap is doubled up using to backing plates, each 40 cm long.

Horizontal Gaps

Horizontal gaps in the PRY were studied as well. Figure 7 shows simulation results for the 200 MeV flip mode. The figure shows that the stray field behind the PRY by comparison is far less sensitive to horizontal gaps. Even gaps of 20 cm width produce only an increase in stray field of about 1 mT.

MATERIAL CONSIDERATIONS

The PRY is planned to be made out of AISI 1010 steel, which is a cost efficient material for magnetic shielding.

Copyright © 2013 CC-BY-3.0 and by the respective authors

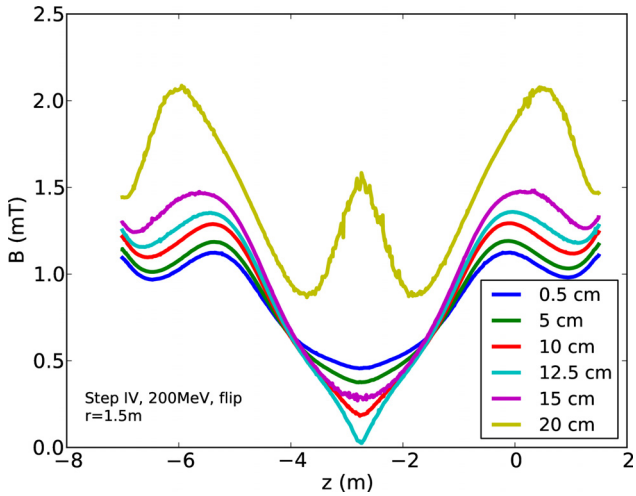

Figure 7: Modulus of the residual magnetic field at a radius of 1.5 m. The simulation assumes a horizontal gap in the PRY at beam height.

One of the disadvantages of AISI 1010 steel is the variation of the magnetic properties depending on the exact composition. In general the higher the iron content the better the magnetic properties. In order to estimate the shielding performance we use measured magnetization curves of 1010 steels which have been used in various HEP experiments [4]. For comparison three magnetization curves are chosen: one representing very good magnetic properties (labeled 'ARMCO Atlas'), one with intermediate magnetic properties (labeled 'St1010 Germany') and one with poorer magnetic performance (labelled 'St1010 ATLAS').

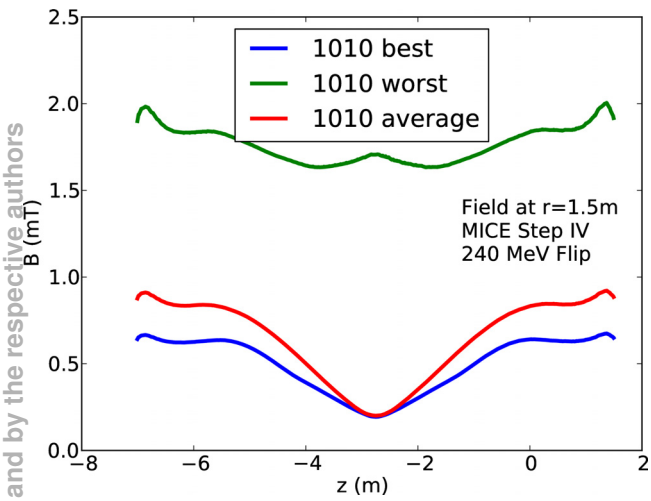

Figure 8: Stray magnetic field for different 1010 steels at a radius of 1.5 m (PRY finishes at a radius of about 1.35 m) and vertically at beam height.

The expected shielding performance can be seen in Fig. 8, which shows the residual stray magnetic field at a radius of 1.5 m or about 10 cm behind the PRY at beam height. The figure shows that the stray magnetic field (for 240 MeV flip configuration) varies between 0.6 and 2 mT. For average properties of 1010 steel a residual magnetic field of about 1 mT can be expected.

To limit the variability of the magnetic properties a better quality steel, for axample AISI 1008 or AISI 1006 can be chosen. In addition the PRY thickness can be increased which improves the shielding performance and hence the safety margin.

SCHEDULE

The PRY material procurement and fabrication is presently estimated to be completed in August 2014.

SUMMARY

This paper summarizes the engineering design of a partial return yoke for the Muon Ionization Cooling Experiment. A support structure was described which is capable of supporting the dead weight and magnetic forces on the PRY during operation. Both stresses and deflection are acceptable.

Penetrations of the PRY were studied and it was found that vertical gaps have a detrimental effect on the shielding performance. To avoid flux leakage vertical joints in the PRY are doubled up with two backing plates. Horizontal gaps are less critical and can be tolerated up to a width of several cm.

The designated material for the PRY is AISI 1010 steel. The magnetic properties of 1010 steel can vary significantly depending on the exact composition. Magnetization curves from literature of HEP physics experiments have been used to estimate the effect. It was found that the shielding performance for a 10 cm PRY varies from 0.6 mT up to 2 mT. To mitigate this a steel with a higher guaranteed Fe content can be chosen (for example AISI 1008 or 1006) and the PRY thickness can be increased to 12 cm.

PARTIAL RETURN YOKE FOR MICE – GENERAL CONCEPT AND PERFORMANCE*

H. Witte†, S. Plate, Brookhaven National Laboratory, Upton, NY, USA
J. Tarrant, STFC Rutherford Appleton Laboratory, Didcot, UK
A. Bross, Fermilab, Batavia, IL, USA

Abstract

MICE, which is an acronym for Muon Ionization Cooling Experiment, is a technology demonstration which is presently assembled at the Rutherford Appleton Laboratory in Didcot, UK. MICE aims to demonstrate ionization cooling experimentally, which is an essential technology for potential future accelerators such as a muon collider.

The MICE channel consists of up to 18 large bore superconducting solenoids, which produce a substantial stray field. This stray field can jeopardize the operation of electrical and electronic equipment in the MICE hall.

The concept of a partial flux return yoke has been developed, which reduces the stray field in the MICE hall to a safe level. This paper discusses the general concept and expected performance.

INTRODUCTION

Ionization cooling can be regarded as an essential technology for future HEP particle accelerators such as the muon collider, as it is the only known technology fast enough to reduce the emittance of a muon beam.

MICE, which aiming to demonstrate the concept [1], will be assembled in several steps. At the time of writing it is aimed to finish construction of Step IV by summer/autumn 2014. MICE Step IV consists of 12 large bore superconducting solenoids. The MICE solenoids produce a substantial amount of stray field (in excess of 50 mT), which is a concern as some of the technical equipment in the MICE hall may not work.

This paper discusses the design concept of a partial return yoke (PRY) for the MICE solenoids for Step IV. The engineering design is described in [2, 3].

METHODOLOGY

For the analysis of the problem and performance estimate two commercial finite element packages are employed: COMSOL Multiphysics (COMSOL AB, Tegnergatan 23, SE-111 40 Stockholm, Sweden) and Opera 3D from Cobham/Vectorfields (Cobham CTS Limited trading, 24 Bankside, Kidlington, Oxfordshire, OX5 1JE, UK).

The two software packages use different physics implementations, which allows to verify the obtained results. COMSOL solves for the magnetic vector potential:

$$\nabla \times \left(\mu^{-1}\nabla \times A\right) = J \ . \tag{1}$$

In this equation μ is the magnetic permeability, A the magnetic vector potential and J a current density. In contrast to this Opera 3D solves for the magnetic scalar potential ϕ:

$$\nabla\mu\nabla\phi - \nabla\mu\left(\int_{\Omega_J}\frac{J\times R}{|R^3|}\mathrm{d}\Omega_J\right) = 0 \ . \tag{2}$$

Contributions to the magnetic field from current carrying structures at a distance R are usually evaluated using Biot-Savart law and integrated over the domain Ω.

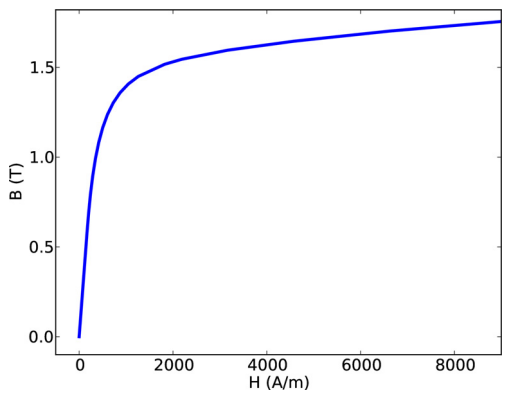

Figure 1: Magnetization curve of AISI 1010 steel.

For the simulations we assume that shielding iron will have the magnetic properties shown in Fig. 1. The magnetization curve was taken from Opera and is valid for AISI 1010 steel.

The coil geometries used in the simulation are summarized in Table 1.The MICE solenoids will be run in five different configurations. In two configurations the magnetic field flips in the centre of the MICE channel ('flip modes') whereas in three it does not ('solenoid modes'). The current densities for all cases are summarized in Table 2.

GENERAL CONCEPT

All MICE magnets are large diameter solenoids, which are relatively thin and short. From a shielding point of view an ideal solution is to encase the MICE magnets in a soft-iron cylinder. This is of course not practical; however, it is possible to achieve good shielding by only encasing MICE partially in this way. Fig. 2 shows the concept.

As shown in the figure, the MICE PRY covers an azimuthal angle of about $\pm 60°$ just outside of the cryostats. The remaining parts are left unshielded because of spatial constraints. In practice the MICE PRY consists of eight 1.5 m wide and 4 m long iron plates. For the thickness we consider two cases: 10 cm, which is the nominal case, and 12 cm which offers a better shielding performance. Each shielding plate is tilted by $11.5°$ towards MICE to satisfy spatial restraints and to aid the shielding efficiency. In longitudinal direction the PRY is completed by additional shielding plates which connect the two side halves of the PRY (apart from a small opening with radius 250 mm for the beam).

PERFORMANCE

The magnetization in the PRY is equivalent to a magnetic field 1.1T for all operational modes of MICE Step IV. At this level the relative permeability of the shielding iron is about 1700–2000, which was found to be sufficient to suppress flux leakage.

Fig. 3 shows the stray magnetic field at a radius of 1.5 m at beam height, which is about 10 cm radially away from

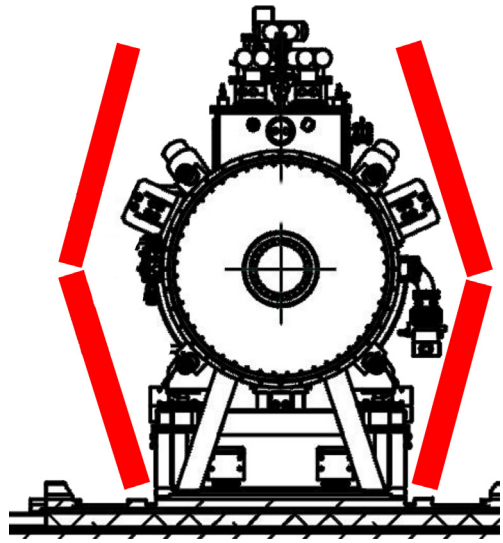

Figure 2: General Concept, frontal view. The partial return yoke is shown schematically in red.

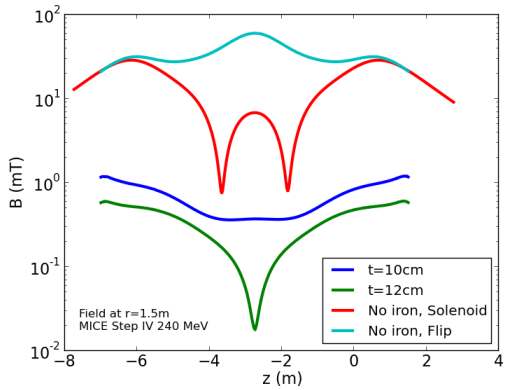

Figure 3: Modulus of the magnetic fringe field at a radius of 1.5 m at beam height.

the PRY. The figure shows a comparison between two unshielded cases (240 MeV flip and solenoid mode) and two shielded cases (solenoid mode). The two shielded cases differ in the thickness of the shield, which is 10 or 12 cm.

As shown in the figure, the PRY is effective in reducing the field level to 0.6–1.1 mT depending on the chosen thickness. This is a reduction by more than 50 to the unshielded case, where the stray fields are between 30–70 mT.

Fig. 4 visualizes the 5 Gauss line in 3D. The 5 Gauss line is important because of health and safety considerations. Shown is a comparison between the unshielded (left) and shielded case (right figure). The figure emphasizes that the fringe field extent is significantly reduced. In longitudinal direction the 5 Gauss line is reduced from about 13 to 8 m. In horizontal direction the 5 Gauss line finishes with the PRY, which is located at about 1.4 m. In vertical direction, which is not covered by the PRY, the 5 Gauss line is moved from 4.5 m to about 2 m.

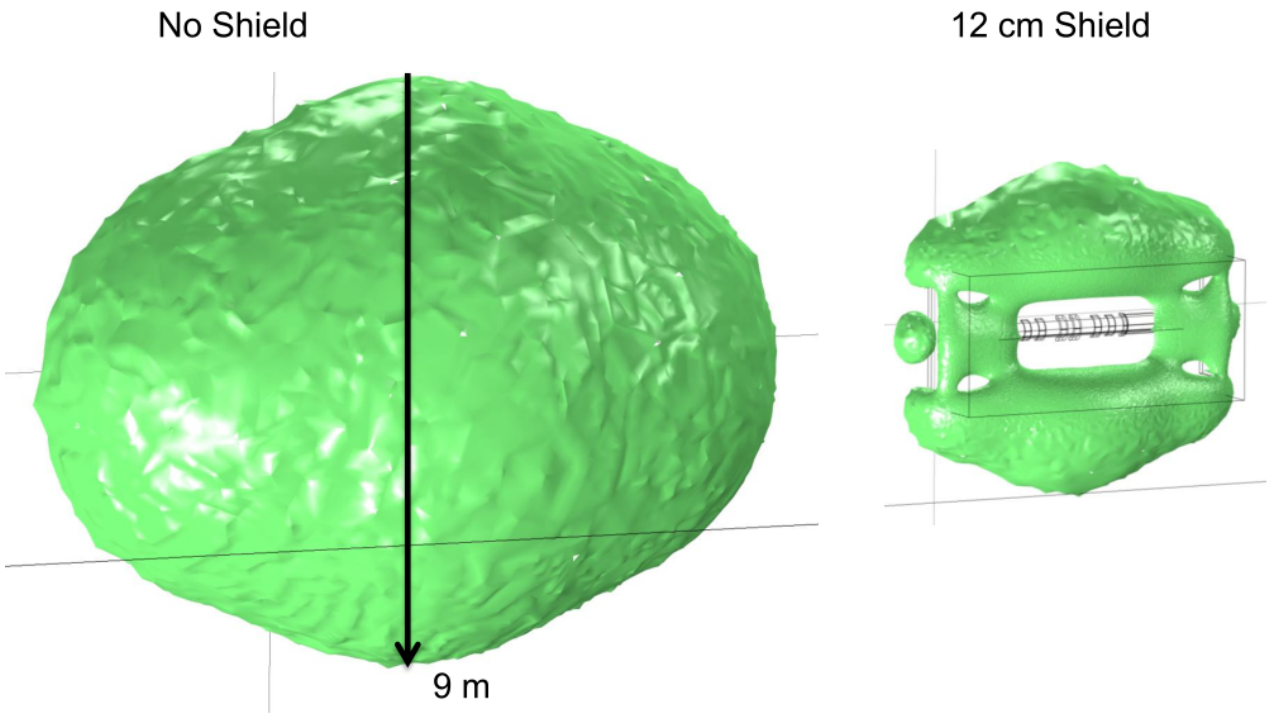

Figure 4: 5 Gauss iso-surface plot of MICE for the 200 MeV flip mode. The left figure shows the 5 Gauss surface for an unshielded scenario (no iron present) versus the case where the PRY is adopted.

EFFECT ON THE BEAM

The additional iron in close proximity to MICE changes the magnetic field in the channel. A particular concern is the asymmetry of the PRY due to the fact that in vertical direction MICE is unshielded. This leads to an asymmetric error field which can be detrimental for the performance of MICE. A particle tracking study using MAUS (MICE Analysis User Software) was carried out to address this [4].

The simulation consisted of 100,000 muons; simulated was the 200 MeV case (flip mode). It was found that due to the error field the mean beam position is shifted by about 100 μm, the beta function changes by about 10 mm and the discrepancy between emittances is about 1 μm.

The results indicate that the changes introduced by the MICE PRY have a barely measurable effect and therefore do not compromise the experiment.

SUMMARY

This paper outlines a shielding concept for the international Muon Ionization Cooling Experiment MICE, which is capable of reducing the stray fields in the MICE hall to a tolerable level. The MICE channel will not be encased fully due to spatial constraints, but the as shown the shielding performance is still sufficient to shield large parts of the MICE hall.

Two different shield thicknesses were studied; in comparison to a 10 cm thick PRY a 12 cm version reduces the stray magnetic field at a radius of 1.5 m by a factor of two or more and offers therefore more margin.

Simulation results suggest that the 5 Gauss line in the MICE hall in horizontal and longitudinal direction would be located just after the PRY. In vertical direction the distance to the 5 Gauss line is reduced by about a factor of 2.

The effect on the beam was studied using particle tracking simulations and it was found that the effect of the additional iron is negligible.

A STRIPLINE KICKER DRIVER FOR THE NEXT GENERATION LIGHT SOURCE*

N. Butler, F. Niell, J. Kinross-Wright, M. Gaudreau, M. Kempkes,
Diversified Technologies, Inc., Bedford, MA 01730, USA

Abstract

Diversified Technologies, Inc. (DTI) has designed and prototyped a novel high voltage pulse generator applicable to beam deflector applications. This work is funded by an SBIR grant from the U.S. Department of Energy in support of advanced accelerator development. The technical goals include 10 kV output into 50 Ω with 2 ns rise time and a repetition rate of 100 kHz. These challenging specifications were based on the original Next Generation Light Source (NGLS) fast deflectors (stripline kicker) required in the proposed beam switchyard. DTI believes the advanced pulse generator will have numerous applications requiring fast risetime and high repetition rate. This paper describes the current status of the project.

BACKGROUND

In Phase I of the project, DTI investigated several high-speed switching circuits, using a variety of emerging solid-state switch technologies, including GaN and SiC. After much experimentation, DTI has settled on an inductive adder circuit topology, using a two-step, silicon MOSFET Marx approach in each stage. The use of parallel FETs at each stage of the inductive adder allows a flexible design which can be adapted to new requirements. The Phase II prototyping efforts have validated the design approach. Figure 1 shows an operational prototype pulse generator.

Motivation

The NGLS facility concept uses a high bunch rate accelerator (1 MHz) to efficiently supply beam to 10 independent X-ray FEL beam lines. Each beam line receives pulses at 100 kHz, though the fields in the deflector must settle in less than 1 μs to avoid perturbation of un-deflected pulses in the bunch train from the accelerator.

It is envisioned that the deflection will be imparted by a symmetric pair of shaped parallel deflection electrodes, pulsed in opposition at 10 kV. Matching 50 Ω resistors terminate the deflector to avoid the creation of backward-traveling waves.

SYSTEM ARCHITECTURES

Various system designs were explored for producing the required pulse wave forms. The options included a direct series high voltage switch, solid-state Marx bank, inductive adder, or more conventional pulse transformers and transmission-line adders, several of which were considered in detail. The inductive adder was ultimately selected as the preferred development path for the remainder of the program. The favored embodiment of the overall pulse generator was based on measurements, multiple circuit test boards, extensive modeling, and practical considerations regarding component performance in the sub-nanosecond regime.

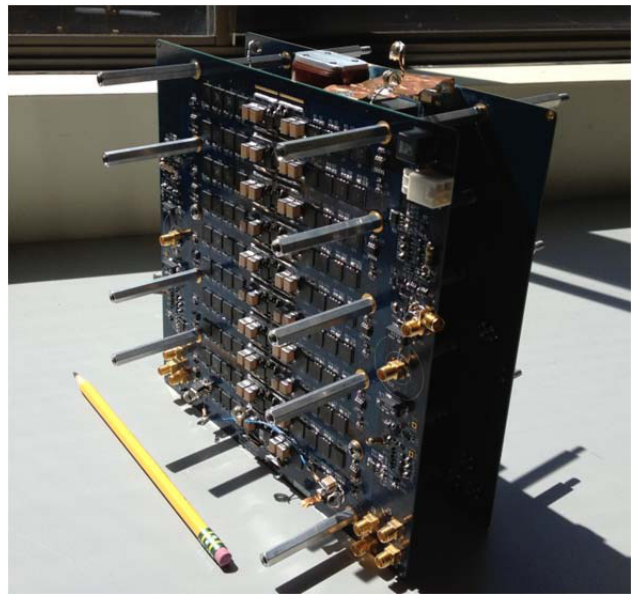

Figure 1: Prototype pulser hardware. In the center of the rectangle at the top is the output connection, and the two circuit boards on either side carry the pulse amplifiers and MOSFETs.

Pulse Generation

The overall pulse generation network is presented in Figure 2. This represents the principal schema, but variants on this approach have been developed as well. The key components exhibited in this figure include:

- Each stage is comprised of a pair of STMicroelectronics STL21N650 compensated silicon MOSFETs, capable of 2 nanosecond-class switching speed, along with extremely fast charge-pump driver circuitry to enable such fast switching. Note that the gate drivers must be referenced to the source pins in the diagram, meaning that one set of gate drivers must be floating – a key technological issue in this speed domain.
- A set of transformer cores, Tn, to couple the 1 kV pulses into a common tapered secondary structure. Matching the impedance of the output structure to

*Work supported by the Department of Energy

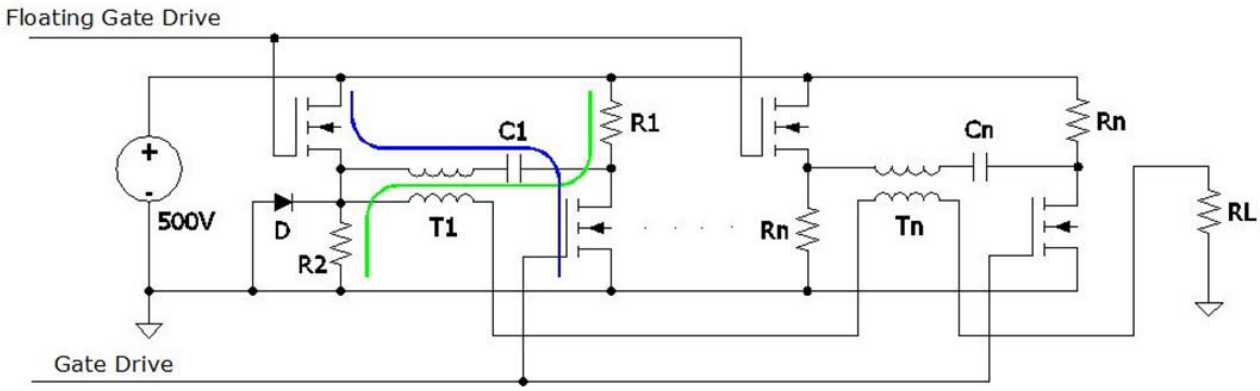

Figure 2: Basic inductive adder scheme, showing "n" stages. Note that the gate drives are shown all in parallel. This is due to DTI's innovative gate driver architecture which enables high voltage charge pump circuitry to drive multiple compensated-silicon MOSFETs with the speed required to achieve nanosecond-class switching. In this Marx arrangement, C1 is charged through resistors R1 and R2 (GREEN). The MOSFETs then discharge the capacitors through the transformers T1 through Tn, applying two times the charge voltage, or 1kV in the arrangement shown (BLUE). The secondaries of the transformers are a tapered stripline to match the output impedance of each stage to the load impedance RL. Diode D enables sharp turnoff to meet the stringent turnoff specification.

each stage's output impedance in a tapered fashion enables the fast leading edge required by the application.

Not shown is the gate driver circuitry or the circuit board itself. The pulse amplifier developed for driving the STL21N650 transistors was designed with minimum group delay and maximum gain to effectively utilize charge-pump drive techniques. This charge-pump design has been successful in prior work at DTI, and is ideally suited to this application. The circuit board itself is highly tuned for this pulse application—extreme care has been taken to achieve very low trace inductances. Plane-to-plane spacing was kept to 0.003 inch in order to achieve power traces under 300 pH. This was critical in order to switch 500 V and 50 A per transistor in roughly 3 nanoseconds. The small, low inductance parts allow for the fast switching speeds. This board technology was crucial and left the intrinsic inductance of the packaged parts as a limit to the achieved rise times.

In order to keep the overall size and parts count down, a 10-stage 1 kV-per-step approach was chosen. The Marx topology at each stage allows 1 kV to be applied to the transformer cores while still using the fast 650 V transistors. Four MOSFETs are used in parallel at each position to carry the current and keep the inductance down. Measured inductance of each stage comes to less than 8 nH, dominated by the leakage of the coupling transformer. Capacitors Cn are chosen to have low inductance and acceptable voltage ripple and recharge time. The pulse amplifiers used to drive the transistor gates are tailored specifically to pump the appropriate amount of charge required to turn the devices on, while still having a propagation delay in the 8 ns range and being driven by TTL signals. The amplifiers consist of four stages; first a FET stage for level shifting and inversion, then bipolar followers, and finally FET inverters backed by followers. Each was chosen specifically to utilize their respective strengths (FETs for fast turn on, bipolars for current, etc.). Additionally, the gate pulse amplifiers for the floating side of the Marx are floating, referenced to the source of those power FETs only. Blocking cores are used to stand off the pulsing and float the stages at AC, but still provide a DC charging path to ground.

In the absence of diode D in the circuit above, the core reset of T1 through Tn happens through recharging of the capacitors in the Marx stages. However, this process is lengthy and somewhat chaotic, so diode D shuts off the secondary current flow due to recharge, effectively damping the ringing at turnoff and removing any stray pulses allowing the output to settle to better than 1 V in less than 1 μs.

Current Results

An example waveform is shown in Figure 3. The purple trace shows the command pulse, the green shows a capacitively-coupled probe with an arbitrary scale, and the red trace shows the voltage into 50 Ω on a 2 kV/division scale. Note the turn-on of 10 ns, the turnoff of 10 ns and the flattop of 30 ns. The peak is 8 kV at 160 A, the power is 1.28 MW. At this power level, the system was run at 1 kHz repetition rate on the bench with anything but a fan for cooling of the FETs. The peak temperature of the FETs was 65 C. With more aggressive cooling, operation at 10 kHz repetition rate should be possible.

Figure 4 shows operation at 10 kV, 200 A into 50 Ω; a full 2 MW per pulse. The red trace is the command pulse and the gray trace is the output pulse at 2 kV/division. Note the 7 ns rise and 8 ns fall times with 20 ns flattop.

Current pulser hardware is capable of pulses as long as 70 ns without any additional electronics for core reset. Additional core reset circuitry has been explored, but is not necessary at this time to meet the requirements of the

Copyright © 2013 CC-BY-3.0 and by the respective authors

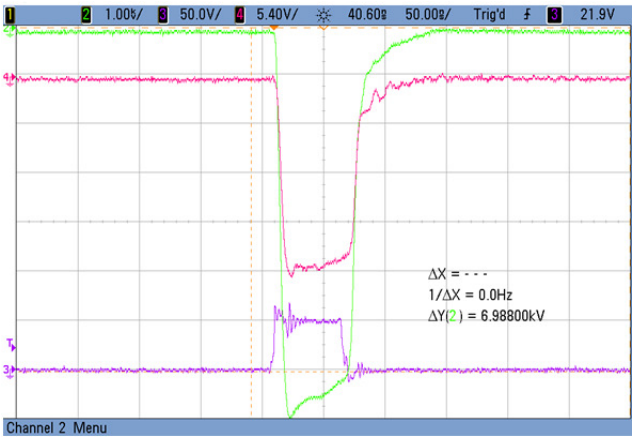

Figure 3: Performance at 8 kV into 50 ohms. Red trace is 2 kV/division. Note the 10 ns rise and 10 ns fall.

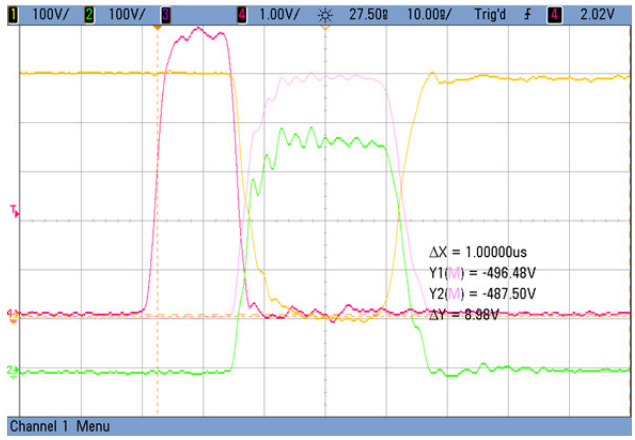

Figure 4: Operation at 10kV into 50 ohms. The faint gray trace is 2kV/division. At this higher power level, the transistors operate a touch faster, and the rise and fall times consequently are faster than at the 8 kV case.

NGLS kicker. Exploration of the current hardware limitations is underway, and it is likely that much higher currents are possible. The 200 A at 10 kV result was achieved with only 3 transistors at each location, and with the possibility of 4 transistors on the PCB. Perhaps 10 kV at 250 A may be in the future.

FUTURE PLANS

DTI is in the process of adapting this circuit architecture for other applications, including pulsed RF sources, pulsed plasma surface treatment systems and others. The remaining questions surround the maximum pulse rate and delivered power levels. Additionally, given the small size of the 2 MW pulser hardware, high voltage insulation and cooling are challenging. DTI will initially investigate immersion in oil bath, and later in phase-change cooling with refrigerants.

The current work is based on the C6 generation MOSFETs from STMicroelectronics. STMicroelectronics is currently shipping higher performance C7 generation devices, which will translate into faster pulses with more current capacity per device, or perhaps higher pulse repetition rates at the existing power levels. As these devices are available, we will be examining their performance in the current hardware.

Additionally, there are larger devices that are capable of as much as 125 A per device in single-state tests. This could project to a peak pulse of nearly 500 A at 10 kV, and testing is ongoing to explore the full performance envelope of the current architecture.

SUMMARY

The DTI team has designed and demonstrated the key elements of a solid-state kicker driver capable of meeting the NGLS requirements, and extension to a wide range of kicker driver applications. The MOSFET array switch itself is suitable for many accelerator systems with < 10 ns kicker requirements.

PROGRESS ON THE MSU SUPERFERRIC CYCLOTRON GAS STOPPER MAGNET QUENCH PROTECTION AND COOLING SYSTEM

S. Chouhan, M. A. Green, G. Bollen, and A. F. Zeller, FRIB, Michigan State University, East Lansing MI 48824, USA; J. DeKamp, C. Magsig, D. Morrissey, J. Ottarson, and S. Schwarz, NSCL Michigan State University, East Lansing MI 48824, USA

Abstract

The MSU gas cyclotron stopper system is designed to decelerate rare isotope ions from energies from >50 MeV to energies in the 10 keV range. The ions are decelerated in low-pressure helium gas in vertical cyclotron magnet. The magnet and the system for decelerating the ions are mounted on a high voltage platform. The cyclotron gas stopper magnet is a warm iron superconducting cyclotron sector dipole. The maximum field in the gap (0.18 m) is 2.7 T. The outer diameter of magnet yoke is 3.8 m, with a pole radius of 1.1 m and Br = 1.8 T m. The desired field shape is obtained by the pole profile. Each coil of the two halves is in a separate cryostat and connected in series through a warm electrical connection. The entire magnet system will be mounted on a high voltage platform. The magnet coils have been fabricated and installed in their cryostats. The iron poles have been machined and assembled. This paper presents the progress on the magnet system fabrication and assembly.

INTRODUCTION

The fragmentation of fast heavy-ion particles enables fast, chemistry-independent production, separation and delivery of exotic isotope beams. The resulting beams of exotic nuclei have high energies (>50 MeV/u) and large emittances. The range of possible experiments with the fast beams can be extended by slowing down the fast ions. The ReA3 [1] re-accelerator under construction at MSU will re-accelerate the thermalized ions to provide low emittance exotic beams over a range of energies. The thermalization of the fast ions and their extraction using existing techniques are limited by space charge and other limitations.

A proposed solution to thermalize and extract light to medium mass ions and high intensity beams is to apply strong gradient-dipole magnetic field in a large magnetic gap (0.18 m) that forces the fast ion beams to follow spiral trajectory while slowing down in the gas. Concentrated thermalized ions near the central extraction port are then transported in to central extraction orifice via an RF-carpet. These extracted ions will be transformed into low energy beams using a differentially pumped ion-guide. The low energy ion beams can be transported directly to low-energy experiments or to other accelerators for reacceleration. The high performance and high field (2.7 T) super-ferric cyclotron gas stopper sector-magnet at National Superconducting Cyclotron Laboratory (NSCL), Michigan State University (MSU) will enable the capture of short-lived rare isotopes produced in nuclear reactions.

The cyclotron gas-stopper magnet design has evolved since its original design in 2007 [2]. A gradient dipole field is produced in a gap of 180 mm between sector cyclotron iron poles. The peak field in the gap is ~2.7 T. A pair of superconducting solenoid coils produce the field. The warm iron poles can be separated so that the deceleration system can be maintained. Each pole coil has its own helium cryostat and superconducting coil that operate at 4.3 K. The 300 K iron poles are physically connected through the magnet iron flux return path, but the superconducting coils are not physically connected. The forces on the magnet coils are transported to the iron return yoke through the cold mass supports. The magnet is oriented so that the common axis of the solenoid coils is horizontal. Thus the beam plane for the super-ferric cyclotron magnet is vertical. Each of the two magnet superconducting coils will be cooled using three PT-415 pulse-tube 4 K coolers with remote valves.

IRON POLES AND RETURN YOKE

The split iron poles and return yoke are shown in Fig. 1. One of the sector cyclotron pole pieces is shown in Fig. 2. Table 1 presents the parameters for the magnet [3].

Table 1: Cyclotron Gas Stopper Magnet Parameters [3]

Parameter	Value
Number of Magnet Coils	2
Iron Pole Radius (m)	1.10
Iron Return Yoke Outer Radius (m)	~1.90
Average Induction in the Gap (T)	~2.0
Average Pole Half Gap (mm)	~90
Number of Coil Turns per Layer	31
Number of Layers per Coil	57
Coil Cross-section R / Z (mm)	80 / 80
Coil Peak Design Current (A)	200
Peak Coil Current Density (A mm^{-2})	54.9
Peak Magnetic Induction in Coil (T)	2.05
Magnet Self Inductance Assembled (H)	178
Magnet Peak Stored Energy (MJ)	3.56
Coil Cold Mass per Pole (kg)	~370
Magnet Cold Mass per Pole (kg)	~1240
Magnet Iron Mass (metric tons)	~167

MAGNET COILS AND QUENCH PROTECTION

The 1767 turn magnet coils were wet wound and molded to fit into the 80 mm by 80 mm final shape. A 22-turn non-inductive work hardened 6061-Al resistor with a resistance of 2.26 ohms was wound on the outside of the coil as part of the quench protection system [4]. When the magnet quenches, the diodes fire shunting the current into the resistor, which heats the coil from the outside. A quench, which fires the diodes, will cause the full current of the coils to flow in the resistor. It takes ~100 ms, for the outside of the coil to be heated to 10 K. The calculations show that both magnet coils will become fully normal in <4.3 s. At the start of the quench at full current 89 kW of heat will come from the resistor. This will boil the helium in the cryostat as well cause the coil to turn normal. Once the coil has turned normal, the coil rapidly discharges.

The coils were inserted in 304-stainless steel helium vessels so that there is space between the coil and the helium vessel to circulate helium in a thermal-siphon cooling loop used to cool and cool-down the magnet coils. The helium vessel is stiff to prevent deflection of the cold mass when the magnet sees unbalanced magnetic loads while in the iron. The helium vessel necks contain the quench protection [4] diodes (see Fig. 3), the LTS leads that connect of the bottom of the HTS leads through a vacuum tight feed-through between the helium vessel and the cryostat vacuum vessel, and 5 L of liquid helium out of the total of 7.4 L per coil. The LTS leads are designed so that their length is less than a minimum propagation zone length at the full design current of the magnet. In addition, the LTS leads within the helium vessel are designed to be cryogenically stable in helium gas.

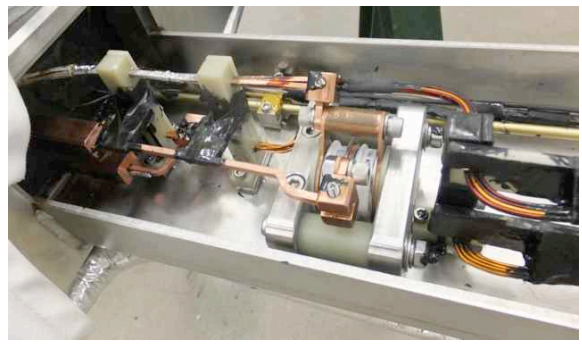

Figure 3: Quench Si diode assembly in the cryostat neck.

MAGNET COOLING SYSTEM

The tops of the HTS leads are connected thermally to the first stages of the coolers. Electrically the leads are insulated from the first-stages. The heat from 293 K to the top of the HTS leads at 45 to 50 K is conducted through the electrical insulation to the cooler first-stages at a temperature <40 K. The heat conducted down the leads to the cooler first-stages is ~20 W all other sources of heat to the cooler first stages amount to < 10 W. The projected cooler first-stage heat load is 10 W per cooler.

Each coil of the cyclotron gas stopper magnet is cooled and cooled-down using three PT-415 two-stage pulse tube coolers with remote rotary valves and ballast tanks. These coolers produce 1.35 W at 4.2 K while procucing 36 W at 40 K. The cooler cold heads mounted in the top of the turret are shown in Fig. 4.

Figure 4: The top of the coil 1 turret cryobox showing the cooler cold heads (labled A, B, and C), the current leads, the instrumentation plugs, and the safety vent tubes.

The cooler cold heads and the ballast tanks, which are mounted on the cryostat turret, are at a high voltage (up to 60 kV) with respect to ground. The rotary valves and the

Copyright © 2013 CC-BY-3.0 and by the respective authors

hoses to the compressors are at ground potential. The helium pipes between the rotary valves and the cooler cold heads are insulators that hold off up to 60 kV. Figure 5 shows a mockup of the coolers on the cryostat turret.

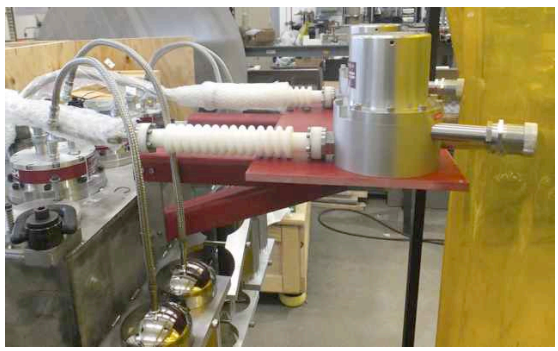

Figure 5: The coolers mounted on the coil turrent.

During a cool-down, the three coolers on each coil cryostat operate in parallel [5]. Helium gas from the magnet enters the three condenser heat exchangers from the top. The gas is cooled in the condenser boxes and is sent to the bottom of the magnet cryostat. Figure 6 shows two of the three condenser boxes. After entering the magnet cryostat, the cold helium goes up past the magnet coil along the inside and the outside of the coil. The helium leaving the top of the coil returns to the condenser boxes to be re-cooled. The thermal siphon circuit flow is by natural convection. The projected cool-down time for the magnet cold mass of 2480 kg from 293 K to 4.3 K is ~4 days using six coolers. The time to fill the helium vessels with 16 L of helium by liquefaction of 293 K gas is an additional day.

Figure 6: The condenser heat excahngers for two of the three coolers. Warm gas from the magnet enters the condenser from the top. Cold gas leaves from the condenser bottom.

CONCLUDING COMMENTS

Both magnet coil cryostats were leak checked and pumped out in preparation for the first test of the cryogenic system. Since the thermal siphon cryogenic cooling system only works when the axis of the magnet is horizontal (so that the condenser is ~3 meters higher than the bottom of the coil cryostat), the cooling-down and the testing of the cryogenic system can only be done with the magnet coil cryostats mounted on the iron poles. The magnet coils were mounted in the iron during September of 2013 in preparation for a magnet cool-down using all six of the PT-415 pulse tube coolers (see Fig. 7). During the fall of 2013, the magnet instrumentation will be connected and the high voltage system will be installed on the magnet. The first magnet cool-down using helium from gas bottles is expected in the winter of 2014. With luck, cryogenic testing and magnet coil training is expected to occur in the first half of 2014.

Figure 7: The magnet coil mounted in the cyclotron gas stopper magnet iron return yoke.

MECHANICAL DESIGN OF THE CRYOGENIC SUB-SYSTEMS FOR ReA6 QUARTER WAVE RESONATOR CRYOMODULE*

M. Shuptar#, F. Casagrande, A. Fox, M. Johnson, M. Leitner, S. Miller, T. Nellis, M. Patil, T. Xu, Y. Xu, Facility for Rare Isotope Beams (FRIB), East Lansing, MI 48824, USA

Abstract

The driver linac for the Facility for Rare Isotope Beams (FRIB) consists of 49 cryomodules operated at 2 K utilizing 4 different types of superconducting resonators and 2 solenoid lengths which in turn requires 7 individual cryomodule configurations. The mechanical design requirements of the internal cryogenics of an FRIB cryomodule are determined by the piping and instrumentation diagram, which is discussed in the paper based on the FRIB quarter wave cryomodule type. In addition, heat load requirements and spatial constraints of other cryomodule sub-systems influence the cryomodule cryogenics design. The paper describes detailed design choices for the cryogenic headers and piping, a 2 K heat exchanger inside the cryomodule, solenoid current leads, and the bayonet connections to the cryogenic distribution system inside the accelerator tunnel. Different operating modes, which influence the cryogenic design, are summarized.

INTRODUCTION

FRIB is a US $700 million nuclear physics project to be built at the Michigan State University under a corporate agreement with the US Department of Energy (DOE) with a 7-year timetable [1]. According to the current FRIB baseline schedule fabrication and procurement of linac components will start mid-2014. Actual linac installation will begin end of 2016 after completion of conventional facilities and cryoplant construction [2].

Due to the heavy mass and correspondingly low velocity of the accelerated ions the FRIB driver linac [1] utilizes four different low-beta SRF resonator designs in cryomodules. Each cryomodule is equipped with niobium cavities which will operate at 2 K providing acceleration to the heavy ions. Due to the large number of cryomodules the FRIB project lends itself to a manufacturing mind-set that incorporates large scale production into the design of individual modules types. As a part of the manufacturing mind-set FRIB is currently developing a prototype cryomodule that will utilize 8 superconducting quarter-wave cavities, and is referred to as the ReA6 cryomodule. Upon completion the ReA6 cryomodule will test not only the general cryomodule design, but also the manufacturing methodology [3]. Even though ReA6 is a prototype module it will implement some design choices that differ from a typical FRIB cryomodule. The usefulness of the ReA6 module will not end with proof of concept of mechanical and manufacturing principals; after testing the module becomes a permanent part of FRIB's Re-Accelerator located in the experimental area of the facility.

* This material is based upon work supported by the U.S. Department of Energy Office of Science under Cooperative Agreement DE-SC0000661. Michigan State University designs and establishes FRIB as a DOE Office of Science National User Facility in support of the mission of the Office of Nuclear Physics.

shuptar@frib.msu.edu

BASIS OF REQUIREMENTS

Each cryomodule design starts by obtaining the system's requirements and then designing the specifications. For the cryogenics inside the ReA6 Quarter Wave Resonator (QWR) cryomodule the requirements are defined by; piping and instrumentation diagram (P&ID), heat load budget, cost and spatial constraints.

The ReA6 P&ID differs from an FRIB module because the operating constraints of the ReA6 are slightly different from an FRIB module. Since the ReA6 module will be built ahead of the FRIB cryoplant and will not be located in the tunnel its cryogenic layout specified on the P&ID includes a liquid nitrogen circuit not present in FRIB Cryomodules. ReA6 Resonators will also operate a 4.5 K compared to an FRIB module's resonators operating a 2 K [4].

Heat Load Budget

The heat load calculations outline the allowed heat load for each module. Constraining the heat load to each module budget ensures that the cryoplant is sized correctly. The heat load budget requirement for ReA6 cryomodule is shown in Table 1 [5].

Table 1: ReA6 β=0.085 Cryomodule Heat Loads

	Resonators (4.5 K)	**Focusing Magnets (4.5 K)**	**Thermal Shield (80 K)**
Static (W)	6.0	50.7	180.6
Dynamic (W)	80.0	1.3	23.2
Total (W)	**86**	**52**	**204**

The heat load budgets are also necessary to estimate the mass flow for three separate cryogenic loops. Calculation of the helium and nitrogen interfaces to the cryogenic distribution are given in (Table 2) [5]. To minimize vapour velocity and maximize helium capacity the headers needs to be sized effectively.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Table 2: Flow Conditions for ReA6 Cryomodule

	T (K)	P (atm)	ṁ (g/s)
Nitrogen Supply	82	1.6 – 1.7	1.1
Helium Supply	4.5 – 5	3.0 – 3.5	8.5 – 9.9
Cavity Helium Return	4.5	1.286	4.6 – 5.4
Solenoid Helium Return	4.5	1.286	3.9 – 4.6
Megnet Leads Return	300	1.1	0.09
Nitrogen Return	82	1.6 – 1.7	1.1

Using Equation 1, the velocity vapour can be estimated.

$$\dot{m} = v\rho A. \quad (1)$$

Where ṁ is the mass flow rate, v is velocity of the vapour, ρ is the density of the gas and A is the minimal cross-sectional area needed to achieve the desired vapour velocity. The mass flow is taken from the heat budget and a vapour velocity limit of 7 m/s was imposed [6]. This limit prevents drag on the liquid within the header and also minimizes any vibratory disturbances. The calculation was done for each of the cryogenic circuits in the module.

The resonator circuit has a design contingency of facilitating 2 K helium. The header for resonators was calculated to need a minimum cross-sectional area of 18.08 cm^2 (or pipe with an inner diameter greater than 4.79 cm). The resonator header, magnet header and thermal radiation header have been sized with a 6" Schedule 5 and 4" Schedule 5 IPS pipe respectively. The benefit of a larger helium inventory inside the cryomodule will allow static pumping for 2 K operation given cryoplant and pumping limitations.

Spatial Constraints

The physical layout of the cryogenics within the cryomodule is constrained spatially by the other sub-systems; super-conducting resonators, thermal radiation shield, magnetic shield, alignment support structure and vacuum vessel as seen in figure 1.

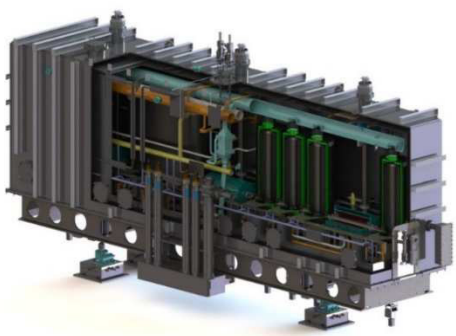

Figure 1: Cross-Section of ReA6 β=0.085 QWR Cryomodule.

Structurally the cryogenics will be supported from the vacuum vessel via G-10 plates and preloaded bellville spring washers to allow for thermal contraction. The cryogenic circuits are connected to the sub-systems using flexible couplings to minimize the transmission of micro-phonics.

CRYOGENIC CIRCUITS

The cryogenics of the ReA6 cryomodule is composed of three circuits: resonator, focusing magnet and thermal shield. The resonators and focusing magnets are placed on independent circuits so that they can be warmed and cooled independently which allows the resonators to be warmed above T_c and perform solenoid degaussing cycles [7]. Each circuit is based on a thermal siphon. The headers in the thermal siphon function as a liquid-gas phase separator; supplying liquid to the components and allowing gas from boil-off to be sent to the gas return. Each cryogenic circuit's temperature is dictated by the cryomodule's operating mode.

Resonator Helium Circuit

To reduce the number of components and simplify the fabrication, a single supply line supplies helium to the resonators and focusing/steering magnet circuits within the module. One circuit is used exclusively for cooling the resonators. For the resonators; the 4.5 – 5.0 K flow passes through a heat exchanger in series with a Joule Thomson (JT) valve to isenthalpically expand the helium. The heat exchanger for the ReA6 is sized for 10 g/s of flow. Even though ReA6 is designed to operate at 4 K but will have the ability to test at 2 K with batch pumping mode.

Focusing Magnet Helium Circuit

The focusing magnet helium circuit cools the focusing magnets (solenoids), magnet leads and thermally intercepting conductive components. The vapour cooled magnet leads will be purchased from a commercial vender. The circuit's other function is to minimize the heat loads to the resonators by thermally intercepting all components that provide a thermal heat load to the resonators. The helium from the 4.5 – 5.0 K supply passes through a JT valve to reduce its temperature before it enters a 4.5 K helium bath. To minimize the temperature of the liquid to each thermal intercept the circuit runs parallel flow to each intercept location. Intercepting components in parallel prevents excessive formation of large bubbles in the cryogen, reducing the effective heat transfer between the fluid and the thermally intercepted component.

Thermal Shield Nitrogen Circuit

The nitrogen circuit, which is unique to the ReA6 module, primary function is to reduce thermal radiation heat loads to the coldmass (the string 8 cavities and 3 solenoids within the module). The nitrogen circuit thermally intercepts all sub-systems between the room temperature vacuum vessel and the 4.5 K coldmass. The

Copyright © 2013 CC-BY-3.0 and by the respective authors

circuit also supplies nitrogen to the thermal shield which is responsible for minimizing the radiant heat loads.

BAYONET BOX

The nitrogen and helium are supplied to the cryomodule circuits by a bayonet box as shown in figure 2. The bayonet box is integrated into the cryomodule as its own sub-system. The modular box is utilized on the 49 cryomodules in the linac. This sub-system is geared toward a large scale manufacturing methodology. It is designed to be fabricated independently and then later mounted onto the cryomodule. From there the cryogenic circuits are welded to the bayonet box creating a permanent leak tight assembly. The bayonet box interfaces with the main cryodistribution by U-tube bayonets. The effective implementation of assembly line manufacturing is very important design for FRIB. ReA6 will be an important part of testing this manufacturing process.

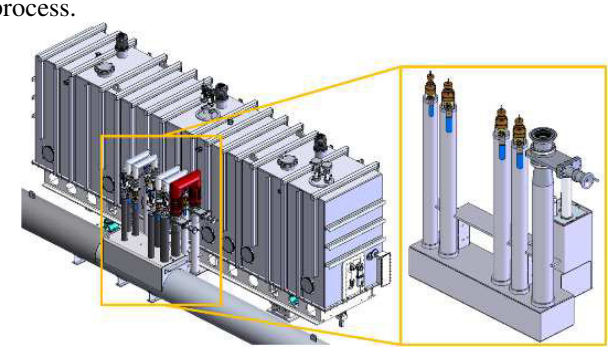

Figure 2: Cryomodule bayonet box interface to the helium distribution line.

CRYOGENIC PIPING & SAFETY

To design for manufacture, the cryogenic circuits were modelled after industrial piping systems. This approach reduces the number of custom made speciality parts without compromising quality and safety. Custom parts were minimized by using readily available industrial weldable components. Cryogenic piping was selected that adhere to the process piping code (ASME B31.3) and BVPC section VIII. Commercial piping selected adheres to the ASME Design by Rule and need for Design by Analysis was minimized. Commercially available formed bellows have been used which have been verified as per the ASME BPVC section VIII, Div. 2 code. Commercially available flexible metal hoses with welded end connection which are designed in accordance with ASME BPVC by the vendor have also been selected to couple the cryogenics circuits to the sub-systems. Welded bellows and the final system will be pressure tested in accordance with UG-99 (hydrostatic test) or UG-100 (pneumatic test).

Circuits have been equipped with lift-off plates and pressure relief valves to ensure that the cryogenic circuits do not produce pressures which would reach the yield stresses of the niobium resonators. The pressure relief valves are sized with a mass-flow rating for a failure mode during cryomodule cool down which would occur when there was a closed return valve and open supply valve. The lift-off disks operate for an operation failure mode. This failure mode would occur during accidental beamline or insulating vacuum loss with operating levels of liquid helium in the resonator and focusing magnet circuits [8].

IMPACT OF RADIATION ON THE MU2E PRODUCTION SOLENOID PERFORMANCE*

V.V. Kashikhin#, N. Dhanaraj, M.J. Lamm, N.V. Mokhov, V.S. Pronskikh,
FNAL, Batavia, IL 60510, USA

Abstract

The Muon-to-Electron conversion experiment (Mu2e) is under development at Fermilab to detect direct muon to electron conversion and provide evidence for processes violating muon and electron lepton number conservation not explained by the Standard Model of particle physics.

The Mu2e magnet system consists of three large superconducting solenoids. One of the magnets is Production Solenoid (PS) named after the pion production target installed in the magnet bore. The superconducting coils are protected from the secondary particle radiation by a massive Heat and Radiation Shield (HRS) made of bronze, which was optimized for the energy absorption and cost. This paper describes the impact of radiation on the magnet cooling, stability and quench.

INTRODUCTION

The Mu2e magnet system consists of three large superconducting solenoids [1]. PS is the first magnet in the chain [2], which collects and focuses pions and muons generated in interactions of an 8-GeV proton beam with a tilted high-Z target and directs them towards Transport Solenoid (TS), by supplying a peak axial field of 4.6-5.0 T and ~1 T/m gradient within a 1.5 m warm bore.

It is a challenging magnet because of the relatively high magnetic field and a harsh radiation environment. The PS coils are protected from radiation by 50-cm thick water-cooled HRS made of high-resistivity bronze, placed within the warm magnet bore. An extensive simulation effort has been carried out to optimize the shield parameters and get the radiation load below the tolerable levels with a sufficient safety margin [3].

The radiation heat reaching the coils must be extracted to the cryogenic system to maintain the necessary operating margin. It is achieved using a system of thermal bridges made of pure Al connected to the cooling tubes [4]. Electrical and thermal properties of the thermal bridges and the cable stabilizer are significantly degraded under the irradiation that impacts the cooling efficiency, magnet stability and quench performance.

RADIATION ANALYSIS

Simulations were performed with the MARS15 code [5] on the model shown in Fig. 1. The neutrons were propagated down to 0.001 eV. The full set of critical radiation quantities was calculated. The superconducting coil material was described using homogeneous approach (the material was represented as a mix of all elements with appropriate weight factors).

* This work was supported in part by Fermi Research Alliance under the U.S. Department of Energy Contract DE-AC02-07CH11359.
#vadim@fnal.gov

The peak calculated Displacement Per Atom (DPA), which characterizes the radiation damage in metals, was ~$2.5 \cdot 10^{-5}$ yr^{-1} and the peak power density was 12.6 μW/g [3]. Corresponding peak absorbed dose for the coil insulation is 240 kGy/yr; total dynamic heat load in the cold mass is 28 W. While the total dynamic heat load is relatively small, the power density distribution in the cold mass is strongly non-uniform, as shown in Fig. 2 that creates a localized hot spot in the middle of the first coil.

Taking conservative safety factors into account, the calculated DPA translates into the degradation of RRR in Al and Cu from the initial values of 600 and 80 to 100 and 50 respectively in about one year of experiment's operation [6]. These numbers are regarded as the minimum allowable values. The magnet will be equipped with RRR gauges that monitor the material property changes during the operation. Once the critical resistivity degradation is detected, the magnet will be thermo-cycled to the room temperature that restores the original resistivity in Al and ~87% of that in Cu [7]-[8].

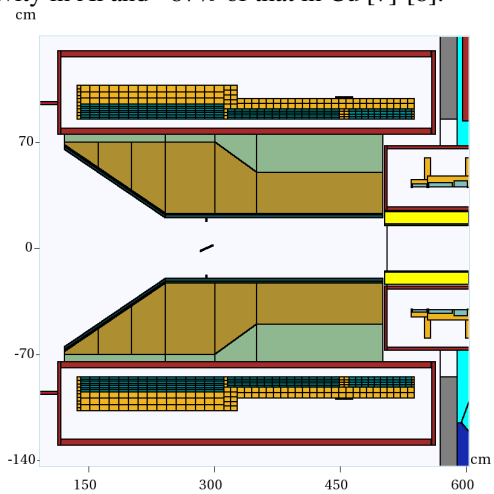

Figure 1: MARS model.

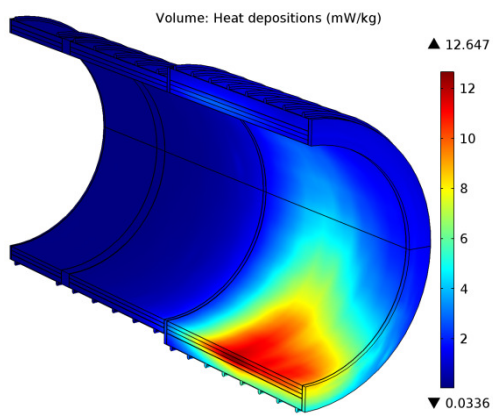

Figure 2: Radiation power distribution in the cold mass.

THERMAL ANALYSIS

The 3D FEM model of the cold mass has been created using ANSYS code [9]. It contained all the relevant features, including the coil layers, interlayer and ground insulation, thermal bridges, structural support shells and the cooling tubes with the corresponding material properties. The cold mass is cooled using a thermo-siphon system that maintains the LHe temperature of 4.7 K.

The radiation heat is extracted from the coils using a system of thermal bridges made of pure (5N) Al attached to the inner and outer coil surfaces and connected to the cooling tubes on the outer cold mass surface [10]. The thermal bridge RRR will degrade under the irradiation.

Fig. 3 shows the temperature distribution in the coil when the material RRR is reduced to the minimum allowable values defined earlier. The local hot spot coincides with the magnet peak field location and therefore affects the operating margin.

The peak coil temperature shall not exceed 5.1 K in order to maintain the required thermal margin of 1.5 K with respect to the current-sharing temperature of 6.6 K at the peak field location. Fig. 4 shows the peak coil temperature as a function of Al RRR for the static (beam is off) and total (beam is on) heat loads. The peak coil temperature rises by ~200 mK after turning the beam on and gains another ~70 mK due to RRR degradation in the operating cycle that is accounted for in the magnet design.

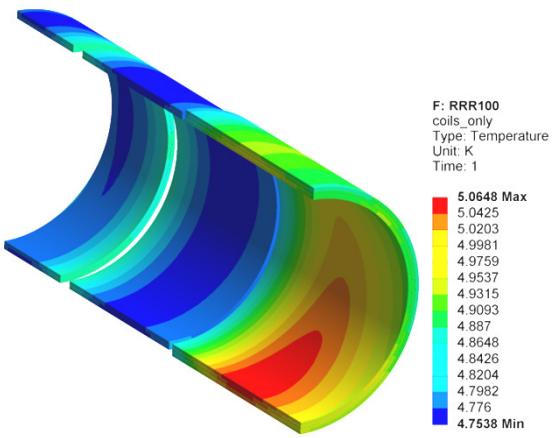

Figure 3: Temperature distribution in the coil.

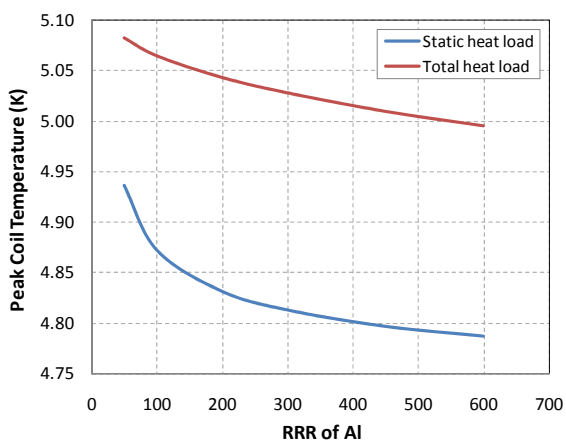

Figure 4: Peak coil temperature vs. RRR of Al.

MINIMUM QUENCH ENERGY

Stability of the superconducting state is characterized by the Minimum Quench Energy (MQE) that is the minimum energy released in the superconducting cable that triggers a quench. Both the electrical and thermal conductivities of the stabilizer material play an important role in the magnet stability.

MQE of the PS magnet has been analyzed using COMSOL Multiphysics code [11] for the stack of cables shown in Fig. 5, which included coupled thermal and electrical transient models. The analysis has been performed for the coil peak field location that has the smallest margin and consequently the lowest MQE.

The results of simulations are presented in Fig. 6. It is expected that most of the heat perturbations in the coils associated with cracks in the insulation and in the strand-stabilizer interface will occur during the commissioning without the beam. The relatively high initial MQE value of ~175 mJ, comparable to MQE in other large solenoids, will help to stabilize the magnet during that period.

The MQE degrades by ~25% due to coil temperature rise when the beam is on and gets progressively lower during the operation, reaching ~40 mJ at the end of the operating cycle. Thus the magnet becomes a factor of 4.4 less stable than during the commissioning, however, it is not expected to cause problems for DC operation.

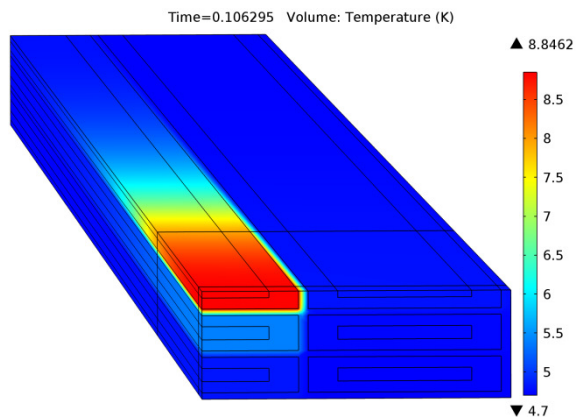

Figure 5: 1/8 of the cable stack model with the temperature distribution 0.1 s after the initial perturbation.

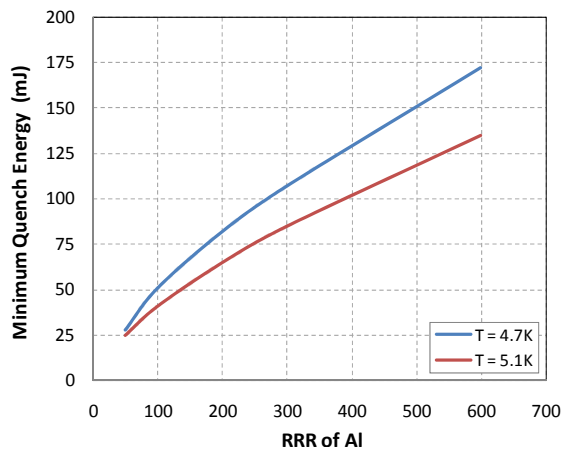

Figure 6: MQE vs. RRR of cable stabilizer.

QUENCH PROTECTION

The purpose of the quench protection system (QPS) is to limit the peak coil temperature to 130 K and the peak coil to ground voltage to 600 V during any normally protected quench. It is achieved by detecting the resistive voltage rise associated with the quench development and extracting the stored energy to an external dump resistor.

The 3D FEM model of the PS magnet, created within the COMSOL Multiphysics code, contained all the relevant features, including the individual coil layers, interlayer and ground insulation, thermal bridges on the inner and outer surfaces of the coils, coil support structures, and the HRS. The energy dissipation due to eddy currents induced in the support shells and the HRS was also included. Extensive simulations of different normal and fault scenarios have been performed [12].

It was found that irrespective of the RRR, the highest coil temperatures during the normally protected quenches occur at the peak field quench location. Propagation of a quench originated at the peak field location is shown in Fig. 7 at the time when the multiple resistive zones are induced due to quench-back from the support structure. The peak coil temperature and the resistive voltage go up by ~23 K and ~510 V respectively as the result of RRR degradation in the operating cycle as shown in Fig. 8; however, they remain below the limits.

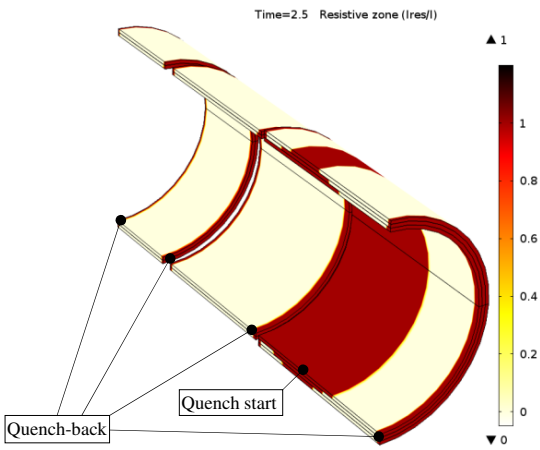

Figure 7: Resistive zone propagation (dark region).

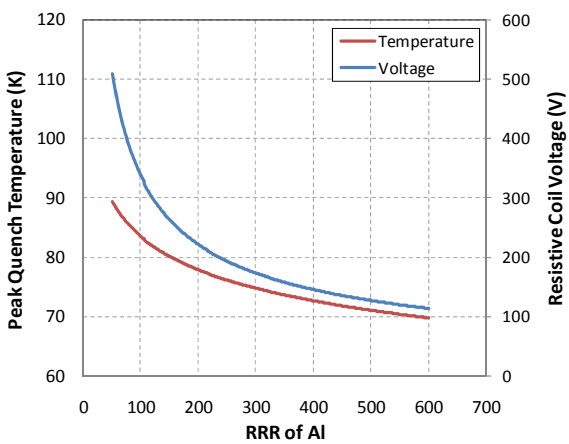

Figure 8: Quench temperature and voltage vs. RRR of Al.

Protection from the radiation has indirect structural effect on the magnet design due to field interaction with eddy currents induced in the HRS during quench. HRS is made from high-resistivity bronze to minimize the eddy currents; however because of the large HRS volume, the peak dynamic force on the cold mass is ~115 kN, which nearly equals to the cold mass weight. It is normally subtracted from the much larger PS-TS attractive force, but leads to force reversal when the TS is off. To address this issue, the cold mass has a 2-way axial support system designed to counteract the force in either direction [13].

SUMMARY

Radiation from the pion production target has a significant impact on the PS performance. In addition to the highly localized heat dissipation in the cold mass, the electrical and thermal properties of the stabilizer and the thermal bridges are considerably degraded, which is taken into account in the magnet design. Once the critical degradation is detected, the magnet will be thermo-cycled that will largely restore the original performance.

A HIGHLY CONFIGURABLE AND SCRIPTABLE SOFTWARE SYSTEM FOR FULLY AUTOMATED TUNING OF ACCELERATOR CAVITIES *

J. M. Nogiec#, R. Carcagno, S. Kotelnikov, A. Makulski, R. Nehring, D. Orris, W. Schappert,
FNAL, Batavia, IL 60510, USA

Abstract

A software system has been developed to automate cavity tuning machines as part of a multi-laboratory collaboration. The system is based on a plugin framework containing a configurable set of components. Each component runs asynchronously and uses a framework for message based communication. Components run in either manual or automatic mode. In automatic mode, the system interprets a user-selected control script which executes a sequence of measurements, model calculations and tuning operations. A tuning script iterates until the prescribed tuning criteria are satisfied, or until aborted or paused by the user. In manual mode, the user controls the tuning process, deciding when and which component to run, and when tuning is complete. The software framework incorporates the blackboard architecture for sharing data and results between the various plugins. The results of the measurements and tuning are persisted in an XML-based data store, and components exist that retrieve and visualize the data. The software system is portable (Linux, Windows) and has been successfully deployed and used by Fermilab, DESY, and KEK.

INTRODUCTION

The Cavity Tuning Machine (CTM) is a result of collaborative efforts among DESY, KEK and Fermilab [1] [2], with the Fermilab team responsible for developing system electronics and software [3]. The goal for the project was to automate tuning of accelerator cavities with the intention to support high-throughput cavity fabrication for construction of large SRF-based projects.

The tuning process includes a sequence of measurements and model-based calculations to determine the required tuning parameters, followed by the actual tuning. This process is iterative and is continued until the π-mode frequency and field flatness as well as the cavity mechanical alignment are all within the required tolerances. Automating the tuning process shortens the time required to tune the cavity and ensures the repeatability and predictability of this process. In addition, trained operators can replace RF experts at performing cavity tuning.

The main building blocks of the CTM apparatus include the base frame with a positioning system that moves the cavity between various positions, the eccentricity measurement device to measure the shape of the cavity, the gate with actuators for tuning (mechanically deforming) the cavity cells, the bead-pull measurement system, the laser-based alignment setup, and various electronic components, such as motion controls, interlocks, a network analyser, DAQ boards, and a weather station [3].

Figure 1: The cavity tuning machine.

ARCHITECTURE

The software architecture of the CTM system is based on the concept of plug-ins, a solution built on the ability to dynamically load and execute specified components. The framework consists of a shell module and a set of plug-ins (see Fig. 2). The shell implements a queued state machine and provides the overall system control logic, data saving, control of plug-ins, and user interface integration. Each plug-in implements a separate measurement (e.g., eccentricity, field flatness) or functionality (e.g., positioning, model, assessment) and constitutes a complete module with its own user interface, logic and DAQ. A plug-in's front panel is integrated into the overall user interface. Plug-ins communicate via message queues.

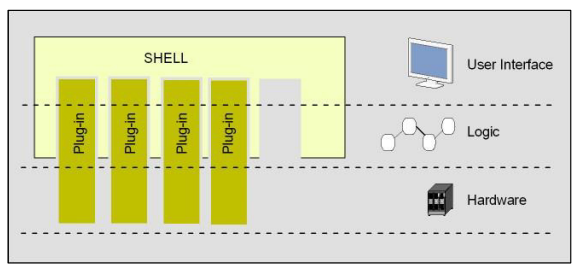

Figure 2: Plug-in architecture.

The system can operate in two modes: *manual* where the operator can use the controls available from the plug-in's front panel and *automatic* where the plug-in's front panel is disabled and the system controls the execution of plug-ins according to the logic specified in the script.

This design, based on loosely coupled components, allows for separation of concerns and encapsulation and, therefore permits concurrent development of highly independent modules corresponding to the major measurements and functionalities defined in the system. The CTM framework utilizes a blackboard architectural model for implementing exchange of data between components, which aids in integrating the specialized modules and implementing diverse control strategies. Although functionally independent, plug-ins rely on a set of shared modules to uniformly implement common aspects such as logging, error handling, configuration and calibration data access, and data saving. Hardware access is also organized by a set of shared modules implementing logical devices.

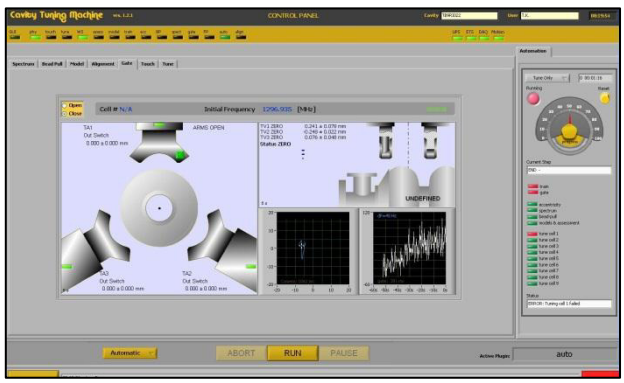

Figure 3: A plug-in executing in the automatic mode.

COMPONENTS

The CTM system has a number of plug-in components implementing its functionality. Each plug-in is designed as a state machine that executes a series of steps. This execution may be terminated (aborted) or temporarily paused. The user interfaces for each of the plug-in components are displayed inside a panel provided by the shell (see Fig. 3). The plug-ins' functionalities are as follows:

- The **train** plug-in is responsible for transporting the cavity along the base frame of the apparatus. It can move between predefined positions and also automatically position each cell inside the gate for tuning. When controlled manually it can move to any requested predefined position or move until stopped.
- The **eccentricity** plug-in performs calibration and measurement of cavity alignment by measuring the concentricity of individual cells to the cavity axis, the length of the cavity and the perpendicularity of its reference planes.
- The **spectrum** plug-in uses the network analyser to find all mode frequencies including the π-mode frequency.
- The **bead-pull** plug-in performs a field flatness measurement using a small metal bead that is moved along the cavity axis to perturb the electrical field. This perturbation results in a frequency shift measured by the network analyser. The component implements three variations of this measurement.
- The **tuning model** plug-in determines the change in the cell frequencies required to bring the π-mode frequency to the required target value with acceptable field flatness. This module has two models to be used depending on this how far the cavity is from being in tune.
- The **eccentricity model** plug-in calculates the differential deformation of the cavity cell walls required to straighten the cavity, and the expected deflection of the alignment laser as each cell is deformed. In addition, this plug-in examines the cell frequency changes required to tune the cavity, and calculates the amount by which the cells should be pre-detuned, if necessary.
- The **assessment** plug-in compares the results of the eccentricity tuning model's calculations and determines whether the cavity is acceptable for tuning or is already adequately tuned.
- The **alignment** monitoring plug-in tracks the cavity alignment using a laser and a camera attached at one end of the cavity, and a mirror at the opposite end. The camera detects the reflected laser beam spot and when the cavity bends, the laser spot shifts its position. This position is used by the machine to control and correct cavity alignment by moving the laser spot to the calculated desired position.
- The **gate** plug-in controls the tuning arms and jaws when closing and opening the cavity cells while following the pre-defined trajectory of movements. While operating arms and jaws, this component monitors both the frequency from the network analyser and the laser spot location.
- The **tuning** plug-in controls the three tuning jaws that squeeze or stretch the cavity cell according to the tuning plan calculated by the model plug-ins. During tuning both the alignment (laser spot position) and the frequency are monitored. The process is iterative and includes a sequence of adjustments followed by frequency measurements and continues until the resulting frequency is within an acceptance range.
- The **weather station** plug-in continuously acquires and records temperature, humidity and atmospheric pressure.
- The **automation** plug-in allows the user to run the automation scripts. Each script interacts with other plug-ins and performs a desired sequence of operations.
- The **interlock** plug-in ensures the safe operation of the machine. It enables the operator and scripts to examine and reset machine interlocks and prevents human access when the machine is in operation. It also monitors the internal statuses of various

Copyright © 2013 CC-BY-3.0 and by the respective authors

machine elements such as the motor controller, the UPS, instrumentation rack temperature, and the emergency trip system.

SCRIPTING

The automation plug-in executes automation scripts, which can perform all the measurements as well as cavity tuning, or just some select functionality such as calibration, cavity mounting or fine tuning. Users can supply their own scripts to further extend or customize the functionality of the machine. As with any other plug-in, the execution of a script can be suspended or aborted.

Automation scripts are sequences of instructions interpreted by the automation plug-in. The system uses a dedicated scripting language having 44 different instructions, which allow for communicating with plug-ins, controlling plug-in execution, controlling script flow, calling parameterized subroutines, handling exceptions, prompting the operator and accepting his responses, event logging and data saving, testing and resetting interlock status, manipulating indicators, obtaining the locality of the system, controlling tuning, switching between user interface panels, and sounding alert signals. In addition, automation scripts may have common sections which can be included inside several scripts, such as a set of subroutines that can be invoked from several scripts.

DATA HANDLING

The CTM software saves diverse data from all stages of the tuning process in files using the standardized XML format. This allows the use of a hierarchical structure for the output data and promotes self-describing data, where one can identify the values, names, and types of the data from the tags that describe them.

Each cavity has its own data file. Inside that file a sequence of sections represents the full history of measuring, evaluating and tuning of that cavity. The sections are chronologically ordered and represent outputs of various components. Each section is written immediately after the plug-in completes its action, thus allowing for restarting and continuation of an interrupted tuning process.

Since XML is a language used to represent data, and as such is not especially suited for human interpretation, a set of XSL transformations has been developed to aid in presenting cavity measurement and tuning results in a human-oriented form.

HARDWARE DEBUGGING

A separate program has been developed to facilitate testing, calibrating and adjusting hardware as well as debugging mechanical and electrical problems. It allows manual activation of all motors, and access and control of all connected instruments and peripherals, such as network analyser, weather station, DAQ boards or camera-based laser position system. Similar to the main tuning program, the maintenance program is configurable and can be extended by adding more test modules.

CONFIGURATION

The CTM system is highly configurable. A configuration consists of a list of components to be included in the system together with a set of their properties stored in an XML file. Each section of the file describes a set of parameters for a different plug-in component, such as eccentricity, bead-pull, train, arms, or jaws. A special program has been developed for examination and modification of these parameters. The program is extensible, and new sections can be easily added to support new plug-in components.

SUMMARY

The CTM system, a result of international collaborative efforts, has been successfully commissioned at DESY, Fermilab and KEK. Experience shows that the system has delivered on the promise to automate and shorten the tuning time of cavities.

The software developed to control and automate those machines is based on a plug-in architecture with loosely coupled components. The system is very modular, extensible and fully configurable. The blackboard-based design allows for integrating diverse specialized components and implementing various control strategies. The system's functionality can be extended or modified via scripting.

Data management, including measurement and tuning results as well as configurations and calibrations, is uniformly based on XML data format.

The system has been developed with a strong emphasis on operational safety and EU certification. It also has provisions for localization, with different behaviours specified for different laboratories. The CTM software system is portable and has been deployed on both Windows and Linux platforms.

ACKNOWLEDGMENT

The authors would like to thank their colleagues from DESY A. Goessel, J. Iversen, D. Klinke, G. Kreps, D. Proch, W.-D. Moeller, C. Mueller, and J.-H. A NEW FACILITY FOR TESTING SUPERCONDUCTING SOLENOID MAGNETS WITH LARGE FRINGE FIELDS AT FERMILAB

D. Orris, R. Carcagno, A.M. Makulski, J. Nogiec, R. Pilipenko, R. Rabehl, C. Sylvester, M. Tartaglia, Fermilab, Batavia, IL, USA

Abstract

Testing superconducting solenoid magnets with no iron flux return can be problematic for a magnet test facility due to the large magnetic fringe fields generated. These large external fields can interfere with the operation of equipment while precautions must be taken for personnel supporting the test. The magnetic forces between the solenoid under test and the external infrastructure must also be taken under consideration. A new test facility has been designed and built at Fermilab specifically for testing superconducting magnets with large external fringe fields. This paper discusses the test stand design, capabilities, and details of the instrumentation and controls with data from the first solenoid tested in this facility: the Muon Ionization Cooling Experiment (MICE) coupling coil.

INTRODUCTION

There has recently been a need to test solenoid magnets at Fermilab that have no iron flux return so the fringe magnetic fields could be relatively large. The Muon Ionization Cooling Experiment (MICE) Coupling Coil (CC) solenoid is the first such solenoid intended to be tested.

Since the existing dewars at Fermilab's Magnet Test Facility (MTF) are not large enough to test a MICE CC solenoid a new cryostat would be required. In addition, the large fringe field that would be produced by the solenoid would interfere with operations at MTF. At full operating current (210A) the 600 Gauss line would be at a radius of 3m and the 5 Gauss line would be at a radius of 15m. The 5 Gauss level is the limit for personnel with pacemakers and the 600 Gauss level impacts both personnel safety as well as the operation of equipment.

Several options were researched and the final decision was to build the solenoid test facility (SolTF) at the Fermilab Central Helium Liquefier (CHL) [1]. This location was selected because it had adequate space for the large test cryostat and the large fringe magnetic fields would not impact personnel and equipment operations: Personnel access could be managed to meet safety requirements. In addition, there was a sufficient source of liquid helium available to operate the new test facility.

SOLENOID TEST FACILITY

The new solenoid test facility (SolTF) would have to meet the cryogenic cooling, mechanical support, powering, quench protection, and data acquisition requirements for testing the MICE coupling coil at Fermilab. Table 1 lists some of the MICE CC specifications that SolTF must accommodate.

Table 1: MICE Coupling Coil Specifications for Testing

Parameter	Specification
Coil Design	96 Layers, 166 Turns in Series
Superconductor Strand	Cu/NbTi (MRI) 1.0 mm x 1.65 mm
Magnet Outer Structure Diameter	1860 mm
Magnet Weight	2.2 Tons
Cryogenic Cooling	Conduction Cooled
Helium Flow Rate	10 g/s
Cool Down Delta-T Limit	50 K Across the Magnet
Magnet Inductance	596 H
Maximum Current (4.5 K)	220 A
Stored Energy @220A	14.4 MJ
Peak Field (on axis)	2.6 T
Peak Field (on coil)	7.5 T
5G, 100 G, & 600 G Lines	15 m, 5m, 3m

Solenoid Test Cryostat

The cryostat used for the solenoid test facility was transferred to Fermilab from the National High Magnetic Field Laboratory (NHMFL) at Florida State University. The stainless steel vacuum vessel is 3.34m outer diameter, 3.32m inner diameter, and 2.7m high. The MICE CC coil would be tested in this cryostat using liquid helium conduction cooling.

The MICE CC solenoid is supported by a dished head assembly and four stainless steel rods each connected to a support bracket. The four support brackets are attached to the magnet with a G-10 block sandwiched between them to minimize heat conduction to the coil. G-10 rods between the support brackets and the cryostat wall prevent the magnet form moving horizontally. Although the cryostat was located as far as practical from the building's support columns and other fixed ferromagnetic material, tilt switches and displacement sensors were installed to monitor the magnet's vertical motion, if any, due to forces generated between the magnet and external magnetic material. Figure 1 is shows a 3-D model of the cryostat with the MICE CC solenoid.

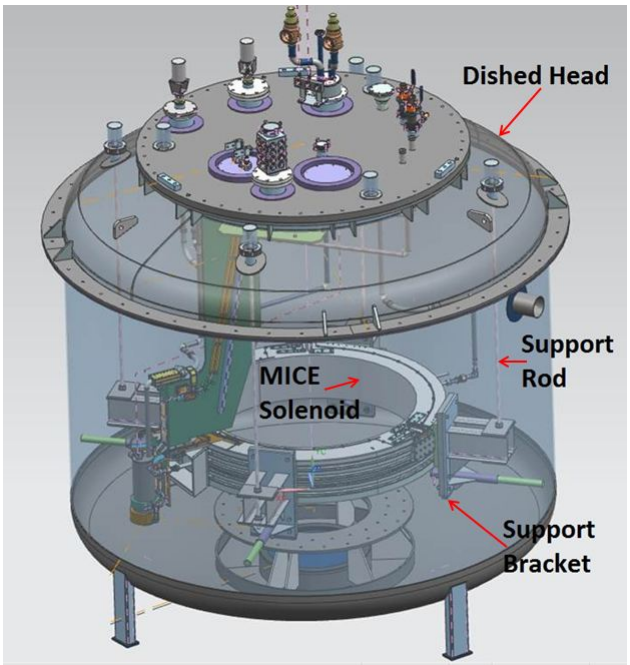

Figure 1: 3D model view of the SolTF Cryostat with the MICE Coupling Coil Supported from the Dished Head

Floor Layout

The solenoid test facility is located in the east annex of Fermilab's Central Helium Liquefier facility. The cryostat is located in the middle of the open floor space to optimize distance from magnetic materials, power panels, etc. A staging area with a support structure for the dished head is east of the cryostat for readying the solenoid for testing and the data acquisition and controls racks are located against the south wall where the maximum field is expected to be less than 20 Gauss.

The floor layout of the solenoid test facility is shown in Figure 2.

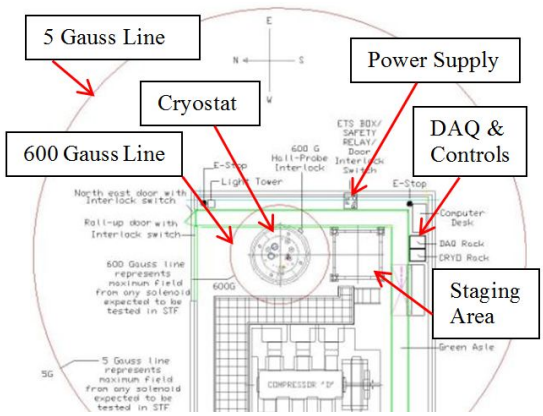

Figure 2: SolTF Floor Layout at CHL.

DATA ACQUISITION & CONTROLS

The DAQ and controls systems includes quench protection, fast and slow data logging for quench characterization, and cryo monitoring and controls. The quench protection and cryo controls are based on National Instrument's Compact-RIO (C-RIO), which uses a real-time operating system and FPGA. The data logging is based on National Instrument's PXI. The computer system consists of two operator stations, one devoted to managing the quench subsystem and another to monitoring and controlling of the cryogenic subsystem and the magnet. Each operator station is equipped with two monitors. Hardwired interlocks for equipment and personnel are also monitoring by this system.

Cryogenic Monitoring & Controls

The monitoring and control system is capable of both monitoring various process variables (temperatures, pressures, levels, flows, etc.) and controlling process variables (valves, levels, power, etc.) using PID regulators. The process interlock logic is a separate process that monitors vacuum, quench status and temperatures; it responds immediately to assigned events by closing or opening valves. The data archiver as well as all user interface programs resides in the top layer, the monitoring and control software resides in the real-time system layer, and the interlock logic and I/O in the FPGA part of the system [2]. Figure 3 shows the cryo monitoring and control display panel.

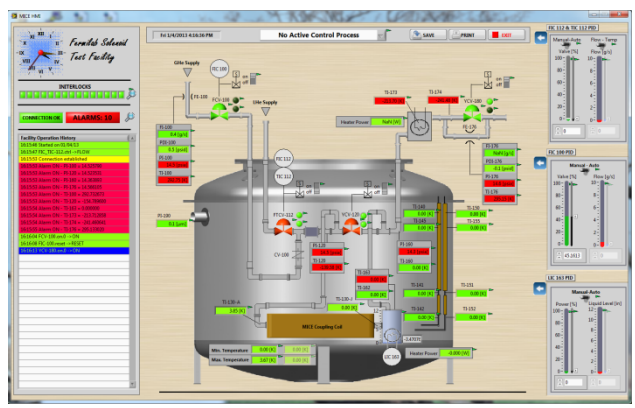

Figure 3: Cryo Monitoring and Control Display Panel. An Image of the cryostat with interactive parameters, such as temperature and pressure, are included in the Display.

Power System & Personnel Interlocks

The MICE power supply system was provided by Lawrence Berkeley National Laboratory (LBNL). This system includes a CryogenicLimited 240 Amp +10/-8.5 V power supply and energy absorber, and a circuit for disconnecting the power supply and enabling the passive diodes in the MICE solenoid. This system is also interfaced to the test stand quench detection system and hardwired personnel interlocks. A hardwired interlock "Electrical Trip System" (ETS) was built to enable or disable power to the bus based on several interlocks.

Copyright © 2013 CC-BY-3.0 and by the respective authors

These include the power supply access door, several "Emergency Off" buttons, etc. This system was installed in the power supply rack.

Quench Protection

The quench protection system uses an FPGA based digital quench detection (DQD) system [3]. Since the MICE CC magnet uses passive diodes for primary quench detection, the digital system provides redundant coil quench protection. The low temperature superconducting leads, however, are protected by the DQD for primary protection and an Analog Quench Detection (AQD) circuit for redundant protection. The quench detection system also provides the trigger to open the relays that connecting the power system to the magnet bus and ramps down the supply. A resistor in parallel with the output of the power system will generate enough voltage to turn on the cold diodes if the relays are opened at currents above ~25 A at 4.5K. Spot heaters were installed on the inner bore of the MICE CC to initiate a quench for verifying the operation of the quench protection system at low current. Figure 4 shows a heater induced quench at 46A while ramping at 0.010A/s.

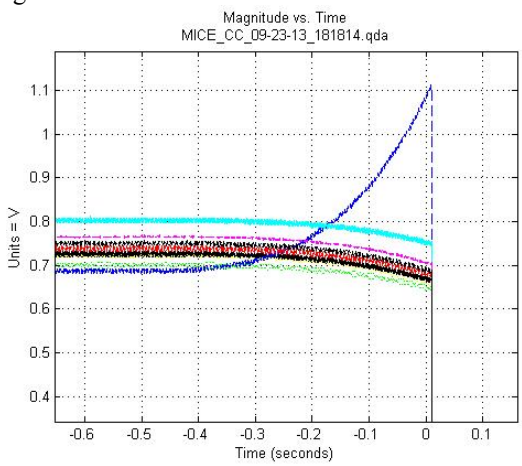

Figure 4: Heater Induced Quench of MICE CC at 46A. Coil 1, closest to the heater, quenched.

COOL DOWN AND TEST RESULTS

The MICE CC cool down is restricted to a 50K difference between the coldest and warmest coils. Since there are no temperature sensors on the coils, the resistance of the coils was monitored during cool down. This was accomplished by exciting the magnet with a trickle current of 10mA to 100mA while all eight coil voltages were monitored by the cryo monitoring scans. The calculated resistances were converted to temperatures based on resistance to temperature calculations provided by LBNL. Figure 5 shows all eighth coils transitioning to the superconducting state.

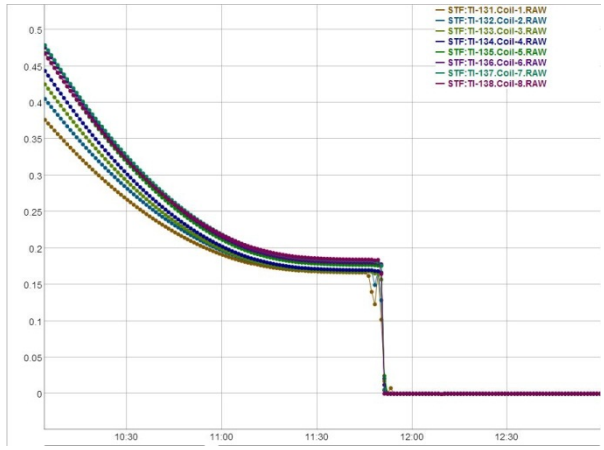

Figure 5: Plot of all MICE CC eighth coil voltages with 100mA current excitation during final cool down. The transition to the superconducting state is clearly seen.

The first ramp to quench occurred at 63A. Further analysis showed that the eighth coil #1 voltage signal rose to the threshold level in ~0.25ms. This was not a slow resistive growth but rather a voltage spike indicative of some coil motion.

SUMMARY

A new Solenoid Test Facility (SolTF) was built at Fermilab for testing conduction cooled superconducting magnets with large fringe magnetic fields. The facility was built in the Fermilab's Central Helium Liquefier (CHL) building since it had adequate space, liquid helium availability, and access to a crane for staging the magnets.

The Muon Ionization Cooling Experiment (MICE) Coupling Coil is the first magnet to be tested in this facility. The coil was recently cooled down and power tests have begun. A prototype capture solenoid coil built by Toshiba Corporation will be tested next. A mu2e prototype transport solenoid is expected to be tested next year.

STATUS OF PXIE 200 OHM MEBT KICKER DEVELOPMENT*

Gregory Warren Saewert#, Mohamed H. Awida, Brian Chase, Howard Pfeffer, Dan Wolff,
Fermilab, Batavia, IL 60510, USA
Daniil Frolov, Kuban State University, Krasnodar, Russia

Abstract

The proposed Project X machine at Fermilab must deliver a widely varying bunch pattern to provide beam to several experiments quasi-simultaneously. H- Beam is delivered to the 2.1 MeV Medium Energy Beam Transport (MEBT) section at 162.5 MHz continuous wave (CW) by a radio frequency quadrupole magnet (RFQ). Unnecessary beam bunches will be selectively chopped out in the MEBT by two identical choppers on a bunch-by-bunch basis and stopped by an absorber. The Project X Injector Experiment (PXIE) will be the test bed to demonstrate a chopper's ability to form an arbitrary bunch pattern. Presently two kicker system versions are under development. One proposed version is a 50 Ω structure driven by a ±250 V linear amplifier. The second proposed version is a 200 Ω helical, microstrip line structure driven by a 500 V bipolar switch. This paper describes the development status of the 200 Ω version and includes the design concept, comparison of 3D modelling work with prototype measurements, 200 Ω hardware description and progress with the driver.

SYSTEM REQUIREMENTS

The challenge for this application is the bandwidth requirement to chop beam continuously. Beam will be delivered to a number of experiments "at the same time", so kicking patterns would vary depending upon the needs of the experiments. Thus, the frequency at which bunches change from being kicked in and out will vary from 1 to 35 MHz average and 81.25 MHz peak for about 20 alternating bunches. This 200 Ω chopper offers a design solution by taking advantage of reduced power requirement and includes the development of a suitable driver.

Beam beta in the MEBT is .067 at 2.1 MeV, so the kicker can be a traveling wave structure (the "kicker") to slow down the propagating voltage pulse to match the beam velocity. The chopper consists of two 50 cm long traveling wave kickers parallel to each other on opposite sides of the beam. Applied voltage to the parallel kickers will always be of opposite polarity.

The MEBT's lattice allows for a chopper either to apply a voltage to only kick beam out to the absorber (the unipolar scheme), or to kick beam both in and out with opposite polarity voltages (the bipolar scheme). The unipolar scheme requires applying 0 V and 500 V and the bipolar scheme ±250 V. Voltage tolerance is ±25 V.

SYSTEM DESIGN

Component power dissipation is a big issue, and current flowing in the kicker does nothing to kick beam. These facts made it appealing to design a higher impedance system than 50 Ω. Power delivered to the load is a factor of four lower at 200 Ω, and the kicker structure's RF I^2R losses in the vacuum are lower by a factor of 16 (all other physical characteristics being the same). The downside is that all system components need to be developed. Figure 1 is the block diagram of intended system.

Helical Kicker

Meander line kickers have been implemented. However, limited power handling and evident pulse distortion suggested considering alternatives. Helical structures have also been built [1]. Constructing a cylindrically helical, 175 Ω microstrip line demonstrated promising results. Subsequent ~200 Ω versions with good mechanical uniformity resulted in good enough performance to proceed with the 200 Ω idea.

The helical wire is #13 flat magnet wire (.105" x .041") held above a copper ground tube by four ceramic spacers. This wire size was chosen to be stiff to hold its shape yet easy enough to wind tightly on a mandrel by hand. Electrodes, each 2-cm wide and .61 cm long, are attached to each turn of wire at the point closest to the beam. Beam aperture between the two facing helices is 16 mm. Figure 2a shows a photograph of a kicker prototype.

The single helix electrical characteristics and performance are affected when the two helices are positioned alongside each other, as in Fig. 2a, and driven with opposite polarities. The electrical effects are that impedance is lowered and propagation velocity reduced at the 3-5% level. Also, the helix microstrip line alone exhibits 900 MHz bandwidth but drops to about 600 MHz due to the second helix's proximity. Therefore, electrical measurements of a single helix are only valid when a zero voltage plane is installed to electrically mirror the missing helix. A metal surface positioned at beam-centre needs to extend the length of the helix, be parallel to the electrodes and grounded to the copper ground tube at both ends.

Magnetic coupling of the helical microstrip line geometry affects its characteristic impedance. The geometry for this 200 Ω helix would be 140 Ω line if laid out flat.

Estimated RF I^2R losses in the wire are about 6 W. However, the design requirements call for handling 40 W of inadvertent beam striking each helix. The ceramic spacers supporting the helix will conduct the heat to the copper ground tube. This nominal 1" diameter copper

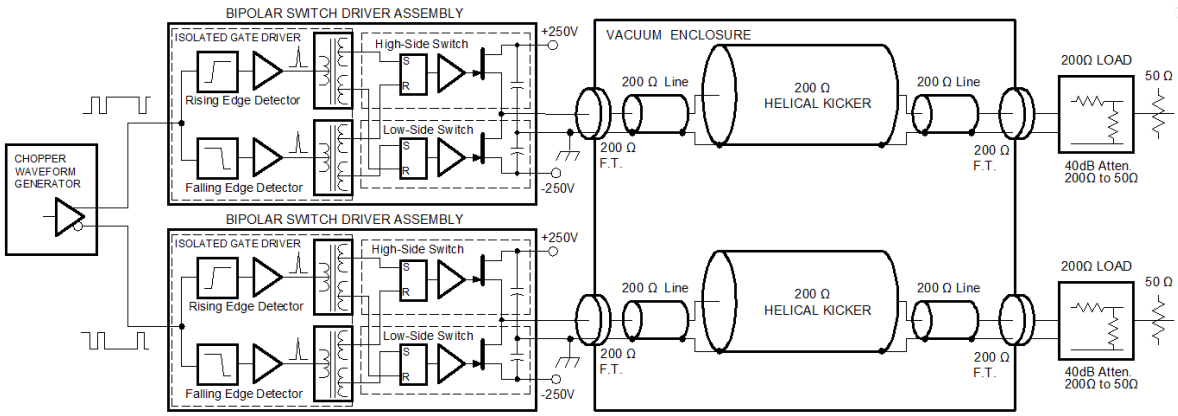

Figure 1: 200 Ω chopper electrical system block diagram. Two such systems are called for in the MEBT. Both driver and load are to be physically very close to the feed throughs.

tube is to be water cooled. The ceramic chosen is a type of machinable AlN having 50 W/m/K thermal conductivity available from Ceramic Products, Inc. Vacuum compatible epoxy is to be applied between all ceramic to copper surfaces to assist thermal conduction. The wire is estimated to rise <10°C but has yet to be confirmed by testing.

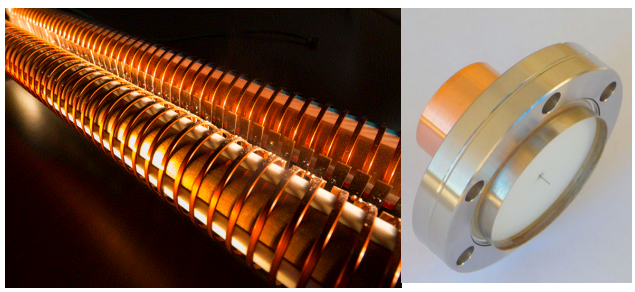

Figure 2: Hardware photos. a) Prototype kicker assembly. b) Cylindrical 200 Ω vacuum feed through.

The helix was modelled with 3D and 2D codes to determine wire height and helix pitch to achieve the desired characteristic impedance and traveling wave velocity. Agreements with a prototype helix were within 3-5%, but not quite good enough to provide precise dimensions. However, sensitivity data was obtained and then used to make adjustments to wire height and pitch of an existing prototype. A helix is in fabrication now with these adjustments.

Voltage tests revealed reflections from the far end of the helix in excessive of 10%, and TDR measurements revealed the characteristic impedance tapers down within the last turn or so at the ends to about 150 Ω. Modelling was used to evaluate optional solutions. The choice was to increase the impedance of the last turn by increasing the wire/ground spacing by 75%. This was done by decreasing the ground tube diameter under the last turn. Figure 4 shows the test result of applying this correction along with other minor adjustments achieving reflection level of ±3%.

Chopper Driver

The approach taking for the 200 Ω chopper driver was to develop a bipolar switch DC coupled to the helix. The required switching rates are those mentioned earlier, and rise/fall times need to be less than 2 ns, 5%-95%. Switching losses must be considered for the average rate of 35 MHz and are not trivial. A transistor's capacitive switching losses are CV^2f in a bipolar switch topology and amount to 3.5 W switching 100 V but 88 W switching 500 V having 10 pF Coss. The appeal to build a bipolar switch as a chopper driver was: (1) it has the DC coupled advantages; (2) designing a circuit from scratch for 200 Ω is easier than for 50 (at least in principle), and (3) the very low capacitance of available GaN FETs from Polyfet Devices, Inc. There is no single transistor available that can switch 500 V and handle its own capacitive switching losses at 35 MHz; but these FET losses come down with V^2 when connected in series to share voltage.

Current development effort is on a bipolar driver using cascode switches. Five FETs would be necessary per switch for 500 V with currently suitable and available FETs. The cascode switch is a modular design to allow for a variable number of common gate stages. A bipolar switch assembly is shown in Fig. 3 composed of 3-FET cascode switches.

Figure 1 shows the driver's major circuit blocks. The high-side switch floats with the load, so gate signal isolation must be designed for the maximum transient immunity of >250 kV/μs—well beyond commercial isolator ICs. (Low jitter fiber optic receivers are too physically large.) Narrow voltage pulses are generated at the ground-level from input rising and falling edges. These pulses set and reset latches on the cascode switches' control level that, in turn, reconstruct the ground-level chopper signal waveform and preserve timing information. Dead time is a settable parameter necessary to prevent shoot-through current. The cascode control board level includes a discrete GaN FET driver circuit, again. Not shown in any diagram is a 1 MHz, regulated AC voltage distribution system that delivers power to every isolated circuit board. Both high and low-

Copyright © 2013 CC-BY-3.0 and by the respective authors

side switches are totally isolated from power/ground. Thus, the driver can be biased with bipolar voltages or with a voltage offset from ground.

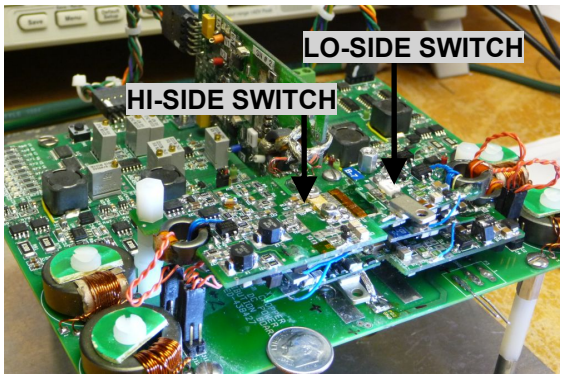

Figure 3: Bipolar switch composed of 3-FET cascode switches mounted to power distribution board.

200 Ω Lines, Feed Throughs and Load

This design is sensitive to reflections at impedance discontinuities particularly downstream of the helix. Reflections are re-reflected off the driver because of its very low impedance. Modelling verified a flat 200 Ω microstrip as the best line type to match to the helix. Feed throughs were custom made by MPC Products, Inc., and designed having isolated, cylindrical 200 Ω geometry; see Fig. 2b. Finally, the 200 Ω load was made by Elab, Inc. utilizing commercial attenuators but includes an input compensation network to minimize reflection.

PRELIMINARY RESULTS

Figure 4 is the through-voltage measurement observed at the 200 Ω load/attenuator output revealing the degree to which the 200 Ω transmission lines and load are matched to the helix. The major reflections are due to helix end effects that are not completely eliminated. Figure 5 shows the hardware included in this measurement. An assembly is currently being constructed that will include the feed throughs.

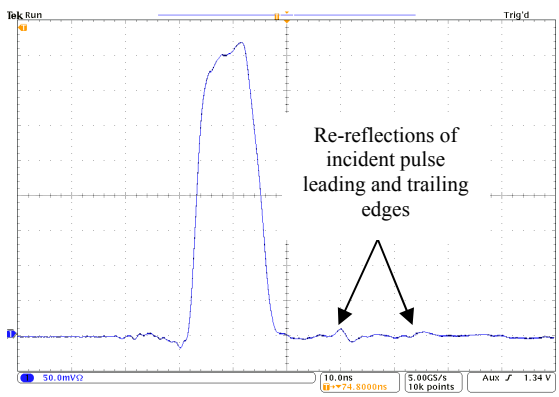

Figure 4: Through-voltage of incident pulse and all re-reflections. Reflection levels are ±3%.

Development efforts first investigated a cascode switch using 5 FETs and achieved 480 V but had issues. These were addressed and incorporated into the current design. A single stage bipolar switch was assembled to demonstrate switching to at least 100 V. This circuit (in Fig. 5) was successfully tested at 35 MHz CW and switches at 81 MHz easily for PXIE's 2 μs requirement. Current efforts are with 3-FET cascode switches in a bipolar assembly, but results are two preliminary to report.

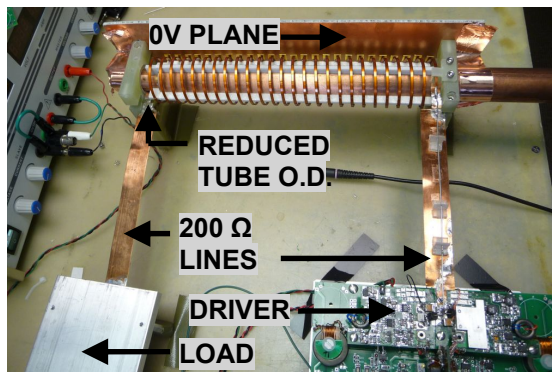

Figure 5: Reflection test setup. Helix is a 26 cm long prototype driven by 100 V (alt. ±50 V) bipolar switch.

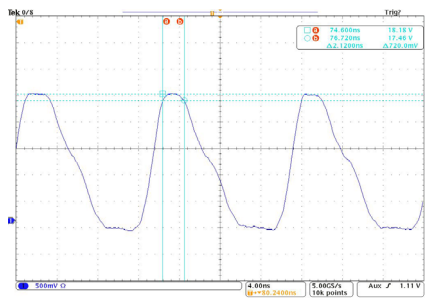

Figure 6: Helix through-voltage driven 0-100V, at 75 MHz. Bipolar switch driver is composed of 1-FET switches: <2 ns rise time (5-95%), fall time includes 2.4 ns dead time, 2.1 ns flattop.

SUMMARY

A 200 Ω microstrip line helix has been demonstrated to be a viable kicker option. Reflections are manageable. GaN FETs have been shown to be a good choice for a fast switch driver. A 100 volt single stage bipolar switch has been built and tested successfully for the continuous and burst mode operation requirement. A 300 volt 3-stage bipolar cascode switch is presently under development.

STORAGE RING AND INTERACTION REGION MAGNETS FOR A $\mu^+\mu^-$ HIGGS FACTORY*

A.V. Zlobin#, Y.I. Alexahin, V.V. Kapin, V.V. Kashikhin, N.V. Mokhov, S.I. Striganov, I.S. Tropin, FNAL, Batavia, IL 60510, USA

Abstract

A low-energy Muon Collider (MC) offers unique opportunities to study the recently found Higgs boson. However, due to a relatively large beam emittance with moderate cooling in this machine, large-aperture high-field superconducting (SC) magnets are required. The magnets need also an adequate margin to operate at a large radiation load from the muon decay showers. General specifications of the SC dipoles and quadrupoles for the 125 GeV c.o.m. Higgs Factory with an average luminosity of ~$2\cdot10^{31}$ $cm^{-2}s^{-1}$ are formulated. Magnet conceptual designs and parameters are reported. The impact of the magnet fringe fields on the beam dynamics as well as the IR and lattice magnet protection from radiation are also reported and discussed.

INTRODUCTION

The major advantage of a μ+μ- collider-based Higgs Factory (HF) [1] is the possibility of direct precise measurement of the Higgs boson mass and width. According to the general concept of such a machine [2], muons - in order to keep their longitudinal emittance and energy spread low - undergo only partial cooling leaving their transverse emittance relatively high (see Table 1). Therefore quite small values (a few cm) of the β-function at the Interaction Point (IP) are required resulting in a large beam size in the Final Focus (FF) quadrupoles.

Together with the necessity of magnets and detector protection from the muon decay showers, this leads to very large magnet apertures imposing challenging engineering constraints for magnet design and creating beam dynamics issues with magnet field quality and fringe fields.

Table 1: Higgs Factory Parameters

Parameter	Unit	Value
Circumference	m	300
Beam energy	GeV	62.5
Transverse emittance, $\varepsilon_{\perp N}$	(π)mm·rad	0.3
Longitudinal emittance, $\varepsilon_{\parallel N}$	(π)mm·rad	1.0
Beam energy spread	%	0.003
β^*	cm	2.5
Repetition rate	Hz	30
Muons/bunch	-	2×10^{12}
Average luminosity	$cm^{-2}s^{-1}$	2.5×10^{31}

Table 1 gives basic parameters of the HF Storage Ring (SR) preliminary design presented in [3]. The conceptual design and analysis of the Interaction Region (IR) large-aperture magnets has shown that the IR magnets with apertures ~500 mm and operation fields ~12 T are feasible using the Nb_3Sn technology.

This paper continues the design studies of the HF IR and SR magnets. The impact of the magnet field quality and fringe fields on the beam dynamics, the IR and lattice magnet protection from radiation are also discussed.

STORAGE RING LATTICE

The HF lattice layout and the beam sizes are shown in Fig. 1 for parameters given in Table 1. The IR includes FF quadruplet (with first quadrupole Q1 at 3.5 m from IP) and dipoles generating dispersion for subsequent 3-sextupole chromaticity correction [4]. The latter is necessary despite small energy spread to compensate the path length increase due to betatron oscillations. The matching section allows for β^* variation in wide range.

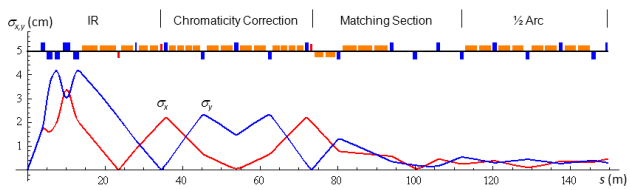

Figure 1: Layout and beam sizes in HF half-ring. Quadrupole magnets are shown in blue, dipoles in orange and sextupole correctors in red color.

MAGNET REQUIREMENTS

Table 2 shows the IR magnet parameters discussed in [3]. The orbit sagitta in IR dipoles is quite large – 8.1 cm. However, it does not affect the IR dipole bore diameter since it is determined by a large vertical beam size.

Table 2: IR Magnet Specifications

Parameter	Q1	Q2	Q3	Q4	B1
$10\sigma_{max}$ (mm)	234	411	339	415	405
G_{nom} (T/m)	74	-36	44	-25	0
B_{nom} (T)	0	2	0	2	8
L_{mag} (m)	1.00	1.40	2.05	1.70	4.10
Coil aperture (mm)	267	444	372	448	438
Quantity	1	2	1	1	2

Tables 3-4 present the maximum values of main parameters for the dipoles (B) and quadrupoles (Q) used in the chromaticity section (CS), the matching section (MS) and the arc (ARC). The most challenging magnets are the CS dipoles (B_{CS}), some MS dipoles (B_{MS}I) and the arc dipoles (B_{ARC}) which need high nominal operation field up to 10 T. This field level requires using the Nb_3Sn technology.

The magnet aperture outside the IR region reduces from 231 mm in CS quadrupoles to 92 mm in arc dipoles. Note, that the aperture size in the arc is defined by the arc dipoles due to a relatively large beam sagitta. To standardize the magnet designs in different sections it was decided to use for this study two different aperture sizes – large ~231 mm in CS and adjacent part of MS, and small ~130 mm in ARC and adjacent part of MS.

Table 3: SR Dipole Magnet Specifications

Parameter	B_{CS}	$B_{MS}I$	$B_{MS}II$	B_{ARC}
$10\sigma_{max}$ (mm)	225	222	127	92
B_{nom} (T)	10	10	6.4	10
L_{mag} (m)	1.8	2.4	3.6	3.0
Coil aperture (mm)	258	255	160	120
Quantity	13	2	3	8

Table 4: SR Quadrupole Magnet Specifications

Parameter	Q_{CS}	Q_{MS}	Q_{ARC}
$10\sigma_{max}$ (mm)	231	130	46
B_{nom} coil (T)	5.3	5.5	3.3
Length (m)	1.0	1.0	1.0
Coil aperture (mm)	264	163	79
Quantity	5	5	4.5

MAGNET DESIGNS AND PARAMETERS

The aperture of magnet coil in this study was defined as $10\sigma_{max}$ plus 30 mm for the beam pipe (BP) and absorber (ABS) plus 3 mm for BP insulation and helium channel. In the IR magnets the coil aperture was increased by ~50 mm with respect to this definition and limited by two sizes, 320 mm in Q1 and 500 mm in Q2-Q4 and B1-B2, to reserve extra space for IR magnet protection against radiation [3]. The coil aperture of CS and adjacent MS magnets was increased to 270 mm, and in ARC magnets and adjacent MS magnets to 160 mm. This allows using thicker inner absorbers in arc magnets if necessary.

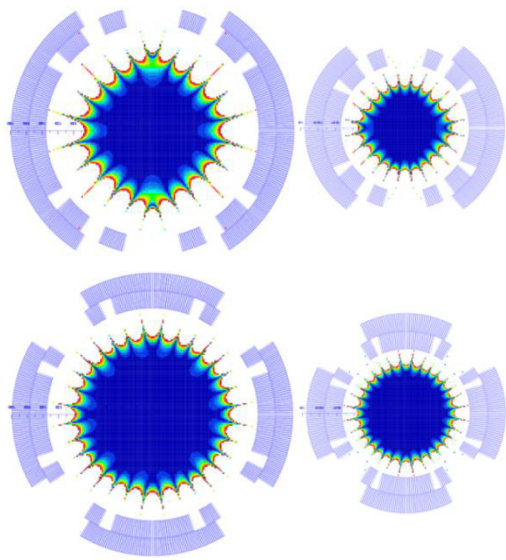

Figure 2: Coil cross-sections of HF SR dipoles (top) and quadrupoles (bottom) with 270 mm (left) and 160 mm (right) apertures.

The coil cross-sections were optimized with the ROXIE code [5] to achieve the required nominal operation field or gradient with margin and good field quality in the beam area of 8σ. As in our previous studies [3] the conceptual designs of the HF SR magnets are based on a 42-strand Rutherford cable, 21.6 mm wide and 1.85 mm thick, made of a 1 mm strand with Cu/nonCu ratio of 1.0. The cable is insulated with a 0.2 mm thick insulation.

All magnets are based on 2-layer, shell-type coils with remote iron yoke used mainly to reduce fringe fields. The optimized D and Q coil cross-sections for CS, MS and ARC sections are shown in Fig. 2.

The main magnet parameters at 4.5 K are reported in Table 5. Relatively low field level in CS, MS and ARC quadrupoles allows using the traditional NbTi technology. Therefore, the parameters of these magnets were calculated for both conductor options, NbTi and Nb_3Sn.

Table 5: Nominal Magnet Parameters at T_{op}=4.5 K

Parameter	Dipole		Quadrupole	
Coil ID (mm)	270	160	270	160
Max B_{op} (T)	10.0	10.0	-	-
B_{max} (T)	14.1	14.2	-	-
Max G_{op} (T/m)	-	-	33	36
G_{max} (T/m)	-	-	54.1*/96.6#	90.0*/160.8#
B_{max} coil (T)	15.8	15.6	8.7*/15.3#	8.3*/14.7#
Fraction of SSL	0.71	0.71	0.61*/0.34#	0.4*/0.22#
L (mH/m)	54.1	20.5	24.5	8.7
E_{op} (MJ/m)	4.33	1.84	0.59	0.12
F_{x_op} (MN/m)	9.25	5.98	0.89	0.25
F_{y_op} (MN/m)	-3.96	-2.66	-0.93	-0.28

* - NbTi; # - Nb_3Sn

The Nb_3Sn dipole magnets operate at 71% and the quadrupoles at 22-34% of their short sample limit (SSL) at 4.5 K. Using the same cable with NbTi strand in both quadrupoles reduces G_{max} to 54 and 90 T/m. However, the magnets still have quite large operation margin, they operate at 61% and 40% of the SSL for 270 mm and 160 mm quads respectively. The final choice of the superconductor for SR quadrupoles will depend on the results of radiation studies for these magnets.

Geometrical field harmonics at the corresponding R_{ref} are reported in Table 6. With optimized coil cross-sections the relative field errors in the area occupied by muon beams is ~10^{-4} (dark blue area in Fig. 2).

Table 6: Geometrical Harmonics (10^{-4}).

	ID, mm	R_{ref}, mm	b_3	b_5	b_6	b_7	b_9	b_{10}
D	270	90	-0.2	-0.1	-	0.2	1.2	-
	160	53	0.0	-0.1	-	0.5	1.1	-
Q	270	90	-	-	0.2	-	-	0.0
	160	53	-	-	0.1	-	-	0.0

The dynamic aperture (DA) on the plane of transverse particle positions at the IP and projection of the IR quad aperture onto this plane using linear optics functions is shown in Fig. 3. The DA analysis with MADX PTC code shows that field errors (after correction) reduce DA by a factor of 2 to a size of the magnet good field region.

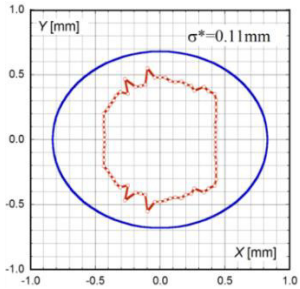

Figure 3: The dynamic aperture at IP and the projection of the IR quadrupole aperture (solid circle).

ENERGY DEPOSITION IN MAGNETS

Energy deposition and detector backgrounds induced by muon decays from both beams were simulated with MARS15 code [6] using our previous approach [7]. All the related details of geometry, materials and magnetic fields of the HF magnets in IR and SR were implemented in the 3D model along with a complete detector model, an optimized tungsten nozzle near IP and other components of the Machine-Detector Interface (Fig. 4).

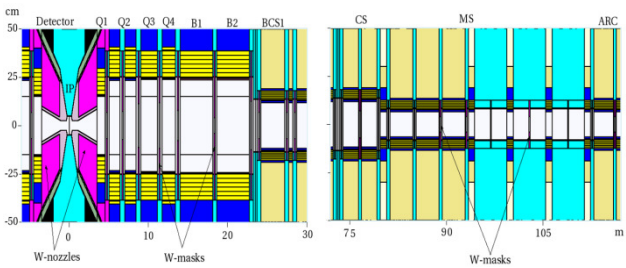

Figure 4: MARS model of HF MDI, IR and SR.

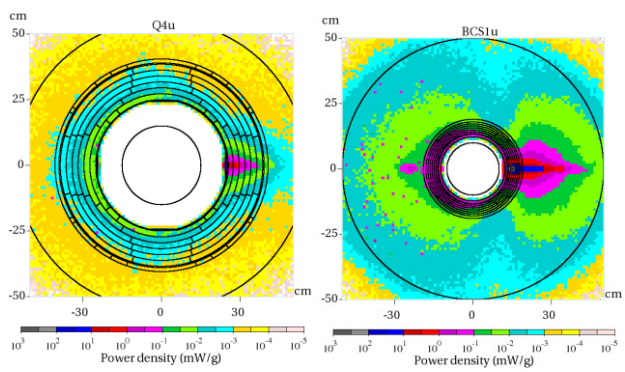

Figure 5: Power density (mW/g) in the IP ends of the Q4 quadrupole (left) and $B_{CS}1$ dipole (right).

To protect IR and SR magnets, 15 cm long, 10σ ID tungsten masks were installed in the magnet interconnect regions. Inner absorbers include up to 10-mm thick stainless steel liners inside each magnet with additional tungsten segments in both horizontal and vertical planes in some magnets along the ring.

Power density distributions were calculated for each collider ring magnet. The protection system performs adequately in the IR quadrupoles where the peak power density P_p is at or below the quench limit of ~5 mW/g for Nb_3Sn coils [3] (Fig. 5, left). However, it is ~10 times above the limit in B1 and B2 dipoles, and ~10^2 times above the limit for dipoles in CS, MS and ARC sections (Fig. 5, right). Additional tungsten inserts with the total radial thickness up to 5 cm, and a proper room for them in magnet apertures, are needed to reduce P_p below the limit.

Figure 6 shows the calculated dynamic heat load W_d in IR and SR magnets for both muon beams. The presented W_d values include both cold and potentially warm parts of magnet cross-section. The W_d in SR magnets is ~1 kW/m for the HF parameters of Table 1 except for the two dipoles at either end of the open section in MS and ARC, where it is ~2.5 kW/m. Note, that in spite of the low beam energy, the high number of decays in the HF keeps the level of W_d large as in the high energy machines [4], [7]. To reduce the W_d in the cold part of SR magnet system by ~100 times to the acceptable level of ~10 W/m, absorbers and masks have to be thermally insulated from the cold masses. It also requires extra space in magnet apertures.

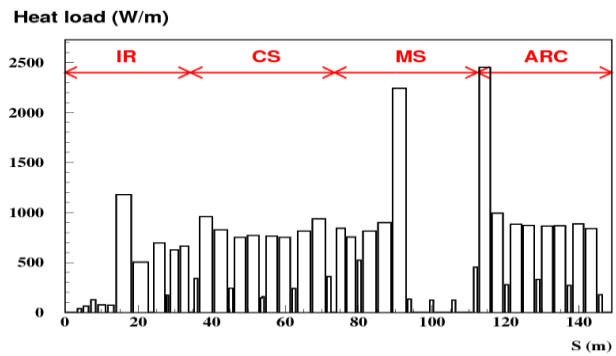

Figure 6: Dynamic heat load in IR and SR magnets.

SUMMARY

Preliminary design of HF based on the 125 GeV c.o.m. $\mu^+\mu^-$ collider including the IR and SR layout and the magnet system design concept was developed, and analysis of the beam dynamics and radiation issues was performed. It was found that protection of SR magnets from radiation and reduction of the dynamic heat load in the cold part of magnet cryostat present a serious problem and need further investigations and improvements including reiteration of the SR magnet system design.

Abstract

The Helical Cooling Channel (HCC), a novel technique for six-dimensional (6D) ionization cooling of muon beams, has shown considerable promise based on analytic and simulation studies. However, the implementation of this revolutionary method of muon cooling requires new techniques for the integration of hydrogen-pressurized, high-power RF cavities into the low-temperature superconducting magnets of the HCC. We present the progress toward a conceptual design for the integration of 805 MHz RF cavities into a 10 T Nb_3Sn based HCC test section. The concept we present includes a decoupling of the RF and magnetic channels and the pressure and thermal barriers needed within the cryostat to maintain operation of the magnet at 4.2 K while operating the RF and energy absorber at a higher temperature.

INTRODUCTION

A HCC consisting of a pressurized gas absorber imbedded in a magnetic channel that provides solenoid, helical dipole and helical quadrupole fields has shown considerable promise in providing six-dimensional cooling for muon beams. The energy lost by muons traversing the gas absorber needs to be replaced by inserting RF cavities into the lattice. Replacing the substantial muon energy losses using RF cavities with reasonable accelerating fields will require a significant fraction of the channel length be devoted to RF. However, to provide the maximum phase space cooling and minimal muon losses, the helical channel should have a short period and length. Demonstrating the technology of such a cooling channel would represent enormous progress toward the next energy frontier machine. We propose to design and build the 10 T, 805 MHz segment of a HCC. This corresponds to the second section of the HCC design discussed in [1].

KEY TECHNOLOGICAL BARRIERS

The key technological barriers include cooling of the helical solenoid coils made of the low temperature superconductor (LTS) in the presence of RF cavities embedded in the channel and operation of RF cavities in the presence of a magnetic field. Recent results [2,3] show pressurizing the RF cavities may solve the latter challenge. The first challenge, we believe, can be addressed by reducing the size of each RF cavity utilizing a low loss dielectric insert to ease physical constraints for a given frequency. This allows enough room between the cavities and the coils for the magnet coils, the magnet cryostat, the hydrogen pressure vessel, and the RF coaxial feeds to the individual cavities. Calculations show that the heat loads will be tolerable and RF breakdown of the inserts will be suppressed by the pressurized hydrogen gas. The work done on this problem is one of the key accomplishments of the project and has led to a solution to the engineering problem of feeding the RF power through the magnet cryostat.

The following sections describe more fully the dielectric cavity design concepts and the design concept for an integrated 10 T, 805 MHz HCC.

DIELECTRIC LOADED CAVITIES

We have reported progress on the design and testing of dielectric loaded cavities for a HCC in detail elsewhere [3,4]. Here we give a summary and then devote more time to the alternative technology of re-entrant cavities (see next section). The key idea behind using dielectric loaded cavities is the reduction of cavity radius and the associated easing of engineering demands that comes along with it. One can decouple the RF and magnetic channels.

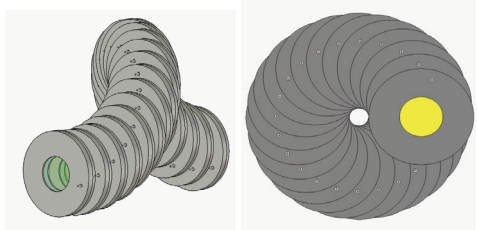

Figure 1: (Left) Illustration of RF cavities aligned to fit inside a HS magnet and cryostat. (Right) The end view shows the dielectric-filled region of the cavity (gray), where the yellow area corresponds to the region that the beam passes through. The small holes indicate the locations of the power feeds. Beryllium grids separate the cavities to make them RF pillboxes while not impeding oxygen-doped hydrogen flow. These are some of the building blocks of the integrated channel (see Figures 4 and 5).

RE-ENTRANT RF CAVITY ALTERNATIVE

As an alternative to using dielectric inserts for reducing the size of the RF cavities in order to fit them into a magnetic channel, we also consider a re-entrant RF structures. It is known that the cavity frequency can be lowered if one employs a half/quarter wave type upper torso. This increases the magnetic field at the perimeter.

Alternatively, one can argue this is a re-entrant structure with capacitive loading.

Both ways lower the frequency for a given radius. The benefits of this approach are:

- Reduced power requirements, even though some real estate length is lost due to smaller gap than cavity length.
- Reduced capital costs for cavities.
- Reduced operational costs for cavities.
- Reduced number of RF sources and cavities per helical period.
- Reduced costs for the RF system
- Required peak power in range of what can be done with magnetrons (< 1MW).
- Structure is easy to build, i.e. with the aforementioned idea of utilizing an outer pressure vessel (no pressure difference across cavities) we can use 3mm thin copper sheets and deep-draw cavity shape similar to SRF cavities, then EBW parts (full penetration welds). Tune and weld.
- High Q0, several factors higher than when using a ceramic.
- No triple joint junction and thus no associated field enhancement.
- Performance not limited by dielectric strength of the ceramic but RF breakdown limit in GH2.
- Mitigation of cross talk between cavities through gridded windows.
- The cavity design makes use of offset windows and re-entrant shapes to follow the helical path. Enough clearance for beam while minimizing Be-window radius. Field asymmetry along helical path is small as re-entrant shape (planar front) homogenized and concentrated field along gap and path of interest.
- More space for instrumentation etc.

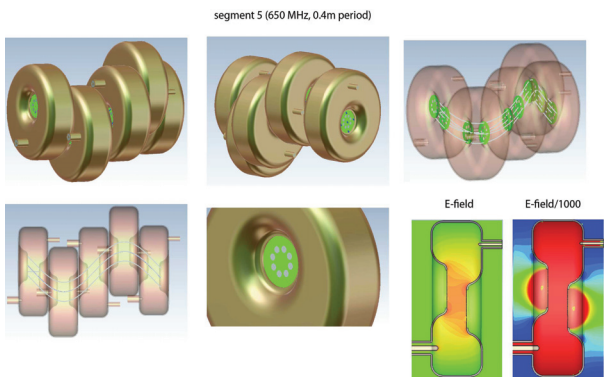

Figure 2. 3D conceptual design and initial simulations for the re-entrant cavities that could be used in mid-section of an HCC.

Currently we have explored two options for reducing the RF cavity sizes. Both options allow the cavities to be embedded in the helical magnetic/high pressure channel. The final technology choice will be made once the detailed simulation of the full cooling channel has been performed.

10 T Nb_3Sn HELICAL SOLENOID

Details of the magnet design effort to date have been reported elsewhere [4]. Here we give a summary for completeness. The invention of the Helical Solenoid (HS) magnet provides a simple configuration of coils to generate the solenoid, helical dipole, and helical quadrupole field components required for the HCC. The HS overcame the difficulty of very high coil currents required to produce the quadrupole field component in an ordinary magnet design. Note that the HS is not a bent solenoid. In a HS the coil planes are normal to the z axis, while a bent solenoid would have the coil planes normal to the equilibrium orbit.

Multi-coil HS magnet sections have been designed, constructed, and tested using NbTi [5] for the lowest field (5T, four coil) and YBCO for the highest field (15 T, 6 coil) HCC segments [6]. The coil design for the intermediate HCC section (10 T, continuous coil) is being made to provide a technology demonstration and develop practical experience with the construction and performance of a Nb_3Sn helical solenoid.

Figure 3: Conceptual drawing (left) and 3d printer version (right) of the Nb_3Sn HS spool and conductor that will be fabricated and tested in the Fermilab Vertical Magnet Test Facility. The test will use two layers of cable.

Additional studies are being performed with elliptical coil configurations. These are beyond the baseline studies designed to see if we can further ease overall engineering burden and improve performance (these studies are presented at this conference [7].

INTEGRATED HCC DESIGN

Figure 4 shows the essential features of a compact design of an HCC module where hydrogen-pressurized, dielectric-loaded RF cavities fit inside HS magnet coils. In this concept, the HS magnet and its 4 K cryostat are thermodynamically independent of the RF cavities and their power sources. Figure 4 shows a cut-away view of a module with 20 RF cavities that could be the first device to be built and tested. Figure 5 shows a three-dimensional view of the same module

Copyright © 2013 CC-BY-3.0 and by the respective authors

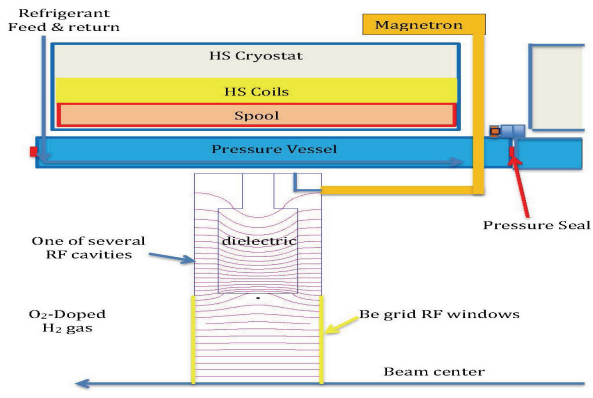

Figure 4: Conceptual diagram showing the features of a beam-cooling module with dielectric-loaded RF cavities, Be RF windows, pressure vessel, HS coil, and its cryostat.

The coax feed for each cavity comes from a magnetron power source fed through a break in the magnet structure where the magnet cryostats end [4]. The pressure vessel wall is refrigerated by circulating liquid or gas (water, LN2, or gaseous Helium), and could be machined to contain the coax power leads. Compared to earlier design concepts, this one has only one break between coils per module and no penetrations of the cryostat by RF feeds.

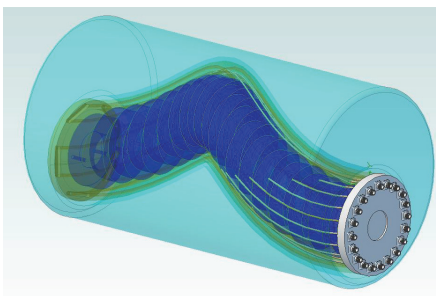

Figure 5: Three-dimensional visualization of Figure 4.

SIMULATION AND OPTIMIZATION

The design will be validated for muon cooling performance via G4Beamline [8] simulations. Of key importance will be the effect of the gaps between cryostats on the cooling performance. From the engineering design we will have detailed understanding of the fields within and between modules. The effect of the gap on the field will be propagated into G4Beamline and the effects studied. It is expected that any ill-effects of the gap can be overcome, at least in part, by having increased fields at the end of the modules. This study will be part of a larger study of field error tolerances.

The details of the dielectric cavities (and re-rentrant cavities) will also be ported to the simulation code. Additionally, all known details including RF coupling scheme will be taken into account in the simulation effort.

The G4beamline simulation will be used synergistically with the RF and magnet design tools to ensure the engineering design is able to provide a system optimized for cooling performance.

SUMMARY

Based on recent results we are moving toward combining several Muons, Inc. SBIR-STTR-developed inventions in an innovative practical engineering solution for a 10 T, 805 MHz muon-cooling channel suitable for a muon collider. The design will incorporate the HCC [9], a HS magnet [10], hydrogen-pressurized RF cavities [11], phase and frequency-locked magnetron power sources [12], emittance exchange using a continuous absorber [9], and be optimized using G4beamline Muon beam cooling simulations. The goal of the project is to optimize beam cooling for maximum collider luminosity while including all known engineering constraints, from material properties to affordable RF power sources and cryogenic loads, and to generate an engineering design of a segment of a channel as a prototype to build and test.

Demonstrating the technology of such a cooling channel would represent enormous progress toward the next energy frontier machine. We propose to design and build the 10 T, 805 MHz segment of a helical cooling channel.

DISPOSITION OF WEAPONS-GRADE PLUTONIUM WITH GEM*STAR

R.P. Johnson*, G. Flanagan, F. Marhauser, Muons, Inc., Batavia, IL, USA
C. D. Bowman, R. B. Vogelaar, ADNA Corp., Los Alamos, NM, USA

Abstract

An accelerator system like the SNS at ORNL can generate spallation neutrons to convert fertile elements like U238 in spent nuclear fuel (SNF) or Th232 into fissile isotopes to provide high temperature heat using technology developed at the ORNL Molten Salt Reactor Experiment. In the Green Energy Multiplier * Subcritical Technology Alternative Reactor (GEM*STAR) [1], the accelerator allows subcritical operation (no Chernobyls), the molten salt fuel allows volatiles to be continuously removed (no Fukushimas), and the SNF does not need to be enriched or reprocessed (to minimize weapons proliferation concerns). The molten salt fuel and the relaxed availability requirements of process heat applications imply that the required accelerator technology is available now. The accelerator can also be used to control the burning of fissile isotopes developed for weapons. A new opportunity is being considered by Russian and American scientists to use GEM*STAR to reduce the world inventory of weapons-grade plutonium leaving only remnants that are permanently unusable for nuclear weapons. This application could expedite the exploitation of this new accelerator-driven technology.

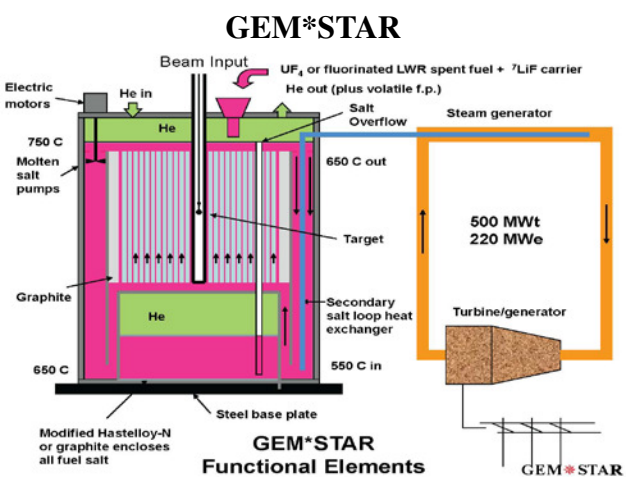

Figure 1: Conceptual arrangement of a GEM*STAR reactor unit configured to produce electricity. To produce diesel fuel, the secondary salt loop heats CH2 and H2O to produce CO and H2 for the Fischer-Tropsch process.

GEM*STAR is a graphite-moderated, thermal-spectrum, molten salt fueled reactor that is operated using an external accelerator to direct protons onto an internal spallation target. GEM*STAR can be operated with many fuels, without redesign, for process heat and/or for electricity generation. Figure 1 shows its basic components, where the active volume is 93% graphite (gray) and 7% molten salt made up of an appropriate eutectic mixture of lithium, uranium, plutonium, and/or thorium fluorides with a melting point above 500 C. Safety features of the design include the 500 MWt power output design limit, corresponding to not needing 1) a critical mass of fissile material for operation or 2) "defense in depth" measures for loss-of-coolant accidents since the heat generated by decays of fission products after the accelerator is turned off can be dissipated by passive external air cooling.

A helium flow over the hot core removes volatile radioactive isotopes and carries them to a relatively small underground tank where they are separated out cryogenically or with a centrifuge and then safely stored while they decay. This reduces the inventory of volatile isotopes in the reactor by a factor of a million compared to reactors used at Fukushima.

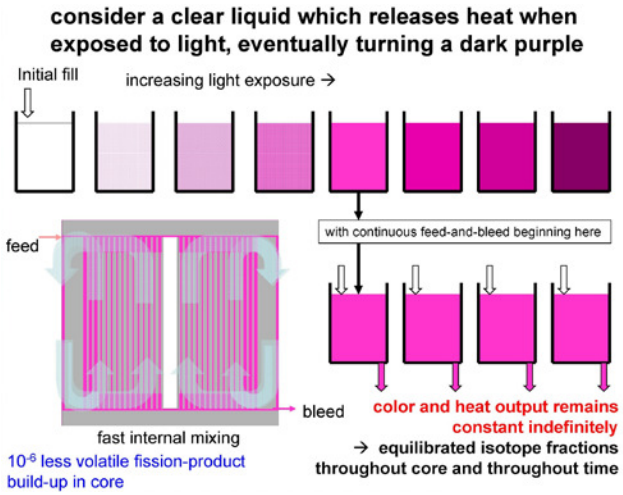

Figure 2: Concept of operating with equal fill and removal rates to maintain a constant reactor performance.

An essential feature of the design is the concept of feeding the reactor with a steady flow of fuel such that the concentration of fission products within the reactor stays constant for most of the 40-year reactor lifetime. As the fuel is fed into the reactor at a rate that maintains the 500 MWt output, an equal amount leaves the core through the salt overflow shown in figure 1 into a storage area under the core. Figure 2 shows an equivalent diagram of how the concentration of fission products reaches an equilibrium that can be maintained by this concept of adding molten salt fuel and removing it at the same rate.

Although the first approach to equilibrium takes some time (~5 years), a subsequent reactor can use the molten salt accumulated under the first reactor to start in an equilibrated state. Note that the heat from decaying reaction products will keep the overflow liquid from

* rol@muonsinc.com

solidifying and that the radioactive fuel under the core can be moved to the next reactor using helium gas pressure.

We take the 1 MWb performance of the SNS SRF Linac at less than 10% duty factor as an existence proof that a CW Linac could make at least 10 MWb. Further, molten salt fuel for off-line process heat is an "end-run" around the reliability questions that have usually been raised regarding accelerator-driven reactors. The most stringent requirement has been the need to avoid accelerator trips of even a few seconds because of thermal stresses and consequent fatigue of solid pellets in fuel pins. This objection is not applicable to molten salt fuels. Longer-term interruptions that may affect electricity production are also not very important for off-line production of diesel fuel, which is our first objective.

One of the required safety aspects of GEM*STAR is the use of a proton accelerator to allow subcritical operation. Without a critical mass in the core, fission stops when the accelerator is turned off. In addition, GEM*STAR with accelerator, molten salt fuel, and graphite moderator allows the reactor itself to be simpler, less expensive, and intrinsically safe. Namely, GEM*STAR does not need mechanical control rods, a containment vessel to protect against escaping volatile radioactive elements, or a pressure vessel. Expensive chemical reprocessing is not needed for several fuel cycles such that it can be put off for 200 years.

In short, the complexity of modern nuclear reactors that many people are concerned by is shifted in GEM*STAR such that the complexity is in the accelerator, not the reactor or the fuel.

People sometimes cite problems with graphite reactors due to the Wigner Effect, wherein accumulated neutron-induced atomic displacements suddenly realign and cause an energy spike. In early days of graphite reactors, the temperature had to be periodically raised above 250 C to anneal the graphite to prevent this (see the Wikipedia articles on Wigner Effect and Windscale Fire). Annealing is not necessary in the GEM*STAR design, which operates above the annealing temperature.

Fast spectrum reactors or breeder reactors are often cited as a method to do what we want to do with GEM*STAR. The usual question is "why use an accelerator to do what can be done with a control rod?"

Here are some reasons. Compared to a thermal spectrum made possible by graphite moderator, the fission cross-sections for a fast reactor are many times smaller and the relative sensitivity to fission products is greater. This means you need many more neutrons (requiring more than 100 critical masses in the reactor), more responsive control rod feedback (the fraction of delayed neutrons is less than in a normal reactor), and the fuel has to be reprocessed to remove the fission products (chemically separated, which is a weapons proliferation concern, and an added expense).

WEAPONS GRADE PLUTONIUM (W-Pu)

The GEM*STAR design is appropriate for many fuels, especially to convert fertile material to fissile ones (U238 to Pu239 and Th232 to U233). Where the need is greatest depends on the country and situation. In the US, SNF is a growing issue that could be addressed with GEM*STAR, while in India, thorium is abundant and power needs are great.

However, with no change in design, GEM*STAR can provide neutrons to control reaction rates for fissile materials that were produced for weapons. As we will show, it destroys W-Pu so well that it is the most compelling first application. That it can turn a $50B expense into a profit for the US also adds to its attraction.

A plutonium bomb uses high explosives to compress Pu239 to form a critical mass. At just the right time in the compression, neutrons are injected into the mass to initiate the explosion. If enough Pu240, a neutron emitter, is in the mass, it can cause the explosion to start prematurely and reduce the effectiveness of the explosion. Weapons-grade plutonium, then, requires less than 7% Pu240. The US and Russia made many tonnes of W-Pu. According to the year 2000 U.S.-Russian Plutonium Management and Disposition Agreement [2], each country should each destroy at least 34 tonnes of it. The agreement specifies that each country must agree to how the other achieves this goal and that the two countries should destroy the W-Pu in lock step.

The present situation is that the US has decided to mix the W-Pu with uranium as oxides (MOX) to be placed in fuel rods to be burned in conventional light water reactors. Russia's plan is to use a fast breeder reactor.

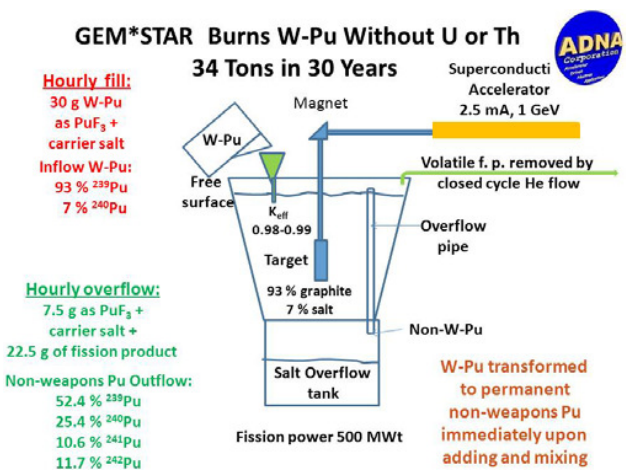

Figure 3: A GEM*STAR unit to generate heat by burning W-Pu while making remnants unusable for nuclear weapons. Four GEM*STAR units will treat 34 tonnes of W-Pu to provide 80 billion gallons of diesel fuel, which is about what the DOD needs for the next 30 years.

Figure 3 shows a conceptual picture of W-Pu utilization in GEM*STAR. A 2.5 MWb accelerator generates 500 MWt, reducing 30 g of W-Pu to 7.5 g per hour and adding the neutron generating isotopes Pu240 and Pu242. Figures 4 and 5 show the qualities of the W-Pu (back row-red) compared to the outputs of GEM*STAR (green), the

Copyright © 2013 CC-BY-3.0 and by the respective authors

Russian BN800 Fast Breeder (dark red), and the US MOX plan using Light Water Reactors (yellow). By passing the fuel through the reactor a second time, additional benefits can be seen. However, in the case of MOX, the fuel has to be reprocessed to remove fission products. GEM*STAR does not require reprocessing for a second pass.

Figure 4 is a comparison of the isotopes produced by the present plans of Russia and the US and by GEM*STAR. GEM*STAR does better because of the effectiveness of the thermal neutron spectrum both to produce Pu240 and Pu242, and to be less sensitive to fission products than MOX-LWR. Pu242 is even more effective than Pu240 to cause premature explosions in that it is a neutron emitter with a lifetime longer than Pu239.

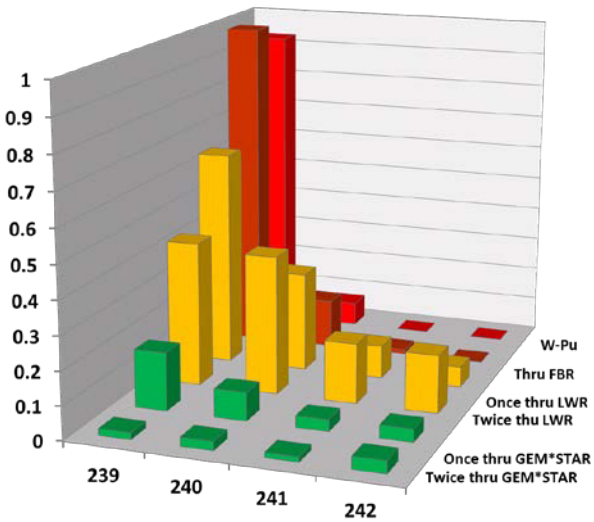

Figure 4: Isotopes remaining from the original W-Pu (red, 0.93 Pu239, 0.07 Pu240) after burning in the Russian FBR (dark red), once and twice in MOX-LWR (yellow), and once and twice in GEM*STAR (green).

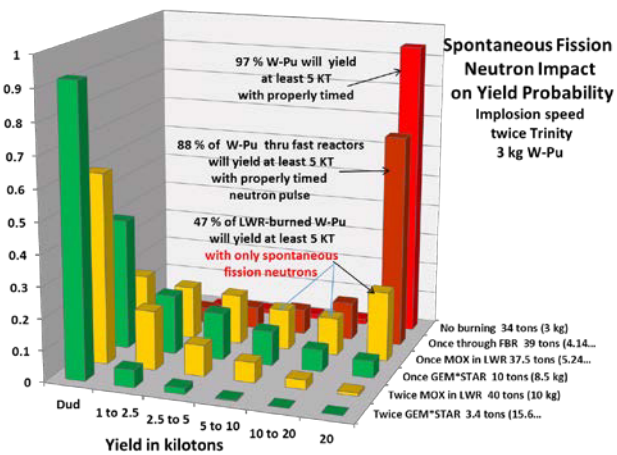

Figure 5: Yield probability of a nuclear weapon made from the output of the three reactors shown in Figure 4.

Figure 5 compares the yield probability for nuclear weapons material made from the output of the three reactors described in figure 4. The numbers have been scaled from calculations by J. Carson Mark [3]. Twice through GEM*STAR is clearly the best in that the amount of Pu239 is greatly reduced as is its utility for a weapon.

SUMMARY

The benefits of GEM*STAR for disposing of W-Pu can be summarized as follows:

- Burned W-Pu never useful for weapons
- Burned W-Pu never decays back to weapons useful material
- Conversion to non-W-Pu in minutes
- Pu isotopic mixture can be reduced from 34 tons to 0.2 tons if desired
- Also converts Commercial Pu (C-Pu) to-non-weapons-useful material
- Never requires a critical mass - no control rods
- No reprocessing or enrichment required
- No conversion to MOX; simple conversion of Pu metal and PuO_2 to PuF_3
- Fission energy converted to diesel and sold as green fuel to DOD
- No stored large volatile fission product inventory as in LWRs (Fukushima)
- Liquid fuel moved by He pressure; no radiation exposure to humans
- Operates at atmospheric pressure - No pressure vessel
- Passive recovery from a loss of coolant accident (LOCA)

The 2000 U.S.-Russian Plutonium Management and Disposition Agreement may be stalled because MOX plant costs at Savannah River have overrun, LWR sites in the US have not agreed to use the MOX fuel, and because the Russian breeder reactor solution lacks funding. The GEM*STAR design has been made to address many safety questions and to solve several problems. As discussed above, GEM*STAR can reduce weapons stockpiles more effectively than MOX or FBR and make a substantial profit doing it. We believe that following this approach in carrying out the US-Russian Agreement will demonstrate the unique features of GEM*STAR that will then lead to other successes in reducing SNF stockpiles and giving a jump-start to a new nuclear technology.

A DIPOLE MAGNET FOR THE FRIB HIGH RADIATION ENVIRONMENT NUCLEAR FRAGMENT SEPARATOR*

S.A. Kahn#, A. Dudas, G. Flanagan, J. Nipper, Muons, Inc., Batavia, IL 60510, USA
M.D. Anerella, R.C. Gupta, J. Schmalzle, BNL, Upton, NY 11973, USA

Abstract

Magnets in the fragment separator region of the Facility for Rare Isotope Beams (FRIB) would be subjected to extremely high radiation and heat loads. Critical elements of FRIB are the dipole magnets which are used to select the desired isotopes. Since conventional NbTi and Nb_3Sn superconductors must operate at 4.5 K, the removal of the large heat load generated in these magnets would be difficult. High temperature superconductors (HTS) have been shown to be radiation resistant and can operate in the 40 K temperature range where heat removal is an order of magnitude more efficient than at 4.5 K. The coils of this magnet must accommodate the large curvature from the 30° bend that the magnet will subtend. This paper will describe the magnetic and conceptual design for these magnets.

INTRODUCTION

The FRIB facility at MSU will provide isotope beams for physics research with intensities not available elsewhere [1]. The facility will enable scientists to study the properties of nucleonic matter providing insight into the nuclear processes in stars as well as tests fundamental symmetries in nuclear physics. Large quantities of various isotopes are produced when a high power 400 kW linac beam hits the target. FRIB will have the ability to accommodate various primary beams from protons to uranium with energies up to 200 MeV/u. The beams will be incident on a carbon target to produce a variety of secondary nuclides with various ionic charge states. The fragment separator which follows the target consists of a series of three quadrupole magnets to provide focusing and two dipole bend magnets to select the desired nuclei. The beam enters the first dipole magnet with a spread of rigidities. The undesired nuclides are removed with a beam dump between the two dipole magnets.

As the production rate for a specific rare isotope can be very small, the magnets in the fragment separator will have large apertures and strong magnetic fields to maximize the collection of these rare isotopes. The radiation level in the fragment separator magnets is quite high and these magnets need to be radiation resistant. The radiation dose seen by the first quadrupole after the target is estimated to be 2.5×1015 neutrons/cm2 per year (10 MGy/year) [2] which corresponds to 10 kW/m of deposited power. The deposited power will drop by an order of magnitude before reaching the first bending dipole. The high radiation environment influences the magnet design and the choice of materials used. Although NiTi and Nb3Sn are robust conductor materials in radiation, they must operate at 4.5 K which is not practical, since the anticipated heat load would be difficult and expensive to remove at that temperature. HTS conductors are reasonably resistant against radiation and have a significant current density at 40 K where the heat capacity of the refrigerants is much larger and the Carnot efficiency is greater making heat removal easier.

Brookhaven National Laboratory has been involved in an R&D program to develop the quadrupole magnets for pre-fragment separator at FRIB [3,4,5,6] using HTS conductor. The design of the fragment separator dipole magnets will rely on the technology that was learned.

MAGNETIC DESIGN

The design parameters of the fragment separator dipole magnet are shown in Table I. There are two such magnets in the fragment separator which is used to select the desired nuclide. Each of these magnets bends the beam by 30º with a nominal field of 2 T. The magnet should have field uniformity better than 0.7% over the useful beam aperture for operating field between 0.5 and 2.0 T. We have chosen a superferric design for this magnet where HTS coils are used to magnetize the iron which provides the desired field. The coils surround the iron poles and are enclosed in their individual cryostat. The coil and cryostat package are recessed behind the iron pole to protect them from a direct exposure to the radiation from the beam. However, the main source of radiation is from neutrons that penetrate into the coils. Most of the radiation and associated heat will be deposited into the iron yoke which is at room temperature. It is estimated that ~1 kW will be deposited into coil cryostats. Figure 1 shows a sketch of the sector bend magnet where only one half of the upper half of the iron is shown. The upper and lower coils must each carry 256 kA-turns to produce the design 2 T field in the beam aperture.

Table I: Fragment Separator Dipole Magnet Design Parameters.

Parameter	Value
Bending Radius	4 m
Bend Angle	30º
Magnetic Length along Beam Path	2.094 m
Nominal Central Field	2.0 T
Operating Field Range	0 to 2.2 T
Field Uniformity in Good Field Region	<0.7 %
Good Field Width in Bend Plane	0.3 m
Good Field Height in Non-Bend Plane	0.2 m
Total Current Required in Each Coil	256 kA-turns
Operating Temperature	40 K

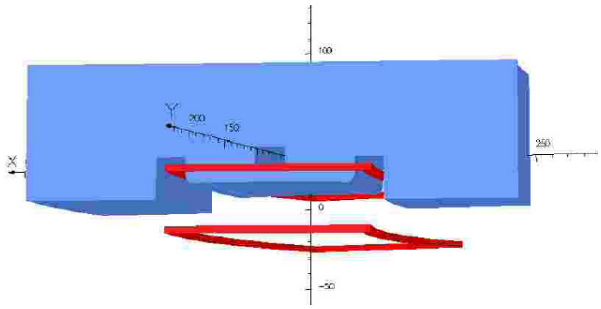

Figure 1: Model of the upper quarter of the magnet.

SUPERCONDUCTING COILS

We plan to wind the coils with YBCO conductor which will be operated at 40 K. The coils are located at a position where the field will be ~2.5 T with comparable radial and vertical components. As the critical current of YBCO conductor is sensitive to the local direction of the field we must design for the field component perpendicular to the conductor plane which has a lower critical current. To provide a safe margin against quenching the coils should be operated at two-thirds of the critical current at 40 K and in the $B_{\perp}$=2.5 T field. We expect that we can obtain 400 A using Super Power 12 mm (SCS 12050-AP) conductor under these conditions [7]. The coils will need 5.5 km of this conductor for the magnet.

An important consideration in the winding of the coils is that the field must preserve the transverse 2D profile. However the inner radius segment of the coil, which would be wound with negative curvature, is more difficult since the conductor will tend to spring back and unwind. Each turn must be constrained to avoid this from happening. A ¼ scale test coil with this configuration using the negative curvature segment was wound [8] and successfully tested. It was however necessary to use epoxy to hold the conductor turns together during the coil winding. We would like to minimize the use of epoxy on this magnet since organic materials can deteriorate in the radiation environment. It was decided to use a coil geometry where the inner radial segment was straight. The role of the coil in a superferric magnet is to magnetize the iron which determines the field quality. The configurations with straight and curved inner segments were compared using the Tosca 3-D EM finite element program. The fields of the two configurations differ by less than 1% in the good field region, which can be corrected by shaping the pole.

FIELD CALCULATIONS

The field error, ΔB/B, should be less than 0.7% for the operating field range from 0.7 to 2.0 T over the good field region defined in Table I. This is achieved by controlling the magnetization in the magnet yoke. Figure 2 shows the relative permeability in the iron. The iron on the smaller radius inner side shows more saturation than on the larger radius outer side. The rectangular hole in the hole is placed to effectively control the saturation. Figure 3 shows ΔB/B as a function of transverse position in the aperture for various field excitations. The field error is less than 0.7% for all values of B_0 in the region ±30 cm from the magnet center.

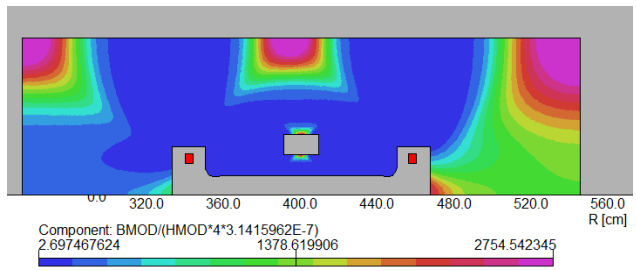

Figure 2: Relative permeability of the iron yoke is shown.

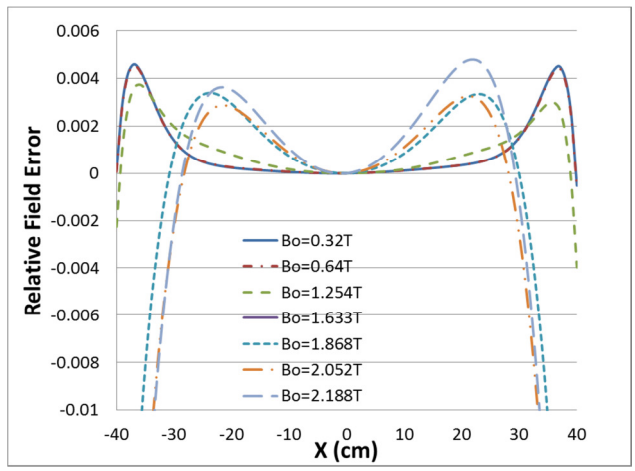

Figure 3: The relative field error, ΔB/B, as a function of position in the aperture. Curves are shown for different central fields ranging from 0.23 T to 2.188 T.

THERMAL AND STRUCTURAL ISSUES

The coils will feel substantial Lorentz forces when the magnet is fully energized. Table II shows the coil forces at the 2.0 T operating field and at the 2.2 T maximum design field. The large forces shown in Table II will require substantial mechanical support to minimize coil movement when the coils are powered. A preliminary study which attempts to constrain the coil forces with a support structure entirely within the cryostat produced coil deflections that were too large. External support that would penetrate into the cryostat and be anchored to the pole or flux return iron will be necessary. By using an external support the coil deflections are reduced significantly and the mechanical stress on the coil is reduced to 41 MPa which is acceptable. This approach will introduce some heat leaking into the cryostat. The design of the coil support will need to minimize the coil movement while also minimizing the heat generated.

Table II: Lorentz Forces per Unit Length on the Coil

Field	Coil	F_{radial}/Length	$F_{vertical}$/Length
Tesla		N/m	N/m
2.0	Outer	120735	105252
	Inner	-108828	108512

Two approaches to cooling the cold mass are being considered. One approach described in the next section is to cool the coil by heat conduction from flowing helium in an aperture in the cold mass. The other approach is to cool by convection by flowing helium through the coil itself.

TEST COIL PROGRAM

A test coil is being constructed as part of an R&D effort for the magnet design. The test coil will be full sized, wound with YBCO conductor, however will have fewer turns to make it affordable with the resources available. The program will develop manufacturing techniques for winding and handling the large coils. It will also demonstrate that the coil can operate in a steady state condition with the anticipated heat load expected for the radiation environment in this magnet. In the test program we will develop the winding tooling and the cryogenic cold mass. The winding tooling shown in Fig. 4 is comprised of the winding bobbin which is attached to a back plate for support. As the winding bobbin is relatively thin it is attached to a back plate to support it during the winding and assembly process. The conductor tape is wound around the outer surface of the bobbin using 6.5 m of conductor for each turn. Stainless steel tape is used between each conductor turn as insulation. The coil and bobbin are wrapped with Nomax to insulate the coil. Two coils are wound on their respective bobbins and put together in a double coil assembly. The conductor on each of the two coils is wound with the opposite sense of rotation so that the coils can be connected in series at the inner conductor attachment slots. The coils wound in this manner will have the same current direction. Table III shows the parameters describing the bobbin. After the two coils are assembled together the back plates are removed.

Table III: Winding Bobbin and Cold Mass Parameters

Parameter	Value
Overall Length w/Coils	241.72 cm
Overall Width w/Coils	120.81 cm
Bobbin Depth	1.27 cm
Bobbin Thickness	3.5 cm
Orbit Curvature	4 m
Curvature of Outer Bobbin Surface	4.54 m
Pole Angle	30º
Distance between Coil and Iron Pole	3.9 cm

Additional tooling will be added to the wound two coil assembly for cooling of the coils and mechanical support. Figure 5 shows a view of the wound coils with the associated tooling. Outside the coils is a stainless steel support followed by a cooling section containing a hole for pressurized helium gas (referred to as outer pusher in the figure). The cooling channel will likely be made of stainless steel to match the expansion coefficient of the support structure. We have chosen stainless steel because of its superior strength and will gun drill the cooling aperture. Because of the size of the coil mass stucture it will likely be necessary to assemble shorter pieces that will be welded together. Heater strips will be inserted during the winding to simulate the heat load. The helium flow rate and pressure will be adjusted to maintain the coils at the operating temperature.

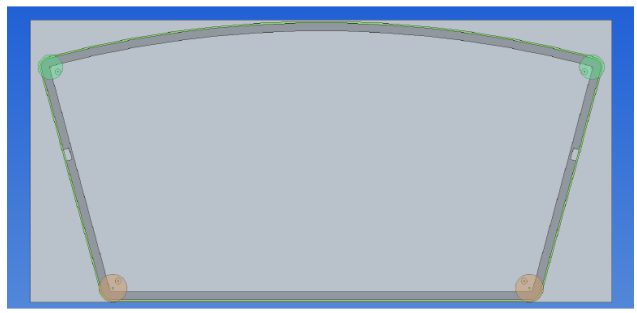

Figure 4: A sketch of the winding bobbin attached to the back plate support.

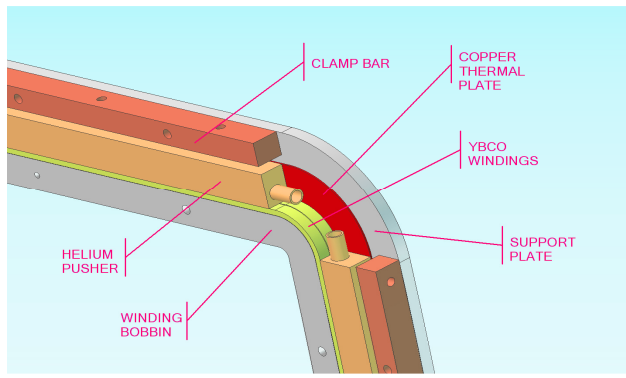

Figure 5: Open view of the double coil plus assembly structure with parts marked. Support plate on near side is removed to make inner parts visible.

RADIATION TOLERANT MULTIPOLE CORRECTOR COILS FOR FRIB QUADRUPOLES*

S.A. Kahn#, Muons, Inc., Batavia, IL 60510, U.S.A.
R.C. Gupta, BNL, Upton, NY 11973, U.S.A.

Abstract

Multipole correction insert coils with significant field strength are required inside the large aperture superconducting quadrupole magnets in the fragment separator section of the Facility for Rare Isotope Beams (FRIB). Corrector coils made with copper can not create the required field and conventional low temperature superconductors are not practical in the fragment separator magnets which will operate at 40-50 K. The corrector coils for this application should be made of HTS as are the main quadrupole coils in this magnet. There is a significant advantage to using HTS in these coils as it can withstand the high radiation and heat load that will be present. This paper will describe the innovative design suitable for coils with the complex end geometry of cylindrical coils. We will look at the forces in the corrector coils from the main quadrupole fields and anticipate possible coil distortions.

INTRODUCTION

The FRIB facility will provide isotope beams for physics research with intensities not available elsewhere. Large quantities of various isotopes will be produced when a high power (400 kW) linac beam from protons to uranium hits the target. The magnets in the fragment separator region, which selects the rare nuclides from the multitude of secondary fragments, would be subject to extremely high radiation and high heat loads [1,2]. Figure 1 shows a sketch of the first part of the FRIB fragment separator. The first quadrupole magnet after the target will see a flux of 2.5×10^{15} neutrons/cm^2 corresponding to 10 MGy/year. Similar high heat loads are faced by other quadrupole and corrector magnets in the fragment separator region. The baseline fragment separator design for the first several quadrupoles is based on HTS magnet operating at 38-50 K as the removal of a heat load of this magnitude would be difficult and expensive for NbTi or Nb_3Sn superconductors since they are operated at 4.2 K. HTS on the other hand have a significant critical current density at 40 K where the Carnot efficiency is greater and the heat capacity of the refrigerants is significantly higher making heat removal easier.

Corrector magnet inserts, which will be placed between the beam tube and quadrupole coils would face the same challenging situation as the other magnets in the fragment separator region. As corrector magnet inserts made with copper coils do not generate enough field strength and because conventional superconductors would not be practical in this environment, HTS wound coils will be necessary for these corrector inserts.

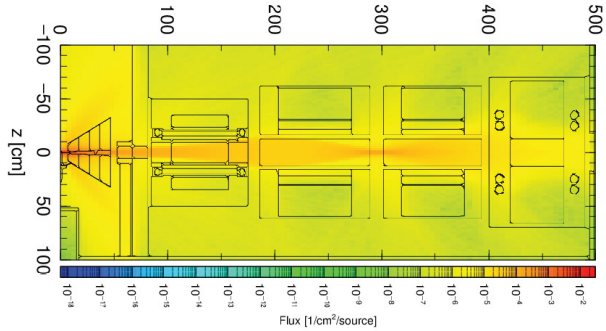

Figure 1: Proton flux seen in the first three quadrupoles of the fragment selector at FRIB. The figure is from ref [2].

CORRECTOR COIL DESCRIPTION

Seven quadrupole magnets in the fragment separator require multipole corrector inserts. Table 1 shows the beam line elements that follow the target. Table 2 shows the quadrupole, sextupole and octopole strengths for the quadrupole magnets that require multipole corrections [3]. The component strengths are evaluated at the reference radius shown in the table.

Table 1: Beam-line Elements in the Fragment Separator

Magnet	Half-gap (mm)	Field or Gradient	Length (m)	Element Position
Quad 1	100	-8,47 T/m	0.55	1.175
Quad 2	120	14.27 T/m	0.65	2.280
Quad 3	160	-11.67T/m	0.65	3.280
Octopole	130	163 T/m^3	0.50	4.570
Quad 4	140	6.53 T/m	0.55	5.350
Dipole 1	100 H, 150 V	2 T	1.75	6.900
Sextupole	100 H, 120 V	-42 T/m^2	0.40	9.320
Dipole 2	100 H, 200 V	-2 T	1.75	10.64
Quad 5	200	10 T/m	0.55	12.24
Quad 6	150	-4.95 T/m	1.357	13.54
Quad 7	160	4.2 T/m	1.357	15.51

The physical length of these inserts range from 0.6 to 0.7 m, with the effective length of the magnet being ~20% shorter. The inner radius of the octopole insert is between 75 and 110 mm adjusted to the various quadrupole apertures and the sextupole insert inner radius will be 5 mm larger than the corresponding octopole insert. The largest quadrupole pole tip field is 2.5 T, so the field at the insert coils is about 2 T. The design will assume that the sextupole and octopole fields at the insert coil radius are 0.25 T. The multipole coils should be shaped on a

cylinder to take up a minimum of radial space and the mounting tube needs to be radiation resistant and should have a minimum mass.

Table 2: Multipole components needed at the quadrupole elements. The component is shown at the reference radius.

Element	Ref. Radius	Quad. Field, T	Sextupole Field, T	Octopole Field, T
Quad 2	0.15 m	2.14	-0.06	-0.21
Quad 3	0.15 m	-1.75	-0.06	-0.12
Quad 4	0.15 m	0.98	0	0.1
Quad 5	0.20 m	2.00	0.21	0.04
Quad 6	0.20 m	-0.99	-0.12	0.09
Quad 7	0.20 m	0.84	-0.22	-0.13
Quad 8	0.20 m	-1.55	0.015	0.103

The BNL magnet division has made HTS R&D quadrupole magnets for the fragment separator region of FRIB [4, 5, 6]. These quadrupoles were super-ferric magnets where the coils magnetized the iron producing an iron dominated field. The magnet yoke is warm and is thermally isolated from the coils which are at cryogenic temperatures. This design minimizes the space for the coils and cryogenics, while allowing a wider pole region to improve magnetic efficiency. Figure 2 shows an Opera-3D representation the quadrupole magnet illustrating the coils and the upper half of the yoke.

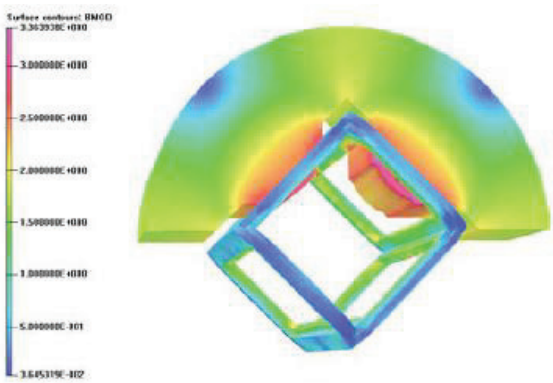

Figure 2: Opera 3D magnetic model of the FRIB fragment separator quadrupole. The sketch shows all of the coils and the upper half of the yoke.

Both YBCO and Bi-2212 are potential candidates to be used for these corrector coils. Both conductors can carry a reasonable current at 38-50 K and are radiation tolerant. In a study at the BLIP facility at BNL, a sample of YBCO conductor was irradiated and shown to withstand the cumulative effects of radiation over the anticipated lifetime of the facility [7]. In that study it was shown that the critical current, I_c, would be reduced by 20% for each dose of 10^{17} protons/cm^2. A similar study with Bi-2212 conductor showed that I_c was relatively unchanged for proton fluences up to 10^{17} protons/cm^2 [8].

The conductor for the corrector coils will be wound on a cylindrical mandrel. The Bi-2212 conductor is available as a round wire which is easier to wind on a cylinder. However Bi-2212 has the disadvantage that it has to be reacted at 890°C in pure oxygen after it has been wound. The YBCO conduct is available in tape form. YBCO conductors are formed by a continuous deposition of conductor and coatings onto a substrate that provides mechanical strength. The I_c of the YBCO conductors is sensitive to the orientation of the conductor in a magnetic field. This is an important consideration for the corrector coils since the dominant quadrupole field can be perpendicular to the conductor plane in various parts of the geometry. As such, YBCO available today, carries sufficient current to meet the requirement.

The end geometry of a coil wound on a cylinder with an YBCO tape conductor is more complicated than wound with a round Bi2212 wire. Since the tape does not want to bend in the "hard" direction, the tape conductor will tilt as it is wound around the ends on the cylindrical mandrel. The tilt angle will be slightly different for each turn. The ends will have to be supported to prevent movement in the small voids between turns caused by the varying tilt angles. Figure 3a and b show two views of the ends of a quadrupole test magnet wound with Nb_3Sn tape as an example.

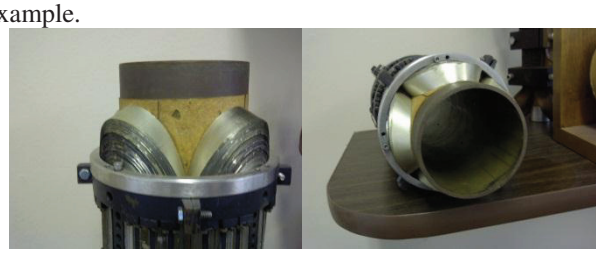

Figure 3: Photograph of coil ends of a test quadrupole wound with Nb_3Sn tape.

MAGNETIC SIMULATION

We have created an Opera2D [9] electromagnetic finite element model using of the correction coils inside the large aperture R&D quadrupole magnet built at BNL for FRIB. Figure 4 shows the sextupole coils inside the quadrupole magnet. (The quadrupole magnet should be rotated by 45° so that the quadrupole coils are on the x, y axes which is the normal orientation in an accelerator.) A similar model has been made for the octopole coils. Each half coil in each sextant (octant) will subtend 20° (15°) of the available 30° (22.5°). These angles are chosen to zero the contribution of the next largest allowed harmonic above the fundamental one. The allotted radial space for each corrector coil is 5 mm which must include the conductor plus its support structure. If YBCO conductor is used, a 3 mm wide tape such as Superpower SCS030 would be appropriate. Table 3 shows the engineering current density, J_E, in the coils required to produce 0.25 T at the multipole coils. Also shown is the conductor current and the corresponding critical current. The corrector coils carry current in the field of the quadrupole magnet. The radial and azimuthal forces in the central part of the magnet (away from the ends) are shown in

Copyright © 2013 CC-BY-3.0 and by the respective authors

Table 4 for the sextupole corrector coils and in Table 5 for the octopole coils. Since the corrector coils have a different symmetry from the dominant quadrupole coils the forces will be different on each individual coil. The correction coils could be deformed by these forces. The mechanical design of these corrector coils will need to be studied to minimize the effects of these forces.

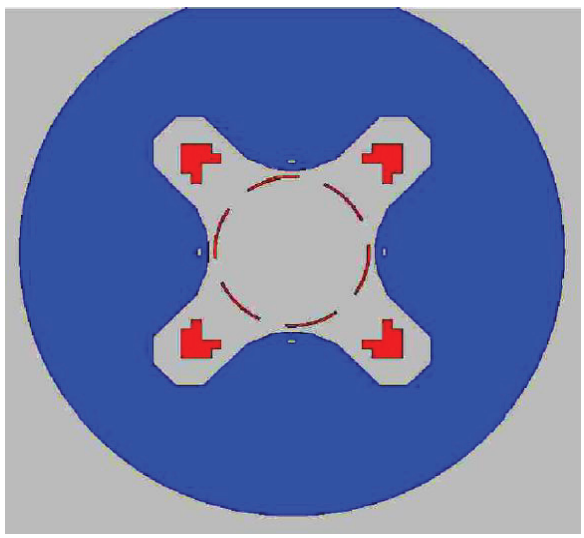

Figure 4: Sketch of the sextupole coils inserted into the BNL R&D quadrupole magnet.

Table 3: Current in the conductor for maximum field seen at the coils is shown along with the critical current of the conductor.

Coils	Field at Coils	J_E, amp/mm^2	I, amp	I_C(40 K)

ELLIPTICAL MUON HELICAL COOLING CHANNEL COILS*

S.A. Kahn#, G. Flanagan, Muons, Inc., Batavia, IL, 60510, USA
M.L. Lopes, K. Yonehara, FNAL, Batavia, IL 60510, USA

Abstract

A helical cooling channel (HCC) consisting of a pressurized gas absorber imbedded in a magnetic channel that provides solenoid, helical dipole and helical quadrupole fields has shown considerable promise in providing six-dimensional phase space reduction for muon beams. The most effective approach to implementing the desired magnetic field is a helical solenoid (HS) channel composed of short solenoid coils arranged in a helical pattern. The HS channel along with an external solenoid allows the B_z and B_ϕ components along the reference orbit to be set to any desired values. To set dB_ϕ/dr to the desired value for optimum focusing requires an additional variable to tune. We shall show that using elliptical shaped coils in the HS channel allows the flexibility to achieve the desired dB_ϕ/dr on the reference orbit without significant change to B_z and B_ϕ.

INTRODUCTION

A muon beam cooling technique, using a continuous gaseous hydrogen absorber inside a helical solenoid channel has shown promise to reduce muon phase space. This goal of this technique is to create bright muon beams with small emittance for use in particle accelerators and storage rings. Of particular interest is the development of a muon collider, which requires the reduction of the beam phase space by at least a factor of 10^6. Simulations have shown that the HCC can provide a significant phase space reduction [1]. The HCC is composed of a magnetic channel filled with pressurized H_2 gas absorber to reduce the particle energy. The lost energy is replaced in the longitudinal direction by RF. The desired field in the magnetic channel is comprised of helical dipole, helical quadrupole and solenoid components [2]:

Helical Dipole:

$$b_\phi = 2b_d I_1(k\rho)\cos(\phi - kz)/k\rho$$
$$b_\rho = 2b_d I_1'(k\rho)\sin(\phi - kz)$$
$$b_z = -k\rho b_\phi$$

Helical Quadrupole:

$$b_\phi = \frac{2b_q}{k^2\rho} I_2(2k\rho)\cos 2(\phi - kz - \phi_2)$$
$$b_\rho = \frac{2}{k} b_q I_2'(2k\rho)\sin 2(\phi - kz - \phi_2)$$
$$b_z = -k\rho b_\phi$$

where b_d and b_q are the dipole and quadrupole strengths, respectively, at $\rho = 0$. Implementing this channel with helical harmonic coils is difficult since $I_n(nk\rho)$ grows exponentially at large radius and the channel has large apertures. The HCC magnetic channel will be implemented with short solenoid coils arranged along the helical reference orbit. Figure 1 is a sketch of the helical solenoid (HS) channel [3]. This approach minimizes the magnetic field at the coils. To be effective the B_ϕ, B_z and dB_ϕ/dr of the HS at the reference orbit must match values from the theoretical formulae. B_ϕ and B_z can be set by HS coil current and adjusting an external solenoid field $B_{solenoid}$ (shown in Fig. 1). dB_ϕ/dr is important to control the beam focusing in the channel. To set this variable to an arbitrary value desired to optimize the channel requires an additional degree of freedom. In this paper we explore deforming the circular solenoids into elliptical rings to control the field gradient.

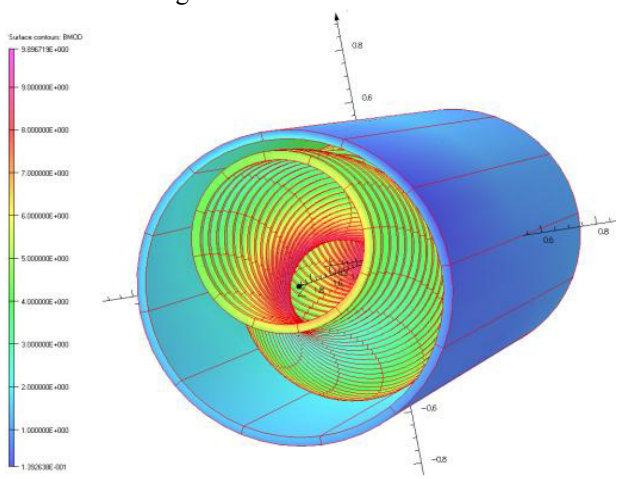

Figure 1: 3D layout of coils for the HCC channel. Note that the HS coils are placed in an external solenoid field.

HCC CHANNEL DESIGN

The HCC channel that is proposed is divided into eight sections with each section providing a smaller final equilibrium emittance which requires progressively larger fields. The design field for each section is shown in

*Work supported by U.S. DOE STTR/SBIR grant DE-SC00006266
#kahn@muonsinc.com

Copyright © 2013 CC-BY-3.0 and by the respective authors

Table 1 [4]. The study concentrates on section 2 at the beginning and section 6 near the end of the channel. Near the end of the channel the coils need to be thick to provide the necessary current to achieve the fields required. Table 2 summarizes the variables to describe sections 2 and 6. The RF cavities are assumed to be filled with a dielectric or made with a re-entrant design to reduce the cavity radius. This permits the use of the smaller radius coils shown in the table.

Table 2: Parameters Describing the HCC Sections Used in the Study

Parameter	Unit	Section 2	Section 6
Helical Period	m	1.0	0.4
Helical Orbit Radius	cm	15.9	6.366
RF Cavity Radius	cm	19	9.4
Coil Inner Radius	cm	25	10.5
Coil Outer Radius	cm	30	20.5
Coil Current Density	Amp/mm^2	256	340
Coils per Period		20	16

A Biot-Savart integration was used to calculate the field from the elliptical coils. The field at each point was determined by integrating over the current from all coils that were within one helical period from that point. Because of the large dimensions of the coils, they were represented by 40-60 filaments distributed over the coil cross section.

ELLIPTICAL COILS

We describe the elliptical shape by its asymmetry, $A = (R_{major} - R_{minor})/(R_{major} + R_{minor})$. R_{major} is aligned with the radial direction, while is in the azimuthal direction. This definition permits R_{minor} to be larger than R_{major} when the ellipse is oblate.

Section 2:

Figure 2 shows the field profiles on the radial axis for the section 2 configuration with different A. The coil current is adjusted to give the desired B_ϕ from Table 1 on the reference orbit. Since the external solenoid field can be set independent of the B_ϕ, setting the external solenoid field $B_{solenoid}$=2.0 T produces the desired B_z. Figures 2a, b, c show B_ϕ, dB_ϕ/dr, and B_z, respectively. Figure 3 shows the value of these fields on the reference orbit as a function of the ellipse asymmetry. The field magnitude at the coils is 6.4 T which is within the range for using NbTi at 4.3 K.

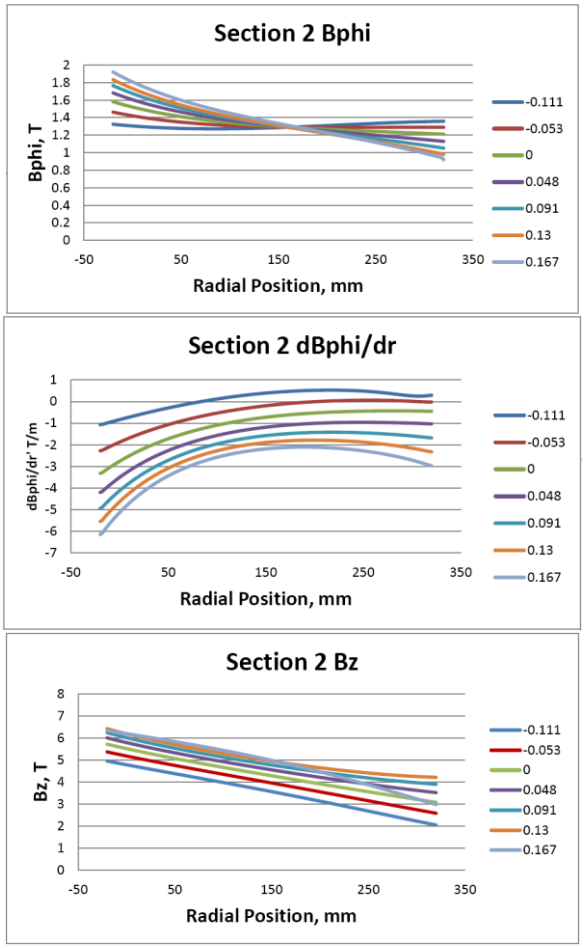

Figure 2: B_ϕ dB_ϕ/dr, and B_z vs. r for section 2. The different colors represent different ellipse asymmetries.

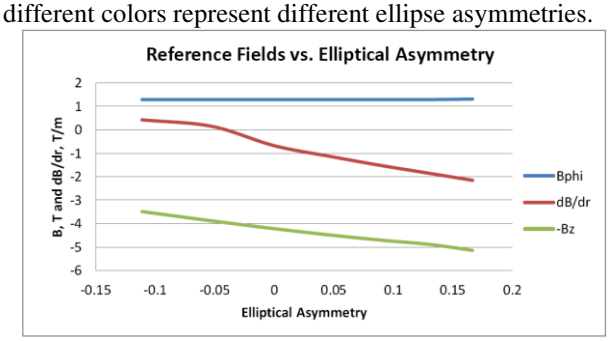

Figure 3: B_ϕ, and $-B_z$ in Tesla and dB_ϕ/dr in T/m on the reference orbit for different ellipse asymmetries.

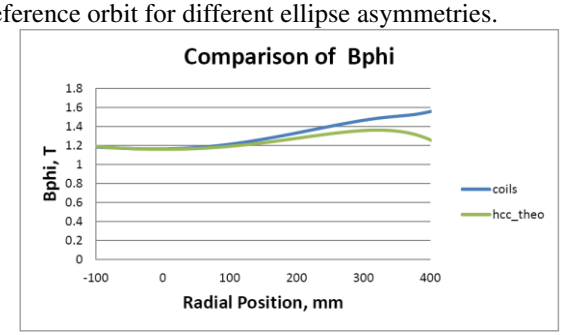

Figure 4: Comparison of the coil description of B_ϕ with the theoretical Bessel function description for section 2.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Figure 4 compares the B_ϕ field from the HS description with the theoretical Bessel function description. The coil description does not yet correct for the sextupole which affects the field at large radius. For section 2, an oblate ellipse description with A=-0.14 produces a reasonable representation of the Bessel function field.

Section 6

Section 6 requires a large magnetic field and the coils must be fairly thick in order to produce that field. Figure 5 shows B_ϕ, dB_ϕ/dr and B_z for different elliptical asymmetries for section 6. Figure 6 shows B_ϕ, dB_ϕ/dr and B_z on the reference orbit as a function of elliptical asymmetry. Figure 7 compares the B_ϕ field calculated from the HS coils to the Bessel function description of the field for the case A=0.106 which approximates the theoretical description over most of the useful beam aperture. The external solenoid field is 14.2 T which can be made with Nb_3Sn conductor. The maximum field at the HS coils is 20 T which suggests that those coils could be wound with Bi-2212 conductor.

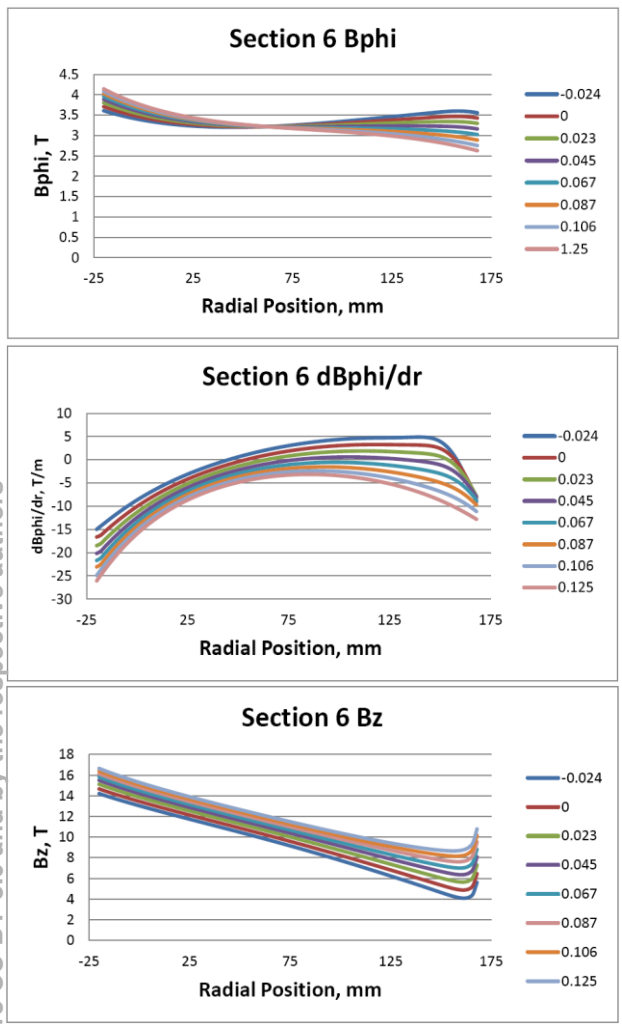

Figure 5: B_ϕ, dB_ϕ/dr, and B_z vs. r for section 2. The different colors represent different ellipse asymmetries.

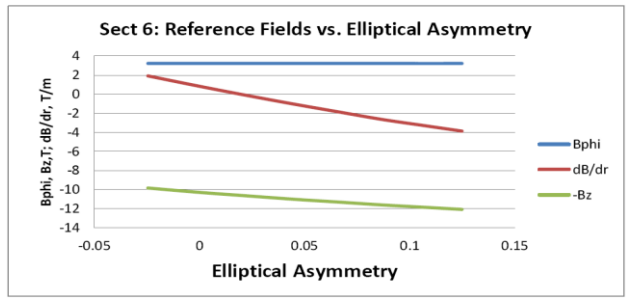

Figure 6: B_ϕ, dB_ϕ/dr, and $-B_z$ on the reference orbit as a function of elliptical asymmetry.

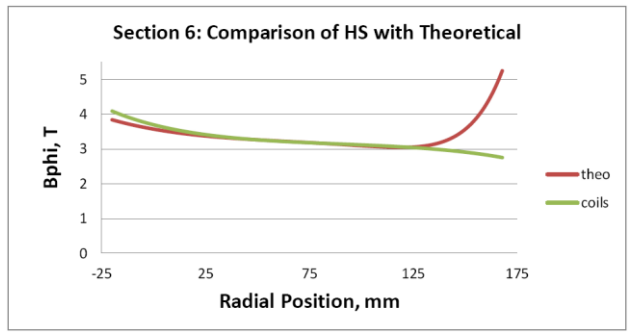

Figure 7: Comparison of B_ϕ calculated from the Bessel function description with that from HS coils.

CONCLUSIONS

Using elliptically shaped instead of circularly shaped coils provides an additional degree of freedom that can be used for matching the HS coils the Bessel function description of the field used for the HCC. Field maps made from the Biot-Savart integration of elliptical coils in the HCC can be used to describe the field for the muon cooling simulation program. This is a work in progress.

SIMULATION WORKSTATION

Thomas J. Roberts#, Muons, Inc., Batavia, IL 60510 USA

Abstract

The Simulation Workstation is a software toolkit that provides a universal Graphical User Interface to most particle simulation codes. This includes: constructing and displaying the simulated system graphically, running multiple simulation codes from a single system description, displaying particle tracks or histories with the objects of the system, flexibly generating plots and histograms, and comparing the results from multiple simulations. The workstation itself knows very little about particle simulations -- that knowledge is contained in the simulation codes themselves. As a consequence, the workstation can handle essentially any problem that any of the supported simulation codes can simulate. These include: beam optics calculations, ion source design, muon cooling channels, spacecraft radiation levels, nuclear reactors, complex shielding calculations, and accelerator driven subcritical reactors. The workstation offers interfaces to most CAD/CAE programs, enabling workflows that include multi-physics analysis by other programs. The Simulation Workstation will be portable among all major operating systems, will be freely available as open-source software, and will initially support these simulation codes: G4beamline [1], MCNP6 [2], and MAD-X [3]; additional codes can be added by users.

INTRODUCTION

When teaching beam dynamics and accelerator physics to students, user-friendly graphical tools are a big advantage, as they permit the construction and exploration of models with very little overhead. And for today's technology-driven students of the "Nintendo generation", graphical interfaces meet their expectations far better than text-based tools. Moreover, there are dozens of modeling codes available, so having a common user interface that can be used with multiple simulation codes will be a major advantage. Existing tools fall short of what is needed.

While the workstation has been designed with students in mind, accelerator physicists will also find it useful in dealing with the plethora of modeling tools and their different languages and data formats. The internal representation of the system is specifically designed to be useable as a text-based description of the system, and to make it easy for users to interface it to essentially any accelerator-modeling tool, regardless of its description language. In particular, this will make it straightforward to use fast but less realistic codes to design and optimize a system, and then use slower but more realistic codes to evaluate its performance. Graphical interfaces are emphasized, making it easy to construct the system graphically, display the system and its beam, and use on-screen controls to vary parameters and observe their effects immediately. Such exploration is essential to give students insight into how systems behave, and can be valuable to the experienced accelerator physicist, for tasks such as evaluating different techniques for tuning a system before it is built.

The user interface is centered around objects, which can be individual accelerator components, or arbitrarily complex collections of components with specified spatial relationships. Objects are stored in Libraries, which can easily be shared with other users. The use of URL-based component libraries will encourage collaboration among geographically diverse teams.

The Simulation Workstation provides the user with a single user interface to construct, design, optimize, analyze, and explore systems involving charged particle beams and other radiation. It is specifically designed to be interoperable with just about any existing simulation or beam optics code. This is possible for one simple reason: they necessarily have a common domain, with common concepts, common objects, and common operations. By abstracting these common elements into a new specification language, called *LinguaFranca*, a single GUI program can indeed interface to many simulation codes with relatively little effort. LinguaFranca has been specifically designed to make it easy to *instantiate* its description for other codes to read. Instantiation is not machine translation, which is known to be a difficult problem, but rather is performed by a sophisticated text-processing system that has been told by human developers how each LinguaFranca primitive is represented in the language of each simulation code.

The architecture of the Simulation Workstation is to be an overall control program that orchestrates the assembly of the various pieces required to prepare, perform, and analyze a simulation. Thus the user works with a single user interface to perform all related tasks. While it relies on interfaces to the simulation codes, the adaptation is always in the workstation, and no simulation code needs to be modified in order to work with it (some codes will benefit from modifications, especially on Windows).

The Simulation Workstation will be portable among the major operating systems (Windows, Linux, Mac OS X), and will be released as open-source software. This is the same overall commercialization model as for our highly successful program G4beamline [1]. The key to G4beamline's popularity is its excellent user interface; this project was inspired by that interface, and by what we perceived as ways to improve it. But rather than just improve this one code, we have chosen to design and develop a system that is customizable to improve the user experience for all related simulation codes.

THE SIMULATION WORKSTATION

The Simulation Workstation presents the user with a window ready to edit a simulation, as shown in Figure 1. The viewer is at the left, showing a 3-D image of the current system; the simulation shown is for the storage ring of a Very Low Energy Neutrino Factory [4]. The right-hand third of the window shows an edit panel at the top and a library panel at the bottom (showing a single row of three objects' icons, with scroll bar).

The 3-D Viewer

As a simple illustration of the viewer's flexibility, Figure 2 zooms in on the transition from straight to arc. This required the following simple user gestures:

1. Use the middle mouse button to pan the display to center the desired region.
2. Use the mouse scroll wheel to zoom in.
3. Use the viewer-control slider to set the solid opacity to 50%.
4. Use a viewer-control button to toggle the display of axes to on.
5. Use the left mouse button to select the last cell of the straight section (highlighted in red).

Total elapsed time: 3-5 seconds. The white line is the design coordinate axis, from the origin off the screen to the left, going once around the ring, and then right (+Z) to infinity. Design coordinates make it easy to lay out an accelerator or beamline by sequentially placing objects along the system centerline; bending magnets are accompanied by a bend in the centerline; they behave just like the implicit reference coordinates of beam optics programs like MAD-X.

The Edit Panel

The edit panel in the upper right is context sensitive, displaying appropriate information in response to user gestures.

The Library Panel

The library panel at lower right displays the objects currently in the library, sorted alphabetically. These can be simple parameterized components such as magnets and RF cavities, or they can be combinations of other objects, such as :Straight and :Arc (which define a cell for the corresponding region of the VLENF). In general there can be multiple Libraries (remote ones are configured via URLs), so library components are named LibraryName:name (no spaces). This is the default library whose name is empty, so the names simply begin with a colon. Objects can be dragged into the viewer and dropped in position; the edit panel can then be used to

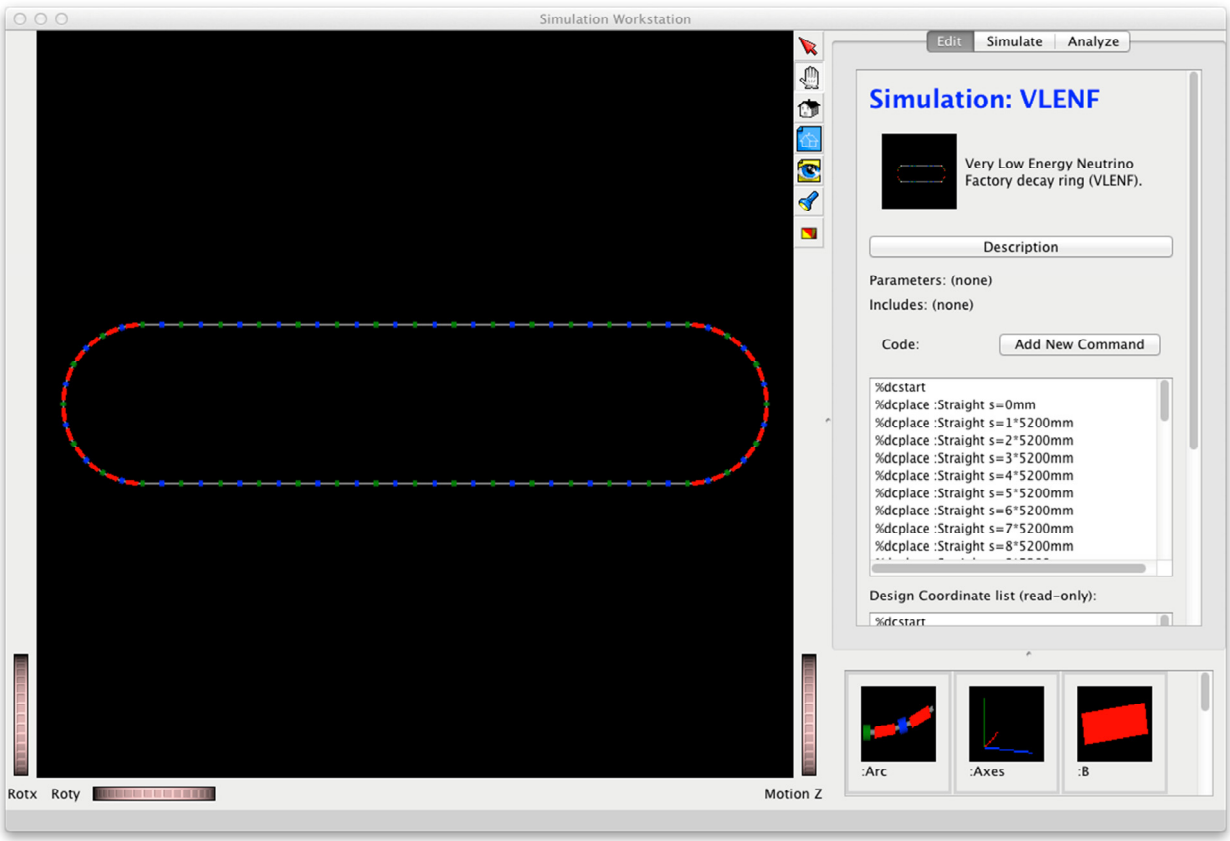

Figure 1: The Simulation Workstation Main Window, editing a VLENF simulation. Focusing and defocusing quads are green and blue, bending magnets are red, and beam pipes are gray. The 3-D viewer can be easily rotated, panned, and zoomed via the mouse, and individual objects can be selected and edited.

Copyright © 2013 CC-BY-3.0 and by the respective authors

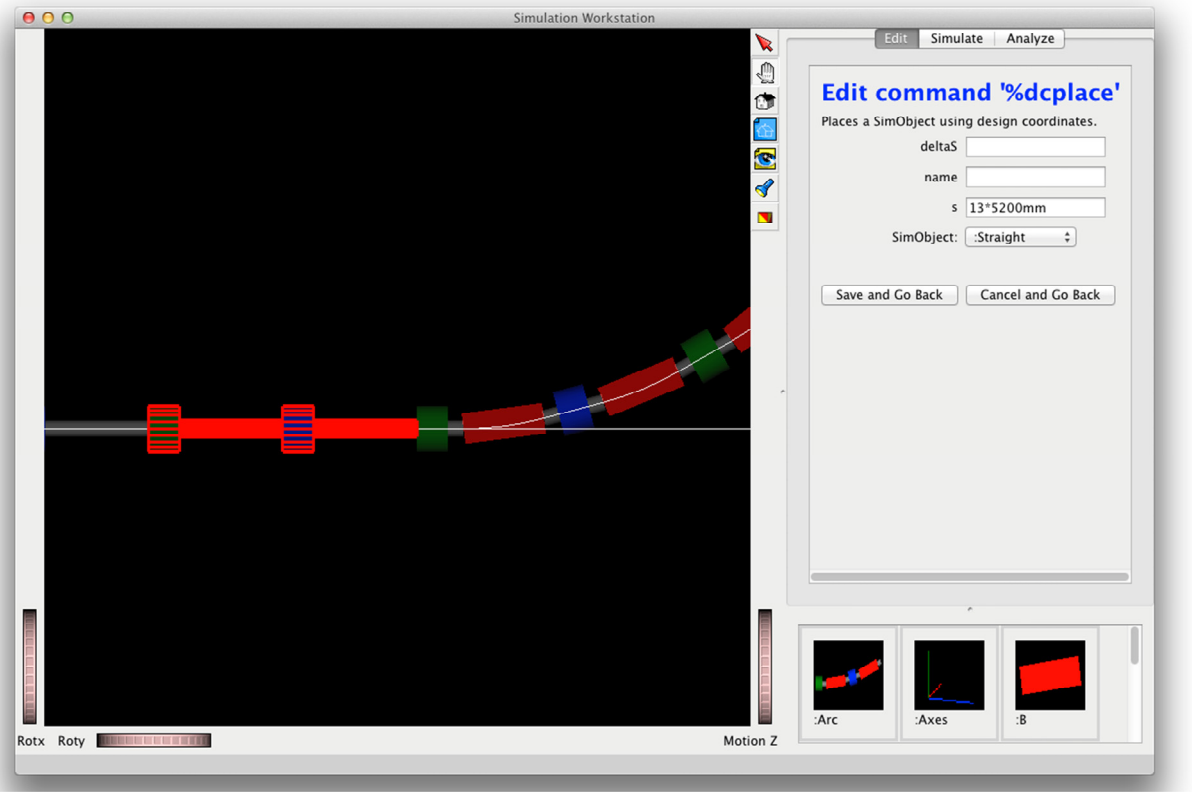

Figure 2: The system of Figure 1, but panned and zoomed, with the last Straight cell selected. Note the editing panel shows the command that put this cell into the simulation, placing the cell along the design coordinate axis.

tweak their position precisely. But for an accelerator system using Design coordinates, once the components are placed into the library they can simply be dragged into the edit panel and dropped – this places them sequentially along the design coordinate axis; The VLENF simulation has magnets and beam pipes placed sequentially into cells, and the cells placed sequentially into the simulation.

The Simulate Tab

The upper right panel has three tabs that change the entire mode of operation: Edit, Simulate, and Analyze. The Simulate tab provides an interface to manage the running of a simulation, using any configured simulation code. As a simulation runs, its output file(s) can be scanned as they are produced, and events displayed in sets of N (which defaults to 10 but is easily changed). A viewer-control slider permits the user to vary the opacity of solids, making it easy to see tracks inside them. Clicking on a track does two things: it hides any other events in the current set, and in the upper right it displays the track values at the point clicked and at track creation. By default tracks are colored by their charge, but the user can configure a color for each type of particle.

The Analyze Tab

The Analyze tab will make it easy for the user to create histograms and plots of quantities of interest. It will incorporate a complete Root [5] package, as well as an interface to simplify the creation of basic histograms and plots, with sliders to apply cuts (updating the plot in real time as the cuts are changed). The Analysis tab will incorporate feedback to the Simulate tab, permitting the user to identify interesting, unusual, or "outlier" events in a plot, and then re-simulate each event while viewing its tracks in the viewer. With G4beamline [1] this has proven to be a very powerful technique for understanding backgrounds and rare processes.

CONCLUSION

The Simulation Workstation is expected to become a useful addition to many students' and accelerator designers' toolkits. It has many innovative features not found in other programs that promise to improve users' productivity; its use of libraries should foster collaboration among geographically diverse teams.

STATUS OF SPALLATION NEUTRON SOURCE CRYOGENIC TEST FACILITY (CTF)*

M. Howell#, A. Coleman, B. DeGraff, S-H. Kim, T. Neustadt, J. Proulx, J. Saunders, W. Strong, D. Vandygriff, ORNL, Oak Ridge, TN 377831, USA
T. Xu, FRIB, East Lansing, MI 48824, USA

Abstract

The Spallation Neutron Source (SNS) is building Superconducting Radio Frequency (SRF) processing and testing facilities to support the reliability and sustainability goals of the enterprise. In addition, these facilities position the SNS superconducting linac (SCL) for improvement programs and future upgrades. Some of the testing facilities require cryogenic helium at both 4 K and 2 K. Currently, the Central Helium Liquefier (CHL) supplies 4 K helium to the linear accelerator and excess capacity is utilized to supply the test cave. As more facilities become available and testing is more frequent, it is essential to separate testing in the SRF facility from the operation of the accelerator. This paper describes the cryogenic system and the commissioning of that system at SNS to facilitate SRF testing needs. The initial phase of the project was to supply 4 K helium to a Vertical Test Area (VTA) and the test cave which is capable of housing either the Horizontal Test Apparatus (HTA) or a cryomodule. The scope of the initial phase of this project has been expanded. The system will be outfitted with warm pumping capability to produce 2 K helium in the testing systems. In addition, a liquid helium fill station will be incorporated to fill portable Dewars.

INTRODUCTION

The Spallation Neutron Source contains a superconducting linear accelerator which consists of eleven medium beta and twelve high beta cryomodules. The availability and reliability of the cryomodules has been high. However, the superconducting section of the linear accelerator has not met the energy specification of 1 GeV [1]. To increase the energy of the beam and meet future upgrade requirements, the performance of multiple cryomodules must be improved. To improve these cavities, there are two options. These cavities can be replaced which will involve removing, disassembling, and rebuilding cryomodules. This approach is cost prohibitive. A second option is to implement additional processing or conditioning of the superconducting cavities. SNS is currently installing and developing superconducting radiofrequency processing and test facilities to develop methodology in increasing beam energy and facilitating necessary repairs. The CTF refrigeration system will provide helium at both 4 K and 2 K to the SRF test facilities.

Multiple repairs of cryomodules have been performed at SNS by in house staff. These include tuner repairs, removal of HOM antennas, and repair of helium circuit, beam line vacuum and insulating vacuum leaks. In one case, a mild plasma processing was applied to a cryomodule to improve its performance [2]. After repair, the cryomodules have been qualified in the test cave using the CHL to supply helium. This couples the testing and qualification process to the actual operation of the linear accelerator. The implementation of the CTF decouples these two differing objectives.

DESIGN OVERVIEW

The original scope of the CTF refrigeration system was to provide 4 K helium to the test cave and the VTA [3]. This scope has been expanded to include adding 2 K capability through the use of a warm pumping system. Because the availability of liquid helium has been scarce, a liquid helium fill station to supply portable Dewars to the neutron instrument and sample environment areas has also been added to the scope. By having this subsystem, the liquid supply chain issues can be mitigated with the helium gas storage that is normally available in the CHL. A block flow diagram of the CTF system is included below in Fig. 1.

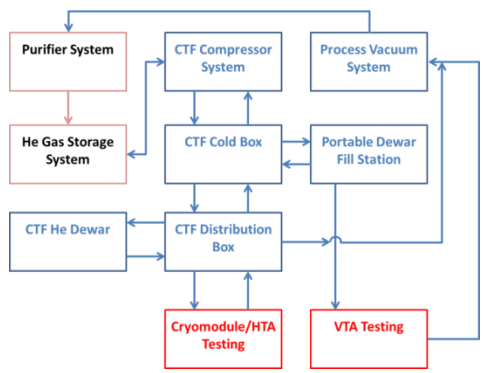

Figure 1: CTF Block Flow Diagram.

As system design has progressed and operational experience has increased, the cryogenic loads in the various testing modes have been further defined. Table 1 summarizes the estimated cryogenic loads of the various test modes. These loads are based on actual test results observed during operation of cryomodules in the test cave.

Table 1: Cryogenic Load Design Criteria

Test System	Nominal T_{bath}(K)	Primary Load (W)	Shield Load @4K (W)	Coupler Flow (g/s)
Cryomodule Test	4	400	200	< 0.5
	2	80	200	< 0.5
HTA Test (single cavity)	4	100	120	< 0.5
	2	20	120	< 0.5
VTA Test (CW)	4	600	None	NA
	2	150	None	NA

The Linde LR280 was specified with a refrigeration capacity of 650 W at 4.4 K and liquefaction capacity of 240 L/hr. This system can operate in multiple operational configurations. The system cold box supplies helium through the distribution box and helium Dewar when servicing the test cave. However, the VTA and fill station are supplied from a second set of bayonets on the cold box.

To operate the test cave, the system will experience a combination of refrigeration and liquefaction loads. The cold box will supply sub-cooled supercritical helium through the distribution box to both the shield and primary circuits. The primary flow will return through the distribution box to the cold box and serve as a refrigeration load. However, the shield flow will return to the warm compressor system through an ambient heat exchanger. This will act as a liquefaction load on the machine along with the coupler flow.

For operation of the VTA or fill station, the CTF will be operated in liquefaction mode. The CTF will supply liquid helium to a 2000 L fixed Dewar within the fill station. This Dewar will be used as a reservoir to either fill the VTA Dewar or a portable Dewar. The detailed design of this subsystem is complete and fabrication is nearing completion. A model of the fill station system is included below in Fig. 2. The fill station is scheduled to be operational in the first half of FY 14.

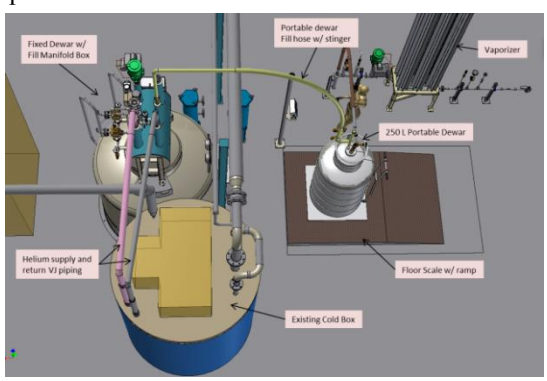

Figure 2: The model of fill station. [4]

The addition of a Kinney pumping skid will enable the system to operate at 2 K. SNS made use of the vast experience of personnel at Fermi National Laboratory in refurbishing this skid. This was a machine originally slated for operation at the SSC. It is a 10 g/s machine equipped with a blower, liquid ring vacuum pump, and oil pump. This portion of the system is scheduled to come on line in FY 14.

COMMISSIONING

The commissioning philosophy was to first start the warm part of the system including the compressor, gas management, and oil removal. This allowed any bugs to be worked out in the warm part of the system while being isolated from the cold box and turbines. The philosophy of this portion of the system was to make it as similar to the existing plant as possible to minimize operator training time, make use of existing control templates, and incorporate the Ganni Cycle [5] to use a floating discharge pressure system to match the load.

The primary goals of this portion of the commissioning were to test the operability, speed control, control functions and interlocks of the compressor, gas management, and oil removal system. Secondary goals were to gain valuable operator seat time and develop internal operating procedures. This test was completed at the end of January with a Linde representative present. The compressor screen shot is depicted below in Fig. 3.

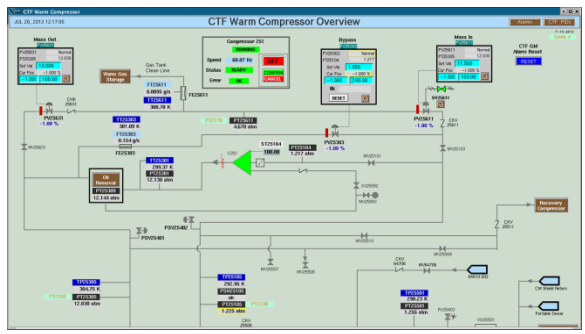

Figure 3: Warm compressor control screen.

After commissioning the warm system, a control logic review was conducted as a collaborative effort between SNS controls personnel and a Linde representative. During this review, the readiness of the controls was verified. The team verified that instrument loop checks, interlocks, operator controls, control algorithms, and initial loop tuning were properly implemented. The cold box PLC logic was reviewed thoroughly and a short action item list was generated and completed within a couple of weeks.

This positioned the team well to move to cold box commissioning. The cold box was operated integrated with the warm system and the helium Dewar. A simplified block flow diagram is included in Fig. 4. An example of the controls screens used during commissioning for this system is shown in Fig. 5. The goals of the cold box commissioning were:

1. Cool down cold box within specified time (< 6 hours)
2. Achieve specified capacities for refrigeration and liquefaction
3. Develop procedures and receive training
4. Demonstrate helium Dewar integrity and achieve specified boil off rate
5. Tune loops and refine control variables
6. Test interlocks and ensures system fails safe.

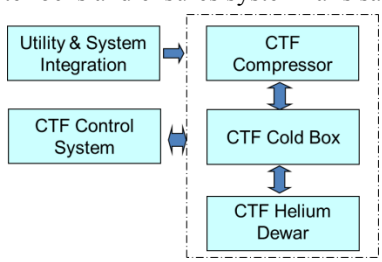

Figure 4: Cold box commissioning block flow diagram.

Copyright © 2013 CC-BY-3.0 and by the respective authors

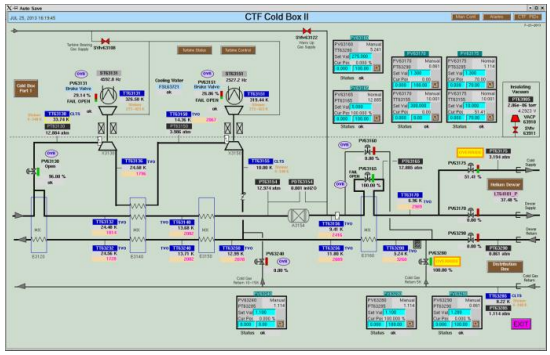

Figure 5: Cold box control screen II.

To commission the cold box in liquefaction mode, the cold box supplied helium to the helium Dewar and a small amount of vapour returned to the cold box. For commissioning, the distribution box was bypassed with three custom made u-tubes. The liquefaction rate was measured in two ways. The first was to observe how much the level increased in the helium Dewar over a specified amount of time. The second was to observe how quickly the helium gas storage pressure dropped in a specified amount of time and convert that to liquefaction rate. These two methods of calculation yielded results of 260 L/hr and 240 L/hr, respectively. Both met or exceeded the specified liquefaction rate. However, it is believed that the calculation method using helium gas storage tank pressure is more accurate than the method of using liquid level due to error introduced by level probe and helium Dewar geometry.

The cold box was commissioned in refrigeration mode by supplying helium to the Dewar and boiling it off with an electric heater. The maximum refrigeration capacity of the system was observed to be 750 W which is greater than the specified capacity. A screen shot of the helium Dewar with the input heater power of 759 W is included in Fig. 6. After the helium Dewar was filled, the system was shut down over night and the boil off rate was measured. It was found to be <0.75% per day as specified.

In addition to achieving the refrigeration and liquefaction capacities, interlocks were tested, internal operating procedures were developed, and loops were tuned. The commissioning gave opportunity to multiple operators to gain hands on experience with the system.

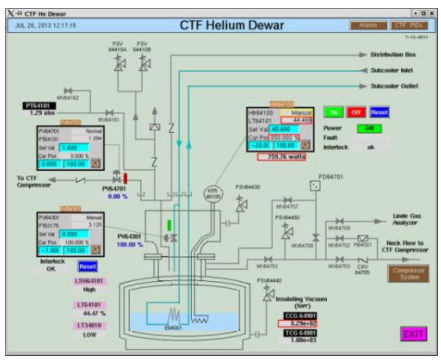

Figure 6: Helium Dewar control screen depicting refrigeration capacity.

LESSONS LEARNED

A few valuable lessons were learned during the design and commissioning of this system. One design change that was incorporated was to take the compressor bypass from after the second stage coalescer to minimize oil carry over. In the CHL system, oil accumulation is witnessed in the low and medium pressure headers. This change has eliminated this concern from the CTF system.

As controls personnel were performing check out of the gas management valves, it was discovered the Weka control valves required 5 atm instrument air pressure to operate [6]. The control valves in the CHL gas management system operate at 3atm air pressure. This required a change out of an air pressure regulator to accommodate operation of the CTF gas management control valves.

Another lesson learned involved bonding the cold box to ground. This was overlooked in the original installation of the system. The temperature sensors gave erroneous readings on both the TVO resistors and cryogenic linear temperature sensors (CLTS) [6]. This was corrected by connecting the box to ground.

This system was specified as a machine with frequent starts and stops that give ample opportunity to regenerate the 80 K and 20 K adsorbers. However in future systems, it may be advantageous to install isolation valves and a bypass. This can be used during warm up iterations and ensure that contamination does not enter other areas of the system.

ACKNOWLEDGMENT

We would like to thank all of the people that have made the fabrication, installation and commissioning of the CTF system possible. We recognize the dedication and hard work put forth by the SNS and Linde teams.

RECENT IMPROVEMENTS IN PARTICLE SIMULATION SUPPORT IN ANALYST-MP*

J. F. DeFord, B. Held, A. Nichols, AWR Corporation, Mequon, WI 53092, USA

Abstract

Recent work on the Analyst product has simplified model development, improved result visualization, and added particle simulation functionality. The Analyst user interface has been updated with a new control layout, and support for automatic session recording, variables/expressions for all inputs, and units. For the study of multipacting and dark current phenomena a new volumetric particle source has been deployed, and changes to the way secondary generations are managed has simplified the identification of multipacting resonances.

INTRODUCTION

Analyst is a finite element-based tool used for design and optimization of three-dimensional structures in microwave engineering. In development of new particle accelerators, Analyst is used on a variety of components including RF modules, feed systems, deflectors, etc. When applied to the multipacting problem, driven RF or eigenmode calculations are performed to obtain field distributions, and these are then used in a separate particle simulation to search for particle resonances.

Recent work has improved the particle tracking algorithms and emission models [1]. The current version of the code employs a statistical secondary emission model that produces from an impact a set of zero or more electrons whose count and properties are obtained from samples of random variables that collectively enforce observed secondary emission behaviour [2]. The Analyst user interface has also been updated in response to user experience in the old system. Development on the particle simulation engine has focused on changes that make it easier to identify and interpret multipacting behaviour. These changes are discussed in the following sections.

VOLUMETRIC PARTICLE SOURCING

Previous versions of Analyst used a simple primary emission model for multipacting simulation. This model emitted one or more particles from each element face that lay on the model boundary. Particles were emitted at regular intervals during the first RF period, and subsequent particle motion and deterministic secondary generation were used to identify resonances. This technique is very efficient, but it does not necessarily require fewer emissions than a volumetric launch if one is to avoid missing resonances.

In addition to supporting primary emission from surfaces, Analyst now also allows initiation of particles in the volume by emitting a specified number from each mesh element (triangle or tetrahedron) during the first RF cycle. The position, direction vector, and emission time of each particle are all randomly chosen. The initial velocity of each particle is obtained by sampling a random variable, with the number of particles emitted per element controlled by a user input, and is typically of order 10^2.

As expected, the efficiency with which resonances are identified is a function of the choice of initial velocity distribution. Robust multipacting resonances involve low energy electrons because it is primarily low energy impacts (< 5 keV) that yield multiple secondary particles. Higher energy impacts can result in single reflected or re-diffused secondary particles, but do not contribute to gain in multipacting resonances. Consequently, initiating particles with high energy is usually of little utility in identifying resonances. In the low energy regime we studied the effects of using different velocity distribution functions, including a delta function (specified value), uniform over a range of values, and Boltzmann with a peak matching the secondary emission yield peak of surface material. We concluded that these functions were largely equivalent in initiating resonances in test structures, and the simplest approach of giving all of the particles the same initial energy (in the 100s of eV) is perfectly adequate. This value is an input parameter in the software, which defaults to the peak energy of the true secondary yield curve. Note that this choice does not imply that only particles with comparable energy exist in the simulation to initiate resonances. High-field regions will accelerate particles to high energies, and subsequent interaction with cavity walls will typically scatter some of these particles into low-field areas. However, with this approach the preponderance of particles in low field regions will be in an energy range to yield true secondaries on impact with common metals, increasing the odds that a resonance will be discovered if one is supported by the geometry/field-structure.

Volumetric sourcing produces an initial cloud of particles that rapidly dissipates, primarily due to collisions with cavity walls that produce no secondary particles. What remains after a few RF cycles is predominantly secondary particles that are in a resonance (Figure 1).

MULTIPROCESSING

Particle tracking is done by secondary generation, with each generation completed before the next one is started. Between generations secondary particles are redistributed across available processors to balance the computational load. Dependence of particle populations on processor count is undesirable, even when it does not lead to

*Work supported by DOE SBIR grant SC0002604.

Copyright © 2013 CC-BY-3.0 and by the respective authors

quantitative changes to the results of interest, and such dependencies are also problematic in automated regression testing systems. To make the results independent of processor count requires the creation of a particle index that does not depend on either processor count nor processor index. This index is formed on the basis of initial emission parameters and secondary history, and is composed of a small number of 64-bit integers (generally 3 or less). The index is unique for each particle, but simple interpretations of its values as integers are not evenly distributed in the set of integers, and as such it is not suitable for use in index-based load-balancing. So for this purpose an index hash (a single integer of a specified maximum size) is created based upon the index which is approximately evenly distributed, but is not generally unique. Load balancing is then performed on the basis of this hash, which has exhibited high-quality partitions in our testing.

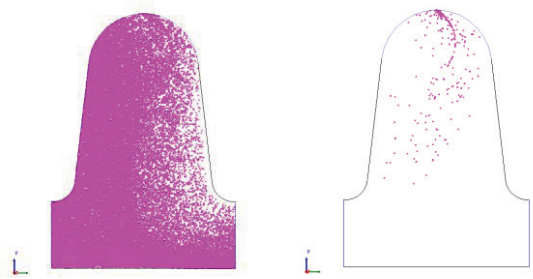

Figure 1: Particle cloud at 1 RF period (left), and after 2 RF periods (right) in 2-D RZ example. Ultimately a resonance is seen about cavity "equator" (top center of cavity).

SECONDARY DECIMATION

The number of secondary particles that are tracked at each generation is controlled via decimation. This is particularly important in highly resonant situations in which the particle growth is exponential. As with load balancing, an index hash is used for this purpose, and only particles with zero hash index are tracked. The existence of the untracked particles is accounted for in accumulated statistics, such as yield, but otherwise they are simply discarded.

MODEL CREATION AND RESULT PROCESSING

The Analyst user interface has been updated to simplify the creation and manipulation of complex geometry models. Changes include mouse-based solid construction, relative coordinate systems tied to geometric entities (for creating a solid at a location/orientation that is relative to another solid), and the aggregation of all model data in a property grid that allows rapid access and modification of model parameters (Figure 2).

Scripting is supported in the Analyst system, and is based upon the Python language. The new software automatically records the complete session in a script that can be replayed in order to reproduce the session. This recording can also be used as the basis for a user script.

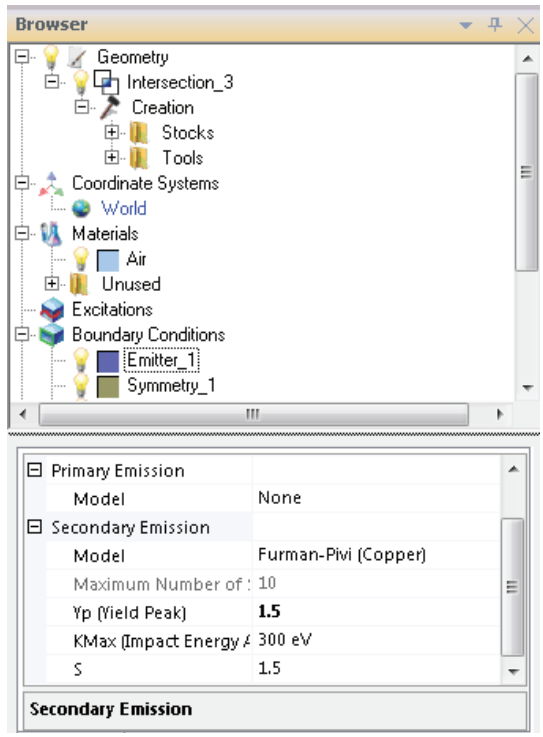

Figure 2: New model data browser in Analyst simplifies access to common elements.

Variables and expressions can now be entered in place of numeric values in all input fields. Variable definitions are collected in a single input panel for rapid access. Units are now comprehensively supported in the user-interface, and a variable has the unit of its associated expression. The expression parser observes rules associated with the use of quantities with units in expressions, so for example, it is not allowed to add a variable with unit of distance to another variable with unit of time. Moreover, values with the same unit but differing scales are handled automatically via conversion to a common scale, so for example, an expression of the form v=1m+1in is allowed and correctly evaluated.

Result visualization has been reorganized to allow simpler addition of filters to view elements (now called "annotations"). Annotations can now be created in advance of a simulation, allowing views that are updated as data become available. Previously in Analyst geometry visualization was done only in its own window, separate window from all result views. In the new system there is no distinction between the two, so geometry and result visualization can be rendered together in the same view.

As an example, we analysed an RF deflector cavity [3] (Figure 3). This structure uses a dipole mode resonant at 2.82 GHz, and the interest was to identify any multipacting bands below about 60 MV/m peak surface electric field. Figure 4 shows the mode electric field, which is a field annotation rendered together with an outline view of the original solid geometry.

Copyright © 2013 CC-BY-3.0 and by the respective authors

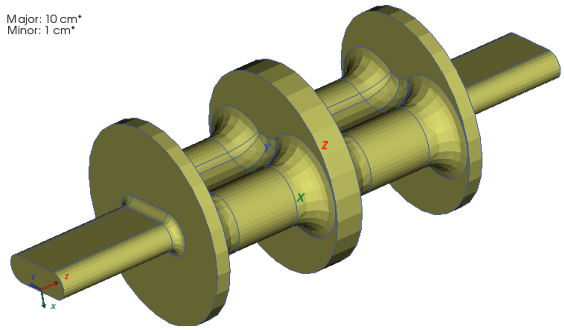

Figure 3: Deflector cavity geometry.

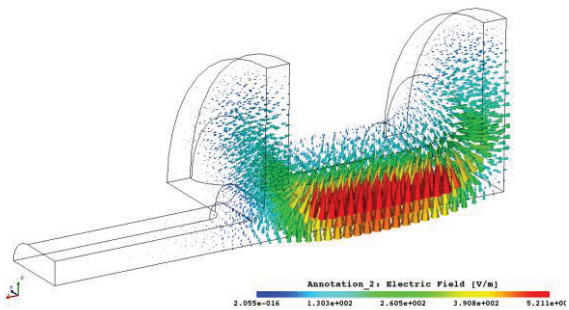

Figure 4: Electric field of mode in deflector cavity. Cavity is shown as modelled using 3 planes of symmetry. View is combination of structure and field annotations.

Running the problem at a single field level and dumping particles allows visualization of particular resonances. Particles can be rendered either as dots (their position at a particular instant in time), or as tracks that show the path of a particular particle or set of particles (Figure 5). In the deflector structure for the particular choice of secondary emission model there is a resonance near 50 MV/m in the vicinity of the connection between the beampipe and the cavity. Particles in this resonance return to the surface once every RF period as can be inferred from the individual particle statistics table that is output by Analyst.

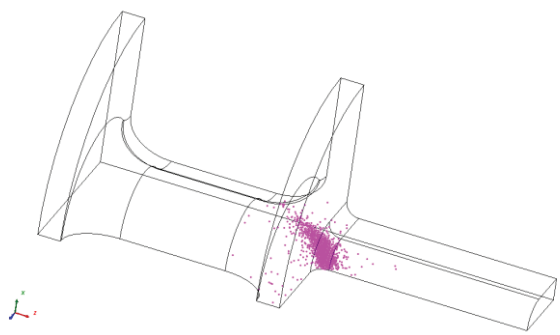

Figure 5: Particle distribution after 30 RF cycles in the multipacting band, showing accumulation of resonant particles near the fillet between cavity and beampipe.

Plots now contain one or more "measurements", which are data sources that can come from a simulation table or some other source. As with annotations, measurements are updated as data becomes available, so if a number of plots have been created and the simulation is rerun there is no need to recreate the plots as they will simply be updated with the new data when the simulation is finished. The enhanced counter function for the deflector cavity is shown in Figure 6. The particle count time history for a field level in the multipacting band is shown in Figure 7.

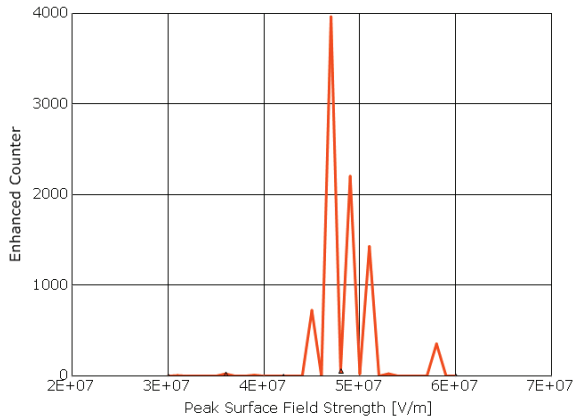

Figure 6: Enhanced counter function (number of particles surviving to 20 impacts including yield) as a function of peak surface electric field.

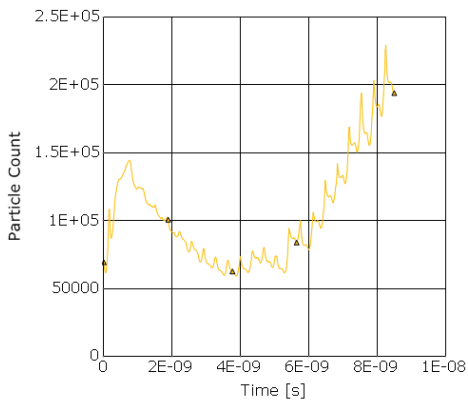

Figure 7: Particle count vs. time in deflector at 49 MV/m. Resonance is evident in late-time growth.

CONCLUSIONS

The Analyst finite-element software package has been updated, including improvements to the user-interface and particle simulation functionality. Changes in the way particles are sourced and secondary particles are managed now allows direct observation of particle count growth in resonant situations. Studies show expected multipacting resonances in test structures.

PARAMETER OPTIMIZATION FOR MULTI-DIMENSIONAL LASER COOLING OF AN ION BEAM IN THE STORAGE RING S-LSR*

Z. He#, FRIB, Michigan State University, USA; Tsinghua University, China
J. Wei, FRIB, Michigan State University, USA

Abstract

S-LSR is a compact ion cooler ring built in ICR, Kyoto University, aiming at creating ultra-low temperature ion beam by laser cooling. In order to approach lowest possible temperature at S-LSR in an experiment, parameters of laser cooling should be carefully chosen by simulation. This paper mainly concerns optimization of laser cooling parameters and prediction of possible low limit of beam temperature at S-LSR. Firstly, the adiabatic capture process of ion beam is introduced and studied. Then, different laser profile parameters are compared and an optimized value is chosen. After that, optimized solenoid field strength for 3-D coupling is proposed. At last, by choosing the parameters proposed, the lowest beam temperature achievable for S-LSR is predicted to be 10 K in transverse direction and 0.05 K in longitudinal direction.

INTRODUCTION

Cold beam, or low emittance beam, usually means less beam loss and smaller necessary beam aperture. Considerable effort towards ultra-cold beam was devoted in 1990's by two European teams (the TSR group at Max Planck Institute [1, 2] and the ASTRID group at Aarhus University [3, 4]). Both teams applied the laser cooling technique [5, 6] to various heavy ions and succeeded in reducing the longitudinal beam. However, the possible lowest emittance is limited by the linear coherent resonance crossing unavoidable in both TSR and ASTRID rings [4, 7, 8]. S-LSR [9], a compact ion cooler ring built in ICR, Kyoto University, has a potential to overcome the difficulties encountered by the European teams. For instance, we can reduce the betatron phase advance per single lattice period near or even below 90 degrees and avoid strong beam heating due to the linear resonance crossing. It is also possible to employ the resonant coupling method (RCM) [10, 11] and enables us to produce an ultimate ion beam that has a temperature near the absolute zero in all three dimensions [12, 13]. This paper mainly concerns optimization of laser cooling parameter and prediction of low limit of beam temperature at S-LSR.

BUNCHED-BEAM LASER COOLING

S-LSR is a compaction cooler ring with an electron cooling system and a laser cooling system. It has six-fold symmetric lattice and each lattice consists of a bending magnetic two quadruples and one 1.86 m long drift line, two of which are occupied by an electron cooler and a laser-beam interaction section as Fig. 1. A 40 keV Mg^+ beam is injected continuously into the ring and captured and bunched by a RF cavity. The laser is set co-propagating with the Mg^+ beam and is slightly tuned below the transmission frequency of the beam. With the synchrotron motion of bunched-beam, particles automatically falls into the cooling region of the laser, thus making bunched-beam cooling possible by single laser. [14]

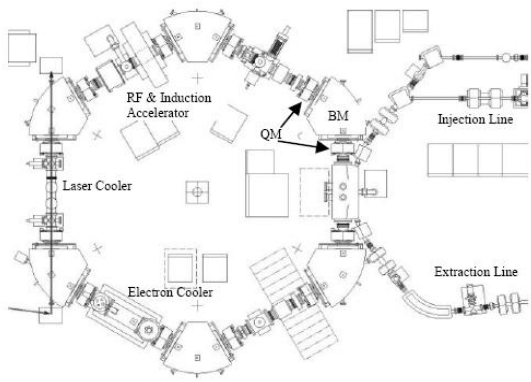

Figure 1: Layout of the ion storage ring [9].

In order to realize multi-dimensional laser cooling, the idea of RCM has been induced [10, 11]. In S-LSR, we adjust the working point around (ν_x, ν_y, ν_z) = (2.075, 1.120, 0.075) for 2-D cooling and working point around (2.075, 1.075, 0.075) for 3-D cooling. Longitudinal direction and horizontal direction are coupled by dispersion; horizontal direction and vertical direction are coupled by solenoid field.

Simulations are specially designed for this single laser bunched-beam cooling experiment at S-LSR. The parameters are all chosen according to the data or past experiment result of S-LSR. A molecular dynamic simulation code, CRYSTAL, developed for the laser-cooling and crystalline-beam study, was used [12].

Copyright © 2013 CC-BY-3.0 and by the respective authors

An ideal cooling method would cool all the particles to a certain low temperature. However, simulation shows that there are always particles not captured by laser in the longitudinal phase space, making a hot corona existing together with a cold beam core. See Fig. 2 for a typical longitudinal phase space distribution after laser cooling.

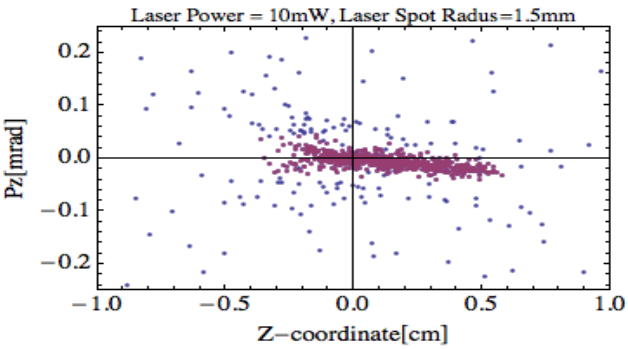

Figure 2: A typical phase-space plot after laser cooling. The magenta dots represent captured particles while blue dots shows hot beam corona.

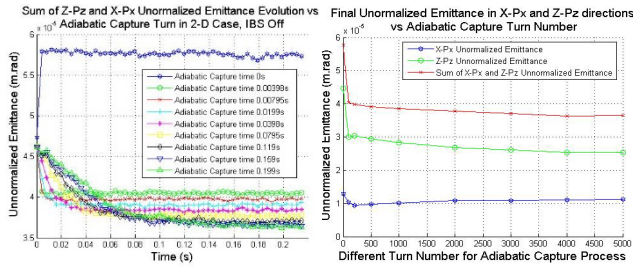
COOLING PARAMETER OPTIMIZATION



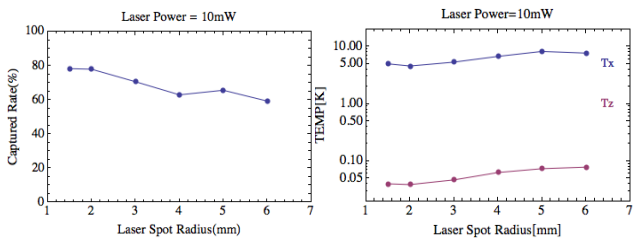
In order to maximize the cooling effect, various parameters should be optimized. Main experimental parameters are summarized in Table 1. Final detuning is chosen as minus half of the natural band width or $-\Gamma/2$, where the friction force is thought to be maximum. In our case, the frequency is 3.34 MHz or -1.1e-5 equivalent momentum spread. Laser scanning is applied in S-LSR to perform continuous laser cooling. Other parameters such as adiabatic capture time, laser spot size with saturation parameter, and solenoid field, should be carefully optimized by simulation. In this part, we assume that intra-beam scattering (IBS) effect is small enough and doesn't change the optimum value of each parameter, so we ignored the space-charge effect in the following simulations unless otherwise noted.

Table 1: Main S-LSR Parameters

Parameter	Value
Circumference	22.557 m
Average Radius	3.59 m
Ion Species	$^{24}Mg^{+}$
Kinetic Energy	40 keV
Frequency	25.145 kHz
Initial Momentum Spread	7.0e-4
Typical Laser Power	10 mW

Adiabatic Capture Process

At S-LSR, Mg^{+} beam is injected continuously in to the storage ring, forming a coasting beam circulating around the ring. To prevent emittance blowing up during the bunching, the adiabatic capture process is conducted in S-LSR. During the adiabatic capture process, the RF cavity voltage increases linearly from 0 to designed RF voltage decided by the synchrotron tune. So the only parameter needs to be optimized is the capture time. It can be easily seen from Fig. 3 that adiabatic capture process is a very effective procedure on preventing blowing up in emittance due to beam bunching process and even a very short period, would be far better than no adiabatic capture process. According to the result, an adiabatic capture time no less than 0.1s would be preferred by avoiding phase space dilution and strong emittance exchange.



(a) (b)

Figure 3: (a) The sum of X-Px and Z-Pz un-normalized emittance evolution vs. different adiabatic capture time in 2-D case (b) Final un-normalized emittance in X-Px and Z-Pz directions vs. adiabatic capture turn number.

Laser Profile Parameter

The total output power of laser available at S-LSR has now become the main constraint. A maximum output laser power of no more than 15mW is now available. On the other side, by maintaining a certain laser power, the laser profile parameters, namely laser waist radius R and centre saturation parameter S are able to adjust where SR^2 is kept constant.

As a result, optimizing laser cooling effect by optimizing laser waist radius and centre saturation parameter is important. In our simulation, laser waist radius varies 1.5 mm to 6 mm. IBS is turned on. And laser is kept at 10 mW. Laser cooling was maintained for as long as 5s. 2-D cooling is applied in these simulations. The cooling result can be seen in Fig. 4.

(a) (b)

Figure 4: Laser profile parameter optimization of certain power of laser in 2-D laser cooling. (a) Capture rate of laser cooling using different vs. laser spot radius, (b) The final temperature of captured particles vs. laser spot radius, IBS on, number of particles simulated is 300.

From the result, we can see that the capture rate goes down while the final captured particle temperature goes up with laser radius going up, indicating smaller laser radius would be more effective in suppressing IBS effect in cold beam cores. If our goal is to get lowest possible captured beam temperature while maintaining a

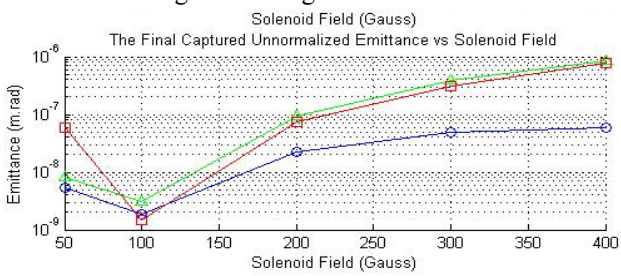
Copyright © 2013 CC-BY-3.0 and by the respective authors

reasonable capture rate in real case, a smaller laser radius of 1.5 mm would be preferred.

Solenoid Field

In 3-D laser cooling process, solenoid field should be turned on to couple horizontal direction and vertical direction. However, an optimized solenoid field for S-LSR remains unknown. In this part, solenoid field is changed from 50 Gauss to 400 Gauss and 3-D laser cooling is put forward and the cooling effect is then checked. The result can be seen in Fig. 5.

According to the calculation, if our final target is to get a cold particle core instead of getting the lowest total emittance, we can find out that the best solenoid field would be around 100 Gauss. And no matter too big or too small solenoid field is not good for coupling condition. Low solenoid would reduce the coupling between vertical and horizontal direction and high solenoid field would break the coupling condition between longitudinal and transverse direction. So a suitable solenoid field should be chosen to attain good cooling effect.



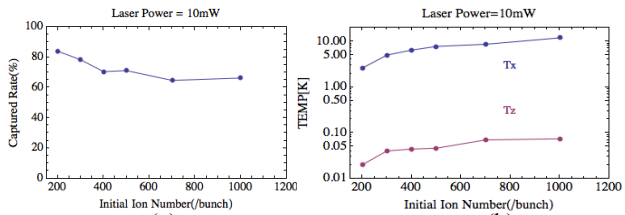


Figure 5: Result combination of cooling result vs. different solenoid field.

PREDICTION OF LOW- TEMPERATURE LIMIT AT S-LSR

Up to now, we have been talking about the optimum choices in bunched-beam laser cooling at S-LSR. Long term study shows that in order to achieve transverse laser cooling, differential resonance condition should be imposed. Laser scanning should also be imposed to increase particle capture. And it has also been suggested that in order to gain a more satisfactory cooling result, adiabatic capture process is needed. With very limited laser power, the laser profile should be adjusted and a small laser radius as 1.5 mm is preferable for compressing IBS heating effect. For 3-D laser cooling, a solenoid is opened to couple X and Y degree of freedom and the optimum solenoid field would be 100 Gauss.

To see how far we can actually go under this real situation, IBS effect is considered in the following simulations. The simulated number of particle is varied from 200 to 1000 to see the particle number dependence of IBS heating in S-LSR. According to the simulation result, capture rate drops, final rms beam radius, normalized cold beam core emittance and temperature goes up with the number of initial particles. This is because IBS effect gets enhanced by larger number of particles. Thus we prefer lower number of particles to reduce IBS heating effect. However, around 1000 particles per bunch are near the limit of detection. At that circumstance, we can achieve around 600 particles cooled. The final temperature of cold beam core would be around 10 K in transverse direction and 0.05 K in longitudinal direction, as shown in Fig. 6.

(a) (b)

Figure 6: S-LSR real situation laser cooling simulation with IBS on. Cool effect of different number of particles. (a) Final rms beam radius vs. number of particles; (b) Final transverse and longitudinal temperature vs. number of particles.

CONCLUSION

The power of the cooling laser currently available in S-LSR is quite limited. We then expect the achievable beam temperature to be much higher than the Doppler limit even with the RCM. Nevertheless, considering the high potential of S-LSR, according to the simulation study, even with this limitation in the laser system, it seems feasible to break the world record of lower limit of the beam temperature. This paper gives useful insights for the laser-cooling experiment under a practical situation. By carefully choosing laser cooling parameters, we can finally arrive in a cold ion beam with temperature around 10 K in transverse direction and 0.05 K in longitudinal direction. However, the result is a theoretical lower limit achievable by current S-LSR system and recent experiment results still arrive in higher temperature after cooling [15]. And we also expect that with an upgrade of the laser system in S-LSR in the future, a colder beam with an even lower temperature would be possible to be realized.

APS FAST ORBIT FEEDBACK SYSTEM UPGRADE*

R. Lipa, N. Arnold, H. Bui, G. Decker, T. Fors, R. Laird, F. Lenkszus,
A. Scaminaci, N. Sereno, S. Shoaf, ANL, Argonne, IL 60439, USA

Abstract

A real-time feedback double-sector controller (RTFB DSC) for the APS Upgrade has been under design for the past year. Using the Xilinx Zynq-7000 All Programmable System on a Chip FPGA residing on the ZC706 board as the base platform, the upgrade path interfaces to the existing accelerator system and modernizes the beam position monitoring and feedback systems. The modernized system increases the RTFB system sample rate from 1.5 kHz to 22.6 kHz. We report the plan for sector-by-sector upgrades that will occur during system shutdowns and allow the upgraded sectors to operate with the existing sectors. The mapping of the RTFB DSC architecture is shown utilizing the targeted FPGA features. These features include the dual ARM Cortex™ A9 processors, multi-port DDR3 memory controllers, gigabit transceivers, and the programming logic interconnect for implementing advanced orbit feedback controller algorithms using floating-point DSP operations. The RTFB DSC FPGA architecture is revealed as well as subsequent progress on the chassis implementation.

INTRODUCTION

The RTFB DSC of the APS storage ring upgrade increases the processing power using modernized electronics to provide the functions, calculations, and interfaces of the present-day system and to improve the beam stability by increasing the sample rate to target a closed-loop bandwidth of at least 200 Hz. The network interface elements and functions on the RTFB DSC incorporate the EPICS software environment to control the process variables to configure and monitor the RTFB system. The RTFB DSC gigabit transceiver cores receive and transmit the global BPM error matrix over the real-time data highway (DH). The digital signal processing cores calculate the corrector drive vector using a response matrix multiplication and global BPM error vectors to obtain the local portion of the corrector drive vectors. The correction is then applied to the steering corrector power supplies located in that double sector. The RTFB DSC interfaces to a disparate and evolving set of equipment. The RTFB DSC advantageously uses the programmable FPGA features to attach to the various rates and protocols used by different equipment. The modern FPGA's integrated features, such as high-performance embedded processors, integrated DDR3 cores, numerous DSP and BRAM cores, gigabit Ethernet controllers, and gigabit transceiver blocks, along with the programmable fabric, allow decreasing the sample period and reducing the delay in correcting the electron orbit.

RTFB DSC SYSTEM ARCHITECTURE

The real-time feedback double-sector controller functions in the middle of the following existing [1] and proposed storage ring elements: monopulse rf beam position monitors (BPMs), Bergoz (i.e., narrowband) BPMs, existing x-ray BPMs, steering corrector power supplies, the Experimental Physics and Industrial Control System (EPICS), the timing and event systems, the low-level rf systems, and a machine (i.e., storage ring) protection system. The modernized RTFB DSC FPGA also provides the capability to interface to commercial BPMs (e.g., Libera Brilliance+ [2]) and to commercial x-ray data acquisition systems (e.g., Libera Photon [3]). Figure 1 is a block diagram of the system showing the RTFB DSC and the other storage ring elements and the interconnections. The upgrade design shows the mapping of the RTFB DSC architecture to a realizable modern implementation.

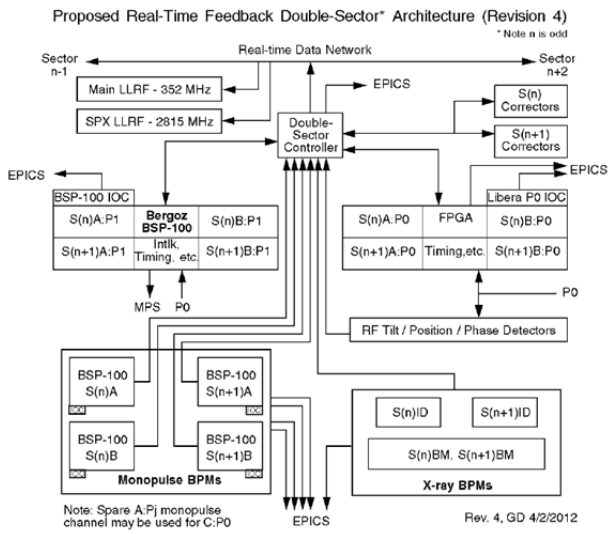

Figure 1: Real-time feedback double-sector controller architecture.

RTFB DSC IMPLEMENATION

The architecture maps into three functional chassis: 1) the APS2VME crate, which interfaces to the exiting reflective memory and EPICS networks; 2) the RTFB DSC chassis, which uses the ZC706 board [4] with its FPGA Mezzanine Connectors (FMC) for interfaces; and 3) the CMPSI-II chassis, which uses a KC705 board [5] and its FMC connectors interfaces as shown in Figure 2.

Copyright © 2013 CC-BY-3.0 and by the respective authors

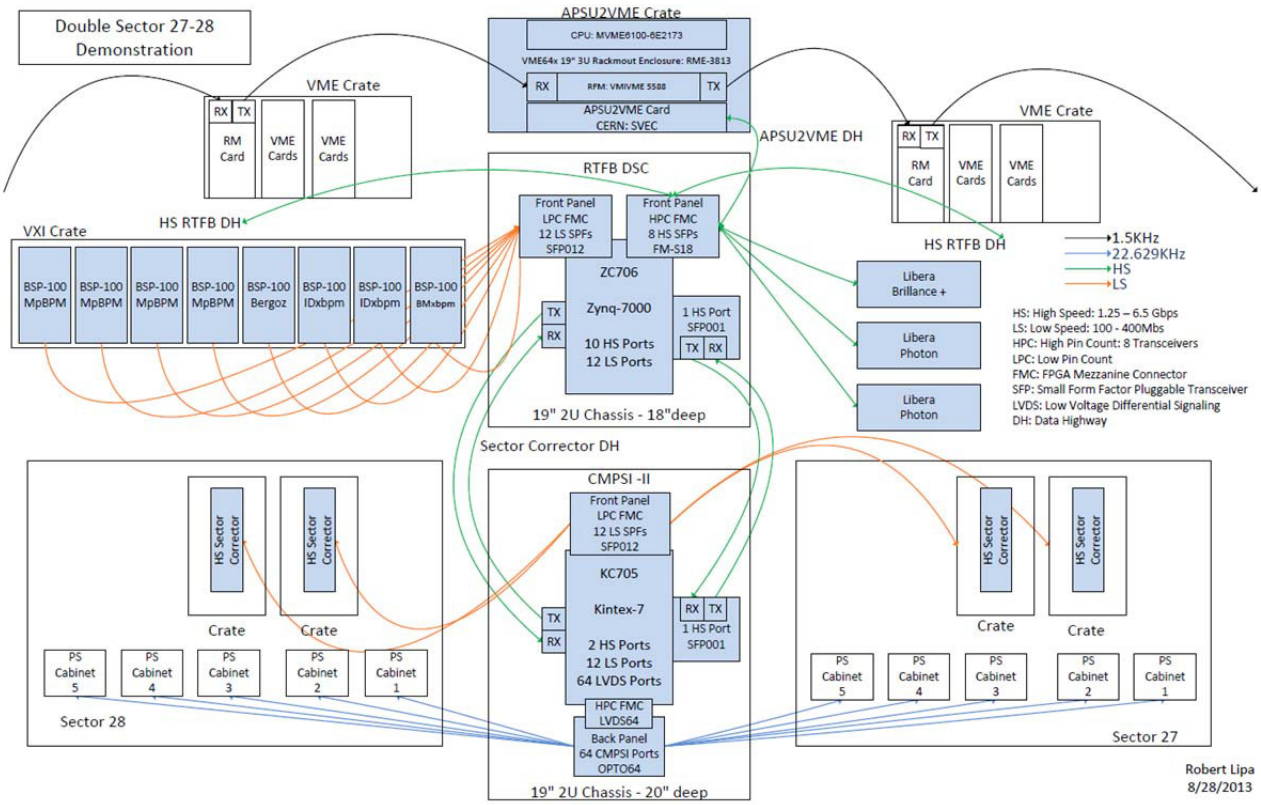

Figure 2: RTFB system architecture implementation using three chassis.

APSU2VME Crate

The APSU2VME crate is a rack-mountable chassis with 3U height accepting up to five horizontally mounted 6U cards. It contains three cards: a CPU, the Reflective Memory card, and the SVEC [6]. The SVEC is a versatile VME64x board with the features necessary to interface with both the existing 1.5-kHz sample network and the new 22.6-kHz sample network. Using the following SVEC features—VME64x backplane connector, front panel SFP module, DDR3 memories, and Spartan6 XC6SLX150T FPGA—the BPM error matrix can be transmitted and received between the two systems.

RTFB DSC Chassis

The RTFB DSC chassis is a custom low-cost 2U rack-mountable chassis interfacing to the BPMs, APSU2VME crate, commercial BPM, commercial x-ray data acquisition systems, and the Corrector Magnet Power Supply Interface—a second-generation (CMPSI-II) chassis. The RTFB DSC chassis contains the following components to be used to execute the RTFB algorithms on the various interfaces: a Xilinx ZC706 board, a Faster Technology FM-S18 FMC [7] with eight high-speed SFP channels, the SFP012, and the SFP001. The SFP012 is a custom 12-port SFP FMC accepting low-speed SFP modules. The SFP001 is a custom single-port SFP card holding one high-speed SFP module. Additionally the chassis contains a 12-V power supply, a fan controller, fans, and external connectors: LC, Ethernet, and USB.

CMPSI-II Chassis

The CMPSI-II chassis is also a custom low-cost 2U rack-mountable chassis. It interfaces to the RTFB DSC chassis, the CMPSI interfaces in the power supply (PS) cabinets, and a potential future high-speed sector corrector power supplies. The CMPSI-II chassis contains the following components to be used for applying the PS setpoints: a Xilinx KC705 board, the LVDS64, and the OPTO64. The LVDS64 is a custom LVDS FMC on the high pin count connector of the KC705. The OPTO64 is a custom board interfacing an LVDS cable to Harting connectors. The OPTO64 mounts an existing PS interface card. The ZC706 board and the KC705 board can communicate directly via the on-board SFP modules and the SFP001. The low pin count (LPC) connector could potentially communicate with a high-speed sector corrector using the currently defined LPC FMC pins.

SECTOR-BY-SECTOR UPGRADE

By replacing existing VME crates with two APSU2VME crates, one at each edge of the sectors being upgraded, and connecting the HS RTFB DHs of the RTFB DSCs with the upgraded sectors containing the RTFB DSCs between the two APSU2VME crates, the storage ring can be upgraded on a sector-by-sector basis during scheduled shutdowns. Thus the upgraded sectors can operate at the 22.6-kHz sample rate as the Sector 27 demonstration targets.

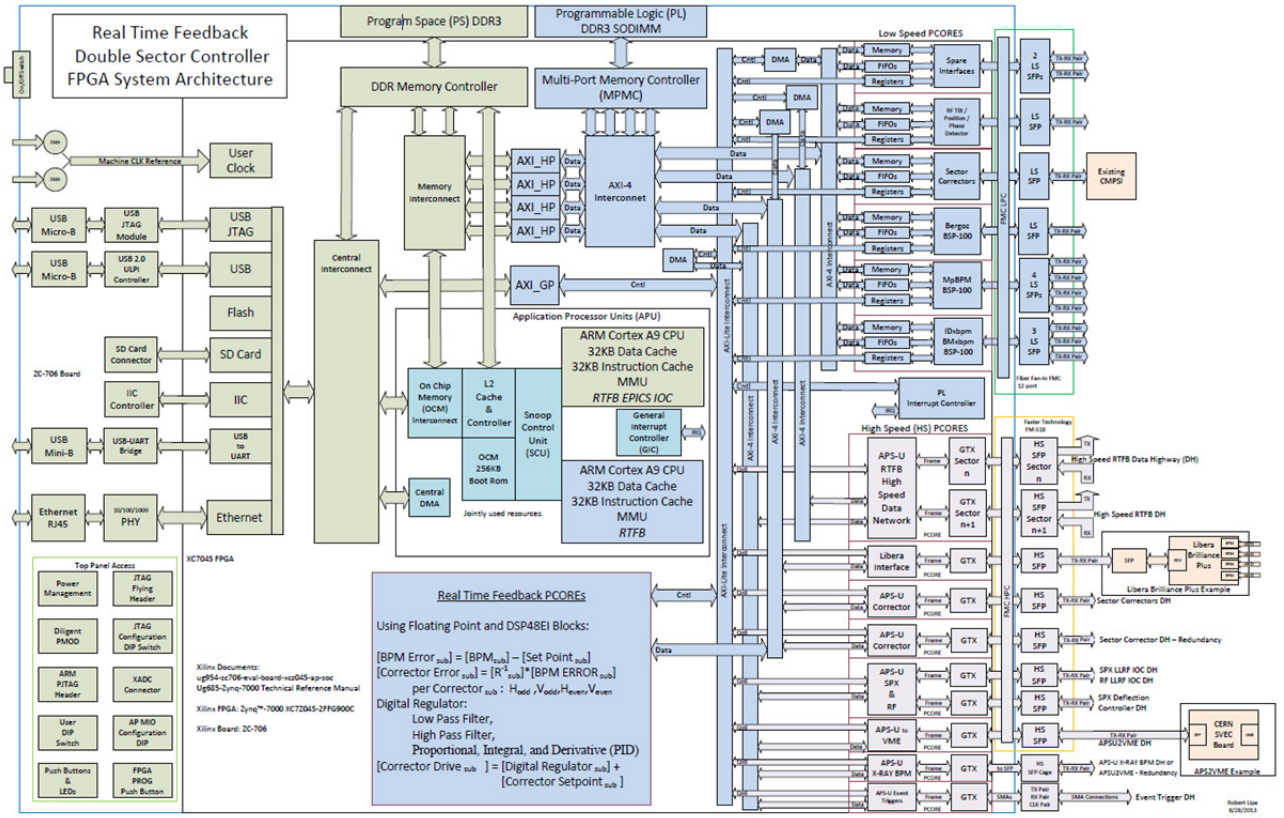

Figure 3: RTFB DSC FPGA architecture using Zynq-XC7Z045 FPGA.

RTFB DSC FPGA ARCHITECTURE

Using the Zynq-XC7Z045 FPGA features [8] and the features of the ZC706 board, the necessary function for the RTFB DSC maps can be realized. EPICS runs from Linux in the program space DDR3 memory on one of the ARM Cortex™ A9 CPUs. The RTFB algorithm runs on the other CPU with hardware assists from floating-point DSP cores in the programmable logic (PL) fabric. Figure 3 shows the FPGA architecture. With Vivado High-Level Synthesis [9] or System Generator, the RTFB algorithms can be implemented using floating-point DSP cores and exported as a PCORE. The PCOREs attach to the DDR3 controllers, GTX, and the CPUs via the AXI interconnect. The RTFB CPU coordinates the flow of the error and response matrix data between the RTFB PCOREs and the LS and HS interconnections via the AXI interconnect using the DMA controllers.

SUBSEQUENT PROGRESS

Routed versions of the SVEC FPGA with a (0) timing score have been created. The FPGA functions to interface to the existing system function and is created using the following FPGA features: VME64x core, VME-to-AXI DPR, 4-port RTFB DDR3 memory controller, Microblaze (MB) embedded processor with local memories and controllers, MB DDR3 memory, AXI interconnect, two AXI DMA controllers, and one GTP core.

CONCLUSION

The Fast Orbit Feedback System for the APS Upgrade utilizes the dual ARM Cortex™ A9 processors, multi-port DDR3 memory controllers, gigabit transceivers, and the programming logic interconnect to advance fast orbit feedback to a 22.6-kHz sample rate.

LINEAR ANALYSIS FOR SEVERAL 6-D IONIZATION COOLING LATTICES*

J. Scott Berg, Robert B. Palmer, Diktys Stratakis, BNL, Upton, NY, 11973, USA†

Abstract

In muon accelerators, ionization cooling is the only viable option for reducing the muon beam emittance to values necessary for a muon collider. An ionization cooling lattice requires a large momentum acceptance, small beta functions, an extremely large dynamic aperture, and a modest amount of dispersion to have good performance. The latter values are a function of beam momentum. One step in understanding the lattice performance is to determine these quantities for a lattice cell being studied. This is modestly more complex than usual since the lattice is generally highly coupled. We first review the general method for computing these quantities for a general lattice. Then we look at several lattices of interest, compute these quantities, and relate their values and momentum dependencies to the performance of the lattices.

ANALYSIS

To try to understand the behavior of cooling lattices, one can used standard techniques for analyzing accelerator lattices. These systems are highly coupled, and they are non-symplectic due to the presence of cooling. The symplecticity is further complicated by the use of kinetic momenta in most tracking codes. Use of canonical momenta would be challenging due to the strong transverse vector potentials that arise from the use of solenoids, but would arise in any case due to the use of short cells and large beam sizes. Symplecticity can be further compromised by use of a non-symplectic integrator with step sizes larger than needed for machine precision and magnetic field approximations that are not divergence-free.

Fixed Energy

At fixed energies, we find the closed orbit through a single cooling cell, then look at the linear map about that closed orbit. We then find the eigenvalues and eigenvectors of the linear map to get the tunes and the beta functions. More specifically, if M is the linear map about the closed orbit, then we find a matrix A such that $MA = AR$, where R is in the form

$$\begin{bmatrix} \lambda_1\cos\mu_1 & \lambda_1\sin\mu_1 & 0 & 0 \\ -\lambda_1\sin\mu_1 & \lambda_1\cos\mu_1 & 0 & 0 \\ 0 & 0 & \lambda_1\cos\mu_2 & \lambda_1\sin\mu_2 \\ 0 & 0 & -\lambda_1\sin\mu_2 & \lambda_1\cos\mu_2 \end{bmatrix} \quad (1)$$

Since M is not necessarily symplectic, we allow $\lambda_k \neq 1$.

We find the lattice parameters as a function of energy. We will not study energies for which the lattice does not have stable orbits in the sense that R is of the form (1).

The matrix A is not uniquely defined. There are three different degrees of freedom. First, one can exchange the first two columns of A with the last two columns, which corresponds to swapping the eigenvalues. Second, one can change the sign of one of the first two columns of A, which corresponds to changing the sign of μ_1 (similarly for the last two columns and the sign of μ_2). Finally, one can multiply A on the right by a matrix of the form (1) (but with different parameters than R). We will define A sufficiently to accomplish three goals: to resolve the sign ambiguity in μ_k in R; to be able to compute the beta functions; and to ensure that the two sets of eigenvalues and the beta functions are continuous functions of the energy (so that the 1 and 2 indices don't swap arbitrarily).

For a given energy, we scale both $\boldsymbol{a}_{2k-1}$ and $\boldsymbol{a}_{2k}$ ($\boldsymbol{a}_j$, $1 \leqslant j \leqslant 4$, is the jth column of A) by the same value, and possibly change the sign of $\boldsymbol{a}_{2k}$, so that $\boldsymbol{a}_{2k-1}^T J \boldsymbol{a}_{2k} = 1$, where

$$J = \begin{bmatrix} 0 & 1 & 0 & 0 \\ -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & -1 & 0 \end{bmatrix} \quad (2)$$

and the order of coordinates is (x, p_x, y, p_y). If we change the sign of $\boldsymbol{a}_{2k}$, we also change the sign of μ_k. There is still an arbitrary rotation on the right side of A; we will insure that subsequent results are independent of that rotation.

Say we compute A_1 and A_2 for nearby energies. We would expect these matrices to be nearly the same, except for an arbitrary rotation on the right side of each one. If the columns of these matrices are $\boldsymbol{a}_{1;j}$ and $\boldsymbol{a}_{2;j}$, we compute the matrix S_{kl} with elements $s_{kl;ij} = \boldsymbol{a}_{2;2k-2+i}^T J \boldsymbol{a}_{1;2l-2+j}$. If $\det S_{11} > \det S_{12}$, then the columns of A_1 and A_2 refer to corresponding eigenvectors. If not, then the eigenvectors are in a different order in A_1 and A_2, and for one of the matrices the first pair of columns should be swapped with the second pair, and the eigenvalues should be swapped as well.

Each eigenvector pair describes a corresponding set of Courant-Snyder lattice functions. They relate the beam size and angular divergence to the area traced out by an ellipse. Since with coupling, oscillation is not in a fixed plane, the corresponding quantities must be independent of direction. They must also be independent of the arbitrary rotation on the right side of A. By analogy to the usual quantities, we can then define

$$\beta_k = a_{1,2k}^2 + a_{1,2k+1}^2 + a_{3,2k}^2 + a_{3,2k+1}^2 \quad (3)$$

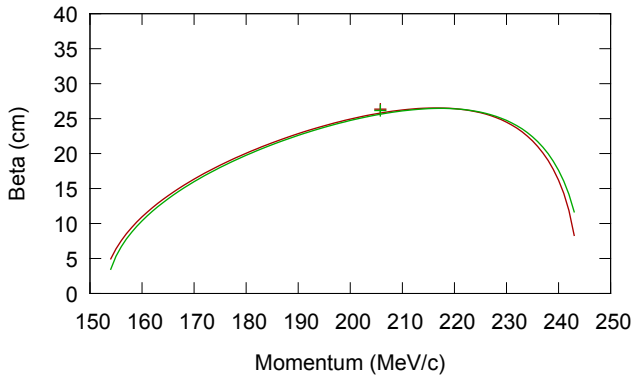

Figure 1: Beta functions vs. total momentum in stage 4 of the rectilinear FOFO (curves). The plus symbols are the beta functions and total momentum for the 6-D closed orbit.

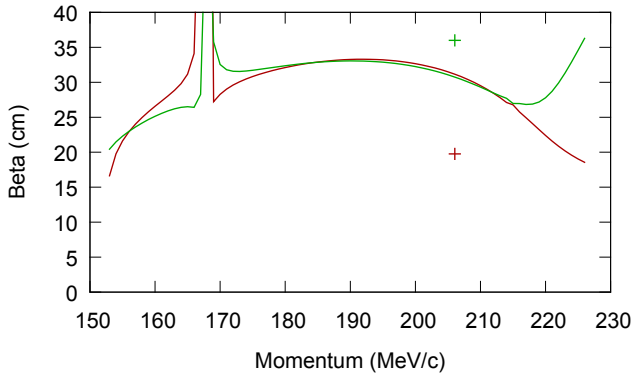

Figure 2: Like Fig. 1, but for the planar snake.

One could similarly define α_k and γ_k, though the usual relationships between these quantities do not necessarily hold since there are additional degrees of freedom due to coupling between the planes.

We calculate dynamic apertures as a function of energy by launching particles along the vector

$$\sqrt{2J_1}\boldsymbol{a}_1 + \sqrt{2J_2}\boldsymbol{a}_3 \tag{4}$$

and keeping track of the number of turns a particle survives as a function of J_1 and J_2.

6-D Fixed Point

We can also find the 6-D fixed point in the presence of acceleration and the average energy loss in the absorbers. All calculations are as for fixed energy but with 6-dimensional phase space vectors. Our additional variables are time and energy. The additional rows and columns of J may need a sign change or scaling factor depending on the exact implementation (blindly using energy and time, plus having momenta in eV/c, leads to a factor of $-c$ in J as used above). The eigenvalues will no longer have unit magnitude even for Maxwellian fields due to the presence of the absorber. Beta functions for the modes which are primarily transverse are computed according to (3).

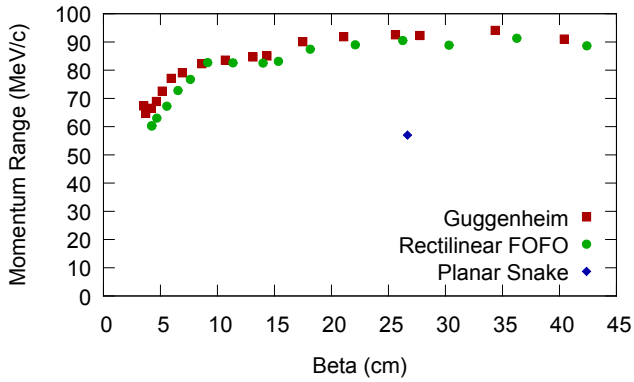

Figure 3: Momentum range vs. the geometric average of the beta functions at the 6-D fixed point.

One can calculate a "lossless" Q factor which arises solely from the average energy loss in the absorber and decays:

$$\frac{d\epsilon_6/\epsilon_6}{dN/N} = \frac{-2\ln|\lambda_1\lambda_2\lambda_3|(pc)\tau_\mu c}{L(m_\mu c^2)} \tag{5}$$

where ϵ_6 is the product of the emittances, N is the number of particles, λ_k are the eigenvalues of the one-cell map, p is the average total momentum for the closed orbit particle, τ_μ is the muon rest lifetime, m_μ is the muon rest mass, L is the cell length, and c is the speed of light. The Q value for the real lattice [1] is lower due to multiple scattering and energy straggling, which increase the emittances and cause particles to fall out of the dynamic aperture, dynamical losses of large amplitude particles, and emittance growth from mismatches and nonlinearities.

LATTICES

We study three cooling lattices. The first is a "Guggenheim" channel [2], where the beamline bends around in a circle while gradually moving perpendicular to the plane of the circle. A dipole field which is mostly in the vertical direction is generated by tilting the solenoid coils. In addition to generating bending, this creates dispersion (in position) at a wedge-shaped absorber. The solenoid field undergoes a single sinusoidal-like oscillation within the cell. The second is a rectilinear FOFO snake [3, 4], which has fields similar to the Guggenheim channel, but with smaller coil tilts and therefore a smaller dipole field, but where the beamline is straight. This requires vertical motion of the closed orbit to correct the bending from the dipole field. The third is a planar snake [5], which is a straight channel like the rectilinear FOFO. However, the solenoid field in one cell is opposite to the field in the next cell. In the presence of the dipole field generated from the tilts, this makes the period of this lattice two "cells" long. In addition, the direction of the tilts is chosen so that instead of dispersion in position at the absorber, there is dispersion in momentum. Thus a parallel-faced absorber can be used instead of a wedge.

Copyright © 2013 CC-BY-3.0 and by the respective authors

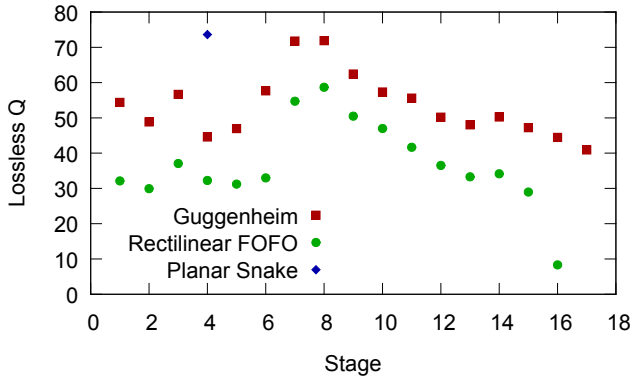

Figure 4: Lossless Q, vs. stage number. The planar snake has a beta function similar to stage 4 of either the Guggenheim or rectilinear FOFO.

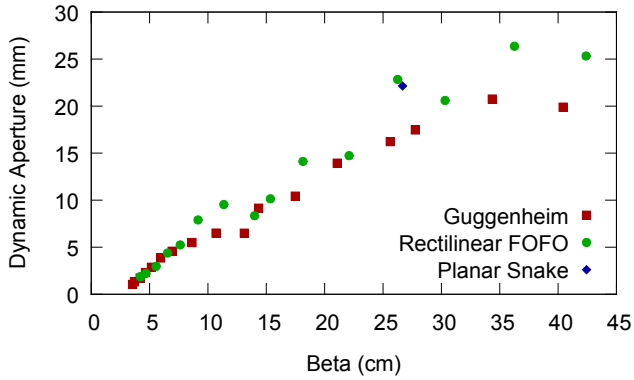

Figure 5: Dynamic aperture vs. the geometric average of the beta functions at the 6-D fixed point. Dynamic aperture is the average over the momentum passband of the smallest value of $J_x + J_y$ (normalized) beyond which there is at least one (J_x, J_y) pair which does not survive for 20 turns.

Calculations are performed using ICOOL [6] and computing linear maps via finite differences.

Figures 1 and 2 show the beta functions as a function of total momentum for a rectilinear FOFO (the Guggenheim is similar) and the planar snake. The rectilinear FOFO and Guggenheim operate in the passband between π and 2π phase advance. The planar snake operates similarly, except that the period is two cells, so what is shown in Fig. 2 is for a phase advance from 2π to 4π. There is thus a linear resonance (3π) near 168 MeV/c, which despite its weakness appears to be enough to truncate the operating passband. One also observes a strong change in the beta functions at the high energy end (there is a corresponding change in the closed orbit) arising from the approach to an integer tune. There are also indications of a coupling resonance near 213 MeV/c.

Figures 1 and 2 also show the beta functions at the 6-D fixed point. For the rectilinear FOFO and Guggenheim, the beta functions are close to what is found in the fixed energy calculation. For the planar snake, however, the beta functions are very different. At the fixed point, the two betatron tunes and the synchrotron tunes have the same fractional part (near 0.25), and one of the transverse eigenvectors and the longitudinal eigenvector have ellipse projections that have nearly equal areas in the transverse and longitudinal directions. Thus the planar snake appears to be operating on a synchro-betatron resonance, similarly to what is described in [7].

Energy acceptance of a lattice is important both to achieve good longitudinal cooling and acceptance as well as to limit losses from energy straggling. One can look at the momentum acceptance that can be achieved for a given beta function at the absorber. The result is shown in Fig. 3. The planar snake has a significantly reduced momentum acceptance compared to the other lattices. The rectilinear FOFO (at least as designed) does not perform quite as well as the Guggenheim for smaller beta functions.

Figure 4 shows the lossless Q for the lattices. Note that the lossless Q is significantly lower for the rectilinear FOFO than for the other lattices. Since this is mainly related to the energy lost or gained in each cell, and the RF gradients in the rectilinear FOFO are similar or larger than those used in the Guggenheim or planar snake, one would expect that the rectilinear FOFO could have improved performance, probably via some increase in the wedge thickness and subsequent tuning. This may explain the lower Q value found for the rectilinear FOFO (maximum of 9.5 [4]) compared to the Guggenheim (maximum of 11 [2]).

Figure 5 shows the dynamic aperture plotted against the beta function for the Guggenheim and rectilinear FOFO lattices. Note that the dynamic aperture is not proportional to the beta function for small beta (it is worse), which ultimately prevents achieving smaller emittances.

A PLANAR SNAKE MUON IONIZATION COOLING LATTICE *

Robert B. Palmer, J. Scott Berg, Diktys Stratakis, BNL, Upton, Long Island, New York, USA

Abstract

Muon Colliders require cooling in six dimensions (x, x',y, y', t, E). Several ionization 6D cooling lattices, using vacuum acceleration, are reviewed: RFOFO lattices, both curved [1] and rectilinear [2] cool one sign to low emittances; A Helical FOFO snake [3] cools both signs, but not to low emittances. A Planar Snake [4] lattice is proposed that cools both muon signs, and appears suitable for low emittances. The parameters and performance for an example suitable for the early stages of cooling is given.

INTRODUCTION

The Muon Accelerator Program (MAP) [5] is studying Muon Colliders with center of mass energies from 125 GeV to several TeV. All require 6 dimensional (x, x',y, y', E, t) cooling to transverse emittances of ≈ 0.31 mm, and longitudinal emittances ≈ 1.5 mm.

In transverse ionization cooling, in a low Z absorber (hydrogen or Lithium Hydride), both transverse and longitudinal momentum are lost. Radio-frequency (rf) cavities (only vacuum rf is considered in this paper) then restore the longitudinal momentum, leaving the reductions of the transverse components. Multiple scattering leads to a minimum (equilibrium) emittance that is proportional to the betatron $\beta_\perp$ divided by the relativistic β of the muon momentum.

For cooling in the longitudinal dimension, emittance exchange is required. Two methods are illustrated in Fig. 1a and b. In a), a wedge absorber is placed in a region with dispersion, so higher momentum muons have more energy loss than those lower. In b) a plane slab absorber is placed where there is angular dispersion. Emittance exchange can also be achieved in a Helical Cooling Channel [6] where absorbing material is everywhere while higher momenta have longer paths.

Periodic lattices allow lower transverse betatron lengths $\beta_\perp$, but introduce integer and half integer resonances defining the operating momentum range. Figure 2a, b, and c show three cases:

a) Simple lattices of equi-spaced solenoids operate above the single π resonance.

b) Bi-periodic lattices [7], with pairs of coils spaced by longer drifts operate between the 2π and π resonances and have an attractively level $\beta_\perp$ between these resonances.

c) Lattices with more complex coils sequences, such as the Helical FOFO Snake and Planar snake, which both operate between the 3π and 2π resonances.

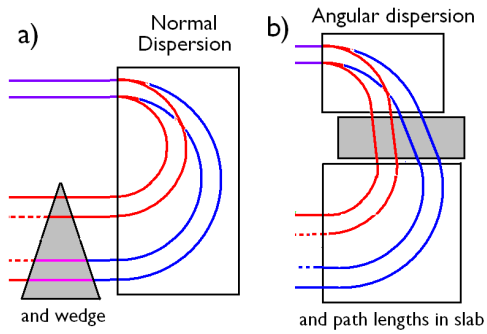

Figure 1: Emittance Exchange: a) using dispersion & wedge absorbers; b) using angular dispersion & slab absorbers.

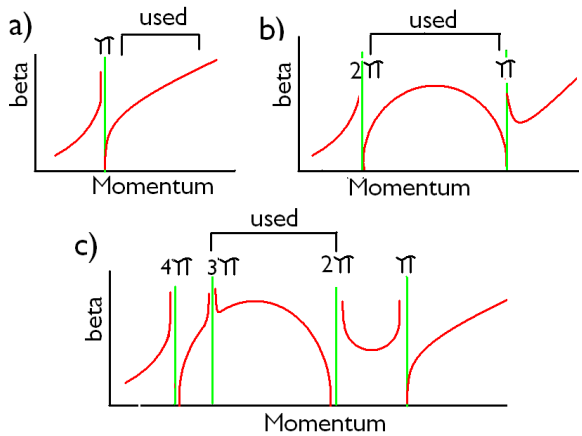

Figure 2: Lattice types: a) Simply periodic alternating solenoids; b) Bi-periodic alternating solenoids; c) Higher tune lattices (Helical Snake & Planar Snake).

GEOMETRIES

Figure 3 shows three lattice geometries. They could be curved, but we consider only straight geometries here.

RFOFO & RFOFO Rectilinear Lattices

Using alternating solenoids, Balbekov [2] has shown that the required dispersions can be generated by small tilts of the coils in either a simply periodic (FOFO) or bi-periodic (RFOFO) lattice. The tilts are small and alternate to generate periodic dipole fields (Fig. 3a). The performance of these lattices is essentially the same as with curved lattices [8], but with simpler engineering. Recent simulations [9, 10], have shown cooling from emittances close to those simulated from the initial phase rotation (15 mm transverse, 45 mm longitudinal) to that required in the baseline design (0.31 mm transverse and 1.5 mm longitudinal) with acceptable particle loss (of order 50%).

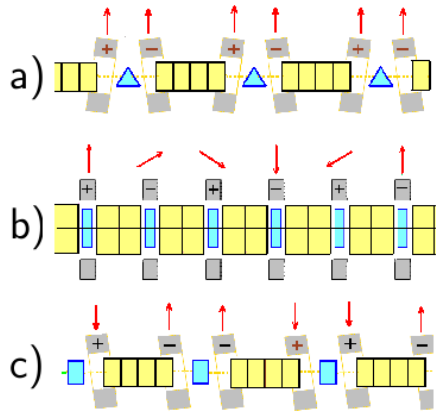

Figure 3: Geometries: a) Rectilinear RFOFO; b) Helical FOFO Snake; c) Planar Snake.

Despite the success of such simulations, there are reasons to seek alternatives. The current densities are high, in part because the coils on either side of the absorber are opposed; and for the same reason, the forces between them are outward, requiring supporting structures. The engineering of wedge shaped liquid hydrogen absorber will not be easy, and the fact that they only cool one sign is less than ideal.

Helical FOFO Snake

The Helical FOFO Snake [3] (Fig. 3b) is based on a periodic FOFO lattice with alternating focus solenoids, but the coil tilts are no longer in a single plane. Instead, the tilt directions rotate in azimuth giving closed orbits that perform an approximation to a helix. Because the lattice does not repeat for multiple sub-cells, there are more resonances, and the operating momenta are restricted to tunes between 3π and 2π - as in Fig.2c.

The lattice has two very attractive characteristics: 1) it uses absorbers with plane parallel windows that would be much easier to build than the wedges; and 2) it works for both signs simultaneously, possible because the lattice employs emittance exchange represented in Fig. 1b. Unfortunately the absorbers are located where the $\beta_\perp$s are at their maxima making it unsuitable for cooling to the smaller emittances.

Planar RFOFO Snake

This lattice[4] (see Fig. 3c) is, like the RFOFOs, based on bi-periodic focusing coils that give low betas at absorbers placed between the nearer pairs. But the polarities of the coils, instead of alternating, have the sequence $+|+-|-+|+$ etc., where the vertical bars indicate absorber locations. The number of field reversals is now only half that in an RFOFO, and the coils on either side of the absorber have the same polarity. Their fields no longer buck one another, and the magnet forces pull them together. A disadvantage is that the phase advances are doubled and the momentum acceptance, between 3π and 2π (see Fig. 2c) is reduced.

An attempt to find tilts that would give dispersions at the absorbers failed, but a solution was found, using very small tilts, giving large angular dispersions. The solution has tilts all in the same direction, resulting in dipole fields with the same pattern as the solenoids. This introduces a transverse resonance, at the tune 2π, at the high end of the momentum acceptance. This dispersion is highly non-linear: low over most of the momentum range, but very high near the 2π resonance, yet, at least for the example simulated, this was not a problem.

EARLY STAGE PLANAR RFOFO SNAKE

This example would be suitable for an early stage of 6D cooling for a Muon Collider. Parameters are given in Table 1. Figure 4 shows a cross section of one complete cell. The solenoid coils are tilted in the same direction alternatively by 7.3 and 17.9 mrad. The rf is at 201 MHz operating at 17 MV/m axial gradient, and a phase of approximately 30 degrees.

Figure 5 shows the betas as a function of length for a few cells. It is seen that, as in a normal RFOFO lattice, the betas are much lower at the absorbers than between them.

Figure 6 shows the dispersions as a function of length over a few cells. It is seen that, at the absorbers, the dispersion is not large, but the x dispersion at the absorber is changing rapidly as a function of length, corresponding to an angular dispersion of approximately 0.4.

Figure 7 shows the emittances and transmission. Cooling is good in both transverse and longitudinal emittance, with the rate of muon loss, after an initial miss-match, dominated by the inevitable decays. The quality factor $Q = (d\epsilon_6/\epsilon_6)/(dn/n)$ has a low initial value where matching losses dominate; a low value at the end as the emittances approach their equilibria; and a maximum value of over 9, which is approximately the same as that with a Rectilinear RFOFO lattice.

The results plotted in Fig. 7 and discussed above were obtained using a mode of ICOOL [11] simulation in which fields are defined along the axis, and the program derives the fields at other locations by a 5th order extrapolation. The lattice has since been simulated [12] with ICOOL using a field map, and also with G4BL [13] using the same map. The results are very similar or slightly better in these simulations.

CONCLUSION

Simulations of Rectilinear RFOFO 6 dimensional ionization cooling has given the required parameters, but there remain engineering challenges and two complete systems are needed for the two particle signs.

A Planar RFOFO Snake, using planar absorbers, can cool both signs simultaneously. An example lattice design of an early stage of cooling has been simulated and gives good performance. It uses coils on either side of the absorber, that have the same polarity, thus reducing the cur-

Half absorber	Liquid H_2	21.3	18

rent densities and forces. Non-linear angular dispersions are obtained with small tilts (0.5-1 deg.), enhanced by the 2π resonance at the high momentum end.

The concept is similar to that of a Helical FOFO Snake [3], but is here generated by alternating dipole fields in a single direction, conceptually giving planar snaking orbits, unlike the azimuthally rotating dipoles in the Helical Snake. The planar RFOFO snake allows betas at the absorbers to be much smaller than elsewhere. This result has been confirmed using field maps in both ICOOL and G4BeamLine. A design reaching the required final emittances has been tried, but its transmission is poor, and is not yet understood.

Abstract

Efforts to experimentally prove the concept of coherent electron cooling are underway at BNL. A short 22 MeV linac will provide high charge, low repetition rate beam to cool a single ion bunch stored in RHIC. The linac will consist of a 112 MHz SRF gun, two 500 MHz normal conducting bunching cavities and a 704 MHz five-cell accelerating SRF cavity. The paper describes the SRF and RF systems, the linac layout, and discusses the project status, first test results and schedule.

INTRODUCTION

Coherent electron Cooling (CeC) is a technique promising significant luminosity improvement in high-energy hadron-hadron and electron-hadron colliders [1]. A Proof-of-Principle (PoP) experiment is under preparation at BNL to demonstrate its feasibility [2, 3]. This experiment aims to cool only one ion bunch stored in RHIC, requiring a high-bunch-charge (up to 5 nC), but low-repetition-rate electron beam. The bunch repetition frequency (78 kHz) is equal to the revolution frequency of ion bunches in RHIC. A short 22 MeV superconducting linac is being built to provide such beam [4]. The linac includes two superconducting RF (SRF) systems and one normal conducting RF system. The two SRF systems are a 112 MHz Quarter Wave Resonator (QWR) SRF photoemission electron gun [5] and a 704 MHz SRF booster cavity cryomodule. The normal conducting RF system comprises two copper bunching cavities [6] to provide velocity modulation for shortening the electron bunches between the two SRF cryomodules. The linac layout is shown in Figure 1. In this paper we describe the SRF and RF systems, report on the project status and test results, and discuss testing and commissioning plans.

112 MHz QWR SRF GUN

A superconducting 112 MHz quarter-wave resonator was developed by collaborative efforts of BNL and Niowave, Inc. [7, 8]. The gun operates at 4.5 K with liquid helium provided from a quiet helium source via the cryomodule cryogenic tower. We expect to achieve the

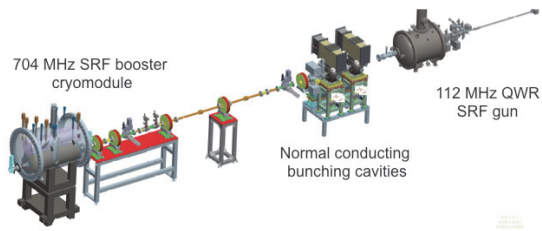

Figure 1: Layout of the CeC PoP linac.

cavity quality factor of 1.8×10^9. The QWR's center conductor geometry naturally accommodates a half-wavelength choke joint and allows mechanical decoupling of the cathode assembly from the niobium cavity [9]. A low-RF-loss photocathode stalk operates at room temperature. It is hollow, allowing inserting a small photocathode pack via a load lock system. We plan to use multi-alkali (CsK_2Sb or NaK_2Sb) photocathodes illuminated with a green (532 nm) light from a laser to generate the electron beam.

The 112 MHz gun is equipped with a dual-purpose fundamental RF power coupler / fine frequency tuning assembly [9]. The fine frequency tuning with a range of about 3 kHz will be used for remote frequency adjustment. It will complement a larger range (>78 kHz) tuner, which will be used only for an initial frequency set up. The mechanical design of the fundamental power coupler (FPC) is described elsewhere [10]. A focusing solenoid is placed on top of the FPC close to the cryomodule's beam exit flange.

After the first cryomodule cold test at Niowave in December of 2010 [7], the gun has undergone modifications. A new cryostat was designed and fabricated to be compatible with BNL's safety requirements and to have appropriate interfaces for installation in RHIC tunnel. The modified gun was cold tested again at Niowave in December of 2012 and February of 2013. During the tests we encountered multipacting zones at very low fields, which were processed only after we modified the RF input coupler to increase its coupling. Eventually, the gun reached an accelerating voltage of 0.92 MV, limited by an insufficient radiation shielding of the experimental set up. Figure 2 shows the gun cavity performance during the cold test.

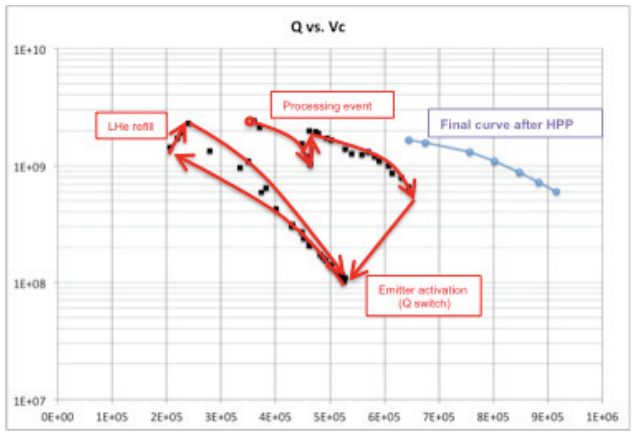

Figure 2: Q *vs.* V_c plot showing the gun cavity behavior during conditioning and the final curve.

After completion of the cold test, the gun was shipped to BNL and is currently installed in the RHIC tunnel. The commissioning will begin in early 2014.

500 MHz BUNCHING CAVITIES

Two single cell normal conducting cavities operating at 500 MHz will serve as bunching cavities, imprinting a velocity modulation along the electron bunch. The bunch will then shorten as they travel in the drift space between the two SRF cryomodules. The cavities are a contribution to the experiment from the Daresbury Laboratory, UK [6]. Formerly, they were installed in the now decommissioned SRS light source [11]. Figure 3 shows a cavity layout and Table 1 lists its parameters.

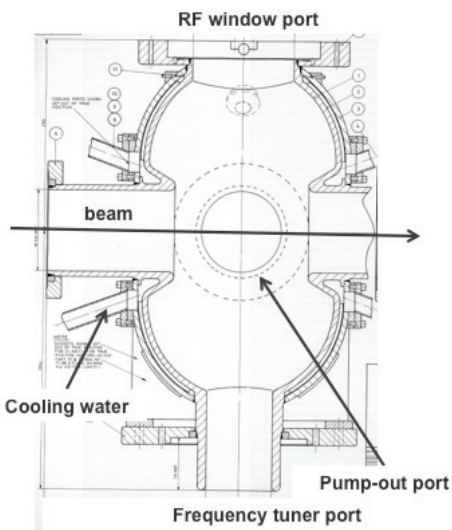

Figure 3: 500 MHz bunching cavity.

The fundamental power coupler is of a waveguide type coupled to the cavity via an aperture (port) at the cavity top, sealed with a disk ceramic window. The coupling is adjusted via moving a reflection plane in the waveguide. The original SRS configuration included a moveable waveguide short, which allowed adjusting coupling for different beam loading. As there will be very small beam loading in CeC PoP, we will adjust the short position for unity coupling only once – no need for a moveable short. The two cavities will be powered in parallel from an IOT-based RF power amplifier.

The cavities were delivered from Daresbury to BNL in early 2012. They have been particulate-free cleaned and refurbished, vacuum baked. The cavities are installed in the RHIC tunnel and being prepared for high power commissioning.

Table 1: Parameters of the 500 MHz Bunching Cavity

RF frequency	500 MHz
Accelerating voltage	0.3 MV
R/Q	178.5 Ohm
Geometry factor	38.2 Ohm
Cavity Q_0	31,000
Frequency tuning range	1.5 MHz
Cavity wall losses at 0.3 MV	16.3 W
Available RF power from IOT amplifier	50 kW

704 MHz BOOSTER CRYOMODULE

The 704 MHz booster cryomodule will house one 5-cell SRF cavity of the BNL3 shape [12-14]. The booster will deliver an energy gain up to 20 MeV. It will operate at 2 K with an internal superfluid heat exchanger to better isolate the cavity from microphonic noise originated in the cryogenic system. The mechanical design of the cold mass is described elsewhere [15]. A sectional view of the cryomodule is shown in Figure 4. A fundamental RF power coupler (FPC) will be of a coaxial antenna type and will be able to transmit power up to 20 kW CW. The cryomodule design is being finalized and its production will begin soon at Niowave, Inc. with the delivery to BNL scheduled for summer of 2014. Table 2 lists main parameters of the booster system.

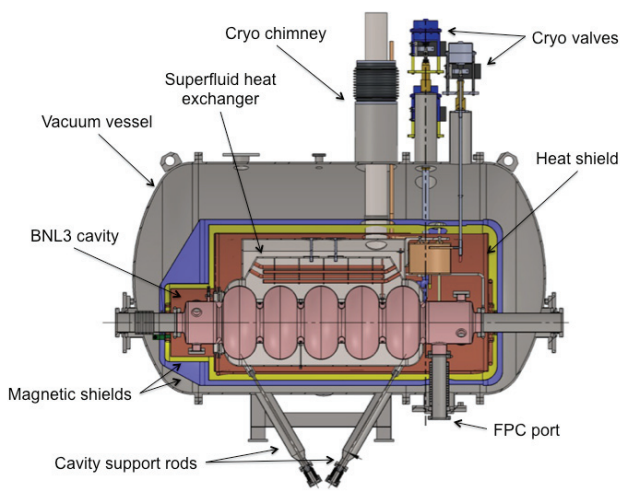

Figure 4: 704 MHz booster cryomodule for CeC PoP.

Two cavities have been fabricated: BNL3-1 by AES, Inc. and BNL3-2 by Niowave, Inc (Figure 5). Both cavities have undergone standard preparation for vertical acceptance testing (bulk BCP, vacuum bake at 600ºC for 10 hours, light BCP, HPR). The tests will be performed in October/November of 2013.

Frequency tuning range	78 kHz
Q_{ext} of FPC, min.	2.8×10^{7}
Available RF power from solid state amplifier	20 kW

Figure 5: BNL3-2 cavity at Niowave, Inc.

SUMMARY

A short 22 MeV linac for the CeC PoP experiment comprises two SRF systems and one normal conducting RF system. The 112 MHz SRF gun cryomodule has been fabricated and tested up to 0.92 MV, limited only by insufficient radiation shielding. It will be re-tested and conditioned to full voltage after installation in the RHIC tunnel is complete in January of 2014. This will be followed immediately by commissioning of the 2 MeV beam line. The beam line will include two single cell normal conducting bunching cavities operating at 500 MHz. The cavities were received from Daresbury in 2012, refurbished, vacuum baked and are currently installed in the RHIC tunnel. Two 704 MHz 5-cell cavities have been fabricated. One of the cavities will be chosen for integration into the booster cryomodule after both are tested in a vertical cryostat at BNL. The booster cryomodule design is being finalized and its fabrication will begin soon at Niowave. Its delivery to BNL is scheduled for summer of 2014. Installation of the booster cryomodule will complete the CeC PoP linac.

NOVEL MECHANICAL DESIGN FOR RHIC TRANSVERSE STOCHASTIC COOLING KICKER

C.J. Liaw, J.M. Brennan, S. Bellavia, J. Tuozzolo, K. Mernick, M. Myers
Brookhaven National Laboratory, Upton, NY 11973, U.S.A.

Abstract

Based on the beam emittance measurement from the pickup, the RHIC Stochastic Cooling kicker uses sixteen narrowband high Q cavities (from 5 to 8 GHz) to kick (or to cool) the bunched beam on each of the two transverse planes in the two rings. The cavities are integrated to two pairs of cavity plates and installed in two UHV chambers. The new kicker features scissor like driving mechanism, frictionless flexure joints, water cooled cavity plates, small frequency shift (less than 0.05%) during the operation and maintenance free. Novel mechanical designs, including cavity plate, vacuum, cooling, driving mechanism, and support structure design, are presented. Structural and thermal analyses, using ANSYS, were performed to confirm chamber structural stability and to calculate the cavity plate deformation due to thermal and mechanical load. Good agreement between the calculated cavity plate deflection and the expected plate deformation from the cavity frequency shift measurements has been achieved. Three assemblies utilizing this design (1 for the vertical and 2 for the horizontal plane) were completed for the FY2012 run. Successful performance has been reported.

INTRODUCTION

RHIC has successfully employed the stochastic cooling technique to counteract the emittance growth in the high frequency bunched beam due to Intra Beam Scattering (IBS) in the past several runs [1]. Two essential components, a pickup (to measure the beam emittance in the transverse directions) and a kicker (to cool the beam transversely), are required for the transverse stochastic cooling. The new pickup design has been reported elsewhere [2]. This paper will focus on the mechanical design of the new transverse stochastic cooling kicker.

To minimize the input power, high Q resonant cavities were chosen as the new kicker in RHIC [3]. During the early stage kicker development, RHIC received a few stochastic cooling tanks from Fermilab as a gift, which were originally developed for the FNAL Tevatron. To take advantage of these tanks, the FNAL original vacuum chambers and the driving mechanisms [4] were used to accommodate those cavities and to drive them from the cooling position (with a smaller aperture) to the standby position (with a larger aperture for the injected beam). There are several disadvantages with these designs: (1) The cavity plate guide shafts could get stuck in vacuum, (2) The beryllium copper RF spring fingers could lose their contact with the beam pipe, (3) The actuator could deliver an excessive force to bend the shaft, (4) The vacuum space is too small for the application, and (5) The cavity frequencies are not repeatable.

The newly developed transverse stochastic cooling kicker has addressed all the mechanical problems described above. Novel mechanical designs for the system are described below. Structural and thermal analysis results are also presented.

*Work supported by Brookhaven Science Associates, LLC under Contract No. DE-AC02-98CH10886 with the U.S. Department of Energy

DESIGN REQUIREMENTS

The mechanical design requirements for the new transverse stochastic cooling kicker are: (1) To provide 16 high Q cavities, spanning the bandwidth of 5 to 8 GHz in 200 MHz intervals, for each kicker, (2) To split the cavities on the median plane and integrate them into two pairs of cavity plates, (3)To maintain repeatable cavity resonant frequencies, with a frequency shift of no more than 0.05% of their frequencies, (4) To provide a reliable actuator for the cavity plates, (5) To keep the cavity aperture at 20 mm, during the operation, and at no less than 124 mm, when not in use, (6) To provide a sufficient space in the vacuum chamber for an easy access and the installation of the cavity plates, (7) To provide adequate structural stability of the vacuum chambers and the support stands, and (8) To provide a bakable (up to 200°C) and maintenance free vacuum design.

TRANSVERSE KICKER ASSEMBLIES

The 16 cavities in each assembly are installed in two UHV chambers. Fig. 1 shows one half of a horizontal and a vertical transverse kicker assembly. One vertical and two horizontal kicker assemblies were completed for the FY2012 run.

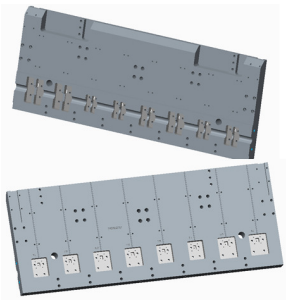

Fig. 2: A Typical Cavity Plate.

Unique Cavity Plate Design

Each 292 x 743 x 38 mm cavity plate is made of aluminum alloy 6061-T6 (Fig. 2), which is copper plated (25 microns thick) by Epner Technology. Flatness requirement on the split surface is within 13 microns along the plate length. Cavity shapes were accurately machined and fine cut by removing a small amount of material at a time to achieve the desired frequencies and the bandwidths. To obtain a repeatable cavity frequency, a closing force of ~ 13.6 kg (for the horizontal kicker) and of ~10 kg (for the vertical kicker), between two mating cavity plates, is required. Extension springs, by Lee Springs, were used on the side of each cavity to provide these forces (see Fig. 3). One cavity plate, with stiffer springs, serves as the hard stop to the mating plate, when the cavity plates are closing to each other.

The 50 ohms .14" (3.58 mm) OD semi-rigid shielded power cables, which were made by Advanced Technical Materials, are supported and cooled by the water cooled cavity plates (see Fig. 3 or Fig.4). Four ¼"-28 silver plated set screws, which are secured by four jammed set screws, are provided on each side of a cavity to tune the cavities (See Fig. 4).

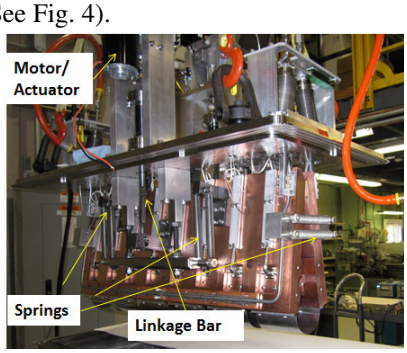

Fig. 3: Scissor Like Actuator.

Scissor Like Actuator

To take advantage of the commercially available frictionless pivot bearings, the scissor like actuators (Fig. 3) were chosen to drive the cavity plates. Each actuator includes a ball screw actuator (Motion Systems, 85151DUB) and a linkage bar, which are driven by a DC motor (Motion Systems, 73464-400 24V). The actuator could be disengaged from the motor at both ends of the 25 mm stroke. Each cavity plate is supported by a pair of frictionless pivot bearings (C-Flex Bearings, JD-20). The cavity plates are lifted and rotated, like a scissor, about their pivot bearings. With both cavity plates rotated an angle of ~ 8 degrees from the vertical median plane in the opposite direction, the required aperture of 124 mm is achieved. A mechanical stop is provided to keep the two cavity plates parallel to each other when they are at the closed position.

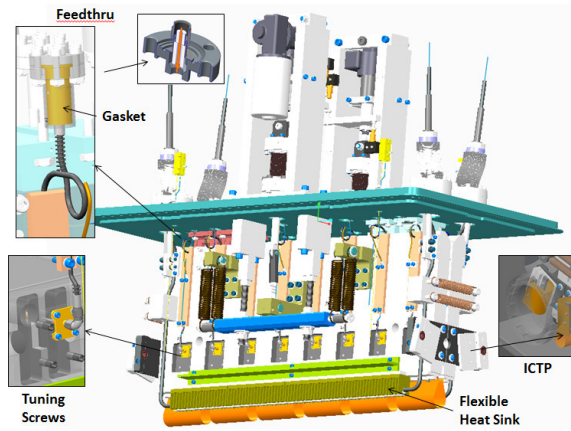

Fig. 4: Cavity Plate Assembly inside the UHV Chamber.

Custom Made Feedthru and Cable Strain Relief

To produce a reliable (high yield and bakable to 200°C) RF feedthru for the kicker, a custom designed RF feedthru was developed. The new 50 ohms SMA power connector is shown in Fig. 4, which has a stainless steel housing, a kovar center conductor, an alumina insulator and a Teflon insulator. The center conductor and the alumina insulator were silver brazed to provide the vacuum seal, which was fabricated by INTA Technologies. Ten custom made feedthrus were fabricated for testing, which were 100% leak tight and bakable to 200°C. To provide a strain relief to the unsupported cable, between the feedthru and the cavity plate, and to provide a vacuum seal to the feedthru, a novel dual purpose tubular shape copper gasket was also fabricated and installed (Fig. 4).

Stress Free Image Current Transition Piece

Image Current Transition Pieces (ICTP) are required to fill the gaps between the cavity plates and the neighboring beam pipes so that the excitation of high-order resonant modes could be avoided. Due to the scissor like motion of the cavity plates, the ICTP would fail easily with the

Copyright © 2013 CC-BY-3.0 and by the respective authors

repetitive and excessive bending and twisting stresses. A novel stress free transition piece has been successfully developed for the purpose (see Fig. 4), which installs a single end flex- hinge (SDP/SI S99FXS-075020) between the ICTP and the cavity plate to prevent the piece from rotating with the plate.

Low Thermal Noise Water Cooling Design

During operation, the power dissipation from each cavity and from each power cable are about 3 Wand 1 W respectively. With a water pipe rigidly attached the cavity plate (see Fig. 3), the calculated temperature gradient and the maximum thermal deformation on the cavities are 0.9°C and 160 microns respectively, which would result unacceptable frequency shifts in the cavities. Part of this deformation is caused by the different thermal expansions between the stainless steel pipe and the aluminum cavity plate. A novel flexible heat sink design (see Fig. 4) was developed to resolve the problem, which press fits the water pipe onto the fins of a convective heat sink (AAVID Thermalloy, Part no: 74925) so that the thermal contraction of the cooling pipe would not deform the cavity plate. Assuming that the water temperature was at 104°F (or 40°C), the thermal analysis result (using ANSYS) showed that the maximum temperature gradient would be ~ 1°C (see Fig. 5) and the maximum thermal deformation would be ~ 25 microns (.001") across the cavities, which is equivalent to a frequency shift of ~5 MHz. The predicted frequency shift agrees with the frequency measurements on the cavities. To meet the design requirement, the frequency shift can be further reduced to ~2 MHz by a proper tuning on each cavity.

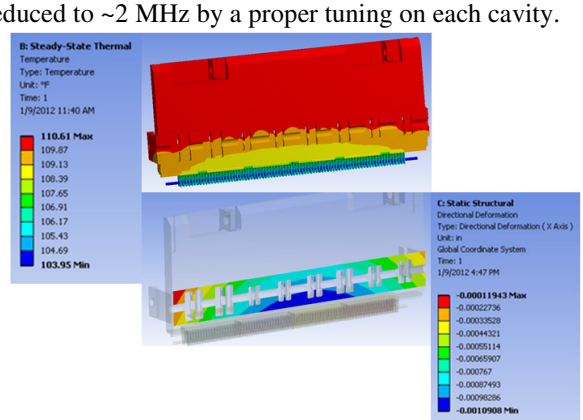

Fig. 5: Temperatures and Deflections on a Cavity Plate.

Large Rectangular Vacuum Chamber

Each UHV chamber has an interior dimension of 851 x 381 x 406 mm to allow install the cavity plates easily. Due to the rectangular opening and the long sealing length (~2565 mm long) on the top lid, no gaskets, including the Helicoflex metallic delta seal, could make a reliable UHV seal on top of the chamber. The solution was to weld the top lid onto the chamber and to protect the weld with a few stiffener bars around the chamber (see Fig. 1). Assuming that a 15 psi (0.1 MPa) external pressure is applied on the stainless steel chamber, the calculated maximum Von Mises stress along the weld is 21086 psi (0.145 GPa) (a safety factor of 1.4 to yielding strength) (Fig. 6) and the maximum deformation on the chamber is 0.3mm.

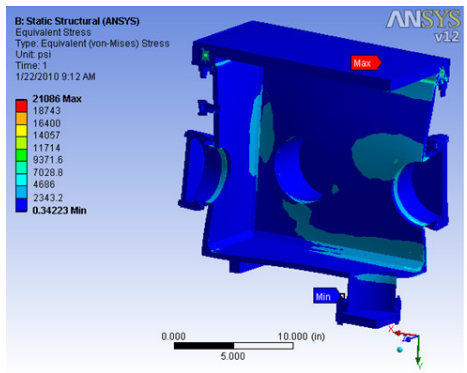

Fig. 6: Stresses on the vacuum Chamber.

CONCLUSIONS

We have developed a novel 5-8 GHz bandwidth bunched beam transverse stochastic cooling kicker, which uses scissor like actuators to drive the high Q cavity plates around the frictionless pivot bearings to obtain the required apertures. With a proper closing force applied on the cavity plates, using the flexible water cooled heat sink, and with some tuning, the cavity frequencies are repeatable within 0.05% of their frequencies during operation. By using the stress free Image Current Transition Pieces, eliminating wearable components, relieving strains on the power cables, silver plating or dicroniting stainless steel hardware, using only continuous water pipe, and venting all trapped vacuum volumes in the vacuum chamber, the vacuum components are virtually maintenance free. Three kicker assemblies were completed for the FY2012 run. Successful performance has been reported.

ROBUST MECHANICAL DESIGN FOR RHIC TRANSVERSE STOCHASTIC COOLING PICKUP

C.J. Liaw, J.M. Brennan, J. Tuozzolo, K. Mernick, V. De Monte, M. Myers
Brookhaven National Laboratory, Upton, NY 11973, USA

Abstract

The RHIC transverse Stochastic Cooling Pickup uses a pair of high resolution 4-8 GHz frequency band planar loop arrays to measure the Schottky signals from the bunched beams in the two transverse planes of the two rings. Precision alignment between the two 381 mm long array boards was achieved by surveying two specially designed alignment fixtures outside the vacuum chamber and using a pair of high resolution, motor controlled, and force balanced actuators. Robust mechanical design was achieved by excluding wearable mechanical joints and fragile electronics inside the vacuum chamber. Both mechanical designs and structural analysis results, for the vacuum chamber and for the array board supports, are presented. Two horizontal and two vertical plane pickups have been fabricated and installed in RHIC for the FY2012 run. Successful performance has been reported.

INTRODUCTION

The injected ion beams inside the two RHIC rings have a typical bunch rate of 10 MHz with 5 ns in length. The number of particles per bunch varies from 2 x 10^8 (for uranium) [1] to 1.5 x 10^9 (for gold) [2]. Due to intra-beam scattering (IBS), beam emittance would grow and reduce the intensity and the lifetime of the beam. RHIC has been successfully applying the stochastic cooling technique to correct this problem in the past 10 years. Based on the experience, a new transverse stochastic cooling system, which includes a broad band pickup and a kicker, has been developed recently. This paper will focus on the mechanical design of the new pickup.

McGinnis (1991) [3] developed a 4-8 GHz bandwidth bunched beam Stochastic Cooling Arrays for the Fermilab Tevatron. Due to the strong coherent frequency components presented in the high frequency bunched beam, the common mode Schottky signals from the two planar loop couplers must be subtracted before taking the measurement, which requires a high precision and repeatable mechanical alignment between the two arrays [3]. Hurh (1993) [4] designed a bunched beam Stochastic Cooling Tank for the FNAL Tevatron, which integrated the loop arrays into a vacuum chamber. The arrays were driven by two stepper motors through two guided plungers, which could provide different apertures for the changing beam size. Hurh's original design, however, has a few disadvantages, which include (1) The Teflon coated array board guiding shafts and the piezoelectric crystal inchworm motor could get stuck in vacuum, (2) The two pieces design BeCu image current transition assembly could buckle and reduce the aperture unexpectedly, and (3) The BeCu spring fingers on the image current transition assembly could lose their elastic strength and the contact forces on the beam pipe after the vacuum bake out.

Wei (2004) [5] applied the coasting beam theory and demonstrated that a 3-D stochastic cooling system with a 4-8 GHz bandwidth could effectively counteract IBS in RHIC. The 4-8 GHz Bunched Beam Stochastic Cooling Arrays, which were developed by McGinnis, were therefore adopted and retrofitted to become the sensor in the new pickup design. The newly developed transverse stochastic cooling pickup has addressed all the mechanical problems described above. Both mechanical designs and the supporting structural analysis results are presented below.

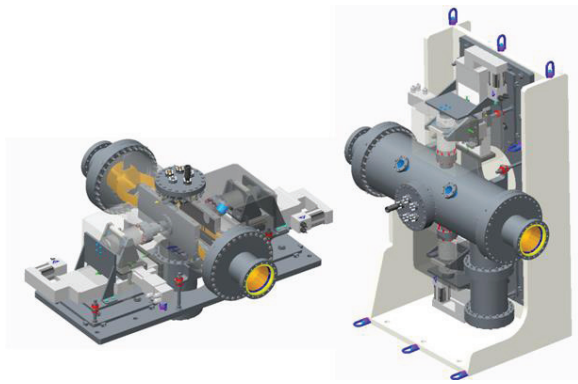

Figure 1: Horizontal and vertical stochastic cooling pickup.

MECHANICAL DESIGN OF THE TRANSVERSE STOCHASTIC PICKUP

The transverse stochastic cooling pickup could be installed either horizontally or vertically (see Fig. 1) to measure the Schottky signals from the RHIC bunched beam in the corresponding planes. The pickup integrates a pair of printed planar loop arrays, produced by Fermilab [3], with two aluminum backing boards being retrofitted into the newly designed UHV chamber. Two pickup leads and a proximity sensor (which is a pair of gold plated SST spring fingers, made by Lairtech) are provided on the two 381 mm x 152 mm x 17.5 mm array boards. Each array board is cantilever supported by a motor controlled precision linear stage, which is mounted on a four axes (X-Y-Z-theta) adjustable table. The linear stages provide a fine tuning on the relative alignment between two array boards in the X and the Z (or beam) direction. The alignment accuracy between the two array boards is required to be maintained within 50 microns

during the operation. Apertures between the two pickup arrays are 0.7" (18 mm) and 3.5" (89 mm) for the operation and the standby positions respectively.

Precision Alignment between Array Boards

Precision alignment between two loop arrays was achieved by accurately monitoring the array positions, using the laser survey technology, and by using motor controlled high precision actuators to drive the array boards. To monitor loop array positions without breaking the vacuum, two special external alignment fixtures (Fig. 2) have been designed and installed on the mounting stages. Each fixture has four targets on the four corners. The distance between two targets was chosen to be the same as the plunger length so that one could measure the misalignment directly on the fixture. To position the array boards accurately, two high precision AeroTech Stages (AST150-100), with a stroke of 1.8" (46 mm), are used to drive the array boards perpendicularly to the beam direction through two rigid plungers (see Fig. 1). One of the AST150-100 stages is stacked with an AST100-050 stage, with a +/- 1 mm adjustment, to provide a longitudinal (or beam) direction adjustment. Both AST150-100 and AST100-050 have a resolution of 0.5 microns with a position accuracy of better than 5 microns. An alignment accuracy of ~15 microns is achievable between the two array boards. All the stages were custom retrofitted with a 'Home' position at the middle of the stroke. Two welded bellows (Standard Bellows SBC 300-200-3) were installed on both sides of each actuator stage to balance the vacuum forces on the stage.

Figure 2: External array board alignment fixtures.

Signal Feedthroughs and Cable Strain Relief

To seek for a more reliable RF feedthrough design, two types of signal feedthroughs were developed and tested on the pickup device for the comparison. One is a custom design and was fabricated by INTA Technologies, which provides the vacuum seal by brazing the alumina insulator onto a kovar center conductor (Fig. 3(A)). The other one is designed and made by SRI Hermetics (SRIVF102), which used the glass seal technology to seal a copper center conductor and a stainless steel housing (Fig. 3(B)). The former has a higher bake out temperature of 300°C and the latter gives a broader bandwidth. Both designs have a reasonable high yield.

To provide a strain relief to the unsupported cable, between the feedthrough and the array board, and to provide the vacuum seal, a dual purpose custom made copper gasket (made of 1/4 hard oxygen free copper) was also developed (Fig. 3(C)).

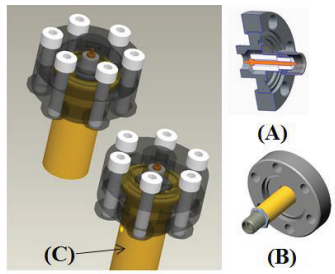

Figure 3: (A)INTA feedthru, (B) SRI feedthru, and (C) dual purpose copper gasket.

Long Lived Image Current Transition Piece

Image Current Transient Pieces (ICTP), which bridge the array boards and the beam pipes, are required to eliminate the excitation of the high-order resonant modes. To accommodate the aperture variations and to have a long service life, a special ICTP had been developed. Each ICTP includes a flexible 13 x 48 x 0.25 mm thick beryllium copper (C17200 Alloy 25) strip and a rigid copper plated 0.76 mm thick stainless steel structure (see Fig. 1), which has a rectangular opening on one end and a circular opening on the other end. Copper plated SST spring fingers are installed on the circular end, which are secured by a stainless steel spring ring, to provide a positive contact to the beam pipe. The stainless steel structure and the spring fingers are bakable to 300°C without losing their elastic strength. Fatigue test result, with repetitive bending between the minimum and the maximum aperture, demonstrated that the life time of the beryllium copper strip could exceed 10 k cycles without a failure, which is far beyond the application.

Maintenance Free Vacuum Design

Materials inside the vacuum chamber, which include stainless steel, copper, carbon coated polyimide, ferrite and aluminum are low outgassing. Vacuum components were cleaned and baked at 450°C for the stainless steel material and at 150°C for other materials before the installation. Venting holes were provided for all the trapped volumes. Stainless steel bolts were silver plated to avoid galling in vacuum. A vacuum pump (SAES Getters Model 4H0426) is installed underneath the vacuum chamber to maintain an UHV inside the chamber. There are no wearable components inside the vacuum chamber.

STRUCTURAL ANALYSES

Stage Linear Bearing Lifetime Analysis

The load distributions on the actuator stages were carefully planned and analyzed to increase the lifetime of the stage linear bearings. Figure 4 shows the actual stage loads vs. load capacities at the calculated CG locations and the expected travel life time for the stage bearings.

Copyright © 2013 CC-BY-3.0 and by the respective authors

The results show that the travel lifetime with the current design would be no less than 2.3 x 10^9 mm.

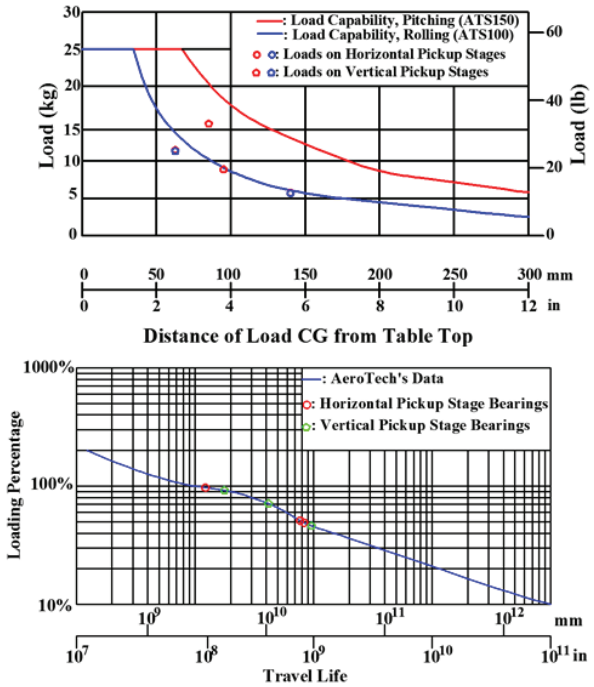

Figure 4: Actuator stage loads and stage bearing lifetime.

Support Structure Stress Analysis

The horizontal and the vertical stochastic cooling pickup assemblies have an overall weight of 193 kg and 315 kg respectively. When the chamber is in vacuum, a pressure load of 15 psi is applied on the surfaces of the chamber. All the components, except the pickup device and the supporting plates (which are made of aluminum), are made of 304 stainless steel. Stress analysis results, using ANSYS, showed that for the worst case when the pickup is supported vertically, the maximum stress and the maximum deformation on the support structure, due to the loads described above, are 6019 psi (41.5 MPa) (with a safety factor of 5 to yield) and .007" (0.18 mm) respectively (Fig. 5). The results have confirmed the structural stability of the pickup design.

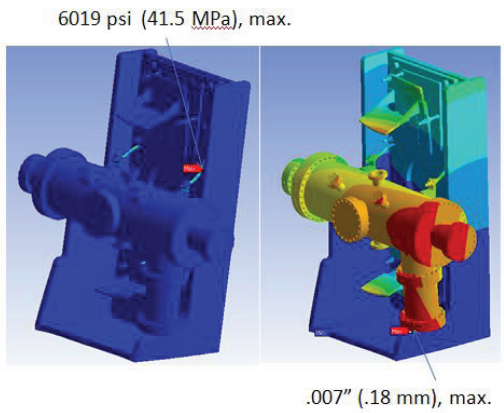

Figure 5: Structural analysis results using ANSYS.

CONCLUSIONS

We have developed a new mechanical design for the transverse stochastic cooling pickup, which can monitor and align the two 4-8 GHz bandwidth bunched beam Stochastic Cooling Arrays precisely without using any wearable mechanical guiding shafts or fragile electronics inside the vacuum chamber. The success of the custom designed image current transition piece, signal feedthrough, and cable strain relief has also improved the reliability of the vacuum components during operation. The pickup has been successfully operated since the 2011 run. The mechanical design has been proven to be robust.

HIGH INTENSITY RHIC LIMITATIONS DUE TO SIGNAL HEATING OF THE CRYOGENIC BPM CABLES *

P. Thieberger, C. Pai, K. Mernick, T. Miller, M. Minty, K. Hamdi, A. Ghosh and J. D'Ambra
Collider Accelerator Department, Brookhaven National Laboratory, Upton NY 11973, USA

Abstract

The signal cables from the beam position monitors (BPMs) in the cryogenic sections of the Relativistic Heavy Ion Collider (RHIC) need to satisfy somewhat conflicting requirements. On the one hand, the cryogenic load due to heat conduction along the cable needs to be small, which led to the use of stainless steel jacketed cables with Tefzel insulation. On the other hand, radio frequency losses need to be reasonably small to reduce heating due to dissipated signal power. As the beam intensity in RHIC increased over the years, and the bunches are becoming shorter, a point is being rapidly approached where these cables will soon become a performance limiting factor. Here we describe an extensive study of this problem including cable loss measurements as a function of temperature and frequency, characterization of the copper center conductor, and simulations using Particle Studio (PS) and ANSYS.

INTRODUCTION

The signal heating limitations of the RHIC cryogenic BPM cables were recognized and analyzed in 1995 [1, 2]. In particular, the Tefzel insulator has an operational temperature limit of 150 °C. Continuing RHIC upgrades to higher luminosities will hopefully lead next year [3] to the new goal of 111 bunches of 3E11 protons each with an RMS bunch length of 20 cm (henceforth the "upgraded beam"). The cable limit is expected to be approached, and more detailed estimates have now been performed to ensure safe and reliable operation.

CABLE LOSS MEASUREMENTS

Cable losses as a function of frequency were measured with a signal analyzer at eleven temperatures ranging from 4 K to the maximum operating temperature of the cable which is 423 K (150 °C). To perform these measurements at the various temperatures two different cryostats, an ice bath and an oven were used. A spare RHIC 125 cm long BPM cable was formed into a 10 cm diameter spiral and connected to two lead-in cables of the same type.

To take into account the temperature dependent losses in these lead-in cables, a short (8 cm long) "dummy" connection was used as shown in the Fig.1 inset, and the results shown in figure 1 were obtained by subtracting at each temperature the losses measured with the dummy from the ones measured with the sample under identical conditions. The frequency range up to 500 MHz contains over 95% of the signal power for 20 cm rms bunches.

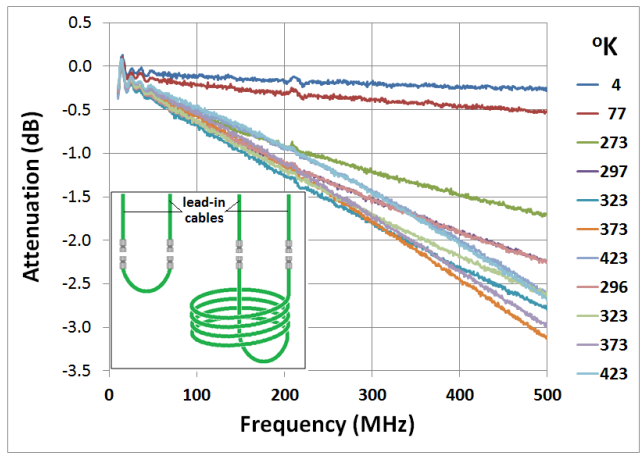

Figure 1: Cable attenuation as function of frequency measured at 11 temperatures ranging from 4 K to 423 K; the operating temperature limit for the cable.

From these curves, the losses per unit length are later calculated considering an effective cable length of 125 – 8 = 117 cm where 8 cm is the length of the "dummy" connection. The Fig. 1 data show that above ~180 MHz, some of the lower temperature losses are larger than losses at higher temperatures. This surprising behavior, which was confirmed by repeating the measurements with different signal analyzers, is probably due to peculiarities in the dielectric losses in the Tefzel insulator.

THERMAL CONDUCTIVITY

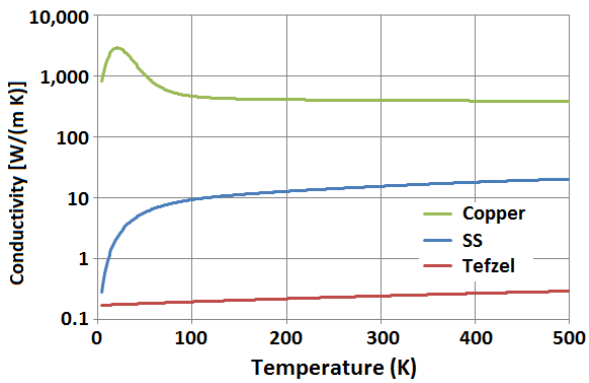

Figure 2: Thermal conductivities used for the simulations.

* Work supported by Brookhaven Science Associates, LLC under Contract No. DE-AC02-98CH10886 with the U.S. Department of Energy.

Copyright © 2013 CC-BY-3.0 and by the respective authors

The thermal conductivity of copper is a sensitive function of the impurity content and was determined by measuring a Residual Resistivity Ratio value of 131. Values of the thermal conductivity parameterized for various RRR values given by NIST [4] were used to calculate the thermal conductivity curve for copper through interpolation. The curve for Tefzel was generated from the room temperature value [7] adopting a slope similar to the one for Teflon. As shown in Fig. 2, this conductivity is so small that it isn't very significant.

SIGNAL AMPLITUDE AND FREQUENCY SPECTRA

The current pulse into 50 Ω generated by a BPM stripline is due to a superposition of charges induced directly by the beam and the ones reflected by the delay-line structure formed by the stripline and the rest of the BPM. In addition, that charge of course depends on the beam position. An extensive series of Particle Studio (PS) [5] simulations was performed to characterize these signals as a function of position for the three types of cryogenic BPMs present in RHIC (see Table 1).

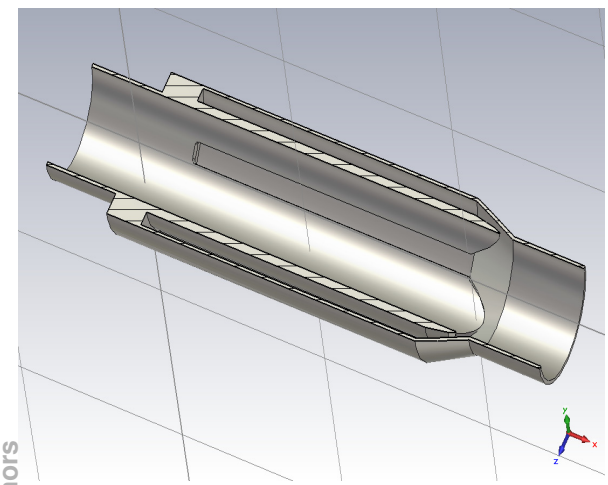

Figure 3: Cutaway view of the Type 2 BPM model used for the Particle Studio simulations.

Figure 3 is a cutaway view of one of the BPM PS models used for the simulations. The number of mesh-cells used was about 195,000. At the ends of the striplines, where in reality 50Ω feedthroughs are located, these feedthrough were simulated by 50 Ω resistors connected between the tip of the stripline and the vacuum housing. Figs. 4 and 5 show some of the results for a Type 2 BPM (see Table 1).

HEAT TRANSPORT SIMULATIONS

Power density inputs for the ANSYS heat transport simulations (Fig. 6) are calculated as if all the losses were dielectric. In reality resistive losses contribute too. The other extreme case of resistive losses only was also simulated with nearly identical results. The cable diameter is small enough to make it practically irrelevant where along the radius the energy is deposited.

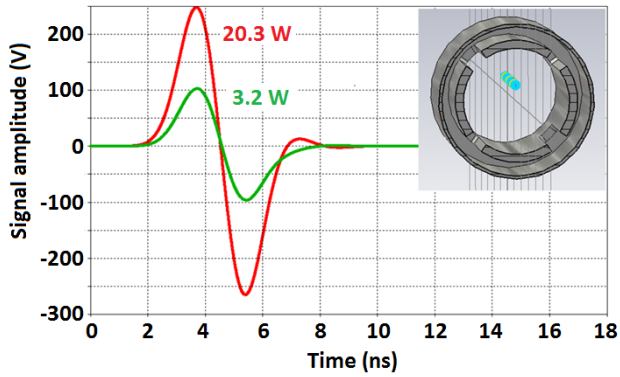

Figure 4: PS simulated signal amplitudes and powers from two opposite striplines induced by an upgraded beam displaced by 10 mm from the center line.

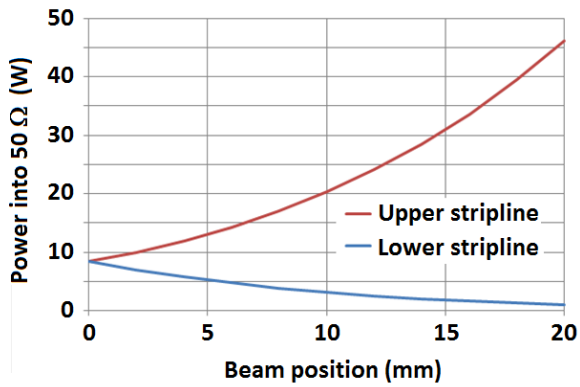

Figure 5: PS simulated signal power as function of beam position from two opposite Type 2 BPM striplines.

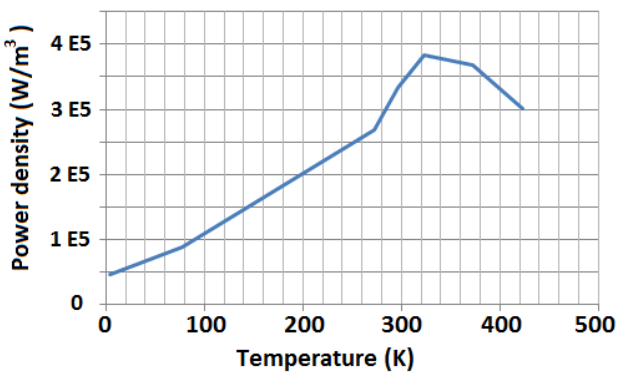

Figure 6: Power density in Tefzel as a function temperature calculated by convolving the cable frequency response with the signal frequency spectrum.

Copyright © 2013 CC-BY-3.0 and by the respective authors

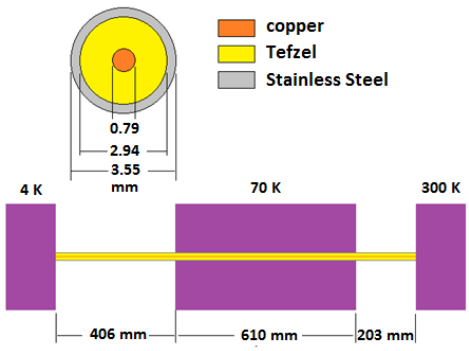

Figure 7: Schematic representation of the geometry used for the ANSYS heat transport simulations.

The geometry used for the ANSYS heat transport simulations is shown in Fig. 7. The curve labeled 1.00 in Fig. 8 shows the ANSYS simulated temperature profile along the cable for a type 2 BPM with a centered upgraded beam. The power or load factors labeling the other curves correspond to powers larger by the indicated factors.

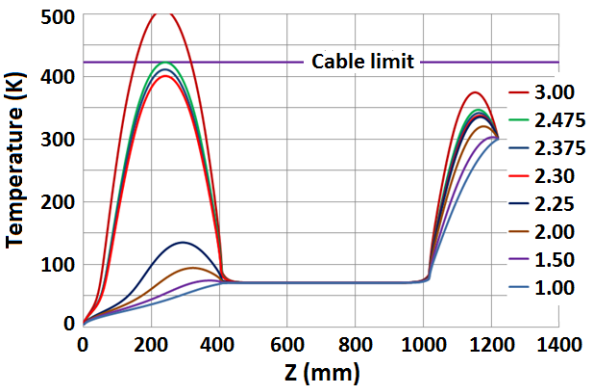

Figure 8: Cryogenic cable temperature profiles obtained from the ANSYS simulations. The curve labeled 1.00 corresponds to the upgraded beam centered in a type 2 BPM. The other labels indicate correspondingly higher power factors.

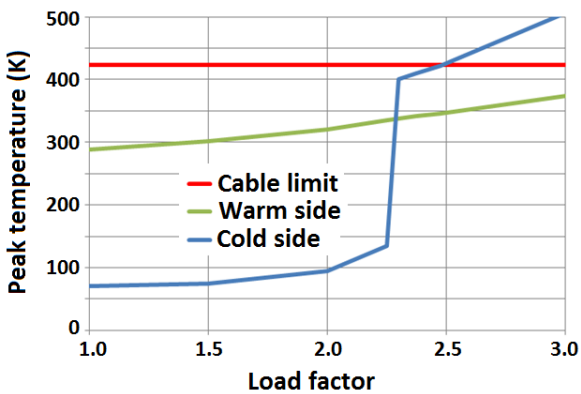

Figure 9: Peak temperatures as function of the load factor where 1.0 corresponds to the upgraded beam centered in a Type 2 BPM. The jump at the "cold" or BPM side of the cable indicates an incipient temperature runaway situation that must be avoided.

RESULTS AND CONCLUSIONS

The maximum allowable beam displacements to just avoid the incipient temperature runaway situation shown in Fig. 9 are shown in Fig.10 and Table 1.

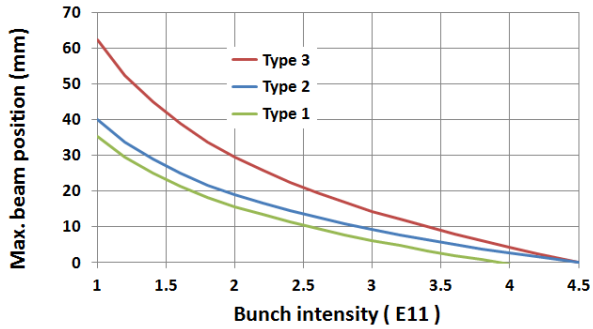

Figure 10: Maximum allowed beam displacements as function of bunch intensity of 111, 20 cm RMS bunches for the three types of BPMs.

Table 1: Maximum beam displacements to avoid cable damage with the upgraded beam for the 3 types of BPMs

BPM Type	#of planes	Location	Radius (mm)	Max. Δx (mm)
#1	1	Arcs	34.5	7.3
#2	2	Arcs	34.5	10.4
#3	2	Triplets	53.7	16.1

These results are more detailed than- but in general agreement with the ones obtained before [1, 2]. As shown in Fig. 10 and Table 1, operation with the upgraded beam should be possible provided excessive beam position excursions can be precluded by the use of beam abort interlocks. In practice, we note that there is some performance uncertainty due to crimping of the cable ends in the early days of RHIC [6]. In the future, we plan to verify the temperature rise predictions presented here with measurements using thermocouples

UPGRADING THE RHIC BEAM DUMP FOR HIGHER INTENSITY*

C. Montag, S. Nayak, L. Ahrens, W. Fischer, H. Hahn, C.J. Liaw,
J. Mi, T. Roser, P. Thieberger, J. Tuozzolo, K. Yip, W. Zhang
BNL, Upton, NY 11973, USA

Abstract

Mechanical analysis of the RHIC beam dump window has shown that present heavy ion beam intensities are close to the tolerable limit, and will likely exceed that limit in future runs. Two approaches to upgrade the abort system for those projected higher intensities have been studied, namely replacing the existing window, and adding a vertical kicker that distributes the individual bunches more evenly across the window, thus reducing the heat load. We present the results of these studies and the present status of the upgrade project.

INTRODUCTION

The RHIC beam is aborted by a set of five kickers that deflect it horizontally into the dump. The dumped beam first passes through a 50 cm long C-C carbon block that dilutes its emittance before it exits the RHIC vacuum enclosure through a pair of 17-7 PH steel windows. Outside the beam vacuum, the aborted beam is diluted further by a second carbon block before it is absorbed by a massive steel block.

The RHIC beam dump system was originally designed for a 100 GeV/nucleon gold bunch intensity of $1 \cdot 10^9$ Au ions/bunch in 56 bunches. During the 13 years of RHIC operation, the actual beam intensity has been increased by more than a factor 2, to $1.3 \cdot 10^9$ Au bunches in 111 bunches. In addition, stochastic cooling [1] now results in much smaller emittances than originally envisioned during the RHIC design phase [2]. These developments led to a re-evaluation of the integrity of the vacuum window.

NUCLEAR INTERACTION AND MULTIPLE SCATTERING IN THE C-C CARBON BLOCK

Due to stochastic cooling the Au beam emittance in RHIC depends strongly on the bunch intensity. A simple scaling law can be derived from the fact that cooling rate and intrabeam scattering (IBS) growth rate counterbalance each other in the equilibrium.

With the cooling rate scaling with the bunch intensity as

$$\tau_{\mathrm{cool}}^{-1} \propto \frac{1}{N} \tag{1}$$

and the IBS emittance growth rate scaling as

$$\tau_{\mathrm{IBS}}^{-1} \propto \frac{N}{\epsilon_\perp^2 \epsilon_{\mathrm{L}}}, \tag{2}$$

* Work supported by Brookhaven Science Associates, LLC under Contract No. DE-AC02-98CH10886 with the U.S. Department of Energy.

Table 1: Double-Gaussian Fit Parameters for the Energy Deposition for Two Different Beam Emittances

emittance [πmm mrad]	4	8
bunch intensity 10^9	0.7	1.6
A_1 [MeV/cm^3]	$43.0 \cdot 10^{13}$	$66.8 \cdot 10^{13}$
σ_1 [mm]	0.51	0.62
A_2 [MeV/cm^3]	$0.77 \cdot 10^{13}$	$1.74 \cdot 10^{13}$
σ_2 [mm]	5.25	5.26

where $\epsilon_\perp$ and ϵ_{L} are the transverse and longitudinal emittances, respectively, the transverse emittance is therefore proportional to the bunch intensity [3]

$$\epsilon_\perp \propto N \tag{3}$$

for a constant longitudinal emittance ϵ_{L}. This scaling rule agrees well with simulation results that show a transverse equilibrium normalized 95 percent emittance of 4πmm mrad for $0.7 \cdot 10^9$ Au ions/bunch, and 8πmm mrad for $1.6 \cdot 10^9$ Au ions/bunch [3].

The interaction of a single incoming bunch with the C-C carbon block and the resulting energy deposition is simulated using the code MCNPX [4]. Nuclear interaction and multiple scattering in the C-C carbon block widens the distribution and reduces the peak intensity of the round Gaussian beam, while at the same time producing significant non-Gaussian tails. The resulting distribution is described by a double-Gaussian fit as

$$\rho(r) = A_1 \exp\left(-\frac{r^2}{2\sigma_1^2}\right) + A_2 \exp\left(-\frac{r^2}{2\sigma_2^2}\right), \tag{4}$$

where r is the radial particle coordinate, and A_1, A_2 and σ_1, σ_2 are the normalized amplitudes and RMS widths of the double-Gaussian distribution. Table 1 lists the double-Gaussian fit parameters for two different emittances. Together with the abort kicker pulse shape, the spatial energy distribution on the abort kicker window for the entire 111 bunches can then be calculated.

MECHANICAL AND THERMAL STRESS IN THE WINDOW

The RHIC beam dump system aborts the beam by applying a horizontal kick. The pulse shape of these abort kickers is designed such that after an initial fast rise that kicks the first bunch across the septum, the remaining bunches are spread out in a straight line by an oscillatory behavior of the kick, as shown in Figure 1.

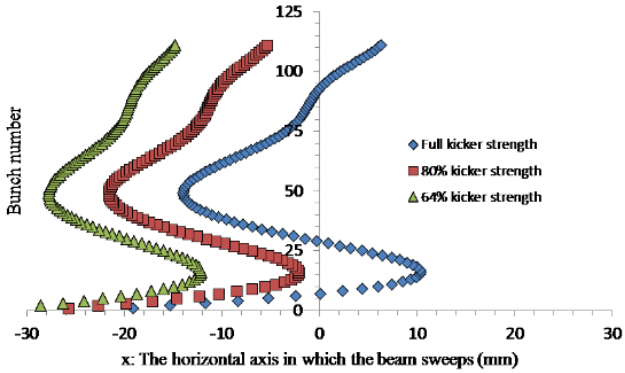

Figure 1: Kicker pulses for full kicker strength, and reduced strengths of 80 and 64 percent.

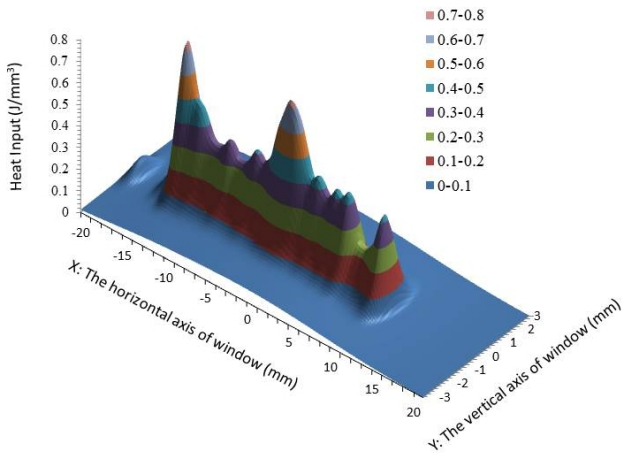

Figure 2: Heat input of 111 bunches of $0.7 \cdot 10^9$ Au ions on the beam dump window, assuming a 95 percent normalized emittance of 4π mm mrad.

This oscillating kick results in several distinct hot spots on the window surface where bunches are dumped in close vicinity due to the near-zero slope of the kicker pulse at its minima and maxima. Figure 2 shows the heat input for 111 gold bunches with a bunch intensity of $0.7 \cdot 10^9$ Au ions/bunch and a 95 percent normalized emittance of 4π mm mrad on the existing steel dump window. Table 2 lists the material properties for the 17-7 PH steel used for the RHIC abort window.

In the numerical analysis of the mechanical and thermal stress in the window we require a safety factor of two. An analysis of the heat deposition in the window reveals that at a 95 percent normalized emittance of 4π mm mrad a maximum bunch intensity of $0.7 \cdot 10^9$ gold ions per bunch is allowable. In this case, the maximum stress reaches half the yield stress of the present 17-7 PH steel window [5]. The success of the stochastic cooling effort results in emittances of 8π mm mrad at bunch intensities of $1.6 \cdot 10^9$. This will shrink the safety margin for the window below an acceptable level, so the beam dump system needs to be upgraded in the near future.

Table 2: Material Properties of 17-7 PH Stainless Steel and of Titanium 6242 Alloy

	steel 17-7 PH	Ti 6242
elastic modulus [GPa]	197	115
Poisson's ratio	0.29	0.32
yield stress [MPa]	940	960
ultimate stress [MPa]	1289	1016
therm. cond. $[\mathrm{W/m \cdot K}]$ (100°C)	16.4	7.1
therm. cond. $[\mathrm{W/m \cdot K}]$ (500°C)	21.8	
therm. exp. coeff. $[\mu\mathrm{m}/(\mathrm{m \cdot K})]$	12	8.1
specific heat $[\mathrm{J}/(\mathrm{kg \cdot K})]$	460	460
melting point [°C]	1400	1700
density $\mathrm{kg/m^3}$	7800	4540

UPGRADE SCENARIOS

To increase the allowable beam intensity at the reduced emittances, two possible upgrade scenarios are being considered. The first scenario involves replacing the 17-7 PH steel window with a different material, while in the second scenario a vertical kicker would be added to increase the spacing between individual bunches in the hot spots on the window surface. Both scenarios have been evaluated for two consistent combinations of intensities and emittances, namely $0.7 \cdot 10^9$ Au ions/bunch at a normalized 95 percent emittance of 4π mm mrad, and $1.6 \cdot 10^9$ Au ions/bunch at 8π mm mrad.

Window Replacement

Replacing the existing window with a high strength titanium 6242 alloy (see Table 2) raises the safety factor from 1.35 to 2.65 for a bunch intensity of $1.6 \cdot 10^9$ Au ions/bunch and the associated normalized emittance of 8π mm mrad, while at a low intensity of $0.7 \cdot 10^9$ Au ions/bunch and an emittance of 4π mm mrad the safety factor of two is exceeded even with the existing window, as listed in Table 3. Based on these results, the safety factor is expected to remain greater than two for intensities up to $2.1 \cdot 10^9$ Au ions/bunch with a corresponding normalized emittance of 10π mm mrad,

Vertical Kicker

To dilute the hot spots on the window, a vertical kicker may be added. The pulse waveform of this kicker needs to be chosen such that the vertical kicker pulse has its greatest slope at times when the slope of the horizontal kickers is near zero. A larger vertical kick amplitude results in a greater spread of the individual bunches on the window and therefore a lower heat load, which increases the safety factor for a given intensity and emittance. However, bunches that experience kicks near the minima and maxima of the sinusoidal vertical kicker pulse hit the window at a different vertical position, but their distance relative to each other is unchanged. The dependence of the resulting safety factor on the amplitude of the vertical kicker pulse is therefore

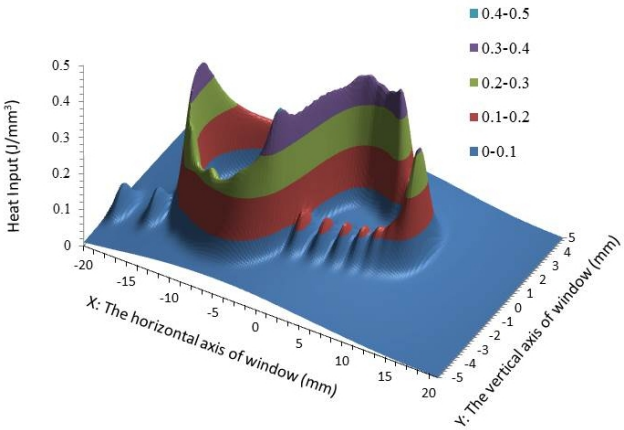

Figure 3: Heat input of 111 bunches of $0.7 \cdot 10^9$ Au ions with an emittance of 4π mm mrad on the beam dump window, with an additional vertical kicker.

Table 3: Safety Factor for the Various Abort System Configurations, for Two Different Beam Intensities. A minimum safety factor of 2 is required for safe operation of the RHIC abort system.

emittance [πmm mrad]	intensity [10^9]	steel 17-7 PH	Ti 6242	steel 17-7 PH and vertical kicker
8	1.6	1.35	2.65	2.47
4	0.7	2.80	5.11	4.88

nonlinear, and the gain increase is reduced at larger amplitudes. At the same time, achieving large kicker amplitudes is costly due to the required high kicker currents and voltages. For these reasons, the maximum vertical kick angle is chosen as $164\,\mu$rad, which corresponds to an orbit amplitude of 3 mm at the window. Table 4 shows lists the design paramters of such a kicker.

Simulations show that the lowest peak heat deposition is achieved by adding a vertical kicker with a cosine-like pulse shape of $8\,\mu$sec period, delayed by $2.64\,\mu$sec w.r.t. the horizontal kicker pulse. Figure 3 shows the resulting heat input distribution for a $4\,\pi$ mm mrad beam with $0.7 \cdot 10^9$ Au ions per bunch in 111 bunches. In this case, the safety factor for the 17-7 PH steel window is significantly raised, Table 3, and a bunch intensity of $2.0 \cdot 10^9$ Au ions/bunch in 111 bunches at a corresponding emittance of $10\,\pi$ mm mrad becomes feasible.

Table 4: Parameters of the Vertical Kicker Assembly

Total length [m]	1.83
Number of modules	3

Beam duration [μsec]	11.7

SUMMARY

We have investigated two scenarios to upgrade the RHIC beam dump system for higher heavy ion beam intensities, which is currently limited by mechanical and thermal stress in the stainless steel exit window. Replacing the existing window with a titanium alloy window would allow maximum bunch intensities of $2.1 \cdot 10^9$ Au ions per bunch in 111 bunches.

Alternatively, additional abort kickers could be installed that spread the aborted beam in the vertical direction, thus reducing the peak energy deposition in the window. A preliminary design of this kicker has been developed, which would allow for a maximum bunch intensity of $2.0 \cdot 10^9$ Au ions per bunch in 111 bunches.

While both scenarios result in very similar improvements of the RHIC beam dump system, replacing the exit window is significantly cheaper than adding a vertical kicker, though also very labor intensive. As an additional advantage, a window upgrade is inherently more fail-safe than an additonal vertical kicker since it is a passive system.

Based on these studies and considerations it has therefore been decided to replace the exit window with a titanium alloy one. A vertical kicker can then still be added in the future should the need arise.

OPTIMIZATION OF THE CAPTURE SECTION OF A STAGED NEUTRINO FACTORY*

H.K. Sayed,† H.G. Kirk, Brookhaven National Laboratory, Upton, NY 11973, USA
K.T. McDonald, Princeton University, Princeton, NJ 08544, USA

Abstract

A proposed staged Neutrino Factory, producing lower muon intensity of 10^{20} muons per year and 10-14 GeV muon beam energy, initially requires target station for 1 MW proton beam power with a proton beam energy of 3 GeV, which could be upgraded to the full power of 4 MW at 8-GeV beam energy. The optimization of the initial Target Station and the following Decay Channel and Buncher/Phase Rotator are discussed.

INTRODUCTION

In the baseline Neutrino Factory / Muon Collider design [1], sketched in Fig. 1, the muon beam is produced from pion decay by bombarding a liquid-mercury-jet target with a 4-MW pulsed proton beam, which delivers an intense muon beam of 10^{14} muons/sec from the incident beam of 10^{15} proton/s. In the proposed staged Neutrino Factory [2] with a 1-MW proton beam of 3-GeV energy, the Target Station uses a solid graphite target and produces a muon intensity of 10^{20} per year The target is embedded in a 15 (or 20) T solenoid magnet for the pion collection, shown in Fig. 2, which is followed by a lower field Decay Channel. The baseline design of the Target Station/Decay Channel will be retained during later stages of the Neutrino Factory to save the cost at the time of upgrade to the full 4-MW scenario.

The target and proton beam sizes and their tilt angles in the initial 3-GeV configuration are given in Table 1, which configuration produces 0.42 muons/protons at the end of the Target System.

Table 1: Proton Beam and Graphite Target Parameters for the Staged Neutrino Factory

Carbon rod target	Proton beam
Length 0.72 [m]	$\sigma_t = 2$ [nsec]
Diameter 0.692 [cm]	$\sigma_{x,y} = 0.0865$ [cm]
Angle to solenoid axis 42 mrad	42 mrad

The adiabatic variation in solenoid field strength along the beam near the target performs an emittance exchange affects the performance of the downstream Buncher, Phase Rotator, and Cooling Channel [3]. An optimization was performed using the MARS15 (2012) [4] and ICOOL [5] codes in which the rate of change of the field along the pion beam near the target was varied to maximize the number of muons that falls within the acceptance of the downstream accelerator chain (muons within 201.25 MHz RF bunches with momentum in the range 100300 MeV/c, transverse amplitude squared less than 0.03 m and longitudinal amplitude squared less than 0.15 m [3]).

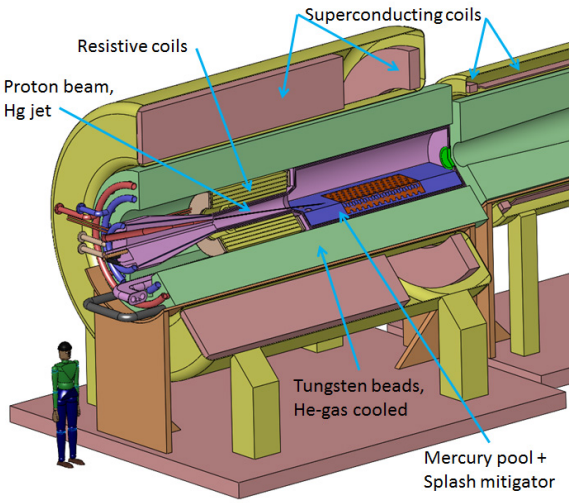

Figure 2: Neutrino Factory/Muon Collider target system.

The Target System utilizes a magnetic-field profile that peaks at $B_i = 15$ T at the target and tapers down to $B_f = 2.5$ T over a distance of $L_{\rm taper}$. In this study we optimized the length of this tapering solenoid $L_{\rm taper}$. The effect of solenoid-field profile on the captured-particle count and their phase-space distribution was studied by simulating the particles captured at the target and transported through the rest of the Front End. Various axial-field profiles were considered, based on an inverse-cubic form [6], from which the off-axis fields were calculated using Maxwellian series expansions. A sample of the axial-field profiles studied is shown in Fig. 3.

PION PRODUCTION AND CAPTURE AT THE TARGET

The MARS15 code [4] was used to simulate the particle production off the graphite target, using an incident 3-GeV proton beam with delta-function time distribution.

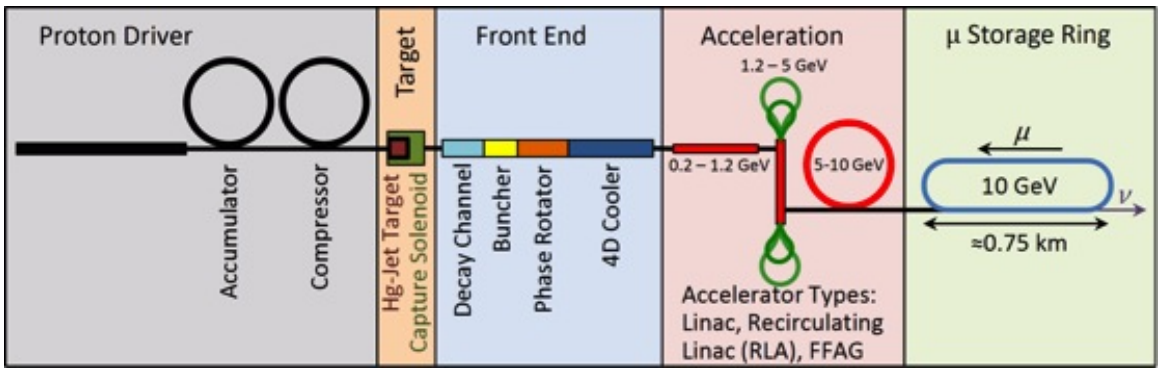

Figure 1: Neutrino Factory/Muon Collider Target System.

The kinematic parameters of the secondary pions, Kaons and muons at end of the graphite target were used as input for an ICOOL [5, 7] simulation through the tapered solenoid field and on to the end of the Cooling Channel. The transverse-momentum distribution of secondary pions at the downstream end of the graphite target is shown in Fig. 4. The beam-pipe geometry was simplified to have a constant 30-cm radius.

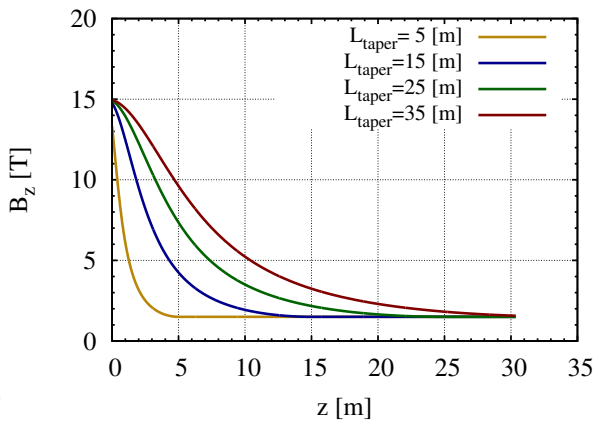

Figure 3: On-axis magnetic field profiles for the Target System.

THE FRONT END

The major systems of the Front End [3] of a Neutrino Factory are: Target System, Decay Channel, Buncher, Phase Rotator, and the Cooling Channel, as shown in Fig. 1. In this study, a constant solenoid field of 2.5 T was used to confined the muon beam throughout the Decay Channel, Buncher, and Phase Rotator, which ends some 150 m from the target, after which the beam was matched into the Ionization Cooling Channel [8] with ±2.8-T axial field in the alternating solenoid magnets.

The pions collected off the target are transport by the capture solenoid to the decay channel of 50-m length where most of the pions decay into muons. The muon beam is then bunched using a sequence of RF cavities with frequencies varying from 320 to 230 MHz over ≈ 33 m, while the bunching-cavity RF voltage increases linearly along the channel from 3.42 to 9.01 MV/m. In the 42-m-long Phase Rotator, lower-energy muons are accelerated and higher-energy ones are decelerated, until at the end of the Rotator and the original 15-m-long bunch of muons of both signs has been formed into a 48-m-long train with 33 bunches of μ^+ interleaved with 33 bunches of μ^-.

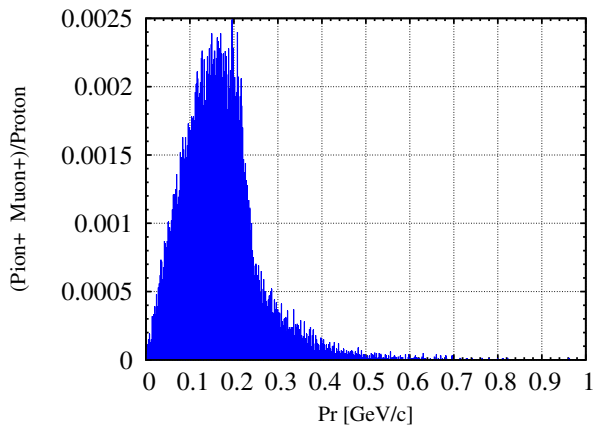

Figure 4: Pion transverse momentum at the end of the graphite target.

The transverse phase volume of the muon beam at the end of the Phase Rotator significantly larger than the acceptance of the later muon accelerator, but this volume is reduced by the Ionization Cooling section. The number of muons with the accelerator acceptances increases nearly linearly in the Cooler from $z = 150$ to 300 m as shown in Fig. 5.

OPTIMIZING THE TAPER LENGTH

The figure of merit for the optimization was taken to be the number of positive muons per incident proton within the subsequent muon-accelerator momentum acceptance [9], $100 < p_z < 300$ MeV/c, and acceptances in longitudinal and transverse phase space, $A_z < 150$ mm and $A_r < 30$ mm. The solenoid-taper length has a distinct in-

Copyright © 2013 CC-BY-3.0 and by the respective authors

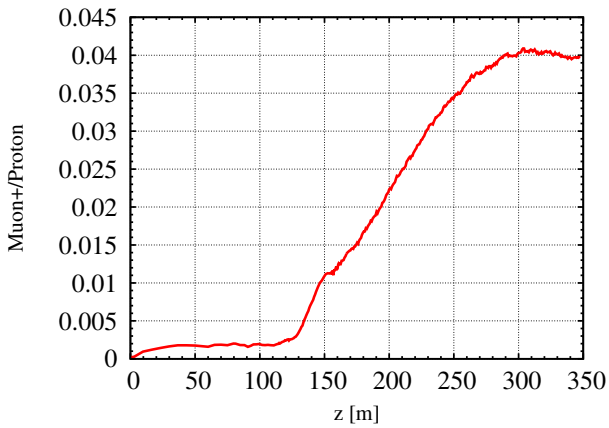

Figure 5: Number of muons within the accelerator-chain acceptance at various distances along the Front End.

fluence on the number of the transported muons to the end of cooling channel. Varying the length of the Taper resulted in higher muons yields, for $L_{\rm taper} \approx$ 3-4 m, as shown in blue in Fig. 6.

As we varied the taper length the longitudinal phase space changed accordingly, requiring RF-phase optimization, which increased the yield by $\approx$ 16-40 See the black curve in Fig. 6.

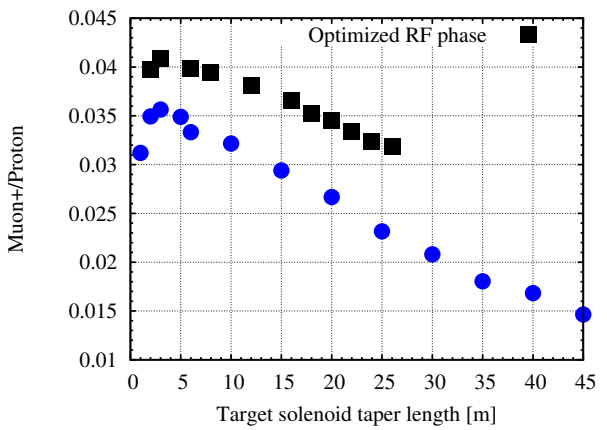

Figure 6: Muon yield from the Front End, within the acceptance of the accelerator chain *vs.* the solenoid taper length. The RF optimization (black curve) increased the Front End performance by $\approx$ 16-40%.

CONCLUSION

An optimization study of the capture section of the Front End of a staged Neutrino Factory was presented. The study was performed on a graphite target bombarded by a 3-GeV proton beam. The figure of merit of the optimization was the number of muons within the acceptance of the accelerator chains that follows the Front End. The target-solenoid field profile used in this study had an initial on-axis field $B_i = 15.0$ T, and final on-axis field $B_f = 2.5$ T, with the taper length $L_{\rm taper}$ being optimized for maximum yield of muons from the Front End (*i.e.*, at the beginning of the Muon Accelerator). Then, an optimization of the RF phase of the Buncher/Phase Rotator RF cavities was carried out. The best performance of the Front End was found to be $0.042\mu^+/p$. The optimum taper length was found to be 3-4 m, which is shorter than the optimum taper length when using an 8- GeV proton beam by 1-2 m.

A HIGH-PERFORMANCE RECTILINEAR FOFO CHANNEL FOR MUON COOLING*

D. Stratakis#, J. S. Berg, R. B. Palmer, Brookhaven National Laboratory, Upton NY, USA
V. I. Balbekov, Fermi National Accelerator Laboratory, Batavia IL, USA

Abstract

An ionization cooling channel is a tightly spaced lattice containing absorbers for reducing the momentum of the muon beam, rf cavities for restoring the longitudinal momentum and solenoids for focusing the beam. Such a lattice is an essential step for a Muon Collider. Here, we explore a new scheme for designing ionization cooling channels for muon related applications. In this scheme, emittance reduction is achieved within a rectilinear channel with wedge absorbers for cooling and tilted solenoids for emittance exchange. Such configuration addresses several of the engineering challenges of a conventional helical channel. We numerically examine the performance of our proposed channel and compare it against conventional designs. We also review the conductor current densities requirements for all of the simulated scenarios.

INTRODUCTION

A key technical challenge in the development of a Muon Collider is that the phase space of the beam that comes from pion decay greatly exceeds the acceptance of downstream accelerators system. Therefore, a cooling channel is required. Given the short life time of a muon particle, ionization cooling is the only practical method that can be realized.

Over the past decade several progresses have been made in the design and simulation of 6D RFOFO cooling rings [1] based on emittance exchange. This is generally accomplished by using a wedge shaped absorber in a region with dispersion. Particles with higher energies will pass through more material than particles with lower energy as a result of dispersion, eventually leading to reduction of longitudinal emittance. Such rings have been shown to provide an impressive to two order magnitude reduction of the normalized 6D phase-space volume with a transmission well above 50%. In order to avoid the complexity arising from the required injection and extraction systems, those rings involved without loss in performance to a RFOFO helical channel [2], commonly known as the Guggenheim. A chief advantage of the Guggenheim is that avoids any issues related to absorber overheating.

Although a helical lattice can be advantageous in paper, still many questions remain. For instance, the beam can be intercepted by the fringe fields from the nearby solenoids. In addition, engineering constraints may arise at the last stages as the radius of curvature becomes less than 1.5 m. To further relax the aforementioned constraints we design and simulate here a rectilinear FOFO snake channel which has been proposed recently by one of the authors [3] and show that it can offer the same performance as the Guggenheim. In particular, we show that by applying a novel tapering scheme in which numerous parameters of the structure change from stage to stage based on the emittance reduction rate and transmission, we can achieve a good cooling efficiency that remains flat through the channel. This is because the beam emittance is always above the equilibrium emittance.

DESIGN PARAMETERS

The main issue with a channel of a fixed radius, cell length, and frequency is its gradual loss of cooling efficiency. Therefore, to keep the cooling process going we examine a tapered channel in which various parameters change in order to avoid reaching equilibrium. In this scheme, parameters such as cell length and radius of curvature progressively change from stage to stage based on the emittance reduction rate and transmission. Recent studies have shown [4] that such a concept improves performance substantially. In addition, with this approach the same emittance can be obtained in much shorter scale.

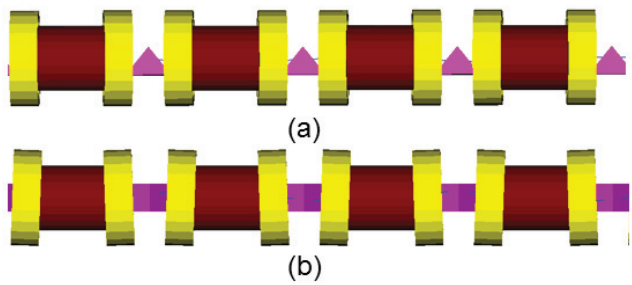

Figure 1: Conceptual design of our proposed rectilinear cooling channel: (a) Top view; (b) Side view. Note that the coils (yellow) are slightly tilted to generate dispersion.

At the first stage of the tapered channel the focusing will be relatively weak to avoid excessive angular divergence that can arise from the large transverse emittance of the initial muon beam. However, the weak focusing implies that the beta function and thus the equilibrium emittance are also relatively large, so the transverse cooling weakens as the limit is approached. To avoid this, this stage is terminated and we couple into the next stage that has a lower beta. This is achieved by simultaneously scaling down the cell dimensions and raising the strength of the on-axis solenoidal field. As a result this will produce a piecewise multi-stage shaped channel where each stage will consist of a series of

identical cells. A schematic of our proposed cooling system is shown in Fig.1. Note that the coils (yellow) are not evenly spaced; those on either side of the absorber are closer in order to increase the focusing at the wedge absorber (magenta). In order to produce dispersion, they are tilted by 1.1-1.3^0. The absorber is wedge shaped so that higher momentum particles go through the thicker part. Each lattice cell contains the same number of rf cavities (dark red) which, depending on the stage, can be 4, 5, or 6. The rf frequencies are either 325 MHz or 650 MHz. Those frequencies are chosen in order to match with the initial linac of Project X.

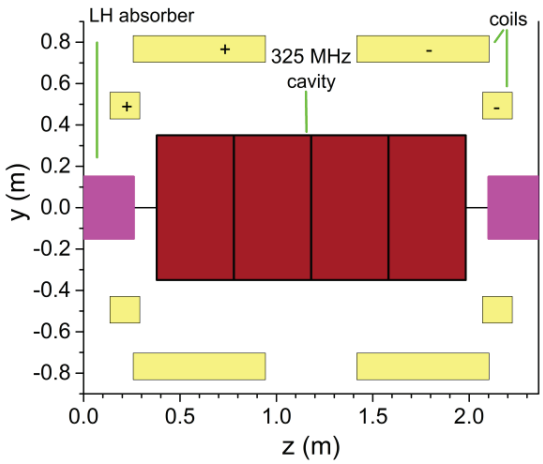

Figure 2: Close view of one cell at an early stage. Each cell has 4 coils and two of them are raped around the cavities. The tilt of the coils is not shown.

Figure 2 shows the side view of one cell at an early stage of the channel (Stage 2). This stage consists of a sequence of 14 identical 2.36 m cells, each containing four 0.4 m-long 325 MHz pillbox cavities, and a wedge-shaped liquid hydrogen absorber, with 28.6 cm central thickness and 100 deg. opening angle, to assure energy loss. Moreover, each cell contains four solenoid coils of opposite polarity, yielding an approximate sinusoidal variation of the magnetic field in the channel with a peak on axis value of 3.1 T and providing transverse focusing with a peak beta value of ~ 36 cm. In order to provide the required dispersion the coils are tilted by 1.1 deg vertically. The lattice transmits in a region from 155 to 248 MeV/c, with a central (reference) momentum of 204 MeV/c.

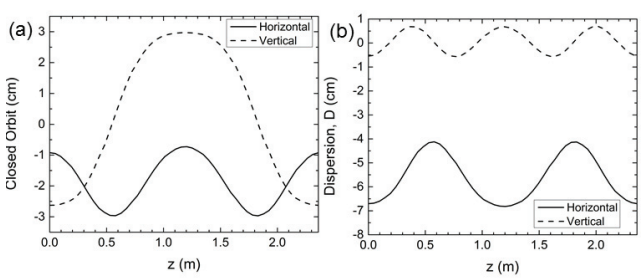

Figure 3: Closed orbit at the reference momentum of 204 MeV/c (left). Dispersion in the vertical and horizontal directions along the cell.

Deviation of the closed orbit along the cell for the reference momentum of 204 MeV/c is shown in Fig. 3(a). Notice that at the central momentum the vertical offset (dashed) from the center is ~ 2.6 cm at the entrance of the cell. Figure 3(b) displays the dispersion functions in x (solid) and y (dashed) along the cell. The dispersion at the absorber has the same sign in both directions and is mostly in the horizontal direction. Notice that the dispersion is maximum at the center of the absorber.

The beta function varies from 40.0 cm to 4.0 cm while the on-axis magnetic field increases progressively from 2.7 T to 13.1 T. It is important to emphasize that the maximum field on the coil at the last stage is 14.1 T with a current density of 196 A/mm^2. This value is below the critical published [5] limit for Nb_3Sn. The RF frequency is increased from 325 MHz to 650 MHz. Ideally, the cooling channel should be tapered with a continuously varying frequency. However, for practical implementation we keep the number of different frequencies as small as possible. As we will illustrate in the next section, 16 stages are enough to achieve the desired emittance for a Muon Collider. Detailed lattice parameters of our proposed channel can be found in Table 1.

SIMULATION DETAILS

Simulations of the channel performance where done using the ICOOL code with 100,000 particles. The simulation is initiated after the bunch merger. We generated 3D cylindrical field maps for each of the stages by superimposing the fields from all solenoids in the cell and its neighbour cells. The rf cavities were modelled using cylindrical pillboxes running in the TM010 mode. The cavities are enclosed with 100 μm metallic Beryllium windows. The wedge material was liquid hydrogen. The absorbers are enclosed in Al windows ranging from 500 μm (Stage 1) to 10 μm (Stage 16).

The lattice cooling efficiency is defined as the rate of change of the 6D emittance divided by the change of muons. It is often used to quantify the lattice performance and it is displayed in Fig. 4. One can see that for a rectilinear channel it remains relatively flat along the channel with a maximum near 9.5. The helical lattice appears to have a slight higher performance. Note that a more detailed comparison between the two schemes can be found elsewhere [6].

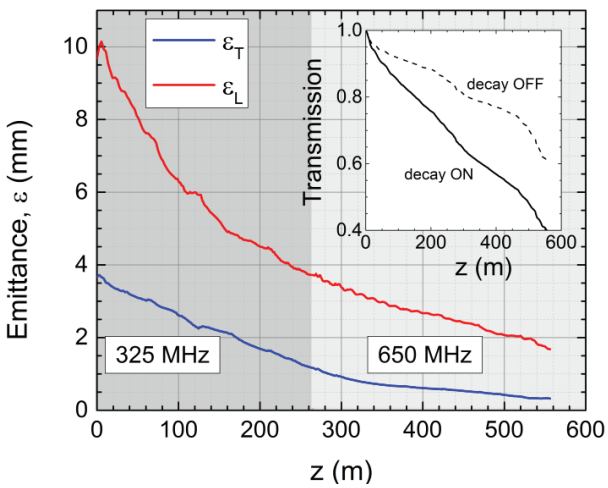

Figure 5: Longitudinal (red), transverse (blue) emittances and transmission as a function of distance along the channel. The final values of the emittances are also shown.

The transverse, longitudinal emittance and transmission including muon decays as a function of distance along stages 1 to 16 are shown in Fig. 5. The simulation produced a transverse emittance of 0.32 mm and a longitudinal emittance equal to 1.6 mm, which is close to the desired values for a Muon Collider. The transmission without decays is above 60%. If space-charge is included in the simulation an additional 10% of losses is predicted [7]. The quoted emittance values are normalized rms.

SUMMARY

Cooling large emittance muon beams is an essential step for a Muon Collider. A rectilinear FOFO snake channel may reduce the engineering challenges compared to conventional helical structures (like in a Guggenheim helix). As this study demonstrated, by performing tapering the desired emittances for a muon collider can be obtained with a transmission above 60% without decays and 40% with muon decays. The cooling rate remains relatively flat along the channel with a peak value of 9.5. Furthermore, the maximum field on the coil is 14 T which is within the published critical limit for Nb_3Sn. The next step would be to improve the matching between individual stages, which will aid in boosting the performance. The authors like to thank P. Snopok and R. Ryne for many fruitful discussions.

SPACE-CHARGE LIMITATIONS ON THE FINAL STAGES OF A MUON COLLIDER COOLING CHANNEL*

D. P. Grote#, Lawrence Livermore National Laboratory, Livermore, CA, USA
D. Stratakis, R. B. Palmer, J. S. Berg, Brookhaven National Laboratory, Upton, NY, USA

Abstract

Muon Colliders use ionization cooling to reduce the emittance of the muon beam prior to acceleration. At the last stages of the cooling channel, the bunch has 4×10^{12} muons, an average momentum of 200 MeV/c, and an rms bunch of 2 cm. With this beam intensity and relatively low momentum, we expect space charge effects to have a significant impact on beam dynamics. Here, with the aid of the particle-in-cell code Warp, a 3D model is developed to examine space-charge for muon cooling lattices and some recent results are presented. The model includes 6D cooling with wedge shaped absorbers. We show that space-charge under certain conditions can cause a notable particle loss. Furthermore, we discuss some potential space-charge compensation mechanisms.

INTRODUCTION

A complete scheme for cooling a muon beam sufficiently for use in a muon collider has been previously described [1]. This scheme uses separate 6D ionization cooling channels for the two signs of the particle charge. In each, a channel first reduces the emittance of a train of muon bunches until they can be injected into a bunch-merging system. The single muon bunches, one of each sign, are then sent through a second tapered 6D cooling channel where the transverse emittance is reduced as much as possible and the longitudinal emittance is cooled to a value below that needed for the collider. The beam can then be recombined and sent through a final cooling channel using high-field solenoids that cools the transverse emittance to the required values for the collider. The baseline cooling requirement for cooling is shown in Fig. 1.

Theoretical estimates predict that at the last stages of the post-bunch-merge 6D cooling channel the rms bunch length is just 2 cm and contains $4\text{x}10^{12}$ muons. Thus, the peak current becomes ~4 kA at a ~200 MeV/c momentum. Due to this large current, space-charge forces can be present and thus, there is cause for concern that the existing 6D cooling lattice design may not work so well. Recent studies [2] with the Warp PIC code [3] confirmed this fact since it was shown that longitudinal space-charge can oppose cooling while simultaneously it causes severe particle losses. To reduce the space charge effects, the overall lattice was redesigned with a higher longitudinal emittance target, increased from 1.5 to 2.0. We note that those previous studies were assuming a matrix for longitudinal cooling and thus, the effect of a real absorber wedge was not taken into account. This paper will present results from recent studies on simulating full 3D space-charge effects on muon cooling lattices with more realistic wedge shaped absorbers.

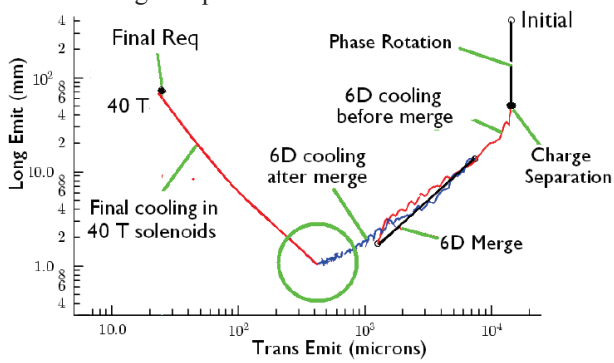

Figure 1: Baseline cooling requirement for the Muon Collider.

LATTICE DESIGN

In order to cool towards the micron scale emittances required for a Muon Collider a 16-stage tapering channel has been proposed. A detailed description of this lattice can be found elsewhere [4]. In this scheme, we apply the concept of tapering [5] where parameters such as cell length, focusing and radius of curvature progressively change from stage to stage based on the emittance reduction rate and transmission.

A segment of one stage of our proposed cooling system is shown in Fig. 2(a). Each stage consists of straight section with a number of identical cells like the one shown in Fig. 2(b) and Fig. 2(c). The coils (yellow) are

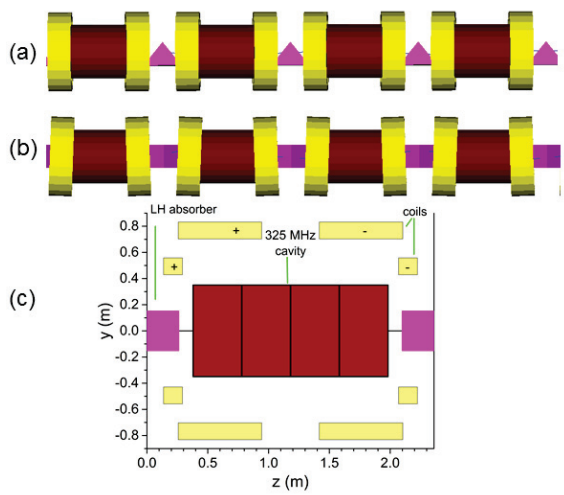

Figure 2: Cooling scheme for the Muon Collider. Fig. (c) depicts one lattice cell. The tilts of the magnets are not shown.

not evenly spaced and in order to produce dispersion, they are tilted by 1.1-1.3^0. The liquid hydrogen absorber (magenta) is wedge shaped so that higher momentum particles go through the thicker part. Each lattice cell contains the same number of rf cavities (dark red) which, depending on the stage, can be 4, 5, or 6. We use only two sets of rf frequencies, namely 325 MHz and 650 MHz. The choice of 325 MHz is made in order to match with the initial linac of Project X. The cavity window material is Be.

SIMULATION RESULTS

The input beam in the simulations has a normalized transverse emittance of 3.63 mm and a normalized longitudinal emittance of 10.17 mm, while the average longitudinal momentum is 218 MeV/c. Note that those parameters closely resemble the baseline distribution of a muon beam before the final 6D cooling sequence of a Muon Collider [1]. We tracked 100,000 particles and included decay of muons. We generated 3D field maps for each of the stages by superimposing the fields from all the solenoids in the cell and its neighbour cells, including the solenoid tilts. The rf cavities were modelled using cylindrical pillboxes running in the TM010 mode.

Space-charge effects were studied by using the particle-in-cell code Warp. Warp was originally developed to simulate space-charge-dominated beam dynamics in induction accelerators for heavy-ion fusion (HIF). The code now has an international user base and is being applied to projects both within and far removed from the HIF community. A layer was added to Warp to read in and parse ICOOL input files allowing identical problem setup. Note though that Warp operates with time as the independent variable whereas ICOOL uses *s*, so there are small numerical differences in the calculations. During the calculation, Warp handles all operations except for the interaction with the material in the wedge absorber, which is handled by calls to the appropriate ICOOL routines.

The lattice as seen in the Warp simulation is shown in Fig. 3. This is a cell in the first stage of cooling. The simulation incorporates all aspects relevant to the beam motion, including the 3D solenoid field map, RF cavities with absorbing Be windows, and the wedge absorbers and windows. The wedges and RF cavity windows both act as perfectly conducting internal boundary conditions on the electrostatic potential. The beam macro-particles were generated with an initially Gaussian distribution in physical and velocity space.

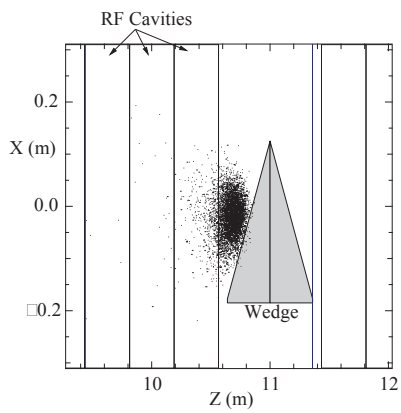

Figure 3: Lattice as known by the Warp simulation.

Before examining the effects of space charge, checks were carried out comparing ICOOL and Warp simulations without space-charge to check correctness of the models. The resulting emittance and particle numbers are shown in Fig. 4. Four cases are shown, ICOOL and Warp with and without muon decay. As can be seen, good agreement was obtained.

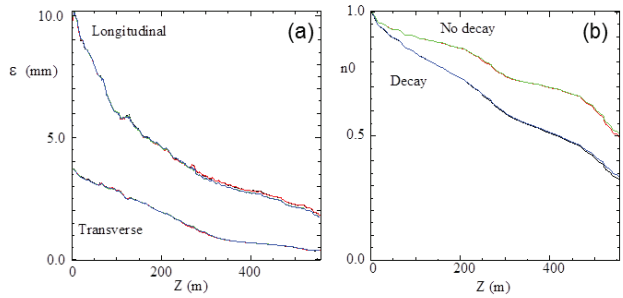

Figure 4: ICOOL and Warp cross-check without space charge (a) emittance, and (b) number of muons. Simulations are carried with and without muon decay using both codes.

In these initial simulations, the electrostatic self-field model was used. The resulting fields from the beam are significant, of order several MV/m, as can be seen Fig. 5. However, this is small compared to RF gradient, which is typically between 17 and 27 MV/m. Note the sharp cut off of the field at the RF cavity windows.

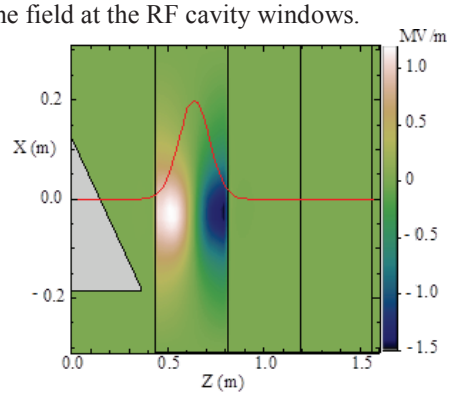

Figure 5: Longitudinal electric self-field. The red curve shows the scale current to show the location of the beam bunch.

The electrostatic potential was calculated on a 3D grid with an initially 2 cm transverse and 1 cm longitudinal cell sizes. As the simulation progresses and the lattice dimensions decreased, the grid cell sizes were correspondingly reduced. The simulations are significant, requiring on the order of a day of wall clock time, depending on the number of processors, because of the large number of time steps, > 500,000, to traverse the cooling channel. Note that the time step size is driven by the need to resolve the variations in the applied fields and not by the space-charge calculation.

Copyright © 2013 CC-BY-3.0 and by the respective authors

The results of the simulations with space charge are shown in Figs. 6, 7 and 8. The main effect of the space charge is to increase the particle loss. Little difference is seen in the emittances. There is a reduction in the longitudinal emittance, but it is associated with the increased particle loss. Most of the particle loss is longitudinal – the increase in the loss is not unexpected since the space charge increases the length of the pulse, pushing more particles out of the RF bucket. The increase in bunch length is shown in Fig. 8. The transverse size is unaffected.

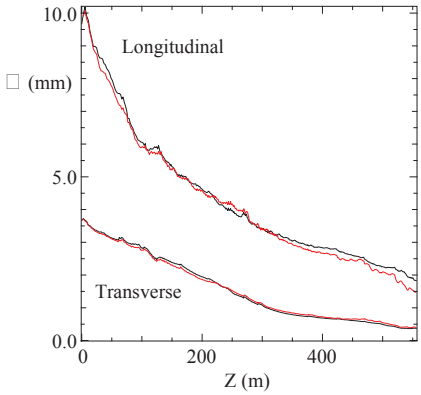

Figure 6: Beam normalized rms emittances along the channel with (red) and without (black) space-charge.

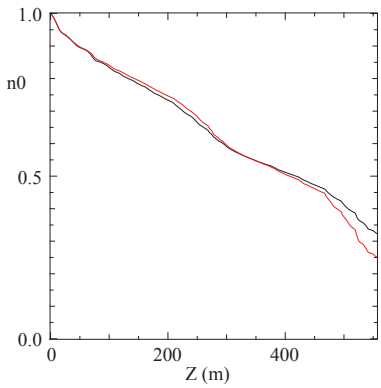

Figure 7: Fraction of beam remaining with (red) and without (black) space-charge.

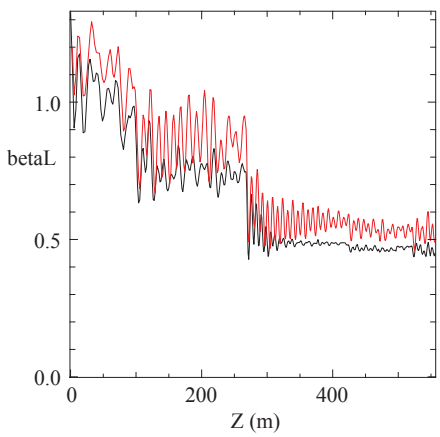

Figure 8: Longitudinal beta function with (red) and without (black) space-charge.

One possible method to reduce the particle loss is to increase the RF gradient, which increases the depth of the bucket. In the previous work [2], this was found to be effective. However, in the current lattice design, increasing the gradient was ineffective. Figure 9 shows the resulting emittances and particle losses with the gradient increased by steps of 1.5 MV/m in the last 8 stages. Note that the red line shows the default value of 26 MV/m while the yellow line corresponds to 46 MV/m which is the maximum gradient simulated. It is possible to obtain better performances if the beam is matched for each gradient accordingly. This will be investigated in more detail in a future study.

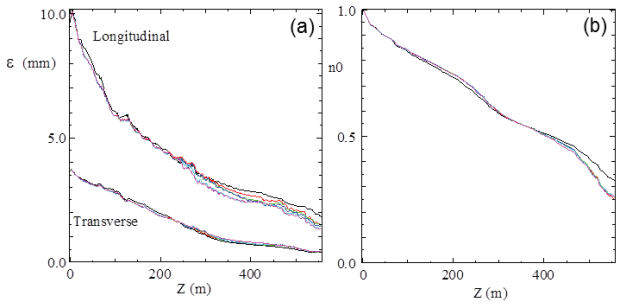

Figure 9: Emittances with varying RF gradients. The emittance is reduced with each 1.5 MV/m increment. The black curve, without space charge, is for reference. (b) Fraction of beam remaining for varying RF gradients. The black curve, without space charge, is for reference.

CONCLUSIONS

Towards the end of the cooling channel, the density of the muon bunch becomes significant enough that space charge effects can become important. A simulation campaign has been carried out, using the Warp code, to examine the effects. Warp uses a fully self-consistent PIC model to include space charge. The simulations show that there is little effect on the emittance, but an increase in the particle loss. Most of the particle loss is longitudinal, out the tail of the bunch. Unfortunately, the simple remediation of increasing the RF cavity gradient was not effective. Work examining other techniques to reduce particle loss will continue.

ACKNOWLEDGMENT

The authors like to thank R. Ryne and I. Haber for many fruitful discussions.

RF CAVITY PHASE CALIBRATION USING ELECTROMAGNETIC PICKUPS*

Abstract

A method is presented using electromagnetic pickup probes for RF cavity phase calibration. (We used capacitive style pickup probes.) Pickup probes provide fast readings, and measurements of the phase difference between a pair of pickup probes provides enough information about the phase-energy curve to yield a fit for the zero-crossing phase. We present an overview of the algorithm and measurement results of an implementation on the ReA3 reaccelerator.

INTRODUCTION

The Facility for Rare Isotope Beams (FRIB) is a heavy ion fragmentation facility to produce rare isotopes far from stability for low energy nuclear science. The facility will utilize a high-intensity, superconducting heavy-ion driver linac to provide stable ion beams from protons to uranium at energies greater than $200\ \mathrm{MeV/u}$ and at a beam power of up to $400\ \mathrm{kW}$ [1]. The baseline design for the linac comprises over 300 accelerating superconducting cavities. A precondition for tuning the linac is calibrating the radio frequency (RF) phase of each of these cavities, which requires a phase scan combined with energy measurements. With such a large number of cavities as it is planned for FRIB, a need arises for an automated approach to calibrating cavity phase.

RF cavity phase calibration is the process of calibrating the cavity phase relative to the phase of the accelerated beam. For this purpose, the zero-crossing phase points (the phase points at which the cavity does not provide any acceleration) are determined. There are two such points in a full 360-degree phase range ($180°$ apart from each other), and we use the one on the bunching side of the phase slope as the reference. The value of the zero-crossing depends on the beam energy, thus the cavities need to be calibrated for every new energy tune. Therefore, cavity phase calibration is a necessary recurring task in operations.

We approached the concrete problem of calibrating the cavity phases on the ReA3 accelerator at Michigan State University [2], which is currently being commissioned. Prior to the installation of Beam Position Monitors (BPMs) in the ReA3 accelerator, the only method available for cavity phase calibration was energy measurements from silicon foil detectors. As these measurements are inherently slow, calibrating the six accelerating cavities currently installed in ReA3 could take up to several hours. Since capacitive style electromagnetic pickup probes provide fast readings, we explored the application of pickup probes for inferring the beam energy and thereby calibrating cavity phase. The capacitive style pickup probes we used were the two BPMs installed on the ReA3 beam line. The details of the BPMs in the ReA3 accelerator are presented in Rodriguez et al. [3]. The phase readouts were averaged over the four buttons for each BPM, so that for this purpose, the BPMs were effectively used only as electromagnetic pickup probes.

PRINCIPLE

The readouts from two pickup probes separated by a certain distance provide the phase difference of bunches at the two locations. It is important to keep in mind, though, that this is not the absolute phase difference, but its value modulo $360°$. In other words, the pickup probes do not provide information about the total number of bunches between the two locations, but only the fraction of the RF period that represents the "incomplete last bunch." The number of "complete bunches" between the two locations needs to be evaluated by other means. As will be shown, however, knowing this information exactly is not essential for the applicability of the method we are presenting.

The phase difference $\Delta\varphi$ between the pickup probes can be translated into the time of flight via

$$t(\Delta\varphi; n) = T_{RF}\left(n + \frac{\Delta\varphi}{360°}\right), \qquad (1)$$

where n is the truncated number of bunches between the pickup probes, T_{RF} is the RF period, and t is the time of flight. The integer n decreases with beam energy, and within energies attainable in the ReA3 accelerator (without deceleration), and with the BPMs separated by $2.08\ \mathrm{m}$, it ranges from 14 (for the beam energy after the RFQ of $600\ \mathrm{keV/u}$) to 8 (for the maximum beam energy after the linac of $1.9\ \mathrm{MeV/u}$). Translating the time of flight (1) into energy (non-relativistically), we obtain the dependence of energy per nucleon E/m on the phase difference $\Delta\varphi$:

$$\frac{E}{m}(\Delta\varphi; n) = \frac{1}{2}\left(\frac{Lf_{RF}}{n + \frac{\Delta\varphi}{360°}}\right)^2, \qquad (2)$$

where L is the distance between the pickup probes, and $f_{RF} = 1/T_{RF}$ is the RF frequency. Equation (2) can be in-

verted eliminating the unknown number of bunches n into

$$\Delta\varphi(E) = \left(360^\circ L f_{RF}\sqrt{\frac{m}{2E}}\right) \mod 360^\circ. \quad (3)$$

This functional dependence, for the relevant range of energies, is shown in Figure 1, which is a graph we refer to as a *mod-360 hyperbola*.

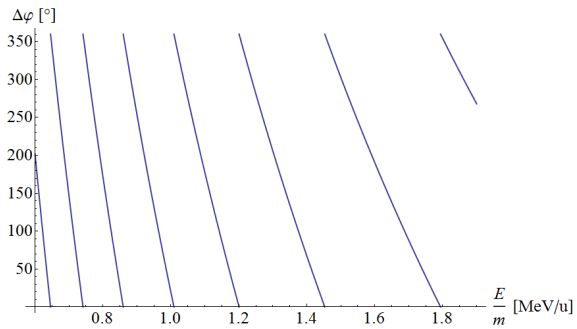

Figure 1: Bunch phase difference at pickup probes $\Delta\varphi$ as a function of beam energy per nucleon E/m. ($L = 2.08$ m)

In the method presented here, the beam energy is varied by changing the cavity phase

$$E(\Phi) = E_0 + QeV\sin(\Phi - \Phi_0)\,, \quad (4)$$

where Φ is the cavity phase, E_0 and Φ_0 are the zero-crossing energy and phase, respectively, Q is the beam charge state (an integer), and eV is the cavity amplitude. The dependence $\Delta\varphi(\Phi)$ of the measured phase difference on the cavity phase (the independent variable) is therefore obtained by composing the sine function $E(\Phi)$ (4) with the mod-360 hyperbola $\Delta\varphi(E)$ (3). Ideal measured data (pickup probes phase difference vs. cavity phase) should therefore be aligned along the curves shown in Figure 2. Note that this plot is not a broken sine function inasmuch as the mod-360 hyperbola $\Delta\varphi(E)$ (3) is not a broken line (cf. Figure 1).

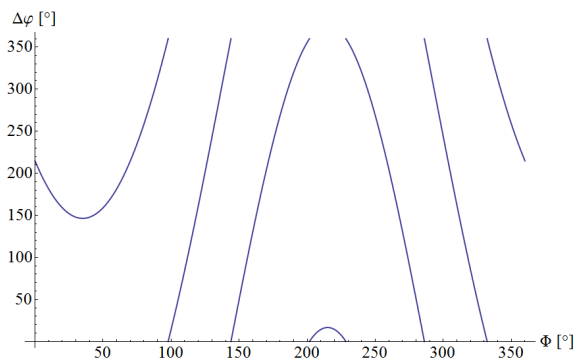

Figure 2: Ideal measured data: pickup probes phase difference $\Delta\varphi$ as a function of cavity phase Φ. ($E_0 = 600$ keV, $eV = 100$ keV, $\Phi_0 = 305^\circ$, $L = 2.08$ m)

Algorithm Outline

The first step in fitting for the sought parameter Φ_0 is to turn data in the form of $\Delta\varphi(\Phi)$ into a continuous-looking function, effectively a "reverse mod-360" operation. We refer to this process as *stitching*. Once the data are stitched, ordinate values are no longer restricted to a 360° window. Next, we eliminate the unknown parameter n from consideration by picking a reasonable estimate for it, and transforming the phase difference data into energy values. Then, we fit the sine curve $E(\Phi)$ (4), which yields three fitted parameters (E_0, eV, Φ_0) including the wanted zero-crossing phase Φ_0. An error in the estimate for n is mostly reflected in the error in E_0, while the effect on the fit in Φ_0 is negligible, as evidenced by numerical trials on measured data.

METHODS

The algorithm as outlined above was implemented in Python, with a curve fitting optimizer provided by the SciPy [4] *optimize* package and a graphical user interface (GUI) written using the *Traits* and *TraitsUI* packages, also included in the SciPy library. The EPICS [5] connection was established via PyEpics [6], which allowed the software to do a fully automated phase scan by setting cavity phase values, and reading cavity phase readbacks and BPM phase data, as well as any other EPICS channels that might be of interest (e.g. Faraday Cup readouts for beam intensity).

In order to be of practical use, in addition to the basic phase scan controls, data collecting, and fitting capabilities, the software also required data resampling functionality to produce meaningful fits. For various reasons, some measured data points need to be discarded. The most commonly observed cause of outliers in the ReA3 accelerator data was sparking between bender plates near the source, due to the fact that the source needs to operate in a high current mode in order for the pickup probes to provide a sufficient signal throughout the phase scan. Sparks would typically produce a single bad datapoint before the beam falls back into its trajectory. We were carrying out several measurements (typically 10, although in some instances 3 were sufficient) for each cavity phase, and such outliers were easily detectable due to a large deviation from the mean. However, other causes of error in the measurements lead to an entire set of measurements for a given cavity phase setpoint (referred to as a setpoint group) to be discarded, either because of a large rms, or as too far removed from the fitted curve. Therefore, the resampling was done at two levels: (1) within a setpoint group: removing single data points that are too far from the mean; (2) among setpoint groups: removing entire setpoint groups whose standard deviation is too large, or whose mean is too far from the fitted curve.

As far as the beam line configuration, we note that the locations where the BPMs were installed in the ReA3 accelerator were not chosen with this particular purpose in mind, and were less than ideal: they were about 0.6 m down-

Copyright © 2013 CC-BY-3.0 and by the respective authors

stream from the last accelerating cavity with no focusing or steering elements after the cavity, and separated by a distance of 2.08 m. These were the only two BPMs available, and so were used for all the cavities. The upstream cavities were therefore more challenging due to their greater distance from the BPMs.

RESULTS

Several test runs of the software were carried out on the ReA3 accelerator. The beam used in each case was molecular hydrogen H_2^+. The issue that made the calibration process slow at first was the tuning required to prepare the beam, which was not trivial due to the position of the BPMs and the lack of focusing and steering elements around them. Moreover, in order to obtain usable data, the beam must be tuned so as to provide a good signal from the BPMs throughout a full cavity scan. This is complicated by the fact that due to the design of the ReA3 superconducting RF cavities, they steer the beam as a function of phase setting [7]. Tuning was more challenging with the upstream cavities due to the greater distance to the BPMs and because of the effect of the cavity kicks is proportionately larger on the lower energy beam at the beginning of the linac. In the first runs, tuning was taking up to a few hours per cavity. As the tunes were developed, this time was significantly reduced, and in the last run tuning was taking an average of about 10 minutes per cavity.

We have empirically verified the claim presented above that the fit for the zero-crossing phase is not affected by an inaccurate estimate of the number n of bunches between the pickup probes. For all the measured data, varying n between extreme values attainable in ReA3, the resulting change in the fitted zero-crossing phase Φ_0 is less than $0.1°$, which is less than the estimated accuracy of the method.

In the last run, carried out in September 2013, we have developed a procedure to phase the linac sequentially, using the fitted zero-crossing phase value of the last cavity to set the cavity phase to nominal acceleration phase (in ReA3: $-20°$ off peak) before proceeding with the next one. The energy plot of the data for one cavity (after resampling), along with the fitted sine curve, is shown in Figure 3.

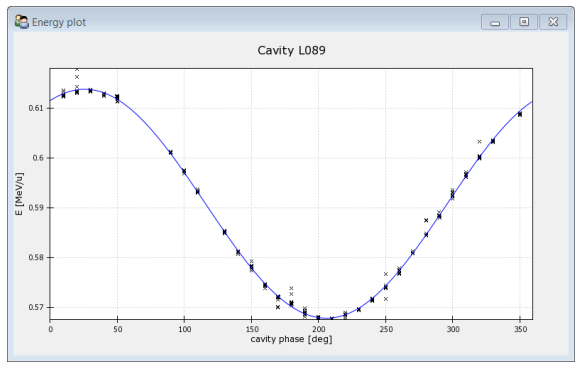

Figure 3: A screenshot of a window of the cavity phase calibration software that shows energy vs. cavity phase data (black) with the fitted sine curve (blue) for one of the accelerating cavities in the ReA3 linac.

CONCLUSION

A method for calibrating cavity phase using two capacitive style pickup probes by measuring the relative difference in phase between the two pickup probes was presented. No other measurements are necessary: the method does not require absolute energy measurements, since a reasonable estimate of the number n of bunches between the pickup probes is sufficient to yield an accurate fit for the zero-crossing phase Φ_0. The principle is based on simple equations: phase difference data are stitched together and transformed to the energy domain, where a sine function is fitted, and the abscissa offset represents the desired parameter Φ_0.

This algorithm was implemented and tested on the ReA3 accelerator. The implementation software had a direct connection with EPICS channels, automating the full cavity scan process, and it included data resampling features to deal with unacceptable levels of noise in the data. In the best case, a usable full cavity scan took only a couple of minutes, however this time is dominated by the time needed to tune the beam in order to prepare it for the scan. The latter time is strongly dependent on the position of the pickup probes relative to the cavity, and their separation distance, as well as the availability of tuning and focusing elements, and the reproducibility of previously developed tunes, all of which were less than ideal in our case. We still successfully calibrated the accelerating cavities in the ReA3 accelerator using BPMs as pickup probes.

MICE SPECTROMETER SOLENOID MAGNETIC FIELD MEASUREMENTS

M. Leonova# *on behalf of the MICE collaboration*
Fermilab, Batavia, IL 60510, USA

Abstract

The Muon Ionization Cooling Experiment (MICE) is designed to demonstrate ionization cooling in a muon beam. Its goal is to measure a 10% change in transverse emittance of a muon beam going through a prototype Neutrino Factory cooling channel section with an absolute measurement accuracy of 0.1%. To measure emittances, MICE uses two solenoidal spectrometers, with Solenoid magnets designed to have 4 T fields, uniform at 3 per mil level in the tracking volumes. Magnetic field measurements of the Spectrometer Solenoid magnet SS2, and analysis of coil parameters for input into magnet models will be discussed.

INTRODUCTION

The MICE experiment [1] located at Rutherford Appleton Laboratory consists of a dedicated beam line, which generates muons in a range of input momenta between 140 and 240 MeV/c and emittances between 2 and 10 π mm, and a cooling cell sandwiched between particle identification detectors (PID) and Spectrometer Solenoids (SS) equipped with scintillating fiber trackers, see Fig. 1. The cooling cell is designed to reduce the transverse emittance of a passing muon beam by about 10% using the ionization cooling principle.

Each spectrometer consists of a 4 T superconducting solenoid, and a tracker [2] composed of five planar scintillating-fibre stations, whose pacing has been chosen to optimize the performance of the reconstruction (track-finding efficiency and parameter resolution). Together, the spectrometers are required to determine the expected relative change of approximately 10% between the "before" and "after" beam transverse emittances with a precision of ±1% (i.e. 0.1% absolute measurement of the emittance). Therefore, the fields in the tracking volume should be known with high accuracy.

The MICE SSs were built at Wang NMR (Livermore, CA, USA). A schematic representation of the magnet (not drawn to scale) is shown in Fig. 2. The cryostat consists of a liquid helium vessel, an 80 K thermal shield, cold mass supports and a stainless steel vacuum vessel with 40-cm diameter bore. Each solenoid consists of five superconducting Nb-Ti coils wound on a single aluminum mandrel. Two Matching coils (M1, M2) match the muon beam in the SSs to the beam in the cooling cell. Two End coils (E1, E2) positioned around a Center coil (C) are designed to generate a uniform 4 T field over a 110-cm-long and 30-cm-diameter volume. The coil parameters

** This is at the maximum design current, which is based on the worst-case currents for the five coils.
^ The inductance of the two end coils and the center coil in series is about 74 H.

Figure 3: As built parameters of the second MICE SS.

given in Fig. 3 [3] are "as built", which are different from the original design and design by vendor. Each coil layer was thicker than anticipated with fewer turns per layer, thus, the currents in the coils were adjusted accordingly.

A model of the solenoids (together with other magnets, equipment and structures in the MICE experimental hall) will be used to simulate the fields for each momentum/emittance case for use in MICE data analysis. Thus, the magnetic field mapping is important to verify the coil geometry for the model and effects of magnetic material (detector shielding) on the field.

HIGH PRECISION MAGNETIC FIELD MEASUREMENTS

CERN Detector Technologies Engineering and Mechanics group built a dedicated system for mapping MICE magnets [4]. The system includes: a 5-m long support system, the chariot containing a detachable service module for an NMR probe, disk with seven 3D Hall probes, and the Data Acquisition system. The setup of the magnet measurement device is shown in Fig. 4.

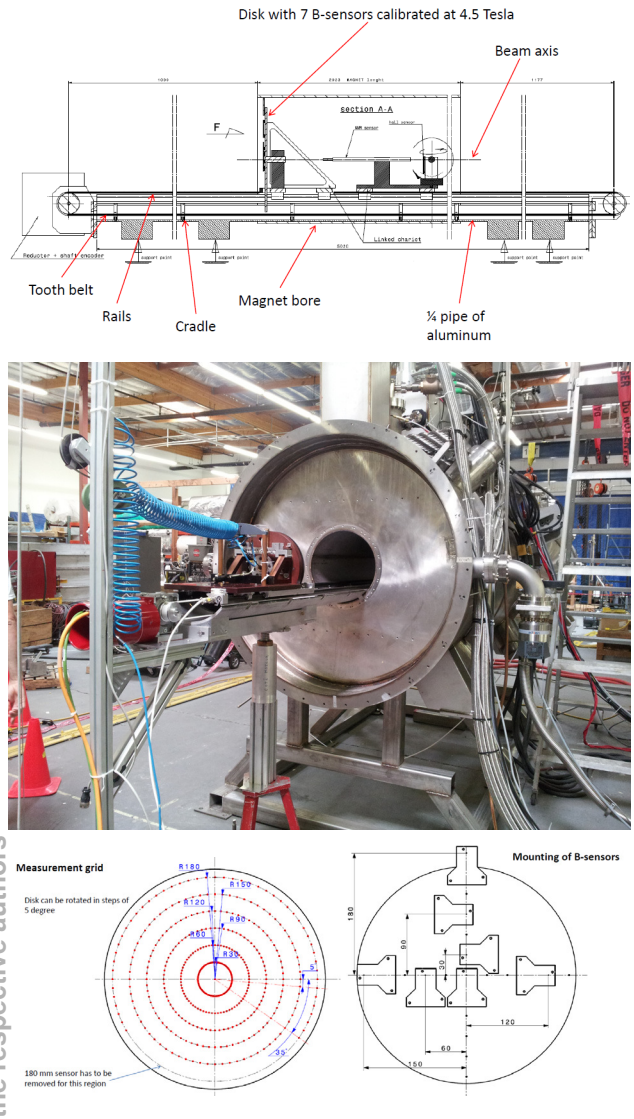

Figure 4: (Top) Magnet measurement device setup. (Center) Photo of the system in use for SS2 magnet. (Bottom left) Measurement grid of the device. (Bottom right) Mounting positions of the seven 3D Hall probe sensors on the disk.

The support is made of ¼" aluminum pipe. Other components of the device are made of non-conducting materials to avoid eddy currents. The chariot is moved by a motor with reduction gear box and encoder on the outgoing shaft. The disk with seven 3D Hall probes can be rotated in steps of 5°. The probe at 180 mm radius needs to be dismounted for rotation angles between 225° and 355° due to interference with the chariot.

The system is characterized by the following uncertainties: ± 0.5 mm probe radial position; ± 1 mrad disk rotation angle; < 0.5 mm longitudinal position; and ± 2 mT magnetic field measurement in 1 to 4 T region.

Magnetic measurements of MICE SS2 magnet were performed for two setups: without any magnetic material present near the solenoid, and with steel (US1010) plate and cage, mounted on the E2-coil side of the solenoid for shielding detectors present in MICE channel.

For each setup, a series of measurements were done for two coil current configurations: "Solenoid Mode" and "Flip Mode", corresponding to the two MICE cooling cell magnetic field configurations when operating with muons with an average momentum of 240 MeV/c and a β-function at the center of the absorbers of 420 mm. Figure 5 shows an example of one set of measurements; measurements for all 3D Hall probes at different radii are plotted (0 mm – 18 mm), thus, the scatter in the points.

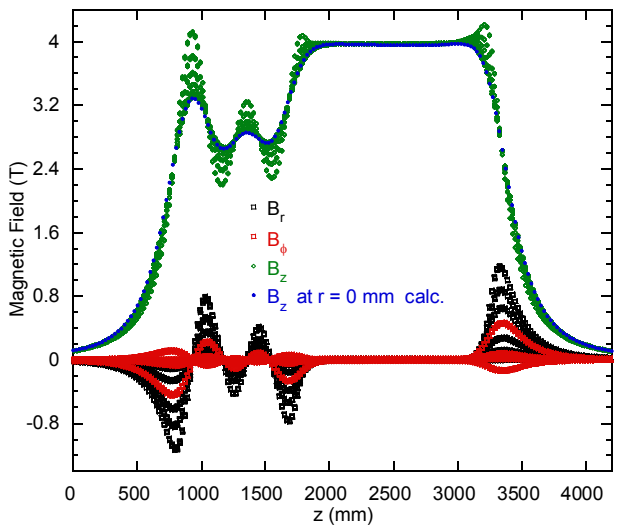

Figure 5: Measured field components for all probes, and a numerical calculation of the longitudinal field on magnetic axis using "as-built" coil parameters.

The typical measurement format was with 2 cm longitudinal steps and 20° disk rotation steps. There were additional faster measurement sets at currents adjusted to various percentage of a full current configuration to check linearity of field with current and study the hysteresis effect in the field (due to introduction of material in shielding plate). For these, the measurement format was with 5 cm longitudinal steps at only four disk rotation angles (0°, 40°, 180°, 220°). There were also additional studies to check for systematic uncertainties introduced by probes mounting on the disk (only 5 longitudinal positions, but with 5° disk rotation steps). We also measured coils powered at low current of 30 A: coils M1, M2, E1 and E2 individually, and coils E1-C-E2 together; the measurement format had varying longitudinal steps and 30° disk rotation steps.

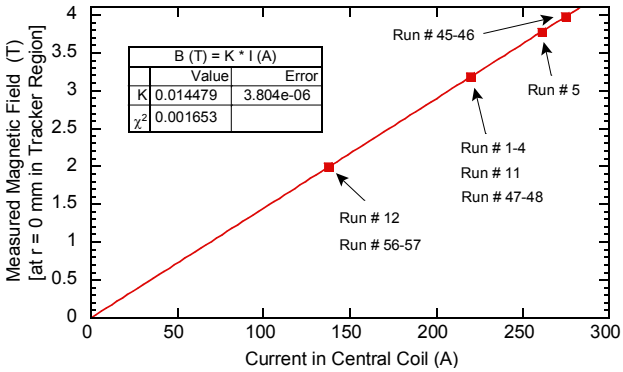

Figure 6: Magnetic field linearity study.

Figure 6 shows analysis of magnetic field linearity with current for a set of measurements without shielding plate, for "Solenoid Mode". There are several overlapping points at 80% current and 50% current, as indicated. The currents in coils were stable to ~0.05A (maximum variance) over ~2.5-hour measurement set, and set currents were reproducible to ~0.03A, as measured by the shunts installed to read coil currents directly [5]. The magnetic field is linear with current, with no indication of measurable offset at 0A.

Figure 7 shows zoom-in on the tracker region. Spread of the field measurements at each radial probe position comes from measurements at different disk rotation angles, and is due to shift of mapping device axis with respect to magnetic axis, as also indicated in Fig 8. An ~3% discrepancy between measurements and simulation was also observed in preliminary measurements [6], when we did not have a direct measurement of coil currents and precise survey of the mapping axis. These results together with the linearity

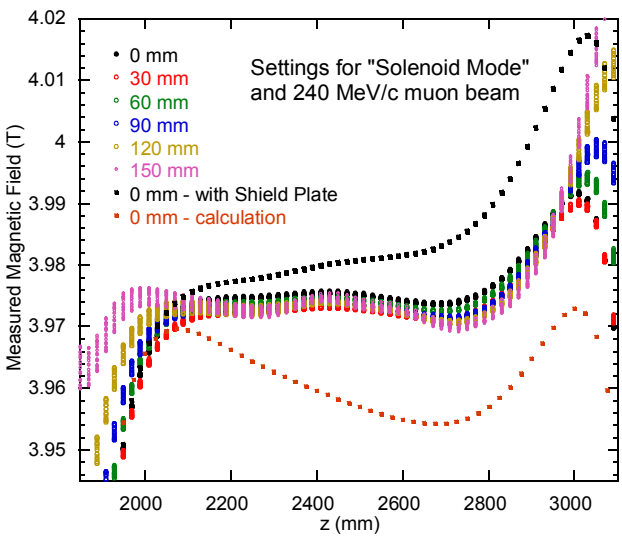

Figure 7: Longitudinal magnetic field component in the tracker region: measurements for 3D Hall probes at different radii for a case without shielding plate, measurements at 0 mm for a case with shielding plate, and a numerical calculation on axis (no shielding plate) using "as-built" coil parameters and measured coil currents.

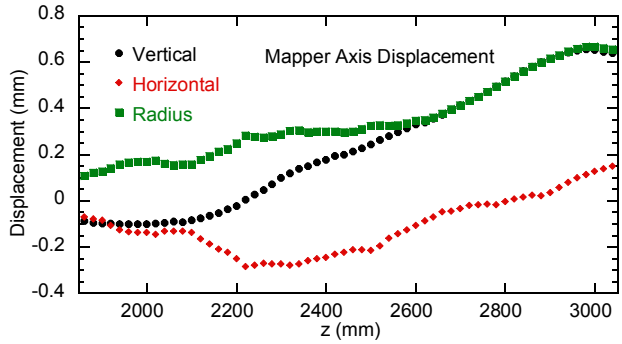

Figure 8: Survey of magnet measurement device axis (zoom-in on tracker region) in a coordinate system aligned to the cold mass axis.

studies indicate that this discrepancy does not come from control or measurement systems, but is due to the coils themselves. It is likely that the number of turns in coils E2, C, and possibly E1 are not as specified in [3], thus, the currents in the coils need to be adjusted to achieve the desired field configuration and uniformity.

The effect of shielding plate on magnetic field inside the solenoid agrees with the studies [7], indicating that reduction of current in the outer coil (E2) of ~2.5% is required to keep the desired magnetic field configuration. We plan to perform more field measurements around the shielding plate during the mapping of the MICE SS1.

ACKNOWLEDGEMENTS

We would like to thank the CERN Detector Technologies Engineering and Mechanics groups for magnetic measurement systems' design, fabrication and measuring and analysis support.

STATUS OF THE MUON IONIZATION COOLING EXPERIMENT (MICE)*

Y. Torun, Illinois Institute of Technology, Chicago, IL 60616, USA†
M. Zisman, LBNL, Berkeley, CA 94720, USA
for the MICE Collaboration

Abstract

A muon collider and a muon-based neutrino factory are attractive options for particle physics. Their realization requires demonstration of muon ionization cooling, the only technique to rapidly reduce the emittance of the short lived tertiary muon beam. MICE, performed by a team from the U.S., Europe, and Asia at Rutherford Appleton Laboratory, will provide this demonstration. The experiment comprises one cell of a representative cooling channel, bracketed upstream and downstream by muon detection stations, each with a spectrometer solenoid (SS). Characterization of the RAL/ISIS muon beam line is complete. Fabrication of the two SS is nearly complete, with one having passed its acceptance tests, and the second nearly ready for testing. The first focus coil is presently being tested, with a second unit ready shortly. The cold mass for the coupling coil prototype is under test and its cryostat is in fabrication. Other required hardware, including RF cavities and liquid-H absorbers, is also being built. Their status and plans for carrying out the experiment are described.

CONCEPT AND STAGING

Ionization cooling of muons involves reducing the total momentum through energy loss while replenishing the component along the reference orbit with acceleration. MICE is a demonstration of muon cooling using a full cooling cell surrounded by tracking and particle identification detectors to measure each muon before and after it traverses the cell [1]. This way, a virtual beam can be constructed in software and its emittance measured with unprecedented precision. The goal is to measure a reduction of order 10% in normalized transverse emittance with a relative precision of 1% under different configurations of input beam and magnetic channel optics. Figure 1 shows the staging of the experiment. Step I, aimed at characterizing the beam using the particle identification detectors, is now complete. In addition, preliminary momentum reconstruction and emittance measurements were performed at this stage using the time-of-flight (TOF) detectors [2]. Reconstructed trace space distributions agree well with simulations for different combinations of momentum (140, 200 and 240 MeV/c) and normalized transverse emittance (3π, 6π and 10π mm). The first measurement of cooling with absorbers will take place in Step IV [3]. This will be followed by the final stage (Step VI) with the full cooling channel cell in place including RF acceleration [4].

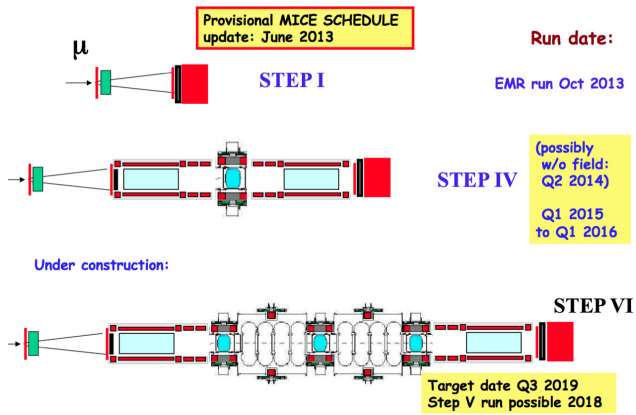

Figure 1: MICE staging and schedule.

BEAMLINE

A target system [5] utilizing a linear electromagnetic drive moves a Ti cylinder vertically toward the edge of the shrinking proton beam envelope just before extraction. In addition, a vertical closed orbit bump has been developed to steer the ISIS beam to meet the target at the correct phase and reduce losses in the machine induced by the MICE target [6]. Figure 2 shows the beamline elements and instrumentation. The pion beam from the target is captured by a quadrupole triplet (Q1-3) and momentum selected in a dipole (D1) before being directed into a decay solenoid (DS). A variable thickness proton absorber at the exit of the DS is used to remove protons from the beam. Momentum selection on the muons from pion decay is performed by

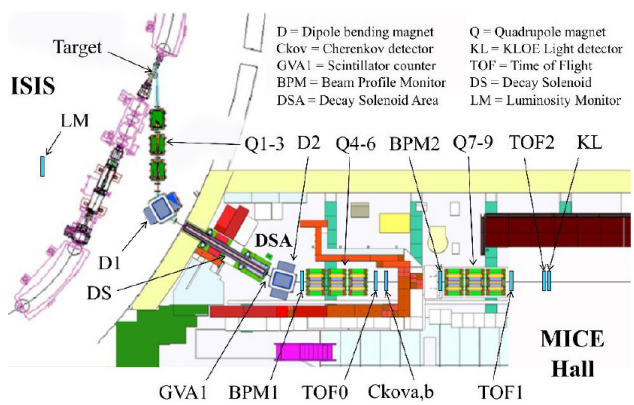

Figure 2: MICE beamline and instrumentation.

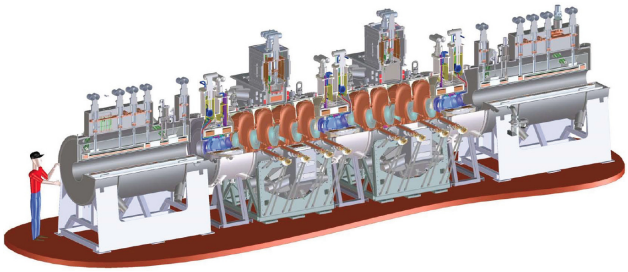

Figure 3: Partial cross section of the MICE channel showing, from the outside in: spectrometer solenoids; AFC modules with liquid hydrogen absorbers; RFCC modules with RF cavities, couplers and Be windows.

another dipole (D2). Two more quadrupole triplets (Q4-6, Q7-9) focus the muon beam. A variable thickness diffuser [7] is used to increase the emittance of the beam at the end of the beamline for some of the settings. The beamline settings have been successfully commissioned [8] and meet the experimental requirements [9].

COOLING CHANNEL HARDWARE

Figure 3 shows the layout of the final stage (step VI) of MICE. The cooling cell includes three AFC (Absorber-Focus Coil) and two RFCC (RF Cavity-Coupling Coil) modules.

AFC Modules

Liquid hydrogen absorber development is complete and the first absorber has been built and successfully tested [10]. Solid absorbers will also be tested in Step IV [11]. A cylindrical disc absorber has been built out of LiH and a wedge-shaped absorber has been designed [12]. Training and testing of the first AFC module magnet is complete and the second unit will be delivered to RAL shortly.

RFCC Modules

Ten RF cavity bodies have been built and most of the thin Be windows and ceramic vacuum windows are in hand [13]. One of the cavities was electropolished at LBNL [14] and is being assembled for operation in a vacuum vessel at the Fermilab MuCool Test Area (MTA) [15]. The tuning system for this cavity was built at Fermilab and LBNL and will be tested soon [16]. The first pair of RF power couplers is under fabrication at LBNL. A test stand at Daresbury Laboratory is being used to develop the RF amplifier chain that consists of four 2-MW systems. RF power and control system design is complete and installation is under way [17]. The first amplifier will be operated in the MICE hall soon. The cold mass for the first prototype coupling coil (CC) magnet is under test at a recently commissioned magnet test facility at Fermilab [18] and cryostat fabrication at LBNL is nearing completion. This CC magnet will be installed at the MTA in 2015. In the meantime, cavity tests will be carried out in the fringe field of a smaller magnet [19].

Spectrometer Solenoids

Assembly of both spectrometer solenoids is complete [20]. The first is on its way to RAL after successful final testing and magnetic field mapping [21]. Testing of the second is about to start.

DETECTORS

Two scintillating fiber trackers have been built [22] and successfully tested. The trackers will be installed inside the spectrometer solenoids and used to reconstruct muon position and momentum. The rest of the detectors are used for particle identification and most are labeled in Fig. 2. The two upstream TOF hodoscopes (TOF0, TOF1) [23], together with the Cherenkov counters (Ckova, b) [24] allow identification of incoming muons while the downstream calorimeter (KL) and electron-muon ranger (EMR) [25] next to it are used to reject muon decays and high energy pions [26]. The TOF counters also provide a measurement of the time coordinate for each muon. Assembly of the last detector, the EMR, was recently completed at the University of Geneva and a commissioning run will begin shortly to complete installation at RAL. The data acquisition system is complete and the software framework for Monte Carlo simulation, reconstruction and analysis of detector data is in place [27].

MAGNETIC SHIELDING

The MICE magnetic channel contains 18 large-bore superconducting coils over a length of about 15 m with no flux return. Steel walls have been installed at the edges of the MICE hall to shield the rest of the building (including the MICE and ISIS control rooms). However, detailed modeling has shown that the magnetic field within the hall would potentially interfere with operation of some components. This will be addressed by relocating some of the sensitive hardware and installing a partial return yoke (PRY) [28] around the magnetic channel to capture the flux. The conceptual design of the PRY is shown in Fig. 4 and detailed engineering is in progress.

OUTLOOK

The beamline has been operating successfully and all major cooling channel components are on track for delivery within the next few years. Commissioning of the last particle ID detector (EMR) is about to commence. Installation of the support infrastructure in the hall is well under way and a framework for controls and monitoring [29] is in place. Step IV of MICE will be ready early in 2015 for the first measurement of emittance reduction after a long ISIS shutdown. The latest version of the schedule can be obtained from the MICE website [30]. MICE is on track for demonstration of ionization cooling by the end of this decade which will pave the way for future muon based accelerator facilities [31].

A CHARGE SEPARATION STUDY TO ENABLE THE DESIGN OF A COMPLETE MUON COOLING CHANNEL*

C. Yoshikawa#, C. Ankenbrandt, R. P. Johnson, Muons, Inc., Batavia, IL 60510, U.S.A.

Abstract

The most promising designs for 6D muon cooling channels operate on a specific sign of electric charge. In particular, the Helical Cooling Channel (HCC) and Rectilinear RFOFO designs are the leading candidates to become the baseline 6D cooling channel in the Muon Accelerator Program (MAP). Time constraints prevented the design of a realistic charge separator, so a simplified study was performed to emulate the effects of charge separation on muons exiting the front end of a muon collider. The output of the study provides particle distributions that the competing designs will use as input into their cooling channels. We report here on the study of the charge separator that created the simulated particles.

INTRODUCTION

One of the most challenging components for a muon collider is the 6D cooling channel that must cool muons by six orders of magnitude in phase space before they decay (τ=2.2μs). The two most promising candidates are the Helical Cooling Channel [1,2] and Rectilinear RFOFO [3] designs. The Muon Accelerator Program (MAP) is a national effort headed at Fermilab that is charged with accessing the feasibility of building a muon collider and/or a neutrino factory based on a muon storage ring. A down-select competition between these contenders had been announced over the summer of 2013 with the expectation for each design to have results of simulations of all components in their channel by end of calendar 2013. Both concepts operate on a single sign of electric charge of the muon, but a charge separator had not been designed. The tight time constraint forbade the design of a realistic charge separator, so a study was performed to emulate the effects of a simplified charge separator on muons exiting the front end of a muon collider. The output of the study provides particle distributions that the competing designs will use as input into their cooling channels.

INITIAL STUDY

This study benefits from an earlier effort [4] that used bent solenoids to separate the opposite charges in the beam. Upon scrutiny of that study, we realized that it was possible to design a configuration that would separate the charges without the need to accelerate the muons above the momentum of 250 MeV/c expected from the front end of the system. A cartoon of the coil configurations that illustrate the basic layout of the charge separator is shown in Figure 1. There are two bent solenoids; the first "forward bend" (shown in white in Figure 1(a)) separates the charged beams vertically, while the second "reverse bend" (shown in red and blue in Figure 1) directs each beam back into the mid-plane. Each bend has three sectors: two "Norem matching" sectors [5] of half a Larmor oscillation length ($\lambda_L/2$) each and a mid-sector that has half the bending radius (and thus twice the vertical displacement angle) to adjust the vertical displacement at the end of the first bend. One of the beams will need to drift in a straight solenoid for a full λ_L in order to create separation between the two reverse bend sets of coils. For consistency with the earlier study, we chose the μ+ beam to traverse the longer path. Since there is no RF in the separator, the beam in the longer path is subject to larger longitudinal emittance growth, and that drives the performance of the charge separator. We will thus design to optimize the μ^+ beam and subsequently analyse the μ^- beam in the shorter channel.

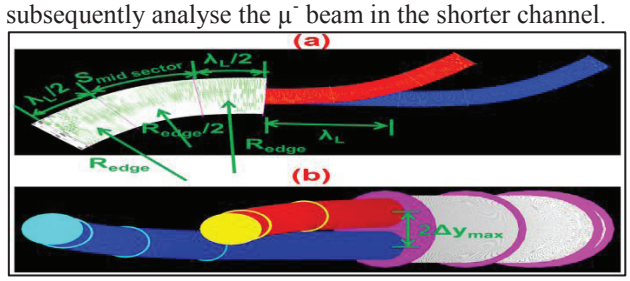

Figure 1: Cartoon of coil configuration illustrating the concept of a charge separator from a top view (a) and at the downstream end looking upstream (b).

A SIMPLIFIED CHARGE SEPARATOR

Designing a realistic charge separator will involve:

1. Dealing with fringe fields at the end of the forward bend and start of the two smaller solenoids.
2. Dealing with fringe fields between the two downstream solenoids.
3. Possibly tilting the coils in the downstream segments if the path difference introduced by the vertical displacement of the coils has a negative impact on performance.

The above complications and the time constraints motivated the need for a simulation setup that can extract the effects of a properly designed charge separator without having to design a realistic charge separator. Such a setup is illustrated in Figure 2 where the simple charge separator is introduced by way of two separate channels, one for each sign. Each channel incorporates large radii coils throughout both bends as well as in the

Copyright © 2013 CC-BY-3.0 and by the respective authors

middle straight in the case of the longer μ+ channel. All coils are confined to lie in the mid-plane as would be done for the forward bend in a realistic charge separator. The coil configurations produce magnetic fields that are well understood and produce expected particle trajectories. Collimators are introduced in the sections downstream of the forward bend to mimic the effect of coil apertures in a realistic charge separator.

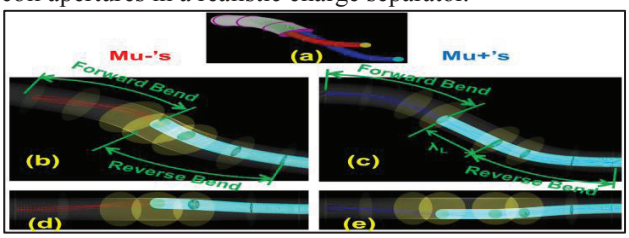

Figure 2: Association of a charge splitter coil concept in (a) to two separate simplified charge splitters (one for each sign) with transparent large radii coils. Yellow discs demarcate sectors. Oblique view of μ^-s in (b) and side view in (d) show vertical rise in forward bend and vertical drop in reverse bend. Oblique view of μ^+s in (c) and side view in (e) show vertical drop in forward bend and vertical rise in reverse bend.

OPTIMIZATION

The simple charge separator is utilized to optimize for maximum throughput and minimal longitudinal emittance growth, recalling there is no RF in the separator. As mentioned above, we will optimize for μ^+s which traverse the longer channel. Particles out of a 325 MHz version of the front end of a muon collider [6] were used as input, and since there is a roughly 20% loss of muons in the 4D cooler, we focused the optimization on particles exiting the phase rotator. Configurations considered in the optimization are given in Table 1, where each was designed to have the same vertical separation at the end of the first bend. Simulations were performed with G4beamline [7], and results of the optimization process are shown in Figure 3, where we have chosen the configuration with R_{edge}=6.32 m as the optimal based on transmission.

Table 1: Configurations in the Optimization

P=Pz	MeV/c	250						
B	T	2						
$\lambda_L=(2\pi P_z)/(B_\varphi c)$	m	2.62						
R_{edge}	m	3.21	4.25	5.28	6.32	7.36	8.39	9.43
α_{edge}(vert angle)	deg	7.4	5.6	4.5	3.8	3.2	2.8	2.5
$S_{mid\ sector}$	m	0	0.42	0.85	1.27	1.70	2.13	2.55
Δy_{max}	m	0.342						
$S_{Longer\ Channel}(\mu^+)$	m	7.86	8.71	9.56	10.41	11.26	12.11	12.96

LONGITUDINAL DISTORTION & ITS REMEDY

The μ^+s exiting the optimal charge separator configuration determined above will need to be caught into RF buckets immediately following the separator. Examination of the longitudinal phase space reveals distortion as shown in Fig. 4. Quantifying the particle losses and behaviour of ε_L in Fig. 5, a 9% loss and ε_L oscillation above the HCC acceptance is expected.

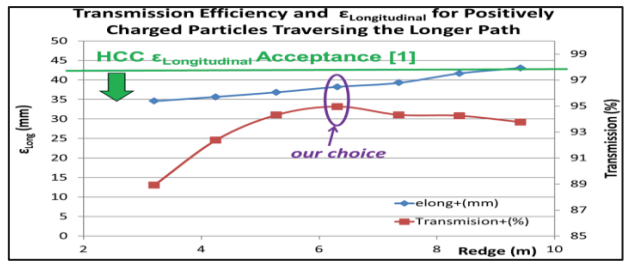

Figure 3: Results of optimization.

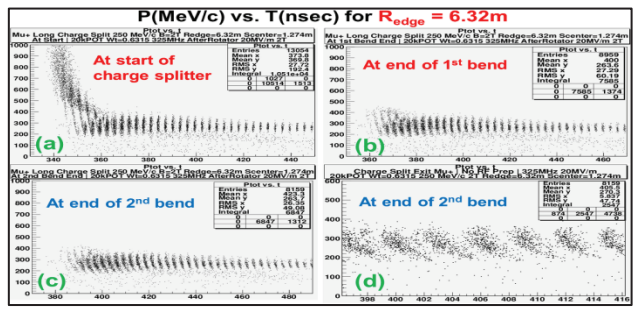

Figure 4: Longitudinal distortion at end of optimal configuration. P(MeV/c) vs. T(nsec) for μ+'s entering the charge separator are upright in (a) and begin to show some distortion at the end of the first bend in (b). Muons overlap neighboring bunches in (c), which is more easily seen in the zoomed-in view in (d).

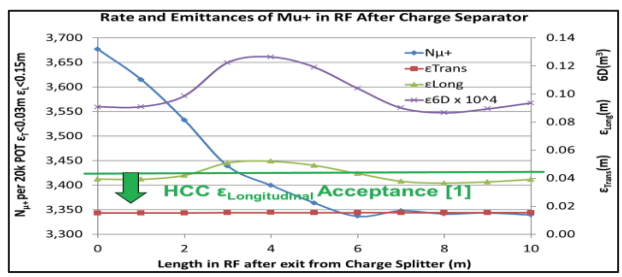

Figure 5: Rate and emittances of μ^+'s in RF after the charge separator.

A solution to counteract against this longitudinal distortion is to prepare the muon beam upstream of the charge separator as illustrated and explained in Figure 6, where RF gymnastics are applied to create a more upright ellipse in longitudinal phase space at the exit of the charge separator. Figure 7 shows the optimal configuration where particles exiting the phase rotator drift for 3 meters, followed by 4 m of RF (20 MV/m @ 325 MHz, same as upstream phase rotator) before traversing the charge separator and being caught and analysed in 10 m of RF of the same gradient and frequency. Figure 8 shows the longitudinal phase space of particles at the key locations described in Figure 6. While not perfectly upright, the particles that were subjected to the beam preparation in Figure 8(d) appear to have less distortion than those not having gone through the preparation in Figure 4(d).

Copyright © 2013 CC-BY-3.0 and by the respective authors

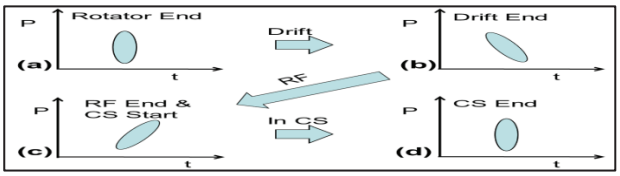

Figure 6: Longitudinal Phase Space Preparation Strategy. Longitudinal phase space of muons at the end of rotator in (a) are allowed to drift, resulting in (b) where RF is turned on to take advantage of the PvsT correlation. The rotated longitudinal phase space at end of the RF is shown in (c), which enters the charge separator and exits with an upright ellipse in (d).

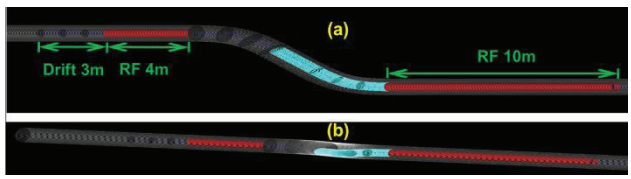

Figure 7: Oblique view in (a) of 3 m drift following phase rotator, followed by 4 m of RF (20 MV/m @ 325 MHz; same as rotator), followed by transit through the charge separator, followed by 10 m of RF to recapture the μ^+ beam. Side view is shown in (b).

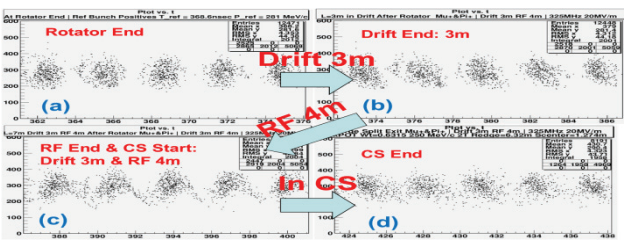

Figure 8: P(MeV/c) vs. T(nsec) for μ^+ through RF Preparation with 3 m of drift and 4 m of RF and traversed through the Charge Splitter. Panels a-d correspond to the same conditions as in Figure 6.

The improvement in rate of accepted muons and the reduction in the longitudinal emittance via the beam preparation are clearly seen in Figure **9** for μ^+s and Figure 10 for μ^-s. In the longer μ^+ channel, ε_L is lowered and remains within the HCC acceptance. The yield is also increased and remains flat in 10 m of RF, resulting in a net transmission increase of 14.6%. In the shorter μ^- channel, Figure 10 shows that while ε_L was within the HCC acceptance before the preparation, it is lowered further because of it. The increase in rate is not expected to be as dramatic, but is still significant at 10%. Final results are summarized in Table **2**.

SUMMARY

We presented a study to emulate the effects of a charge separator on muons exiting the front end of a muon collider to enable the design of a 6D cooling channel in absence of a realistic design of a charge separator. The output of this study provides particle distributions that the competing 6D cooling teams will use as input into their channels in the evaluation to be the baseline in MAP.

MAGNETIC BUNCH COMPRESSION FOR A COMPACT INVERSE COMPTON SOURCE

B.R.P. Gamage[1*] and T. Satogata[1,2]
[1]Center for Accelerator Science, Old Dominion University, Norfolk VA, 23529, USA
[2]Thomas Jefferson National Accelerator Facility, Newport News VA, 23606, USA

Abstract

A compact electron accelerator suitable for inverse Compton source applications is in design at the Center for Accelerator Science (CAS) at Old Dominion University (ODU). Here we discuss two options for transverse magnetic bunch compression and final focus, each involving a 4-dipole s-chicane with M_{56} tunable over a range of 1.5-2.0m with independent tuning of the final focus to an interaction point β*=5mm. One design has no net bending, while the other has net bending of 90 degrees and is suitable for compact corner placement.

INTRODUCTION

There is significant interest in X-ray sources beyond those available at large third-generation, lab-based synchrotron light sources. Medical phase imaging, and industrial applications have been developed that have motivated development of compact light sources based on inverse Compton scattering (ICS) [1] that provide single beamline operation at a cost of about $10-15M. A compact ICS source is in design at the ODU CAS with an X-ray energy of up to 12 keV, flux of approximately 1.6×10^{14} photon/sec, and average brilliance of 1.5×10^{15} photon/$(\mathrm{s} \cdot \mathrm{mm}^2 \cdot \mathrm{mrad}^2 \cdot 0.1\%\mathrm{BW})$ [2].

This project consists of an optimized 500 MHz superconducting electron gun, 4K 500 MHz superconducting spoke cavity linac [3], and a bunch compressor to provide a short, high-brightness electron bunch to collide with an incoming laser beam to produce inverse Compton scattered photons. The electron beam requirements are shown in Table 1. The bunch length requirement of a few ps and energy spread requirement of 3×10^{-4} indicate the need for small longitudinal emittance (<7 eV-m) and well-corrected bunch compression. A practical system will also have tunable M_{56} to optimize the scattered photon beam.

Table 1: Electron Beam Parameters at Collision

Parameter	Value	Units
Energy	25	MeV
Bunch charge	10	pC
Repetition rate	100	MHz
Average current	1	mA
Normalized emittance	0.1	mm·mrad
$\alpha^*_{x,y}$, $\beta^*_{x,y}$	0, 5	-, mm
FWHM bunch length	3.0 (0.9)	psec (mm)
RMS energy spread	7.5	keV

DESIGN PHILOSOPHY

Traditionally dispersion-free chicanes are used for magnetic bunch compression, with $M_{56} < 0$ and $T_{566} > 0$[4]. However, these chicanes are not very compact and cancel dispersion only to odd orders. M_{56} tunability is also directly connected to the chicane transverse dimension, and so is limited.

For a compact design with tunable M_{56}, we have been investigating 4-dipole s-chicanes that alternate the bending directions of the center dipoles. A chicane of this type was investigated for the final bunch compressor of TTF-FEL [5]. S-shaped compressors are dispersion free to all orders, have greater M_{56} tunability, and can be wrapped in on themselves with large central bend angles to be made compact. As described in [5], M_{56} is tunable by adjusting the central dipole angle.

Initial designs considered combining quadrupoles in the compressor with quadrupoles outside the compressor to tune the final focus. However, the aggressiveness of the design final focusing to $\beta^* = 5$mm is best handled with a separate independent low-beta focus section. This sacrifices some small measure of compactness of the design, but greatly improves the orthogonality of tuning knobs for achromaticity, M_{56}, final focusing, and upstream matching. The linac design for this ICS suggests that a reasonable range for M_{56} tuning is 1.5-2.0m.

A typical s-shaped chicane compressor ensures achromaticity by having a net horizontal phase advance of 2π, with a pair of symmetrically-placed horizontal focusing quadrupoles to tune achromaticity and a vertical focusing quadrupole at the center symmetry point to control vertical betas. Here the compact design pushes us towards stronger focusing, and we investigate two designs: one with net 3π phase advance and a net 90° bend for corner use, and one with net 4π phase advance for larger dispersion and M_{56} lever arm. M_{56} is tunable for both designs by adjusting the center symmetric bend angles and rematching achromaticity and final focus.

DESIGNS AND RESULTS

We use elegant from the APS for lattice design, optimization, and particle tracking, including simulation of short quadrupole end effects as described in the next section. Each lattice has three quadrupoles in two symmetric families between the center dipoles. For a given central

Table 2: 3π Bunch Compressor Parameters

Parameter	Value	Units
Final β_x,β_y	0.005	m
Final α_x,α_y	$< 10^{-8}$	-
Maximum β	≈ 85.8	m
M_{56}	1.498	m
Floor Dimensions	3×4	m
Dipole Lengths	0.8,1.0,0.8,1.0	m
Dipole Bend Angles	70,-115,-115,70	°
Max Quadrupole Gradient	≈ 9.5	T/m
Quadrupole Length	0.1	m

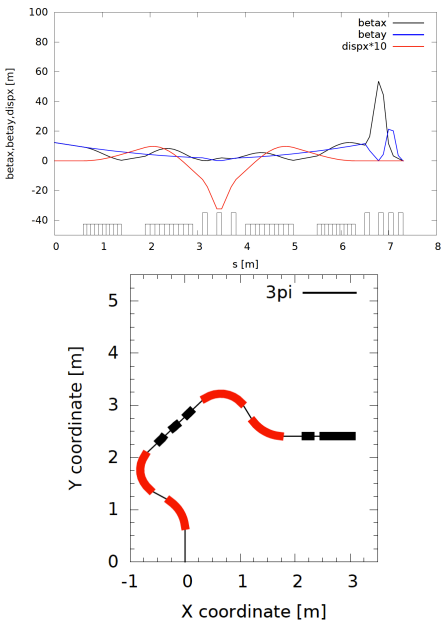

Figure 1: 3π bunch compressor optics and floor plan.

Table 3: 4π Bunch Compressor Parameters

Parameter	Value	Units
Final β_x,β_y	0.005	m
Final α_x,α_y	$< 10^{-8}$	-
Maximum β	$\approx$29.5	m
M_{56}	1.4	m
Floor Dimensions	2×4.3	m
Dipole Lengths	0.35,1.134,1.134,0.35	m
Dipole Bend Angles	40,-175,175,-40	°
Max Quadrupole Gradient	≈ 9.15	T/m
Quadrupole Length	0.1	m

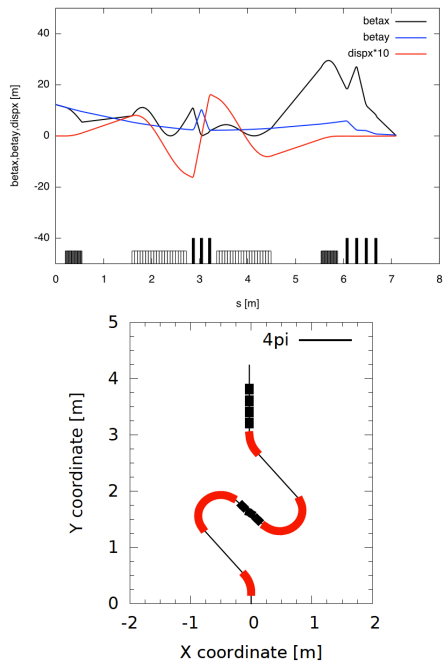

Figure 2: 4π bunch compressor optics and floor plan.

dipole bend angle (and hence M_{56}),

- The pair of symmetric quadrupoles are tuned to make the compressor achromatic.
- The center quadrupole is tuned to control vertical beam size entering the final focus section.
- The final focus is retuned to match collision IP conditions of $\beta^*_{x,y} = 5$mm and $\alpha^*_{x,y} = 0$.

In both designs, peak beam sizes are well-controlled, and chromatic effects of the final focus are minimal, indicating no need for nonlinear corrections that would otherwise distort the transverse phase space. Neither design includes sextupoles to control T_{566} as of present, though their inclusion should be straightforward at high dispersion locations in the bunch compressor to control longitudinal distribution linearity [9].

3π Compressor

The first compressor, denoted "3π", has a total dispersion phase advance of 3π and a net bending of 90°, making it suitable for a compact corner design. Four quadrupoles are used in the final focus. The floor layout and the transverse optics are shown in Fig. 1, and relevant parameters are shown in Table 2. The compressor fits in a 3.5×4m area, and in these conditions is tuned for $M_{56} = 1.498$m. Note that for this compressor, the first and fourth dipoles bend in the same direction to provide the dispersion cancellation and overall bend.

4π Compressor

The second compressor, denoted "4π", has a total dispersion phase advance of 4π and no net bending; it is more transversely compact than the 3π design. three quadrupoles are used in the final focus. The floor layout and the transverse optics are shown in Fig. 2 and relevant parameters are shown in Table 3. The compressor fits in a 2.0×4m area, and in these conditions is tuned for $M_{56} = 1.4$m. Additional quadrupoles may be added in the outside drifts for extra optics control.

QUADRUPOLE CONSIDERATIONS

Fringe Fields

Since the quadrupoles in this design are comparatively short, we investigated the effect of inclusion of fringe fields on the transport and matching. Considering the fringe field to be symmetric on both ends, we used the single parameter Enge function [6] to calculate the required integrals for elegant to calculate the final beta functions with effects from the fringe fields from the quadrupoles. Elegant requires the normalized quadrupole fringe field $\tilde{k}(s)$ to be normalized [7], so using the field profile shown in Fig. 3 we found the Enge coefficient a_1=4.6.

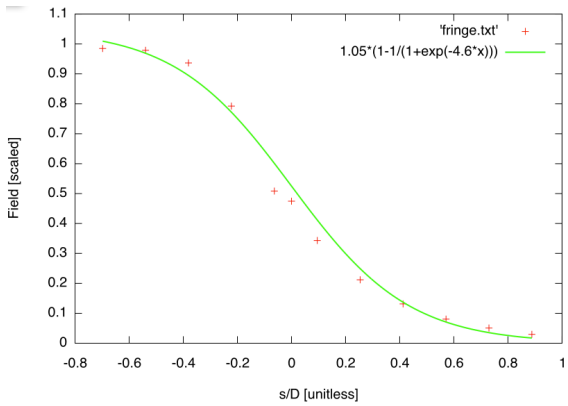

Figure 3: Fit of normalized fringe field for typical compressor quadrupole design.

Design Availability

The quadrupoles in both designs are typically 10 cm long with an exception of the focusing quartet of 4π compressor, which are 15 cm long, with a maximum field gradient of nearly 10 T/m. Some parameters for various quadrupoles used in these design are shown in Table 4.

With the design beam pipe diameter, these parameters match those of commercially available quadrupoles such as those from RadiaBeam. The air-cooled diamond quadrupole BEMQD-01-155-245 [8] is such a magnet which is close to the required dimensions while having a max gradient of 12 T/m.

Table 4: Quadrupole Data

Parameter	Value(range)	Units
Bore	0.04	m
Magnetic Field Gradient	2.5-9.7	T/m
Length	10	cm
Total Current (NI)	434-1684	A
Conductor cross-section (air-cooled)	4.3-16.84	cm^2
Conductor cross-section (water-cooled)	0.43-1.684	cm^2

Table 5: RadiaBeam Diamond Quadrupole

Parameter	Value	Units
Bore	0.0394	m
Max field gradient	12	T/m
Magnetic length	∼9.74	cm
Total current (NI)	1940.4	A-turns

FUTURE DIRECTIONS

Further optimization work on the bunch compressors will focus on tunability, chromatic compensation in the final focus, and T_{566} nonlinear longitudinal focusing to correct longitudinal bunch distortion from the linac. T_{566} should be straightforward to independently control to first order with the inclusion of sextupoles at high dispersion locations in the bunch compressor [9]. Beam dynamics will follow those in [10]. Plans of adding an upstream matching block between the linac and the compressor are in consideration

IMPROVEMENT OF DIGITAL FILTER FOR THE FNAL BOOSTER TRANSVERSE DAMPERS

T. Zolkin*, The University of Chicago, Department of Physics, Chicago, IL 60637–1434, USA
N. Eddy†, V. Lebedev‡, FNAL, Batavia, IL 60510–5011, USA

Abstract

Fermilab Booster has two transverse dampers which independently suppress beam instabilities in the horizontal and vertical planes. A suppression of the common mode signal is achieved by digital notch filter which is based on subtracting beam positions for two consecutive turns. Such system operates well if the orbit position changes sufficiently slow. Unfortunately it is not the case for FNAL Booster where the entire accelerating cycle consists of about 20000 turns, and successful transition crossing requires the orbit drifts up to about 10 μm/turn, resulting in excessive power, power amplifier saturation and loss of stability. To suppress this effect we suggest an improvement of the digital filter which can take into account fast orbit changes by using bunch positions of a few previous turns. To take into account the orbit change up to N-th order polynomial in time the system requires $(N+3)$ turns of "prehistory". In the case of sufficiently small gain the damping rate and the optimal digital filter coefficients are obtained analytically. Numerical simulations verify analytical theory for the small gain and predict a system performance with gain increase.

INTRODUCTION

Consider a paraxial transverse motion of the particle with equilibrium energy in a circular accelerator. For further calculations we will be neglecting a coupling between transverse planes and consider only one of them for simplicity. Neglecting nonlinear effects, in an approximation of linear optics, the dynamics of a particle can be described by the "time" evolution of the betatron state-vector, $\tilde{\zeta}(s) = [q(s), p(s)]^{\mathrm{T}}$, where the variable s is the path length along the closed orbit and plays the role of time, q is the particle deviation in considered transverse direction with respect to the closed orbit, and $p = d\,q(s)/ds$ is canonically conjugated momentum.

The canonical transformation to the so-called normalized coordinates $(p, q) \to (\mathcal{P}, \eta)$:

$$\begin{aligned} \eta(s) &= q(s)/\sqrt{\beta(s)}, \\ \mathcal{P}(s) &= p(s)\sqrt{\beta(s)} + q(s)\,\frac{\alpha(s)}{\sqrt{\beta(s)}}, \end{aligned}$$

where $\beta(s)$ is a beta-function and $\alpha(s) = -\frac{1}{2}\,d\beta(s)/ds$, is performed in order to reduce the motion (from an initial position s_1 to a final one s_2) to the pure rotation of new normalized vector $\zeta(s) = [\eta(s), \mathcal{P}(s)]^{\mathrm{T}}$:

$$\begin{bmatrix} \eta(s_2) \\ \mathcal{P}(s_2) \end{bmatrix} = \begin{bmatrix} \cos\mu_{12} & \sin\mu_{12} \\ -\sin\mu_{12} & \cos\mu_{12} \end{bmatrix} \begin{bmatrix} \eta(s_1) \\ \mathcal{P}(s_1) \end{bmatrix},$$

where $\mu_{12} = \psi(s_2) - \psi(s_1)$ and $\psi(s)$ is a betatron phase advance

$$\psi(s) = \int_0^s \frac{d\bar{s}}{\beta(\bar{s})}.$$

Damper System

A general transverse damper is an active feedback system consisting of pickup station which measures the beam position, and a kicker which is located downstream and damps the betatron oscillations of the beam as a whole by applying an appropriate kick (see Fig. 1).

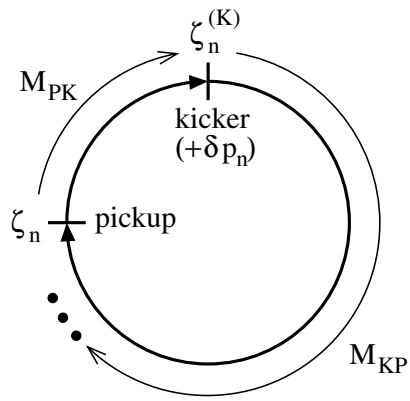

Figure 1: Schematic plot of the one turn transformation of the betatron state-vector in a lattice with damper.

For further considerations we will denote as ζ_n and $\zeta_n^{(\mathrm{K})}$ the normalized betatron-state vector on the n-th turn at the locations of the pickup and the kicker respectively, as $M_{\mathrm{PK}}(\mu_1)$ and $M_{\mathrm{KP}}(\mu_2)$ the transport matrices between pickup and kicker and between kicker and pickup, where $\mu_{1,2}$ are phase advances corresponding to those matrices, and as δp_n the change of particle momentum applied at the n-th turn by kicker. The above determines the betatron tune $\mu_0 = \mu_1 + \mu_2$.

Thereby, a one-turn map that recursively defines a new state-vector at the pickup location can be written as, [1]:

$$\zeta_{n+1} = M_{\mathrm{KP}}\,\zeta_n^{(\mathrm{K})} = M_{\mathrm{KP}}\left(M_{\mathrm{PK}}\,\zeta_n + \begin{bmatrix} 0 \\ \delta p_n \end{bmatrix}\right). \quad (1)$$

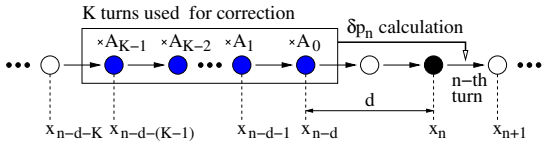

Figure 2: Schematic diagram representing the work of digital filter. Correction algorithm uses $\mathcal{K}$ turns of prehistory (blue circles) in order to calculate the change in momentum δp_n, which will be applied d turns later (for this diagram $d = 2$) after the current turn (n-th turn shown with a black filled circle).

DAMPING DYNAMICS FOR SMALL GAIN

In most general form the the angle correction algorithm which is based on $\mathcal{K}$ previous measurements is given by:

$$\delta p_n = \frac{g}{\sqrt{\beta_{\rm P}\beta_{\rm K}}} \sum_{k=0}^{\mathcal{K}-1} A_k \left(q_{n-d-k} + \delta q_{n-d-k}\right),$$

where g is the dimensionless gain, δq_i is an error of measurement introduced by pickup at i-th turn, A_i are the coefficients which define the properties of digital filer, d is an integer which determine the delay in turns after which the correction to be applied (typically $d = 0, 1, 2$ depending on the system), and, $\beta_{\rm P,K}$ denote a beta functions at the pickup and the kicker locations respectively. The schematic diagram of the algorithm is shown in Fig. 2.

For further simplification one can introduce a complex normalized variable $z = \eta - i\,\mathcal{P}$, which allow to rewrite matrix Eq. (1) as

$$z_{n+1} = e^{i\mu_2} \times \left[e^{i\mu_1} z_n - ig \sum_{k=0}^{\mathcal{K}-1} A_k \left(\Re\, z_{n-d-k} + \delta\eta_{n-d-k}\right)\right],$$

where $\delta\eta_i = \delta q_i/\sqrt{\beta_{\rm P}}$ is the renormalized error, and $\Re\, z$ is a real part of z. Below we will consider the beam dynamics in a presence of damper for the case of small gain.

Damping Rate

Temporarily omitting the heating term, $\delta\eta_i$, and taking into account that the contribution of the z^* term is averaged out for the case of small gain, the last equation can be solved by the use of the first-order perturbation theory. Looking for the solution in the form $z_n = z_0\, e^{i\mu n}$, where $\mu = \mu_0 + i g_d$ and g_d is a damping rate presumed to be small, finally gives

$$g_d = i\,\frac{g}{2}\, e^{-i(\mu_1+\mu_0 d)} \sum_{k=0}^{\mathcal{K}-1} A_k e^{-i\mu_0 k}. \qquad (2)$$

As one can see, the imaginary part of the damping rate should vanish in order to have critically damped system, i.e. $\Im\, g_d = 0$. This imposes an additional restriction on coefficients A_i.

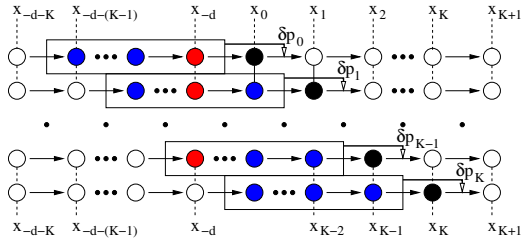

Figure 3: Schematic diagram representing the work of digital filter for $\mathcal{K}$ turns with single erroneous measurement ($(-d)$-th turn shown with a red circle).

Emittance Growth

To estimate the emittance growth excited by noise of the pickup measurements, we will keep only the heating term, while damping term will be omitted. If only one measurement is erroneous, let say $\delta\eta_0$, then summing the effect of $\mathcal{K}$ turns one obtains

$$z_{\mathcal{K}} = \left(z_0 - 2\, g_d\, \delta\eta_0\, e^{i\mu_0 d}\right) e^{i\mu_0 \mathcal{K}},$$

where Eq. (2) was used to find the sum. One can see that every single error $\delta\eta_i$ will contribute $\mathcal{K}$ turns multiplying the effect (see Fig. 3). That yields an increase of the emittance due to a single kick

$$\delta\epsilon = \frac{\overline{\langle \delta z \delta z^* \rangle}}{2} = 2\,\overline{\delta\eta^2}\left[(\Re\, g_d)^2 + (\Im\, g_d)^2\right] = 2\,|g_d|^2 \frac{\overline{\delta q^2}}{\beta_{\rm P}},$$

where in addition to the averaging over initial phases and amplitudes (operator $\langle \ldots \rangle$), we performed averaging over the kick amplitudes (operator $\overline{(\ldots)}$), and

$$\left(\overline{\delta q^2}\right)^{1/2} = \sqrt{\beta_{\rm P}}\, \left(\overline{\delta\eta^2}\right)^{1/2}$$

is the rms error of a single measurement. As one can see the emittance growth does not depends on the choice of coefficients A_i.

DESIGN OF THE DIGITAL FILTER

In general the digital filter should not be sensitive to the equilibrium orbit offset relative to the geometrical center of pickup. Otherwise, the system attempts to correct this offset which leads to increased voltage on the plates of the kicker and inefficiency of the algorithm. It is usually called a notch filter condition and it gives a constraint on coefficients A_i:

$$\sum_{k=0}^{\mathcal{K}-1} A_k = 0.$$

However, it is insufficient if the beam orbit is changing fast. For example, in FNAL Booster, successful transition crossing with high intensity beam requires fast change of equilibrium orbit in time. The present digital notch filter is not able to effectively suppress beam oscillations around transition.

Copyright © 2013 CC-BY-3.0 and by the respective authors

$$\begin{bmatrix} 1 & 1 & 1 & \cdots & (N+1)^0 & (N+2)^0 \\ 0 & 1 & 2 & \cdots & (N+1)^1 & (N+2)^1 \\ 0 & 1 & 4 & \cdots & (N+1)^2 & (N+2)^2 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 1 & 2^N & \cdots & (N+1)^N & (N+2)^N \\ \cos(\delta\mu) & \cos(\mu_0+\delta\mu) & \cos(2\mu_0+\delta\mu) & \cdots & \cos\left[(N+1)\mu_0+\delta\mu\right] & \cos\left[(N+2)\mu_0+\delta\mu\right] \end{bmatrix}. \quad (3)$$

The filter which would not be sensitive to the orbit change up to N-th order polynomial ($q_n^{\rm eq} \propto n^N$) requires at least $\mathcal{K} = (N+2)$ coefficients. It is easy to show, that they are related to the binomial coefficients and up to a common factor

$$A_k = (-1)^k C_k^{N+1}, \qquad k = 0, \ldots, N+1.$$

An additional constraint which optimizes the damping, $\Im\, g_d = 0$, gives

$$\sum_{k=0}^{\mathcal{K}-1} A_k \cos(\mu_0 k + \delta\mu) = 0,$$

where $\delta\mu = \mu_1 + \mu_0 d$. That increases the required number of turns to $\mathcal{K} = (N+3)$. If minimum possible number of coefficients is used, one can write matrix equation

$$\mathbf{M} \cdot [A_0, A_1, \ldots, A_{N+2}]^{\rm T} = 0$$

with the solution

$$A_k = (-1)^k \left[C_k^{N+1} \sin\left(\frac{N+3}{2}\mu_0 + \delta\mu + N\frac{\pi}{2}\right) + C_{k-1}^{N+1} \sin\left(\frac{N+1}{2}\mu_0 + \delta\mu + N\frac{\pi}{2}\right)\right],$$

where $k = 0, \ldots, N+2$, and matrix $\mathbf{M}$ is determined by Eq. 3. A common factor, ± 1, in front of all A_i must be added in order to have $\Re\, g_d > 0$.

Numerical Example for the FNAL Booster

The parameters of the Booster damper system are listed in Table 1. A numerical example of design of the digital filter which suppresses effect of orbit offset, and, its linear and quadratic changes with time is presented in Fig. 4. The real and imaginary part of the gain, g_d, as a function of particle frequency, ν, for horizontal and vertical degrees of freedom is shown in top figure. Optimal values of the coefficients for the digital filter, A_i, as a function of Booster betatron frequency, ν_0, for horizontal (middle figure) and vertical (bottom figure) degrees of freedom are presented as well. All calculations were performed for parameters listed in Table 1.

Table 1: Parameters of the FNAL Booster Damper System

	Horizontal	**Vertical**
Number of missing turns d	0	0
Betatron frequency ν_0	6.75	6.83
Fractional part of tune $\{\mu_0\} = \mu_0 - 6 \times 360°$	270°	298.8°
Pickup-kicker phase advance $\{\mu_1\} = \mu_1 - 6 \times 360°$	67.5°	288.5°

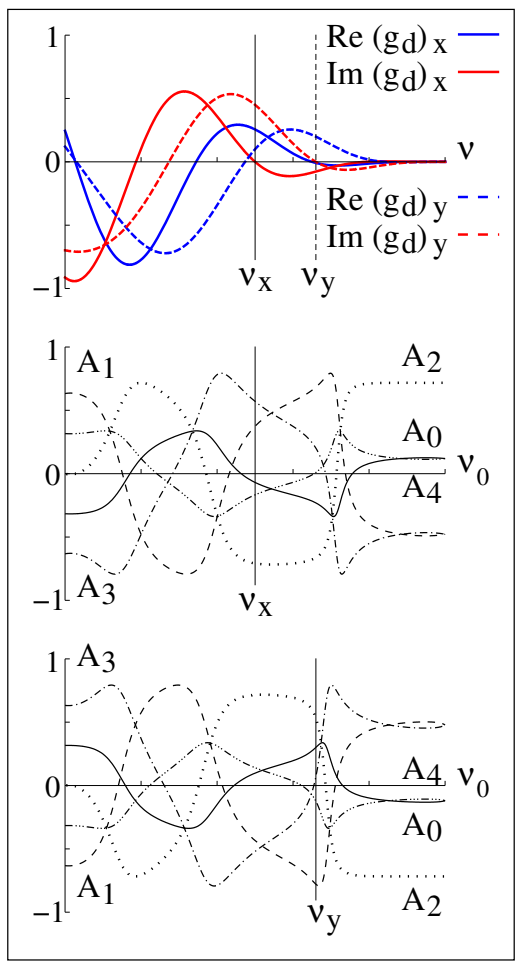

Figure 4: Numerical example of the digital filter design for FNAL Booster, $N = 2$. Both scales for ν and ν_0 are from 6.5 to 7.0.

FAST FPGA BASED LOW-TRIGGER-JITTER WAVEFORM GENERATOR METHOD FOR BARRIER-BUCKET ELECTRONICS AT FAIR*

E. Bayer†, P. Zipf, University of Kassel, Kassel, Germany
H. Klingbeil, A. Klaus, GSI Helmholtz Centre, Darmstadt, Germany

Abstract

A new method for low trigger-jitter waveform generation is presented. The targeted application is the time-delayed, trigger synchronous waveform generation. The method can be implemented on a single FPGA, which drives an ADC. The phase-jitter between a trigger signal fed to the FPGA and the generated single sine waveform is σ= 40 ps and 275 ps peak-to-peak. The response time of the wave form generator is 50 ns. The amplitude and the offset of each sine wave can also be manipulated in real time. The waveform generator was designed for the use in the Barrier-Bucket system of the SIS100 synchrotron at the new Facility for Antiproton and Ion Research (FAIR) in Darmstadt, Germany.

INTRODUCTION

The GSI Helmholtz Centre for Heavy Ion Research in Darmstadt, Germany is an accelerator facility for High Energy Physics (HEP) research. In collaboration with 16 countries and physicists from all over the world, the Facility for Antiproton and Ion Research (FAIR) will be built as a major extension of the existing facility and will be one of the largest accelerator facilities in the world.

The presented waveform generator method is designed for the use in the pre-compression stage of the new SIS100 synchrotron. The existing SIS18 will be used as booster and will inject bunches of particles into 8 of 10 SIS100 buckets. After the particles have been accelerated to the final speed in the SIS100, they have to be compressed to a single bunch that takes 1/3 of the circumference. The preferred method to perform this task is called Barrier-Bucket. In this method, the amplitude of the bucket forming sine waves, which hold the bunches, is decreased adiabatically. After a certain time the bunches merge into a single long particle bunch in between the remaining sine waves. Now, to compress the beam without the loss of particles, one wave has to be moved towards the other adiabatically, means in steps less than 1 ns. Both sine waves have to be generated synchronously to the revolution trigger, coming from the Central Control System, which controls also the amplitude and the voltage offset of the sine waves. The BB-method is illustrated in Fig. 1. The constraints for the waveform generation system, listed in Table 1, are given by the physics of the accelerator and the desired bunch quality.

The task is therefore to gain control over the phase of the generated single sine waves in the sub nano-second region with a low response time. For this purpose a new waveform generation method was developed and implemented.

* Work supported by EU, EURONS contract No. 506065.
† e.bayer@gsi.de

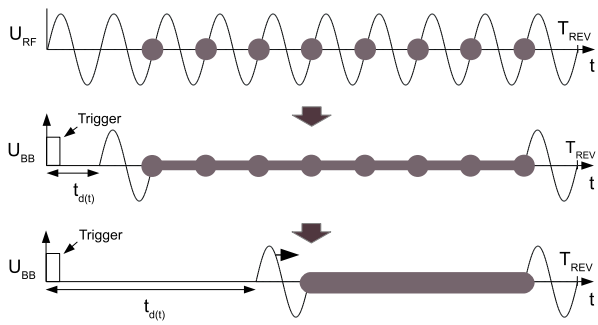

Figure 1: The procedure for beam pre-compression with the Barrier Bucket method (simplified).

Table 1: Specifications for the Barrier-Bucket Low-Level RF-System

Parameter	Value
Barrier Frequency f_b	1.5 ± 0.2 MHz
Revolution Period T_{REV} (= Trigger Period)	9.1 to 3.7 μs
Moving Time T_{MOV}	10 to 200 ms
Moving Step Resolution $\Delta t_{d(t)}$	$\leq$ 1ns
BB signal rise/fall time t_R and t_F	$\leq$ 10ns

We will introduce the new method in the next section. In the section "Design" the design structure and operation are explained. Subsequently, the measured performance of the system will be presented, followed by a conclusion.

WAVE GENERATION METHOD

In existing asynchronous triggered DDS methods, the incoming trigger signal is sampled with the internal system-clock frequency f_{sys}. As soon as a 0/1 transition is detected, a Digital-Analog-Converter (DAC) is driven by the system-clock and fed with the grid points of the desired waveform. The standard deviation of the resulting trigger-waveform jitter equals then $1/(f_{sys} \cdot \sqrt{12})$. To overcome this limitation, additional effort is necessary on both sides - on the input processing as well as on the signal synthesis part. The given task can therefore be divided into two subtasks. First, the relation of the incoming trigger-signal phase to the system-clock signal phase $\Delta\Phi$ has to be determined with a higher precision than simply by sampling the trigger signal and second, the generation of the phase accurate sine wave using this information. This procedure is illustrated in Fig. 2. In the following sections, the methods for a high precision phase measurement and for phase accurate signal generation are introduced.

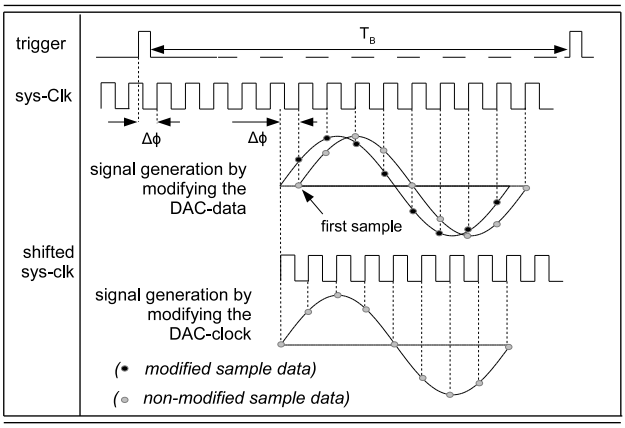

Figure 2: Principle of the phase accurate waveform generation by modifying the DAC data or, alternative, the DAC clock.

Phase Measurement

The first step in generating a low trigger-jitter waveform is the measurement of the phase relation between the trigger signal and the system clock, since the system clock is then used for the DDS algorithm. This corresponds to a time interval measurement. The accuracy has to be as good as possible, because the maximum phase deviation in the whole method is increased by the maximum deviation of the phase measurement. Therefore, to reduce the portion of the measurement inaccuracy, a high-precision FPGA time-to-digital (TDC) method was used for this purpose, which ensures a maximum deviation down to ∼30 ps [1]. The used TDC method is a tapped delay lines (TDL) technique with enhanced accuracy. The details of this TDC design can be found in [1].

Phase Accurate Waveform Generation

Generally, there are already methods for the generation of phase shifted waveforms. For example the CORDIC algorithm can be used to generate waveforms with the desired phase-offset by starting with a certain amplitude offset as is shown in Fig. 2. This approach works well for generation of continuous signals, when the waveform at the beginning and at the end of the waveform is of no interest. If a well shaped single sine wave has to be generated, one has to consider the phase-offset-cut artifacts on the edges of the waveform due to the variable phase offset, which results in large phase-jitter on the sine wave edges. A good alternative avoiding these effects is the shifting of the ADC driving clock instead of the ADC data as is shown in Fig. 2.

The common method to perform phase-shifts of the system clock in FPGA is using the build-in Phase-Locked-Loop (PLL) or a Delay Locked Loop (DLL). Here a phase-shift granularity of $(1/1024) \cdot T_{sys}$ is available [2]. The disadvantage of this approach is the relatively large reconfiguration time of the PLL that can take several microseconds [2]. These parameters exceeded the given constraints of our application. Therefore, a new method for the generation of a phase-shifted clock signal was implemented on a Virtex-4 FPGA. The implemented "phase-shifter" uses the routing resources of the FPGA as delay elements and produces delayed versions of the system clock. This is done by deploying the carry-chain MUX resources to access the clock signal. As the carry multiplexer are arranged in a column an evenly delayed signal can be produced in steps of 100 and 200 ps. The switching is performed within one clock cycle - means: down to 2 ns response time on the current FPGA families [3].

DESIGN

Structure

For the implementation of the waveform generator we take a phase-shifter, a high-precision TDC for phase-relation measurements, two secondary FPGA-TDC to measure phase-shifter delays and the DDS building block, which feeds a 14-bit ADC outside the FPGA. As the shifter delays measurements can be repeated, the secondary TDCs have a lower resolution and need less resources. We deploy the design from [4] for this purpose.

The implemented design makes extensive use of the temperature and voltage dependent gate delays in the FPGA. Therefore additional effort is needed to ensure a stable operation [4]. For this purpose a calibration and continuous recalibration functionality has been implemented on-chip for the phase-shifter delays as well as for the TDCs. The used calibration methodology can be found in [5]. The (re)calibration of these elements is scheduled within the idle phases of each element between the incoming trigger events. Since the trigger frequency may not be sufficient for using the trigger input for calibration, a controllable, system clock uncorrelated, internal pulser was implemented, which can be used as calibration signal.

The coarse structure of the system is shown in Figure 3. Its operation will be described in the next section.

Operation

The first task in the initialization phase of the system is the calibration of the TDCs. The inputs of the three TDCs are switched to the internal pulser and the 2^{16} events for the first calibration are collected. After the shifter TDCs are calibrated, the resulting delay of each shifter position is measured. Using this information the SD-LUT is constructed, which maps each possible needed delay within the system clock period (T_{SYS}) to a shifter position. After these steps the system is fully operational. Before each trigger event, the system receives three optical information streams - two streams containing the amplitude and amplitude offset information and one with the current phase-offset. When a trigger signal arrives, the time interval between the rising edge of the trigger and the following rising edge of the system clock is measured with the high-precision TDC. From this measurement and the current phase offset the required shifter delay is calculated in the event-phase-logic. A coarse counter is then loaded with the coarse portion of the phase-offset, which has a granularity

Copyright © 2013 CC-BY-3.0 and by the respective authors

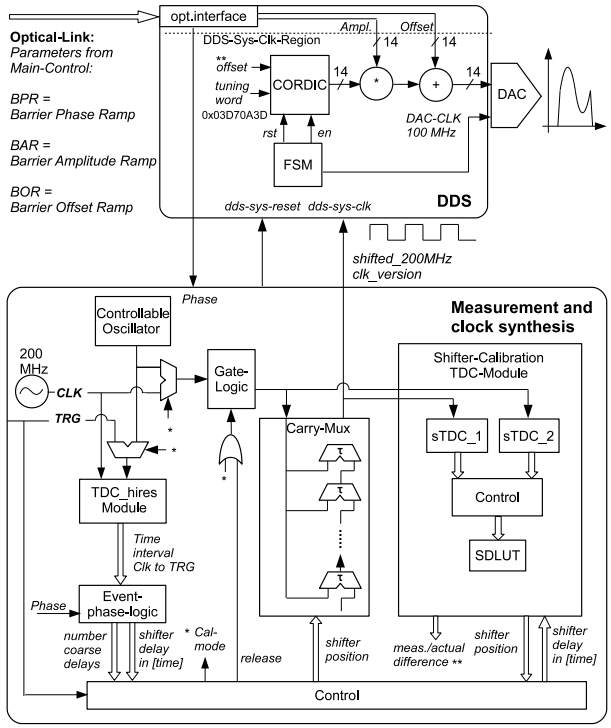

Figure 3: The block diagram of the system. The additional path for the combined mode is marked with (**).

of T_{SYS} and the phase-shifter is switched to the position corresponding to the fine shift value.

All these steps are done within a constant time window, which finishes with the release of the back-running coarse counter. As soon as the counter value reaches zero, the clock gate at the phase-shifter input is released and a defined number of shifted system clock pulses is generated. This pulse train is used as clock signal for the DDS part of the system. There, a finite state machine generates the DAC clock and the corresponding sine grid points by driving a CORDIC unit. At this point, the DAC data values can be manipulated, to adjust the needed sine amplitude and sine offset.

To further improve the jitter characteristics the combination of DAC data and DAC clock manipulation can be applied. For this purpose the difference between the actual delay of the set shifter position and the measurement value is sent to the DDS part of the system to adjust a corresponding offset in the DAC data.

MEASUREMENTS

Although the whole system can be implemented in a single FPGA connected to a DAC, the current setup is distributed between two FPGA boards, featuring together the needed interfaces. The clock pulse train is fed into the DDS-System by a single ended connection and is therefore exposed to the electromagnetic noise. For this reason the achieved performance was characterized by measuring the trigger-jitter of the generated pulse-train, the sine wave generated by DAC clock manipulation only and the sine wave generated by the combined method. The measured trigger-jitter of the pulse-train is σ = 58 ps and 350 ps peak-to-peak. The phase-jitter of the basic/combined method is σ= 63/35 ps standard deviation and 500/270 ps peak-to-peak deviation. Hence, the achievable performance for a single FPGA implementation is $\sigma = \sqrt{35^2 - (63^2 - 58^2)} \approx 25$ ps. The test readings of the sine wave for the combined method are presented in Fig. 4.

CONCLUSION

A new method for triggered waveform-generation was presented. The method of combined manipulation of the DAC-data and DAC-clock implementable in a single FPGA over-fulfills the requirements nearly by two orders of magnitude and outperforms the known instrumentation in means of trigger-jitter and device costs.

STUDY OF MICROPHONICS COMPENSATION FOR SRF CAVITY*

Z. Zheng[#,1,2], S. Zhao[1], Z. Liu[1], D. Morris[1], J. Wei[1], Y. Zhang[1]

Abstract

Microphonics and Lorentz Force detune the resonance frequency of a SRF cavity, leading to perturbations of the amplitude and phase of its accelerating field. Although this disturbance could be compensated by a piezo-electric tuner or with additional RF power, these two methods have conflicts, which is observed as unstable RF fields in a recent experiment. These conflicts could be explained by a model. Further experiments on ReA3 [1] cryomodule validates a conflict suggested by the model. Overall optimization of control algorithm is still needed to effectively combine the two methods.

INTRODUCTION

Microphonics and Lorentz Force Detuning are major disturbances to the accelerating field of an SRF cavity. Usually, people can invest more RF power into the cavity to compensate these effects. However, RF power is expensive, especially for high gradient SRF cavities. An economical substitute is piezo-electric tuner, which sense and compensate the vibration with a fast feedback system. But the compensation is relatively rough, compared with the RF power method. It seems natural to combine the rough and cheap tuner with fine RF power to get an effective and affordable compensation. As we expect a stable accelerating field by simultaneously applying both tuners, we did observe strong interference between them. Section 1 describes these observations.

To understand the conflict in the combo control, we have developed a model in MATLAB. The model reveals a conflict that is resulted from a time delay of piezo tuner control response. When high frequency modulation is induced by RF power modulation, such a time delay corresponds to a large phase difference, which could amplify the unwanted oscillations rather than suppress them.

We added a low pass filter to verify our speculation. The phase fluctuation has been suppressed from ±7° to ±4°, but not completely eliminated. Although the combo control uses two compensation methods simultaneously, their control algorithms are in fact separate. Apparently we need an overall optimization for the combo control algorithm that includes piezo's time delay into consideration.

In this paper, we also compared performance of ADRC algorithm on the piezo tuner with the common PI algorithm. Although ADRC appears to be more efficient than PI in simulation [2], their experimental performance are comparable. Section 2 describes our observation.

CONFLICTS IN THE COMBO CONTROL

To compensate microphonics, a piezo tuner was installed on the quarter-wave resonator (QWR) in ReA3. However, it was only used to suppress helium pressure fluctuations (<1 Hz), not microphonics (>1 Hz). A major source of the microphonics is the vibration of the QWR, with a resonate frequency ~38 Hz. To test the

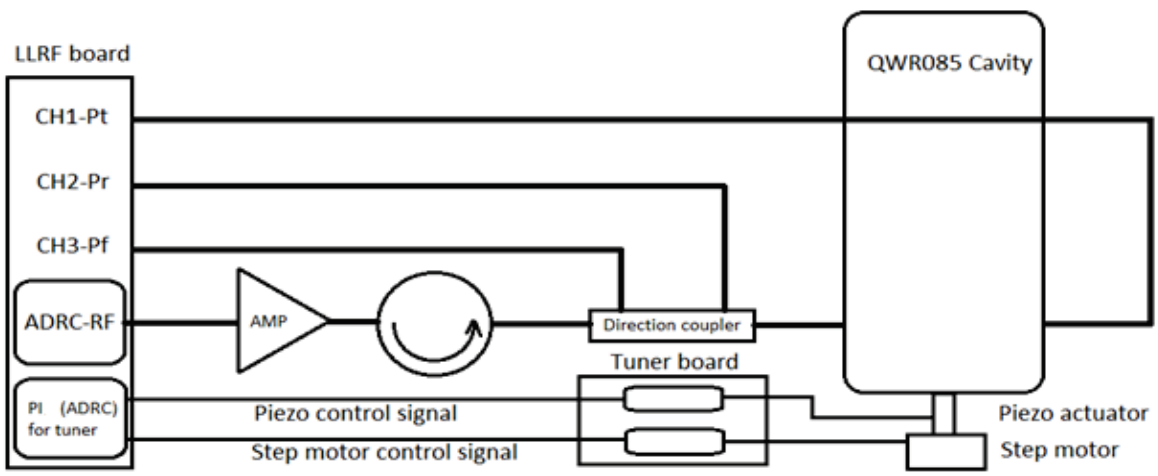

Figure 1: Test setup for a ReA3 cavity. CH1, CH2 and CH3 are three channels on the LLRF board receiving transmit (Pt), reflect (Pr) and forward power (Pf). RF power is controlled with ADRC. Piezo tuner is controlled by PI and later by ADRC.

performance of combo control, we arranged a test as shown in Figure 1. Cavity accelerating gradient was set to be1.3 MV/m.

Single Control by Piezo-electric Tuner

We first would like to observe the performance of single control, i.e., RF control is open loop and piezo tuner is controlled by PI algorithm. A slow tuner, the step motor in Figure 1, is triggered to move when the cavity is detuned out of the frequency range of piezo tuner. The PI controller has a proportional gain (K_p) of 3 and an integral gain (K_i) of 1×10^{-4}. Those parameters were tuned to achieve the most stable response. The performance of piezo tuner is shown in Fig. 2 with a large microphonics and in Fig. 3 with a small microphonics.

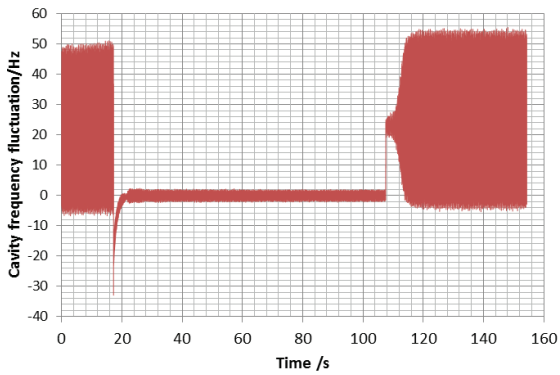

Figure 2: Performance of a piezo tuner with a large microphonics. The tuner was turned on at t=17 s and turned off at t=108 s.

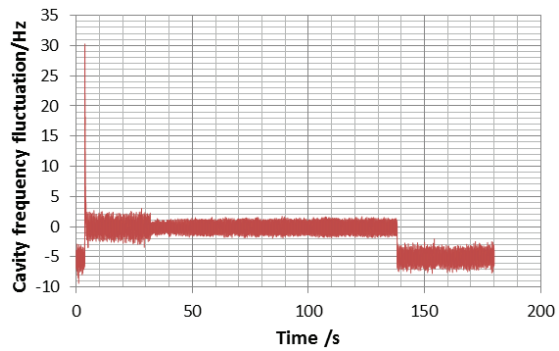

Figure 3: Performance of a piezo tuner with a small microphonics. Tuner was turned on at t=4 s with K_p=0 and $K_i=1\times10^{-4}$, K_p was changed to 3 at t=32 s, tuner was turned off at t=138 s.

It shows that a piezo tuner can reduce modulation of the cavity's resonance frequency to within ±2Hz for both large and small microphonics.

Performance of Combo Control

The motivation to use the combo control is to save the cost of RF power for compensation. But it turns out to be opposite result. Figure 4 shows the unstable phase of accelerating field with the combo control. It reveals conflicts between the RF power compensation and piezo tuner control, which drives a larger phase fluctuation.

To better understand the interference, we constructed a fundamental model, which should include fundamental parameters such as rise time of the piezo electric and basic components such as RF cavity, LLRF system, beam loading, microphonics and slow/fast tuner as Figure 1.

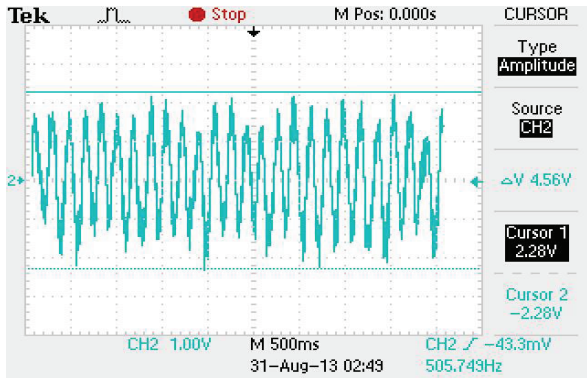

Figure 4: Unstable cavity phase with combo control. Phase fluctuation is up to ±41°.

Piezo tuner has a capacitance of ~36 uF, and an output resistance of 5 Ω. The rise time of charging T_{rc} thus is ~0.54ms (from 10% to 90%). In addition, piezo tuner also has a mechanical rise time. According to the data sheet provided by vendor, its mechanical resonant frequency (unloaded) is 5.5 kHz. Since the tuner is installed under the QWR bottom plate, which is weighed as ~2 kg compared with tuner's weight of 0.2 kg, the resonant frequency of the loaded case is

$$f = 5.5 * \sqrt{\frac{0.2}{2}} = 3 \text{ kHz}$$

The corresponding mechanical rise time is

$$T_{rm} = 1/(3f) = 0.1 \text{ ms}.$$

Since $T_{rm} < T_{rc}$, we use 0.54 ms in the model as the rise time, which is sufficiently fast considering the bandwidth of the ReA3 QWR (70 Hz).

With only rise time specified in the model, the combo control works well, as shown in Figure 5. It reduces the phase fluctuation to ±0.1°. But it is not the case we observed.

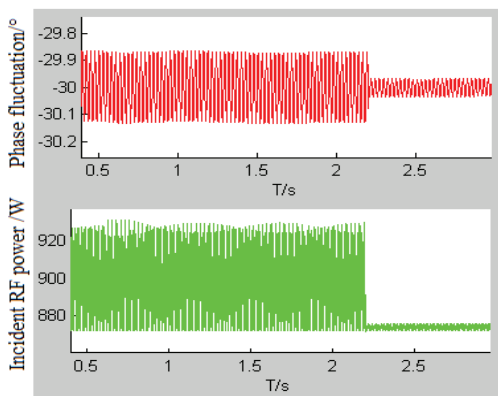

Figure 5: Simulation without piezo's time delay. RF control is on all the time, while piezo tuner is turned on at t=2.2 s.

Copyright © 2013 CC-BY-3.0 and by the respective authors

We adjust the model by including piezo's delay. The combo control becomes unstable when we add a time delay (≥0.16 ms) to the piezo, i.e., piezo tuner responses ≥0.16 ms later after receiving control signal. That delay could actually happen due to: 1) hysteresis and backlash of the piezo; 2) transport of mechanical wave; 3) loop delay of the electronic circuits, where hysteresis could be the most important contribution to the 0.16 ms delay.

Experiment Validation and Suppression

Delay of piezo tuner could cause an additional phase shift between tuner control and RF control. This phase shift is much larger for high frequency signal than low frequency, which enhances the high frequency fluctuation brought by RF compensation. To validate this concept of interference, we add a low pass filter before the tuner control. In simulation, it eliminates the unstable fluctuation when the delay is set to be 0.16 ms.

Experimentally, the low pass filter is added in the DSP code of the tuner control. The original microphonics is measured as ±7°.

To use the combo control, we closed the RF phase control loop and tuner control loop, while kept RF amplitude control loop open. When the low pass filter is bypassed, phase of the cavity acceleration field became unstable (±41°) as in Figure 4. After we applied the low pass filter as in the simulation, the phase fluctuation is reduced to ±4°, as shown in Figure 6.

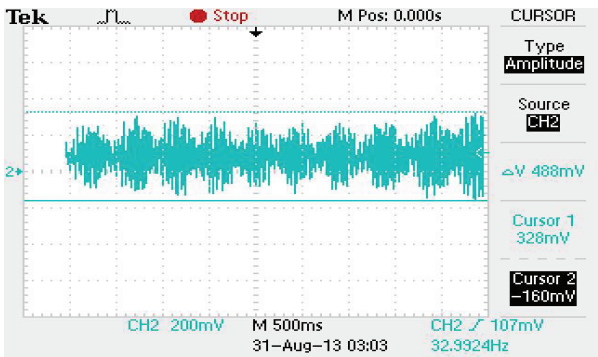

Figure 6: With low pass filter added before piezo tuner control, the phase fluctuation is reduced to ±4° for combo control.

Comparing with the background microphonics, the combo control reduces the phase fluctuations from ±7° to ±4°. The combo control works to some extent, but not as well as signal control. It did validate the conflict in the model, although a low pass filter cannot thoroughly mitigated the interference in the combo control. Since the cavity operated at a low gradient (1.3 MV/m) during experiment, no obvious reduction of RF power was observed in this experiment.

To optimize the performance of combo control, multi parameter optimization is needed for its control algorithm. There is no easy solution to use single parameter optimization approach in the combo control.

ADRC BASED PIEZO ELECTRIC TUNER

Besides the combo control test, we also applied ADRC algorithm on the piezo tuner to compare with PI controller. Different from what we expected in the simulation [2], the performance of ADRC (Fig. 7) is comparable with PI (Fig. 3), no obvious improvement. Both PI and ADRC performances are likely to be compromised by the hysteresis of the piezo tuner.

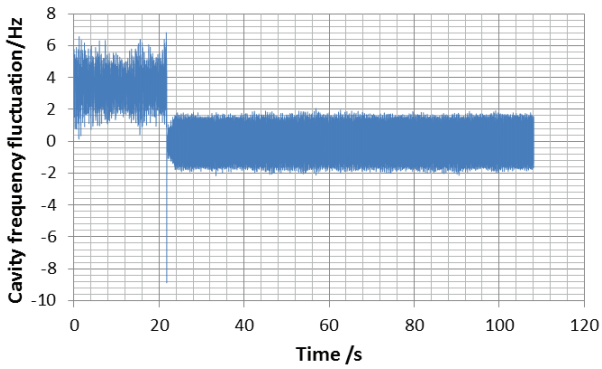

Figure 7: The performance of ADRC based piezo electric tuner. This is single control by piezo electric tuner. Tuner was turned on at t=22 s.

CONCLUSION

We did a series of experiments to benchmark the proposed combo control for microphonics compensation. It reveals that hysteresis induced time delay creates conflicts between piezo tuner and RF power control. A low pass filter before the piezo tuner control could suppress some interferences but not all of them. To achieve a good performance of combo control, a multi parameter control algorithm is needed.

We also compared ADRC and PI algorithms for the piezo tuner control, but found little difference.

NEXT GENERATION CW REFERENCE CLOCK TRANSFER SYSTEM WITH FEMTOSECOND STABILITY

P. Orel, S. Zorzut, P. Lemut, R. Hrovatin, Instrumentation Technologies, Solkan, Slovenia
S.G. Hunziker, V. Schlott, Paul Scherrer Institute, Villigen, Switzerland

Abstract

Present and future fourth generation light sources, such as the Swiss FEL, are placing strict requirements on current CW reference clock transfer systems. Both the added jitter and the long-term stability criteria need to be in the range of a few femtoseconds. In order to meet these requirements, the existing Libera Sync CW transfer system has been redesigned. All of the aspects of the system design have been revised and improved, from new measuring methods and better evaluation of components to careful pre-design testing and simulation. New fiber link topology, new approaches in thermal stabilization, improved power supply distribution and interconnection of carefully selected electrical and state-of-the-art optical components has led to a significant reduction in added jitter and excellent long-term stability of the system. Measurements repeatedly show the jitter performance to be below 6 fs_{rms}, integrated over the frequency range of 10 Hz to 10 MHz. Preliminary measurements of the long-term stability place the system in the range of a few tens of femtoseconds peak-to-peak of drift per day.

INTRODUCTION

Free Electron Lasers (FEL) require high performance synchronization throughout the entire machine; otherwise, its performance may be degraded or even fail. Typically, this high performance synchronization system is composed of two key subsystems. One is the source where a Reference Master Oscillator (RMO) is used. Its frequency range spans from a few 100 MHz to a few GHz. It has high close-in spectral purity and extremely stable frequency. The other extremely important element is the reference clock transfer system. Its goal is to deliver the reference signal to the users in either the optical or electrical domains while preserving initial reference clock signal purity and stability.

Typical requirements in terms of added jitter and long-term phase stability are below 10 fs for jitter and below 40 fs for phase stability per day [1]. For distances greater that 100m, the use of optical fibers as a transmission media is recommended since they exhibit low insertion loss, are insusceptible to EM interference and are reasonably inexpensive. Within the optical domain, two approaches are available.

The first is a pulsed-based system that uses the Michelson interferometer to detect optical path changes. The benefit of this approach is excellent long-term stability.

The other approach is based on a continuous wave (CW) modulation of an optical carrier in which phase detection and stabilization are done in the radio frequency (RF) domain. It offers the advantage of a system restart without re-tuning, high reliability and lower cost [2].

The Libera Sync 3 transfer system presented in this article is based on the CW modulation scheme.

THEORY OF OPERATION

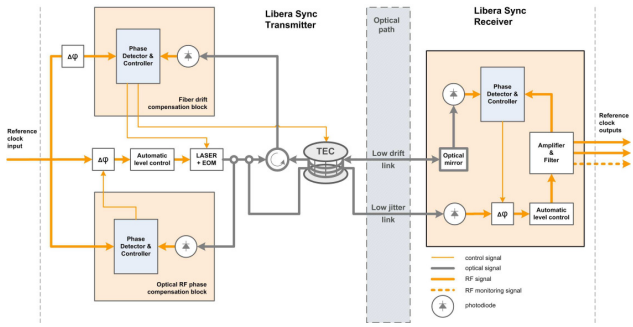

Figure 1: Block diagram of the system.

The figure above is a block diagram of the system that shows the basic principle of operation. The system is composed of a transmitter and a receiver units connected by two optical fiber links. The transmitter input signal is the CW RF reference clock signal coming from the RMO. This signal modulates the 1550 nm optical carrier through an electro-optical modulator. The optical signal is then split and fed into two separate paths. One of the signals along with the on-board control circuitry is used for link phase drift compensation and is partly reflected back at the receiver side. The other path is used for transfer of the low-added jitter signal. In the receiver, both incident optical signals are demodulated back into the RF domain.

In the transmitter unit, the fiber drift compensation is done by comparing the demodulated reflected signal phase with the phase of the input reference signal. The optical path compensation is provided using two principles. The slow changes are compensated by cooling or heating a fiber spool. The temperature of the fibers on the spool is changed in the opposite direction from the temperature change on the optical path between the transmitter and the receiver. Faster changes are compensated by changing the laser source temperature and thus the optical carrier wavelength. In this manner, the optical path is artificially extended or shrunk by taking advantage of the chromatic dispersion in the interconnection fiber.

To overcome optical limitations, two fibers are used, the first one for the transfer of a low-noise signal and the second one for the transfer of a low-drift reference signal.

Copyright © 2013 CC-BY-3.0 and by the respective authors

This combination yields ultra-low added jitter and low drift.

Design Approach and Implementation

In order to meet the tight performance requirements, a new development approach has been followed. Theoretical knowledge with simulations has been combined with prototyping and measurements of the individual components. Based on those results, a careful selection process has been commenced for both electrical and optical components.

Vital subsystems, such as the power supply distribution network, control system, temperature stabilization, mechanical layout and optics, have all been subject to prototyping, testing and tuning before being integrated into the final design.

The power supply subsystem proved to be as vital, and it has been specially developed to provide a low noise power rail for the RF circuitry especially the RF amplifiers.

The environmental conditions inside the box must be kept as constant as possible. In this context, a new temperature stabilization subsystem has been devised in which the temperature is kept stable to within 0.001°C.

The mechanical layout has been specifically designed to facilitate the environmental stabilization system inside the unit while simultaneously ensuring ease of manufacturing.

The RF amplifiers were tested and tuned in order to achieve low noise and low phase noise, respectively.

The layout of the fiber interconnections within the system is as symmetric as possible (temperature/humidity drift compensation). Using one single instead of two different fibers for drift stabilization guarantees independence from dispersion tolerances, as the laser's emission wavelength is varied to correct the link group delay. Rayleigh backscattering noise [3] increases the low-frequency phase noise as well as the phase noise floor in this bi-directional transmission. By reducing the coherence of the reflected light, the first effect can be minimized. To dispense with the added noise floor, a second uni-directional "low-noise" link, that is phase-locked to the first "low-drift" link and "cleaned", transmits the same signal but without backscattering noise. The stability of the "low-drift" link is further increased by operating photodiodes (out-of loop) in low AM-to-PM conversion operating points and by stabilizing the optical power. Furthermore, the optical power has been chosen to be sufficiently large so that the resulting shot noise limit enables achieving the envisaged phase noise floor.

Following that, all of the electronics have been integrated onto a single printed circuit board (PCB), thus allowing for better manageability and greater reproducibility.

Finally, the hardware platform is complemented with a software control system that monitors over 120 different parameters, from environmental data (temperature, humidity and pressure) to electronics and optics (phase detectors outputs, RF power levels, photodiode currents, laser temperature, etc.).

RESULTS

Jitter frequencies below 10 Hz are classified as wander and frequencies at or above 10 Hz as jitter [4]. Measuring these two parameters with a resolution of a few femtoseconds proved to be a challenge. Special measurement techniques along with specially developed equipment have been used.

Jitter Performance

In our case, the added jitter has been measured at offset frequencies ranging from 10 Hz to 10 MHz. The figure below shows the added jitter measurement of the Libera Sync 3 prototype.

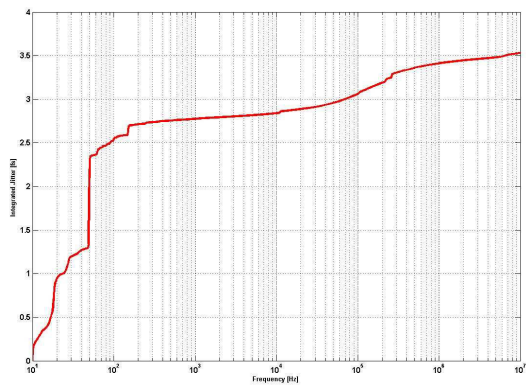

Figure 2: Integrated added jitter.

The majority of the jitter is concentrated in the lower frequency region between 10 Hz and 110 Hz. This has been attributed to mechanical vibrations and the coupling of the 50 Hz frequency component present in the environment at the time of the measurements. The total integrated jitter is slightly over 3.5 fs. This is a preliminary measurement and can be subject to change in the final implementation of the system. However, we do not expect a significant degradation.

Long-Term Phase Stability

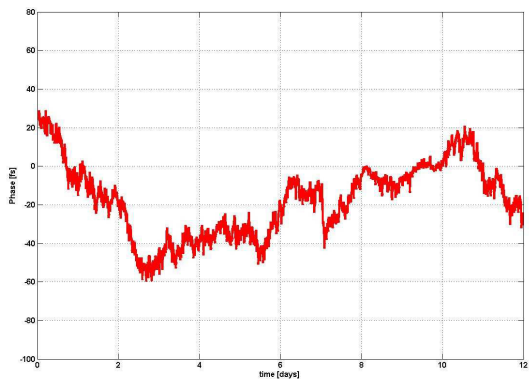

Figure 3: Phase drift.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Phase drift, like jitter, is the undesired variation of the phase of an otherwise periodic signal. However, these variations happen at much lower frequencies and are regarded as a time variable phase offset in relation to an initial arbitrary phase. In our case, the measurement was done over a period of 12 days. The following figure shows phase drift stability of the Libera Sync 3 prototype in relation to a phase stable reference.

The maximum peak-to-peak phase drift has been measured at 88.7 fs while the average day-to-day phase drift has been calculated to be around 30 fs with a standard deviation of 8.9 fs.

Measurement Techniques

In order to measure added jitter in the femtosecond range, a differential technique (saturated mixer) has been used. In this case, the reference signal is split into two branches. One is used as the reference signal while the other contains the device under test (DUT). If the two signals are driven in a quadrature phase relation at the mixer input ports, the resulting baseband output difference signal is 0 V plus a small phase modulation of the carrier, which is regarded as the residual phase noise of the DUT. This residual phase noise is sampled and digitized by a signal source analyzer (SSA). The jitter is calculated by integrating the digitized phase noise spectrum over the offset frequency range and is normalized to the original carrier frequency. Despite limitations induced by non-symmetries and non-linearities of the mixer, the resolution of the measurement can be estimated to be on the order of 0.1 fs [5].

Phase drift measurements have been performed by using a phase detector unit specifically designed for this application. The detector unit has been built by following the same design steps and implementing the same technology that has been used for the Libera Sync 3 system itself. The phase drift measurement is based on the AD8302 integrated circuit (IC). When thermally stabilized and driven with proper RF power levels, this IC exhibits minimal phase drift. Combined with thermally stabilized splitters and special RF cables, the setup can reach an accuracy of about 10 fs of phase drift per day.

DISCUSSION

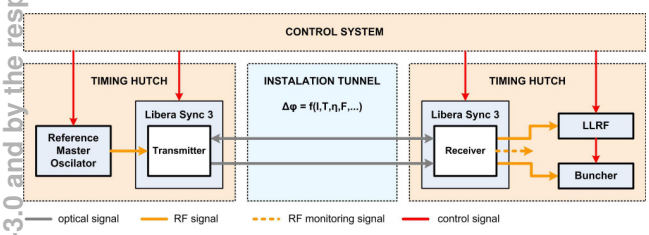

Figure 4: Example of use an accelerator environment.

Figure 4 shows an example of how the Libera Sync 3 transfer system can be integrated into an accelerator environment. The interconnecting RF cables from and to the transmitter and receiver units respectively as well as the fiber cables between them are also vital parts of this system, which require careful consideration.

The use of temperature-compensated RF cables with low temperature coefficients in the range of a few fs/mK is mandatory [6].

Phase drift in the optical fiber depends on link length, temperature and relative humidity variations, mechanical stress etc. Deviations of a few degrees in temperature and some tens of a percentage in relative humidity can contribute high phase drifts in the fiber link. The current Libera Sync 3 prototype provides a phase compensation range of approximately 360 ps. Therefore, if long distance operation is to be achieved, special care in selecting the fiber cable needs to be taken. Only loose type cabling preserves the temperature coefficient of the silica glass optical fiber in the range of 40 ps/kmK. In cases in which the estimated phase drift of the optical path exceeds the phase compensation range of the Libera Sync 3, the use of phase stable optical fibers is mandatory [7].

Finally, the Libera Sync 3 provides a user interface that can be operated manually or remotely. Manual operation is done by accessing the front panel controls along with the display, which is ideal for data examination and link tuning. Remote operation is done using SCPI commands over a standard 10/100 Mbit Ethernet connection, which is ideal for integration into the control system.

The current prototype works on a fixed frequency of approximately 3GHz. Future upgrades include extended operation range and support for other frequencies (6 GHz).

CONCLUSION

The new Libera Sync 3 transfer system integrates a novel approach with state-of-the-art technologies, ultimately providing outstanding performance, high reliability and reproducibility as well as ease of use.

ENERGY DEPOSITION IN THE SECTOR 37 SCRAPER OF THE ADVANCED PHOTON SOURCE STORAGE RING*

J. C. Dooling†, M. Borland, Y. C. Chae, and R. Lindberg, ANL, Argonne, IL 60439, USA

Abstract

The horizontal scraper in the sector 37 straight section of the Advanced Photon Source storage ring serves as a diagnostic to probe both the edge of the beam as well as the physical aperture when the store is lost. Initially, the scraper was meant only to be a diagnostic; high-density, short-radiation-length material used in the device was intended to stop halo, not the full beam. Damage to this device was recently discovered, and as a result, we began an effort to model and improve the scraper. Modeling with `elegant` provides loss distributions for several scenarios such as muting one or both rf systems in combination with firing injection kickers. The loss distributions are used as input to a MARS model of the scraper. Beam dumps from 100 mA dissipate a total of 2600 J. Most of this energy is not deposited locally; however, depending on the geometry and physical make-up, sufficient power density exists to damage the device on beam-facing surfaces. Testing is currently planned to examine the suitability of different beam-facing materials. Because of non-local energy deposition, we are evaluating the secondary role for this scraper as a spoiler rather than a beam dump.

INITIAL DAMAGE AND TESTING

During the Spring 2011 APS shutdown, damage to the sector 37 (S37) scraper was observed, and the device was removed from the storage ring (SR). A photograph of the damaged region is presented in Figure 1; the view is looking downstream. The thickness of the W is 2.54 cm. The

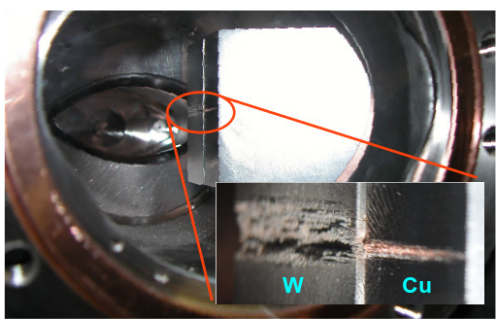

Figure 1: S37 scraper after removal from the SR in April 2011. View is looking downstream.

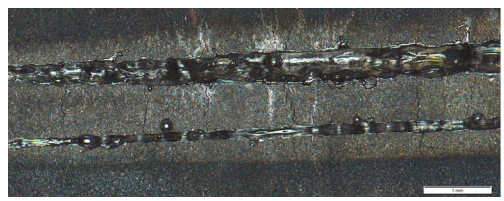
S37 scraper shown in Fig. 1 had been in use for seven years. The scraper was rebuilt using the same geometery and materials with the intention of employing the device only for diagnostics and collimation while a new design was considered. The rebuilt scaper was reinstalled in the SR in January 2012. Because of installation issues, the device was not used until the final day of the Spring 2012 run when beam dump studies were carried out. After shutdown the device was removed from the SR. During the study, beam was purposely dumped on the scraper using both 24-bunch and hybrid fill patterns. An image of the tungsten region damaged by 24-bunch beam dumps is presented in Figure 2.



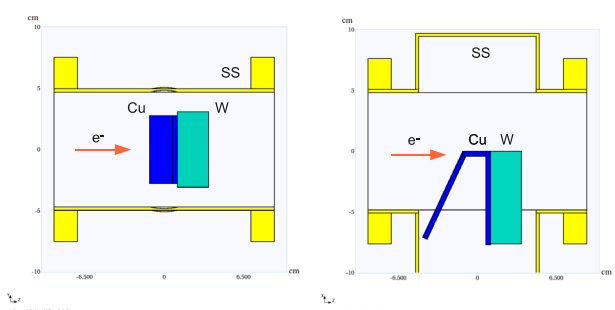


Figure 2: Tungsten region of the rebuilt S37 scraper after removal from the SR in May 2012. Beam motion: left to right.

SIMULATIONS

The particle-matter interaction program MARS [1] is used to estimate energy deposition within the scraper employing loss distributions generated with `elegant` [2]. The scraper components included in the MARS model that directly interact with the beam are shown in Figure 3; the beam travels from left to right. The tapered upstream portion is water-cooled copper. The downstream part is composed of scintered tungsten and is not directly water cooled.

brid fill pattern; the distribution includes beam loading effects and quantum fluctuations [3]. These simulations allow us to test different beam loss scenarios, such as muting one or both rf systems or firing injection kickers after beam dump conditions have been detected. Phase-space loss distribution histograms are presented in Figure 4. The distribution represents the complete loss of 368 nC of circulating SR charge (100 mA) and is simulated with 10^5-10^6 trajectories.

stress on scraper material struck by the lost beam, we need to know the local energy deposition. For MARS simulations, the upstream copper portion of the scraper is divided into five equal-depth regions (Δz=0.357 cm). The tungsten is divided into seven regions, the first six with the same Δz and seventh with 1.1 mm added to make the total W-depth 2.54 cm. Peak dose and resultant temperature rise calculations are presented in Figure 6 assuming 100 mA (368 nC) are circulating in the SR in a hybrid-mode fill pattern. In Fig. 6, the change in temperature is calculated using Eq.(1) assuming all deposited energy appears instantaneously; this assumption ignores diffusion, which will be discussed below. Also, Fig. 6 shows the effect of firing one of the SR injection kickers after a dump has been detected. While firing kickers reduces the temperature increase significantly, it would not be sufficient to prevent melting.

(a) total deposited dose (PDT) (b) instantaneous temperature rise

Figure 6: Absorbed dose and instantaneous temperature excursions.

ANALYSIS

Energy deposition is provided by MARS dose distributions. The instantaneous temperature rise in a given volume element can be calculated from MARS dose distributions, assuming that no heat transfer occurs over the period of energy deposition. Temperature rise due to an absorbed dose D_{ab} is

$$\Delta T = \frac{D_{ab} A_w}{C_v}, \qquad (1)$$

where A_w is the atomic weight, and C_v is the molar heat capacity. According to the Law of Dulong and Petit, $C_v = \frac{\partial}{\partial T}(3k_B T N_A) = 3k_B N_A = 24.94$ J K^{-1}mole^{-1}, where k_B is Boltzmann's constant; most metals differ only slightly from this value. The actual values of C_v for Cu and W are 24.44 J K^{-1} mole^{-1} and 24.27 J K^{-1} mole^{-1}.

The temperature rise given by Eq.(1) assumes that the energy deposition given by MARS occurs at a single instant in time. In a real loss event, however, electrons are lost over several turns, and diffusive/dissipative mechanisms may play a role in reducing the temperature change ΔT. We have analytically estimated the effect of heat diffusion using the axially symmetric Green function solution to the diffusion equation. While this simplified model neglects other factors affecting heat transport, our primary goal was to determine if diffusion might dramatically change the temperature rise predicted in Fig. 6(b). According to our calculations, simple diffusion can reduce the temperature by 40%-60% in 24-bunch mode and between 60% and 80% in hybrid mode. Hence, while diffusion is not neglible, it does not appear to provide significant temperature reductions. Interestingly, scraper damage was more prominant for the 24-bunch-mode beam loss, which qualititively agrees with the diffusion mode predictions.

MATERIAL ASSESSMENT

Our purpose is to safely dump the circulating charge in the SR in case of a machine protection system (MPS) trip or some other sudden beam loss event. Presently, the preferred method is to passively absorb the beam in a scraper that also acts as a beam dump.

We address the choice of appropriate scraper material by considering the ratio of thermal stress to yield stress for a given heat load [4]. At the same time, we recognize that the

Copyright © 2013 CC-BY-3.0 and by the respective authors

heat load for a given irradiation also depends on the material chosen. Material properties affect heat loading because bremsstrahlung is the primary energy loss mechanism for high-energy electrons. The generation of bremsstrahlung radiation is roughly proportional to ρZ^2, where ρ and Z are the density and atomic number of the exposed material, respectively. In addition, our design must live within an allowable footprint in the existing SR.

Thermal stress may be expressed as

$$\sigma_T = E_Y \alpha \Delta T, \tag{2}$$

where E_Y is Young's Modulus of Elasticity, α is the thermal coefficient of expansion, and ΔT is the temperature rise defined in Eq.(1). We define the thermal stress parameter g as

$$g = \frac{E_Y \alpha \Delta T}{\sigma_y}, \tag{3}$$

where σ_y is the yield stress. The stress parameter can be written as

$$\begin{aligned} g &= \frac{E_Y \alpha E_T A_w}{\sigma_y C_{mol} \rho V} \\ &= \frac{E_Y \alpha A_w}{\sigma_y C_{mol}} k_B S_{pc} \frac{N_e}{\pi r_b^2}, \end{aligned} \tag{4}$$

where E_T is the total deposited energy, ρ is the density, V is the volume, k_B is Boltzmann's constant, S_{pc} is the collisional stopping power [5], and r_b is the radius of the beam. We assume the lost charge is uniformly distributed within r_b. In Eq.(4) we used the thin target approximation [6] $E_T \approx \frac{S_{pc}}{S_{pr}} N_e W_o \frac{\rho}{X_o} \Delta z$; also, $S_{pr} = \frac{W_o}{X_o}$, and $V = \pi r_b^2 \Delta z$. S_{pr} is the radiative stopping power, W_o is the electron energy, and X_o is the radiation length.

In Eq. (4), we have separated the material-related terms from the beam terms. S_{pc} is a function of both but varies slowly with atomic weight at 7 GeV. In Table 1, the g-ratio is calculated for several materials assuming $N_e = 2.3 \times 10^{12}$ and $r_b = 0.1$ mm.

Table 1: Material Properties and Thermal-to-Yield Stress Ratio. PG and PB represent pyrolytic graphite and polybutene 1300; both are assumed to be composed entirely of carbon.

Mat.	E_Y (GPa)	$\alpha \times 10^6$ (K^{-1})	C_{mol} $\left(\frac{J}{mole\text{-}K}\right)$	σ_y (MPa)	g
Be	248	12.4	16.44	345	11.6
PG	20.7	0.5	8.28	82.7	0.48
PB	6.9	4	10.08	37.9	2.30
Al	69	25	24.20	310	15.8
Ti	116	8.5	25.06	951	4.72
Cu	110	16.5	24.44	220	49.6
W	345	14.4	24.27	1510	49.6

Table 1 indicates only pyrolytic graphite exhibits a g-ratio less than 1; whereas, copper and tungsten show the largest g. The g-ratio for titanium, though relatively high, is still an order of magnitude lower than for copper. We note that based on the results in Table 1, one might conclude that copper and tungsten should suffer roughly equal damage; however, from direct observations, we know this not the case. In the actual scraper, the damage to the W block was much more severe than to the Cu one due in large part to the shorter radiation length and higher density in the W. Part of this difference may also be due to a horizontal offset in the tungsten that had its outboard surface 0.8 mm closer to the beam than that of the copper surface.

DISCUSSION

In the case of a 24-bunch beam dump, peak power densities are on the order of 10^{15}Wcm^{-2}. Fast beam loss diagnostics [7] indicate that shorter dumps usually found with 24-bunch fill patterns are more destructive. Using higher-melting-temperature, lower-Z materials while moving the beam with a kicker should increase the scraper damage threshold. Work is now underway to build a new scraper that will reduce both impedance and the generation of higher-order cavity modes. Of the 2600 J stored in the beam, only 760 J are deposited in the scraper after 1.24 X_o and 7.26 X_o of Cu and W, respectively. Reducing the scraper length in terms of X_o means the device will absorb even less energy and act more as a spoiler. Simulations of this approach show promise both in terms of survival of the spoiler and protection of downstream insertion devices.

ANDROID APPLICATION FOR ACCELERATOR PHYSICS AND ENGINEERING CALCULATIONS

M. Borland *

Abstract

Smartphones and tablets are increasingly capable computational devices, with fast processors and high-resolution displays. They are also nearly ubiquitous, suggesting that they can support the need of physicists and engineers to perform quick calculations in situations where using a full-blown simulation is not necessary or expedient. In this paper, we report on the design, features, and capabilities of an Android application inspired by these ideas. The application is called "TAPAs," which stands for Toolkit for Accelerator Physics on Androids. As the name—meant invoke the popular snacks of Spanish cuisine— suggests, the application provides a varied selection of calculations for electron storage rings, electron linear accelerators, electron guns, free-electron lasers, undulator design, synchrotron radiation, and engineering. The calculations are organized into separate sub-applications, which share input values to allow performing related calculations without re-entering data. The application is free of advertising and is available free of charge on the Google Play store.

INTRODUCTION

Physicists and engineers have long needed the ability to perform quick "back of the envelope" calculations. This need arises during discussions, meetings, and conferences, when running a simulation code is not possible or would take too long. It also arises in day-to-day work as one explores ideas at one's desk. The ability to perform a quick, reasonably accurate calculation can sometimes make all the difference between being productive and pursing a dead-end idea.

Such calculations may be performed mentally, with a pad and pencil, or with a hand-held calculator. Depending on one's ability to remember the appropriate equations, one might use a published handbook, memorized equations, or a "cheat sheet." In the not-to-distant past, it was not uncommon to have a programmable calculator that facilitated common calculations. At present, one is more likely to have a smartphone or tablet close by than a programmable calculator. Hence, it makes sense to develop smartphone or tablet "apps" to address the need for quick calculations.

Inspired by these ideas, we developed an Android application that performs a number of useful calculations of the sort that commonly come up in day-to-day work. The Android platform was chosen for its open-source nature and the low cost of entry for devices and development. Unlike other smartphone platforms, the Android Software Development Kit (SDK) is free and available for essentially all platforms, which allowed using Linux for development.

We used the Eclipse Integrated Development Environment (IDE), which is advantageous in that it helps one quickly learn both the Java language and the specific methods provided by Android. The web contains many resources, such as Android tutorials and user forums (e.g., StackExchange).

The application is called TAPAs, which stands for "Toolkit for Accelerator Physics for Androids" and also is meant to bring to mind the popular snacks of Spanish cuisine. The application is free of advertising and is available free of charge on the Google Play store.

SOFTWARE DESIGN

Those who are uninterested in software design may wish to skip this section, as it has little to do with how the application is used or what it can do. This section also assumes some familiarity with Android development.

The root activity of the application, MainActivity, is an extension of the ListActivity class, which presents a set of choices as a simple vertical list. In addition, MainActivity provides pop-up dialog using AlertDialog that acquaints users with recent changes. The SharedPreferences facility is used to remember the major and minor version of the last invocation, so that the pop-up dialog appears only on the first invocation of a new version. Finally, MainActivity loads a set of name/value pairs into a hash table, which provides default values for entries in the various calculations. As calculations are used, the values in the table are updated so that other applications have access to the new data. The hash table is part of a class that is implemented as a "static singleton," which means that there is only one instance of the class and it is shared by all methods that attempt to instantiate the class.

Below the main list are a series of sublists that are also instances of ListActivity. The activities in each sublist are implemented using an ActivityWithMenu class derived from the Activity class. As the name suggests, this new class provides an activity class with a predefined menu. This menu is used to control some basic settings of the application. The settings are saved between invocations and shared among activities using the SharedPreferences class. The widgets for each activity are embedded in a vertically-scrolled list, which helps in accommodating various screen sizes.

Individual calculation activities typically consist of a list of numerical entry and output widgets, in some cases accompanied by graphics. The numerical entry widgets use the EditNumber class, which extends EditText. This class provides two entry methods, one being a simple numerical

* michael.d.borland@gmail.com

Copyright © 2013 CC-BY-3.0 and by the respective authors

keypad and the other being a scientific calculator keypad. The latter provides the ability to perform calculations on quantities in the entry widgets, which can then be submitted as the new value for the entry widget used to invoke the calculator. EditNumber also includes a facility to limit the range of entries in order to prevent invalid calculations, as well as methods for setting, retrieving, and formatting numerical quantities. Values are stored to full precision even if they are displayed to partial precision, which helps preserve the consistency of displayed values, something that is not possible with the basic EditText class.

Calculation outputs are displayed using the NumberView class, which extends TextView. Like EditNumber, it provides storage, retrieval, and formatting of numerical values. The font size for the EditNumber and NumberView classes is under user control, which helps to accommodate screens of varying sizes and resolutions. We also extended the TextView and Button classes to make a ScaledTextView and ScaledButton classes, to provide the same control.

The structure of the code is such that it is straightforward to add new menus and calculations. The most time-consuming part is coding the XML file that specifies the graphical appearance of the screen.

FEATURES AND CAPABILITIES

Upon starting TAPAs, one is greeted by a simple list of topics. Clicking on one of these topics brings up a list of related calculations that are available for that topic. Often the calculations within a topic will share certain input values (e.g., the beam energy), so that changing it one calculation will change it in the others. In addition, *computed* values from one calculation are often shared with other calculations. This allows using the calculations in a coordinated fashion, which is why we used the word "toolkit" in the name.

Space does not permit a full account of the capabilities of TAPAs, which as of version 1.42 supports 40 different calculations. Instead, we will list the available calculations and highlight a few to give a flavor of what's available. In addition, space does not permit showing the equations used in the calculations or citing all of the original sources; we hope to do this in a future publication. Many of the calculations are based on formulae found in popular references [1, 2, 3, 4].

The **Electron Storage Rings** menu provides scaling of electron storage rings with size and energy; longitudinal dynamics, e.g., rf bucket parameters; harmonic number optimization; short-pulse x-rays with paired [5], or single crab cavities; tune resonance diagrams; top-up and swap-out calculations; gas scattering lifetime; and quantum lifetime.

The **Undulators** menu provides calculations of photon energy or wavelength from undulator parameters, and vice-versa; maximum field or K as a function of gap and period for hybrid permanent magnet and superconducting undulators; undulator optical effects; and undulator orbit effects. The **Synchrotron Radiation** menu provides energy, wavelength, power, and flux calculations for bending magnets, wigglers, and undulators.

The **Electron Linac** menu provides calculations of magnetic bunch compression; coherent synchrotron radiation effects in bending magnets [6, 7]; alpha magnets [8, 9]; charge, current, and beam power; and beam energy and rf power for SLAC-type linacs. The **Electron Guns** menu provides calculations of Richardson's Law, Child's Law, thermal emittance [10], and photocathode intrinsic emittance [11]. The **Free Electron Laser** (FEL) menu provides FEL calculations based on the one-dimensional equations [12] and Ming Xie's parametrization [13].

The **Electromagnetism** menu provides calculations of skin depth for nonmagnetic materials; cutoff frequency and attenuation for rectangular waveguide; and frequencies of pillbox cavity modes. The **Engineering** menu provides calculations for iron dominated magnet design; properties of dipole magnets and trajectories in dipoles; analysis of one-dimensional static heat flow; and estimates of temperature rise in cooling water.

The **Particle Passage Through Matter** menu provides calculations of radiation length, multiple Coulomb scattering, and brehmsstrahlung for electrons and protons in naturally-occurring elements [14].

The **APS-Specific Calculations** menu provides two calculations that are specific to the Advanced Photon Source (APS), namely, the single-bunch accumulation limit based on the impedance model [15] and the bunch length as a function of current based on a fit to measured data.

As a detailed example, Figure 1 shows the screen for one of the most-used calculations, namely, scaling of electron storage rings. This applies mostly well-known (e.g., [16]) scaling rules to allow quickly estimating equilibrium emittance, energy spread, energy loss per turn, etc., as a given light source storage ring design is scaled in number of cells and beam energy. One can use this application to quickly determine that scaling the 20-sector MAX-IV storage ring [17] ring to 40 sectors would give a ring size of APS which, at 7 GeV, would have an emittance of 222 pm. While most of the calculations are, as in this example, straightforward lists of inputs and outputs, some are more colorful, such as the resonance diagram shown in Figure 2.

Often the user may wish to perform additional calculations prior to entering a value, perhaps based on other values present in the interface. This is supported by an RPN-calculator-based entry dialog, shown in Figure 3. In many instances this dialog includes a menu that allows the pushing quantities from the interface onto the stack. Upon exiting the calculator interface, the top of the stack is placed into the entry box in question. To prevent invalid calculations, the calculator interface is sensitive to the valid return values for the quantity being entered, and will refuse to close if an invalid value (e.g., a non-positive value for the beam energy) is given.

CONCLUSIONS

The cost- and ad-free TAPAs application for Android devices provides a number of quick, convenient calculations

CRYOMODULE PERFORMANCE OF THE MAIN LINAC PROTOTYPE CAVITY FOR CORNELL'S ENERGY RECOVERY LINAC*

N. Valles†, R. Eichhorn, F. Furuta, M. Gi, D. Gonnella, D. Hall, Y. He, V. Ho, G. Hoffstaetter, M. Liepe, T. O'Connell, S. Posen, P. Quigley, J. Sears and V. Veshcherevich
Cornell University, CLASSE, Ithaca, NY 14853, USA

Abstract

Energy Recovery Linacs (ERLs) require strong damping of higher-order modes in main linac cavities to avoid beam loss from beam break-up effects. In addition, the cavities need to have very high intrinsic quality factors to minimize the size of cryogenic plants in CW cavity operation. We present world record results for a fully equipped multicell cavity in a cryomodule, reaching intrinsic quality factors at operating accelerating field of Q_0(E =16.2 MV/m, 1.8 K) $> 6.0 \times 10^{10}$ and Q_0(E =16.2 MV/m, 1.6 K) $= 1.0 \times 10^{11}$, corresponding to a residual surface resistance of 1.1 nΩ, which is more than three times better than the Q_0 design specification.

INTRODUCTION

Cornell University is developing a 5 GeV energy recovery linac (ERL). The SRF main linac of this ERL is designed to support high current beams, each at 100 mA with 77 pC bunch charge (one beam is accelerated and the returning beam is decelerated in the main linac), with small emittance.[1] These demanding beam requirements set tight constraints for electromagnetic and higher-order mode properties of the 1.3 GHz main-linac cavities.[2, 3] In addition to these RF properties of the cavity, the feasibility of operating a 5 GeV SRF linac in continuous wave mode requires the main-linac cavities to have 1.8 K quality factors of at least 2×10^{10} at E_{acc}=16.2 MV/m.[1]

Eventually, six 7-cell cavities along with other instrumentation will be commissioned within a prototype main linac cryomodule (MLC).[4] The precursor to the MLC is the horizontal test cryomodule (HTC) which can contain a single 7-cell cavity, two higher-order mode (HOM) absorbers and other experimental instrumentation.

The first prototype cavity has been fabricated,[5] and is being qualified in the HTC through several stages of hardware implementation. By performing measurements at various stages of implementation, the effects on the quality factor and higher-order mode spectrum can be characterized systematically, leading to tight control of the performance of the structure. In total, there are three verification stages, which have been discussed elsewhere.[6] The instrumentation effecting fundamental mode performance is summarized in Table 1.

Table 1: Key Elements Affecting the 7-cell's HOM Spectrum Incorporated in Each Iteration of the Horizontal Test Cryomodule Experiments. The fundamental mode couples to the on-axis input coupler with $Q_{ext} = 9 \times 10^{10}$ and the high-power coupler with $Q_{ext} = 5 \times 10^7$.

Stage	RF input method	HOM absorbers
HTC-1	On-axis coupler	none
HTC-2	High-power input coupler	none
HTC-3	High-power input coupler	2 SiC absorbers

Meeting gradient and quality factor specifications in each of these tests demonstrates the feasibility of the all the main systems needed for the MLC.

This paper details the final results of the three HTC experimental runs, focusing on the fundamental mode properties. Investigations of the higher-order mode spectrum are presented elsewhere.[7] We present quality factor measurements for all three tests and demonstrate that the cavity fabricated at Cornell exceeds design specifications.

METHODS

Cavity Preparation and Cryomodule Assembly

The construction[8] and preparation of the prototype main-linac 7-cell cavity, ERL 7.1, for HTC-1 has been described elsewhere.[5] An overview is presented here.

Following fabrication, ERL 7.1 received a 10 μm BCP, a 16 hour high-pressure rinse (HPR), was then cleanly assembled and baked at 120°C for 48 hours. The cavity was vertically tested, and found to exceed quality factor and gradient specifications. The cavity's Q vs E curve only showed mild medium field Q slope and reached 26 MV/m, limited by available RF power.

Following the successful vertical test, while maintaining a clean RF surface, the cavity was outfitted with a helium jacket, and installed in a horizontal test cryomodule for HTC-1. An axial RF coupler, (fundamental mode $Q_{ext} = 9 \times 10^{10}$) similar to the one used in the vertical test, was installed on the end of the cavity.

At the next stage of the tests, HTC-2, a high-power side mounted RF input coupler was added to the HTC-1 assembly. This antenna couples to the fundamental mode with $Q_{ext} = 4.5 \times 10^7$, so is strongly over coupled.

The final stage of the HTC tests, HTC-3, added beamline higher-order mode absorbers at each end of the cavity.

* Work supported by NSF Grants NSF DMR-0807731 and NSF PHY-1002467
† nrv5@cornell.edu

Copyright © 2013 CC-BY-3.0 and by the respective authors

To install these absorbers, HTC-2 had to be disassembled to allow removal of the axial coupler. After HTC-2, the cavity was reprocessed with a 5 μm BCP, 120°C bake, and an HF rinse to mitigate field emission in the HTC-2 experiment. HOM absorbers and the high-power RF coupler were installed and the cryomodule tested in its final configuration.

Experimental Procedure

The HTC cavity tests had three main goals: to measure the quality factor vs accelerating field (Q_0 vs E) of the cavity, to determine the quench field of the cavity, and to qualify each major stage of the assembly.

For each HTC experiment, the cavity was slowly cooled from 300 K to 1.8 K while maintaining a small temperature gradient (< 0.3 K) across the cavity in an attempt to prevent thermal-electric currents from trapping flux and degrading the quality factor of the cavity.[6] In HTC-1 the Q_0 vs E points were measured through standard RF methods–utilizing two RF probe ports[9]–and cryogenically by using the helium boil-off rate to determine the power dissipated from the cavity. Quality factor measurements in HTC-2 and HTC-3 required cryogenic methods to determine the performance of the structure, since the strongly over coupled high-power input coupler would not yield accurate Q_0 measurements.[5]

After measuring the cavity's quality factor at 1.6, 1.8 and 2.0 K, the quench field was determined and a Q_0 vs E curve was remeasured to determine whether quenching had a deleterious effect on the quality factor. Subsequently, to return the cavity to its original superconducting state, the cavity temperature was cycled to above its critical temperature, T_c, and the quality factor remeasured.

The BCS losses of the superconductor can be calculated with SRIMP, a code by J. Halbritter, which in turn can be used to determine material properties of the cavity from the temperature dependence of the quality factor.

RESULTS

HTC-1

Q_0 vs E measurements were performed after several thermal cycles.[6] RF and cryogenic measurements of Q_0 were in agreement. The quench field was 17.3 MV/m, and prior to quenching the cavity produced radiation at about 1 R/hr. After the 100 K cycle, the residual resistance of the cavity was ~5.8 nΩ.[5] Thermally cycling the structure led to a 50% increase in Q_0 at the operating temperature, and was maintained even after an intentionally fast cooldown.

After thermally cycling, the cavity exceeded the design specification of $Q(16.2\text{ MV/m}, 1.8\text{ K}) = 2 \times 10^{10}$ by 50%. The cavity set a world record for quality factor of a multicell cavity installed in a horizontal test cryomodule reaching $Q(5.0\text{ MV/m}, 1.6\text{ K}) = 6 \times 10^{10}$, as shown in Fig. 1.

HTC-2

In HTC-2, the quality factor was again measured over several rounds of thermal cycling, described in [6]. After the first 15 K thermal cycle the mid-field Q_0 improved ~50% at both 1.6 K and 1.8 K.[6] Administrative limits prevented quench field determination.

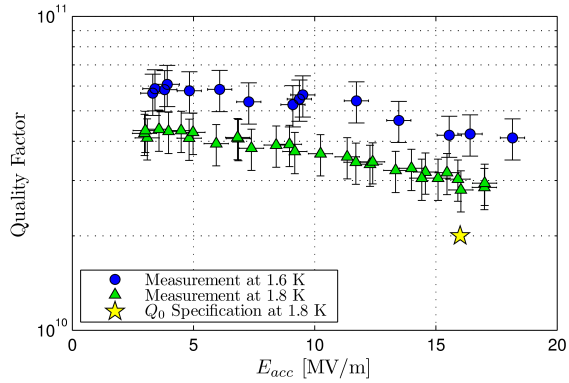

Figure 1: Q_0 vs E_{acc} measurement of ERL 7.1 in HTC-1.

Thermal cycles to 8.9 K and to room temperature did not increase Q_0 in HTC-2. This suggests that the most benefit for thermal cycles is obtained from peak temperatures in the region between 9.0 and 100 K.

In HTC-2, ERL 7.1's met the design specifications, but was limited by field emission coming from the end cell far from the high power coupler. The final Q_0 vs E plot is shown in Fig. 2

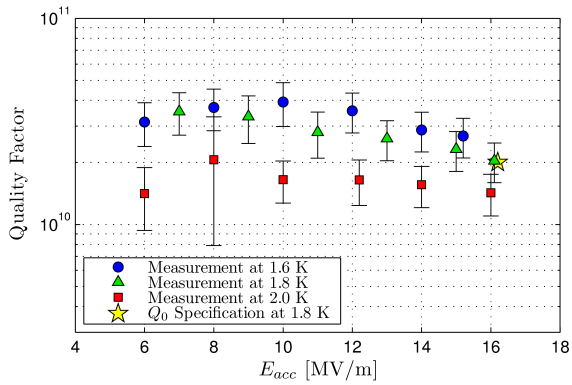

Figure 2: Q_0 vs E_{acc} measurement of ERL 7.1 in HTC-2.

HTC-3

The final stage of the HTC experiments included all the components and instrumentation that would be used in a full 6 cavity cryomodule for Cornell's Energy Recovery Linac. Initial measurements of cavity's quality factor were performed at 1.6, 1.8 and 2.0 K. Q_0 vs E measurements after the first cooldown exceeded the design specification,[6] but a thermal cycle was performed to determine whether or not additional improvement in Q_0 was possible. Fig. 3 shows the Q_0 vs E measurements post 10 K thermal cycle.

The prototype cavity ERL 7.1 was measured to have $Q_0(1.8\text{ K}) = 3.6 \times 10^{10}$, $Q_0(1.8\text{ K}) = 6.1 \times 10^{10}$ and $Q_0(1.6\text{ K}) = 1.0 \times 10^{11}$ at the operational gradient of

Copyright © 2013 CC-BY-3.0 and by the respective authors

16.2 MV/m, setting the world record Q_0 for a multicell cavity operating in a horizontal cryomodule.

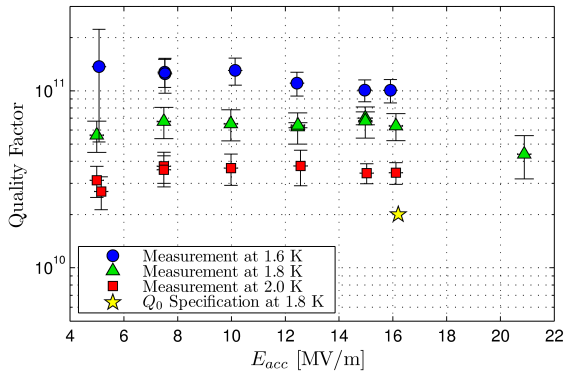

Figure 3: Final Q_0 vs E_{acc} measurement of ERL 7.1 in HTC-3. At the operating accelerating gradient and temperature, the cavity's Q_0 exceeds design specification by a factor of three, reaching 6×10^{10}. Accelerating gradients of 21 MV/m were achieved.

Finally, the superconducting parameters were characterized using SRIMP, finding that the residual resistance after thermal cycling was reduced from $\sim$3 nΩ to a very low value of just $\sim$1 nΩ.[6]

CONCLUSIONS

The main linac cavity exceeded design specifications in all three HTC experiments. Temperature cycling helped to improve the quality factor of the cavity by about 50%, with the most benefit being realized after thermally cycling to low temperatures above T_c.

Measurements of the prototype cavity outfitted with a high power coupler and two beamline HOM absorbers shows exceptional quality factor results at gradients up to 21 MV/m. At 1.8 K, the quality factor specification was exceeded by a factor of three. In addition, ERL 7.1 reached Q_0(16.2 MV/M, 1.6 K)=1.0×10^{11} in a fully outfitted cryomodule in HTC-3, breaking the world record that was set in HTC-1,[10] and demonstrating that very high Q_0 is achievable in horizontal cryomodules.

The HTC experiments demonstrate that extremely high quality factors can be preserved in a fully equipped cryomodule, and Q_0 does not necessarily have to degrade between vertical and horizontal testing.[6] This is clearly demonstrated by Fig. 4, which shows higher quality factors in the HTC-1 experiment than the vertical test, even though no surface treatment was performed between the tests.

Very high values of Q_0 in the HTC experiments are attributed to three factors: First, there are two layers of magnetic shielding in the cryomodule, compared with a single layer in the vertical dewar reducing the ambient magnetic flux in the cryomodule, which leads to a smaller residual resistance. Second, the tightly controlled cooling process of the cavity in the cryomodule minimizes both spatial and temporal gradients across the cavity, reducing flux pinning

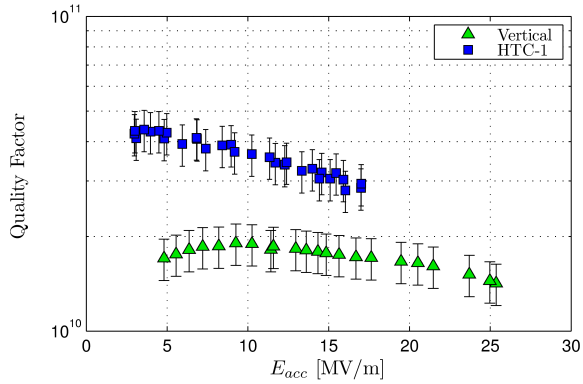

Figure 4: Comparison of Q_0 vs E measurements at 1.8 K of ERL 7.1 in the vertical test and HTC-1. HTC-1 exhibits much higher Q_0 than in the vertical case, though no surface processing was done between the two measurements.

in the superconductor. Third, the combination of HF rinse and a very uniform 120°C bake in a large furnace leads to surfaces having low BCS resistance.

Future work with this cavity will include beam tests in Cornell's Injector Cryomodule in the Fall of 2013. These measurements will use beam to measure the Q_0, R/Q and frequencies of higher-order modes in the HTC.

FERMILAB MUCOOL TEST AREA CAVITY CONDITIONING CONTROL USING LABVIEW

D.W. Peterson, Fermi National Accelerator Laboratory*, Batavia, IL 60510, USA
Y. Torun, Illinois Institute of Technology, Chicago, IL 60616, USA

Abstract

Automated RF cavity conditioning controls have been implemented in the Fermilab MuCool Test Area using National Instruments LabVIEW. Display of RF parameters, cavity gradient and diagnostic signals are provided for real-time monitoring. Oscilloscope traces and operating parameters are logged automatically. Gradient ramping and cavity breakdown detection allow unattended operation. Key parameters are made available to the Fermilab ACNET system for viewing by users.

SYSTEM OVERVIEW

The MuCool Test Area (MTA) consists of a beamline stub and experimental hall off of the 400 MeV H- section of the Fermilab LINAC [1]. The hall contains power supplies and cryogenics for a 5T superconducting solenoid as well as RF feeds for high power 201 MHz and 805 MHz. Cavity conditioning is currently performed at 805 MHz at up to 13 MW of RF power [2][3][4].

The computer test system consists of a Dell GX620 computer running National Instruments (NI) LabVIEW 2012[5]. Waveforms are acquired with the NI PCI-5105 60 MS/s, 12-Bit, 8-Channel Digitizer/Oscilloscope card. A GPIB bus communicates with the HP E4400B RF Signal Generator, LeCroy 625Zi oscilloscope, and Tektronix DPO7104 oscilloscope.

Triggering of acquisitions is by the RF gate TTL signal from a master timing distribution module. Additional signals into the PCI digitizer card are a diode detected sample of the cavity RF probe signal, a sample of the waveguide reflected power, and an optional signal from a cavity photo detector.

SOFTWARE DESIGN

The MuCool Cavity Test software has evolved over more than six years of activity [6][7]. LabVIEW has been used throughout the process. This latest version has implemented some important new features:

- A simplified user interface with multiple floating front panel windows.
- Cavity waveform analysis during each pulse, including cavity breakdown detection.
- A new cavity tuning algorithm.
- Gradient ramping and breakdown recovery.
- Verbose log files.
- Cavity waveforms are periodically saved to disk and can be viewed later.
- Breakdown events are recorded along with data from preceding and following pulses.
- A few key parameters are available on the ACNET control system.

User Interface

LabVIEW routines are called virtual instruments (VIs). Each VI has a front panel for user interaction and a block diagram that defines the program execution. In the cavity conditioning system the main front panel provides a general view of the cavity signals and pulse status. It also provides a launch point for the cavity conditioning control VIs, such as tuner control and cavity waveform analysis. Figure 1 shows the general flow of the program. Figure 2 shows the layering of various VI front panels. During any given user interaction, the panel of interest can be brought to the foreground or minimized as needed. Additional VIs are available for the user to set the data logging interval and to enter comments into the log file.

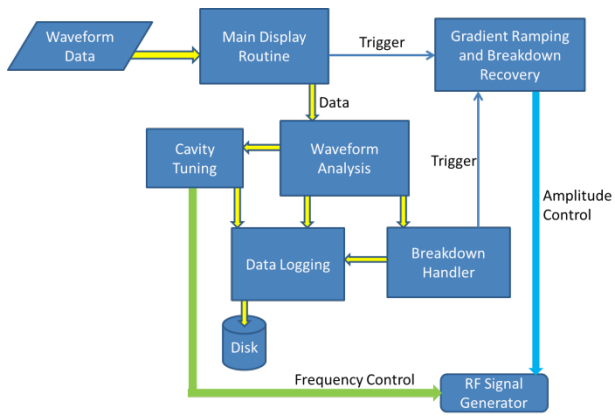

Figure 1: Simplified block diagram of the cavity conditioning program.

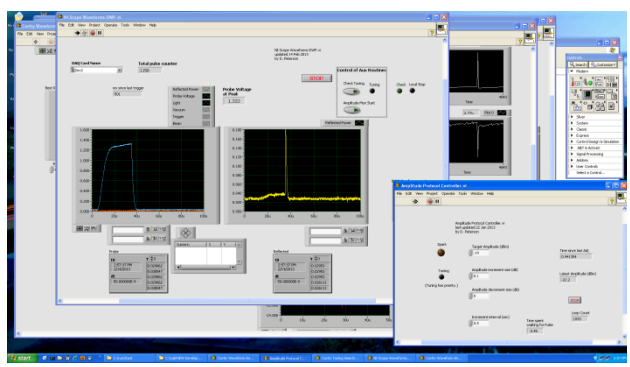

Figure 2: Screen capture of the overall user interface showing the layering of multiple VI front panels.

Cavity Waveform Analysis

As the waveforms are acquired by the digitizer card they are passed to Cavity Waveform Analysis VI for all of the measurements, breakdown detection and triggering of the breakdown logging routines.

Measurements on the cavity probe waveform include peak voltage, rise time, fall time, exponential fits of filling time constant and decay time constant, and integrated values of cavity and reflected signals both inside and outside the RF gate time. Figure 2 shows the user waveform display of a normal cavity pulse with the RF gate signal and reflected power signal.

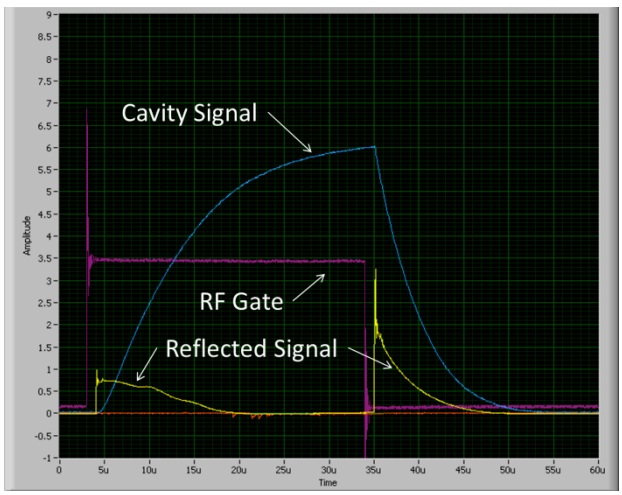

Figure 3: Typical main display showing cavity waveform, RF gate and reflected signal.

Cavity Breakdown Detection

The best way to detect cavity breakdown is to insert a fiber optic cable into the cavity and detect the flash of light when a spark occurs. Figure 4 shows the large light signal during a cavity breakdown event. Unfortunately, not all cavities have been outfitted with optics.

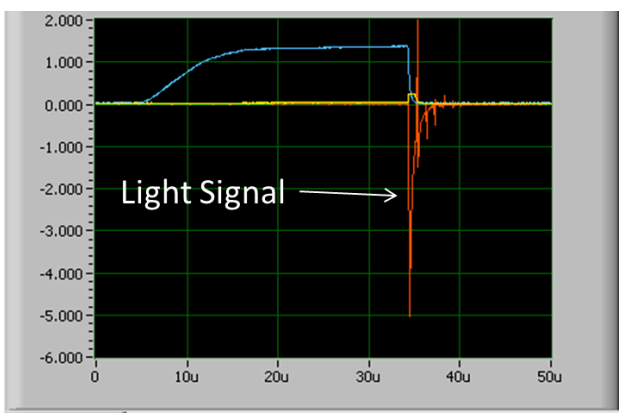

Figure 4: Auxiliary display showing pronounced light signal during a cavity breakdown event.

A reliable alternate method involves measuring the 90% to 10% fall time of the cavity probe waveform and triggering the breakdown capture VIs for any fall time shorter than a user settable trip value. Figure 5 shows a cavity breakdown event with the extremely steep cavity waveform falling edge. The reflected power spikes momentarily until an external high speed circuit detects the event and turns off the RF drive signal before the end of the RF gate. A typical 90% to 10% fall time in recent tests is approximately 12 µs for normal operation and less than 1 µs during breakdown.

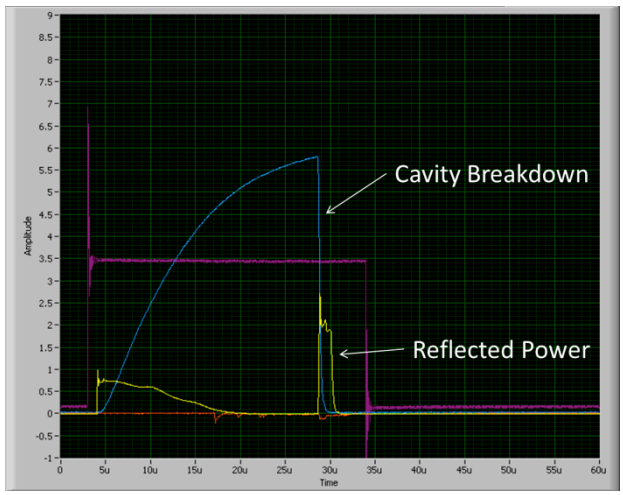

Figure 5: An example of a cavity breakdown event with the accompanying spike in the reflected power.

Cavity Tuning Algorithm

During normal cavity conditioning, enough power is dissipated in the walls of the cavity to raise the temperature and change the resonant frequency. Since the present test cavities do not have any means of compensating for this effect, the RF drive frequency must change to follow the cavity resonance. Previous versions of the software have used a gradient search to determine where the peak resonance occurs. Measurement noise when far off resonance often resulted in the algorithm taking many steps to converge or occasionally failing to converge.

The improved algorithm uses a sequence of n steps to move a predetermined distance, Δf, each side of the present center frequency while also recording either the cavity amplitude response or the ratio of integrated cavity probe signal vs. reflected signal inside the RF gate. The probe/reflected ratio has proven to be a very effective measurement of cavity performance. For efficiency, the step sequence takes the odd numbered steps going down in frequency and even numbers steps going up in frequency. For example, a complete step sequence using 5 steps each side of the center frequency, f_0, would be:

$f_0-\Delta f/n$, $f_0-3\Delta f/n$, $f_0-5\Delta f/n$, $f_0-4\Delta f/n$, $f_0-2\Delta f/n$, f_0, $f_0+2\Delta f/n$, $f_0+4\Delta f/n$, $f_0+5\Delta f/n$, $f_0+3\Delta f/n$, $f_0+\Delta f/n$, f_0.

After the steps are complete the signal vs. frequency array is passed to a Gaussian peak fitting routine which returns the least square fit to the measurements. The algorithm then moves the signal generator frequency by steps of $2\Delta f/n$ to the new calculated center frequency and the tuning cycle is complete. Typical search values in recent cavity testing have been $\Delta f = 10$ kHz and n=10.

Gradient Ramping and Breakdown Recovery

An important part of cavity conditioning is the ability to push the cavity gradient to high field yet not cause serious damage to the cavity surface. The Amplitude Control routine has user settable parameters for amplitude increment step, step interval, and amplitude decrement if breakdown occurs. Amplitude increment occurs at the step interval except when cavity tuning is active. Amplitude decrement occurs immediately upon detection of a cavity breakdown event. Typical settings are an amplitude increment of 0.04 dB, a step interval of 10 seconds, and an amplitude decrement of 3.0 dB if a breakdown occurs.

Recording to Disk

When the LabVIEW program is started at the beginning of each cavity conditioning "Run", it increments the official run number and creates a file folder with the current date if one is not already present. A text log file is created with the date and run number in the file name. Digitizer waveforms are also stored in a file in the same folder. Due to the possibility of multiple runs in one day or one run spanning multiple days, it was decided to keep the log and waveform file sizes manageable by automatically creating a new folder at 00:00:00 each day of running and opening new files with the appropriate run number.

The log file includes time stamped data such as user comments, manual and automatic amplitude setting changes, periodic captures of cavity waveform parameters, and cavity waveform parameters during breakdown events.

Cavity waveform files are recorded periodically and at each breakdown event. A utility program has been written which provides quick viewing of waveforms in a movie format. The user has the option to single step though capture frames and to send the frame image to a graphic file in .png format or send the waveform data to a comma separated spreadsheet file.

The oscilloscopes trigger on every pulse and can also be commanded to write trace information to their internal hard drives periodically and at each breakdown event.

An additional background utility is constantly recording the digitizer waveform data in a circular buffer of 9 elements. When a breakdown event occurs, the buffer continues for 4 more pulses and then the entire buffer is written to a waveform file. This allows the user to view cavity waveforms surrounding the breakdown event.

Writing to ACNET

A background VI uses XML-RPC to write total cavity pulses, number of breakdown events, RF signal generator frequency and amplitude, cavity peak voltage and other parameters out to the Fermilab ACNET control system at a 1 Hz rate [8]. ACNET parameters are easily viewed on the internet and utilities are in place for automatic notification if values go out of user defined tolerances.

SUMMARY AND PLANS

The continued use of LabVIEW has enabled a rapid and efficient upgrade to the MuCool 805 MHz cavity conditioning controls. New measurement and control routines with automatic recording of cavity performance have permitted long conditioning runs over multiple days and will facilitate testing of other cavity designs [9].

Components are being installed to provide similar cavity conditioning capabilities in the 201 MHz RF systems. In addition to the features implemented in the 805 MHz system, the 201 MHz cavity conditioning system will have active resonance tuning control [10].

ACKNOWLEDGMENTS

The authors would like to thank the cavity conditioning teams not only for their long hours of vigilant service but also for their valuable suggestions for improvements in the software.

SSR1 CRYOMODULE DESIGN FOR PXIE*

T. Nicol#, S. Cheban, M. Chen, M. Merio, Y. Orlov, D. Passarelli, T. Peterson, V. Poloubotko, O. Pronitchev, L. Ristori, I. Terechkine, Fermilab, Batavia, IL 60510, U.S.A,

Abstract

Project X is a proposed proton accelerator complex intended to support Fermilab's role in intensity frontier research over the next several decades. It will replace the existing 40-year-old injector complex and add powerful new capabilities to support a large number of experiments in the energy range from 1 to 120 GeV.

Fermilab is planning a program of research and development aimed at testing of critical components. This program, known as the Project X Injector Experiment (PXIE), is being undertaken as a major element of the ongoing Project X R&D program.

PXIE contains two superconducting cavity cryomodules, one utilizing half-wave resonators (HWR), and the other, single spoke resonators (SSR). The first SSR cryomodule, known as SSR1 contains eight cavities and four solenoids in the following order: C–S–C–C–S–C–C–S–C–C–S–C, as well as active steering elements.

This paper describes the design of the SSR1 cryomodule and includes discussions of the system interfaces, vacuum vessel, magnetic and thermal shields, insulating and support systems, cavities, tuners, input couplers, focusing elements, and current leads.

INTRODUCTION

The SSR1 cryomodule will operate with continuous wave (CW) RF power and support peak currents of 5 mA chopped with varying patterns to yield an average beam current of 1 mA. The RF power per cavity at 1 mA average current and 2.2 MV accelerating voltage (β=0.22) should not exceed 4 KW with an overhead reserved for microphonics control.

The current beam optics design for Project X requires that the SSR1 cryomodule contains eight cavities and four solenoids in the following order: C–S–C–C–S–C–C–S–C–C–S–C. Horizontal and vertical dipole correctors are located inside each solenoid. A four-electrode beam position monitor (BPM) is located at each solenoid.

The intent is that this cryomodule has all external connections to the cryogenic, RF, and instrumentation systems made at removable junctions at the cryomodule itself. The only connection to the beamline is the beam pipe itself which will be terminated by "particle free" valves at both ends. Minimizing mean time between failure and repair and in-situ repair of some internal systems are important design considerations in the cryomodule design.

Figure 1 shows the linac layout including the location of the SSR1 cryomodule.

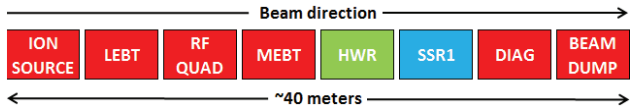

Figure 1: PXIE layout.

CRYOMODULE DESIGN

Eventually, Project X will require several different cryomodule designs for cavities operating at 162.5, 325, 650, and 1300 MHz. The SSR1 for PXIE is the first of these being developed at Fermilab. Details of individual cryomodule components are described below.

Cryogenic Systems and Vacuum Interfaces

There are two ways that cryogenic and vacuum systems are distributed to individual modules in superconducting magnets or cavity strings. Coarse segmentation refers to systems in which the cryogenic circuits and insulating vacuum inside individual cryostats are more or less continuous for long lengths, at least over the length of several cryomodules. Fine segmentation, refers to systems in which the insulating vacuum and the cryogenic circuits are confined to an individual cryomodule, the only connection between modules being the at beam tube. Fine segmentation is the configuration choice for Project X and PXIE cryomodules. Each individual vacuum vessel will be closed at both ends and the cryogenic circuits will be fed through bayonet connections at each cryomodule. Each cryomodule will have its own connection to the insulating vacuum pumping system. Also, each cryomodule will have its own 2 K heat exchanger and pressure relief line exiting near the middle of the module. This configuration provides flexibility in terms of cryomodule replacement and cooldown and warm-up times at the expense of requiring more individual cryogenic connections, cold-to-warm transitions at each end of each cryomodule, and extra space at each interconnect to close the beam tube.

Vacuum Vessel

The vacuum vessel serves to house all the cryomodule components in their as-installed positions, to provide a secure anchor to the tunnel floor, to insulate all cryogenic components in order to minimize heat load to 80 K, 4.5 K, and 2 K, as well as maintain the insulating vacuum. It is 1.219 m (48 inches) in diameter.

Magnetic Shield

Just inside the vacuum vessel, nearly in contact with the inner wall, is a magnetic shield to shield the cavities from the earth's field. Preliminary tests show that a 1.5 mm-thick mu-metal shield at room temperature reduces

* Supported by FRA under DOE Contract DE-AC02-07CH11359
# tnicol@fnal.gov

Copyright © 2013 CC-BY-3.0 and by the respective authors

the residual field inside the cryostat to less than 10 μT. It is likely that separate magnetic shields will be installed around individual magnetic elements to further reduce trapped fields in the superconducting cavities.

Thermal Shield and Multi-Layer Insulation

Each cryomodule will have a single thermal shield cooled with helium gas, nominally at 45-80 K. It is currently envisioned to be aluminum with cooling channels on both sides. Two 15-layer blankets of multi-layer insulation, between the vacuum vessel and thermal shield will reduce the radiation heat load from the room temperature vacuum vessel to approximately 1.5 W/m^2. A 5 K circuit will be available to intercept heat on the input couplers and current leads, but there is no plan to install a full 5 K thermal shield.

Support System

All of the cavities and solenoids will be mounted on individual support posts which are in turn mounted to a full-length strongback located between the vacuum vessel and thermal shield. This enables the entire cavity string to be assembled and aligned as a unit then inserted into the vacuum vessel during final assembly. Presently, the strongback is aluminum, but stainless steel is an option. Maintaining the strongback at room temperature helps minimize axial movement of the cold elements during cooldown, reducing displacement of couplers, current leads, and many other internal piping components.

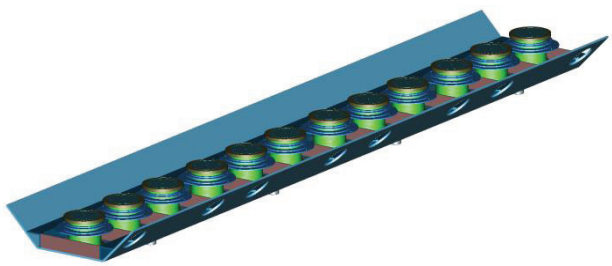

Figure 2: Strongback assembly.

The support posts are similar to supports utilized in SSC collider dipole magnets and ILC and XFEL 1.3 GHz cavity cryomodules. The main structural element is a glass and epoxy composite tube. The tube ends and the intermediate thermal intercepts are all assembled using a shrink-fit technique in which the composite tube is sandwiched between an outer metal ring and inner metal disk [1]. The strongback and support posts are shown in Fig. 2. All the cavities and solenoids are mounted to the support posts using adjustable positioning mechanisms.

Cavity and Tuner

The cryomodule contains eight single spoke, β=0.22, 325 MHz cavities operating in CW mode at 2 K in stainless steel helium vessels. Each has integral coarse and fine tuners that operate through a lever system and push on the cavity end wall. For ease of maintenance, tuner access covers are incorporated into the helium vessel design. The cavity and tuner system is shown in Fig. 3 and described more completely in [2].

Figure 3: Dressed cavity and tuner.

Input Coupler

The input coupler is a 105-ohm coaxial design that supplies approximately 2 kW CW to each cavity in PXIE and ultimately up to 18 kW CW in Project X. The coupler contains a single warm ceramic window. During cryomodule fabrication, the cold section is installed on the cavity in the cleanroom prior to assembly of the string. The warm section is installed from outside the vacuum vessel during final assembly. The inner conductor is solid copper with copper plated bellows to accommodate motion due to misalignment and thermal contraction. The cold end of the outer conductor is 316L-stainless steel. The warm end is copper with copper plated bellows. Heat load estimates don't suggest a significant penalty for not copper plating the outer conductor. A forced-air cooling tube is inserted into the inner conductor after assembly that supplies air to cool the coupler tip. Fig. 4 shows the current coupler design. The input coupler design is described more thoroughly in [3].

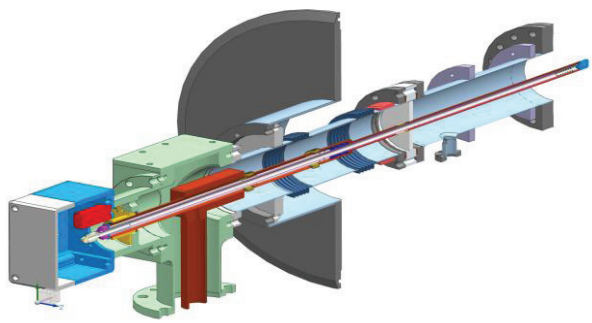

Figure 4: Input coupler assembly.

Current Leads

Each solenoid package contains three magnet coils, the main solenoid, operating nominally at 100 A and two steering correctors each operating nominally at 50 A. A conduction cooled current lead design modeled after similar leads installed in the LHC at CERN is being

Copyright © 2013 CC-BY-3.0 and by the respective authors

developed for use in PXIE [4]. Fig. 5 illustrates the conceptual design for the lead assembly. Thermal intercepts at 45-80 K and 5 K reduce the heat load to 2 K, nonetheless, these current leads represent a significant source of heat at the low temperature end. There will be one lead assembly for each magnetic element.

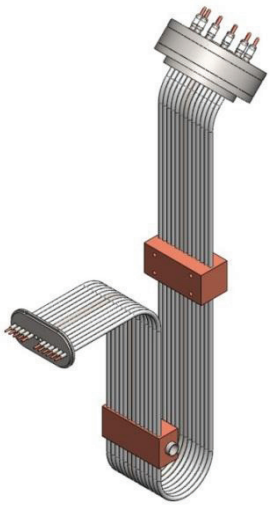

Figure 5: Conduction cooled current lead assembly.

Solenoid and Beam Position Monitor

The four magnet packages in the cryomodule each contain a focusing solenoid and two dipole correctors all operating in a helium bath at 2 K. The Project X lattice provides little room along the beamline for diagnostics either inside individual cryomodules or between adjacent modules. To conserve axial space along the beamline a button-type BPM has been chosen for installation in the SSR1 cryomodules. A total of four will be installed in the cryomodule and tested in PXIE, one at each solenoid. These devices are compact and lend themselves well to incorporation into the solenoid magnet package as shown below in Fig. 6. The bellows at either end of the beam tube allow independent adjustment of each magnet.

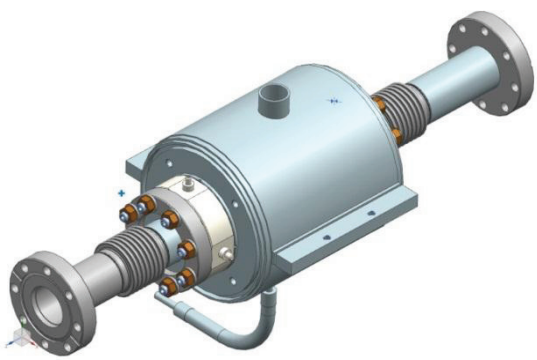

Figure 6: Focusing solenoid and BPM.

Final Assembly

The final assembly of the SSR1 cryomodule for PXIE is shown in Fig. 7.

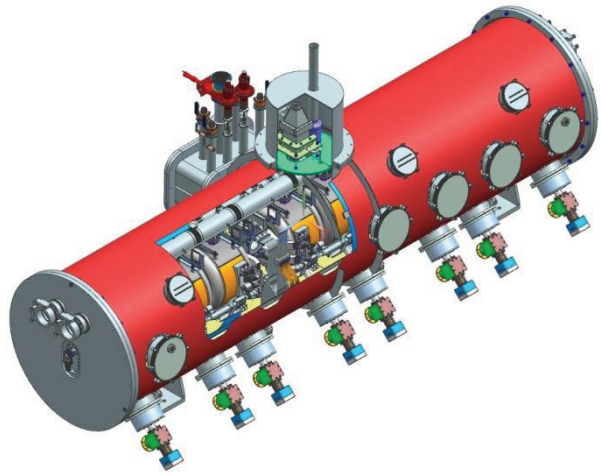

Figure 7: Final assembly.

HEAT LOAD ESTIMATE

Table 1 summarizes the estimated static and dynamic heat loads to each temperature level in the cryomodule assembly from the primary sources.

Table 1: Heat Load Summary for PXIE Cryomodule (W)

SSR1 (8 cav, 4 sol)	**70 K**	**4.5 K**	**2 K**
Input coupler static	42.88	22.56	4.00
Input coupler dynamic	0.00	0.00	2.00
Cavity dynamic load	0.00	0.00	14.24
Support post	33.12	4.32	0.60
Conduction lead assy	85.60	43.60	5.92
MLI (total 70 K + 2 K)	30.54	0.00	1.42
Cold to-warm transition	1.44	0.16	0.02
Total	**193.6**	**70.6**	**28.2**

SUMMARY

The design and modeling of the SSR1 cryomodule for PXIE is nearly complete and detailed drawings for the strongback, supports, and vacuum vessel are ready for procurement. In the coming months further details will be completed with the goal of beginning production of this first 325 MHz SSR1 cryomodule in FY14 [5].

Abstract

In the Neutrino Factory and Muon Collider muons are produced by firing high energy protons onto a target to produce pions. The pions decay to muons which are then accelerated. This method of pion production results in significant background from protons and electrons, which may result in heat deposition on superconducting materials and activation of the machine preventing manual handling. In this paper we discuss the design of a secondary particle handling system. The system comprises a solenoidal chicane that filters high momentum particles, followed by a proton absorber that reduces the energy of all particles, resulting in the rejection of low energy protons that pass through the solenoid chicane. We detail the design and optimization of the system and energy deposition and shielding analysis in MARS15(2012).

INTRODUCTION

The baseline target concept for a Muon Collider or a Neutrino Factory [1] is a free jet of mercury impacted by a 4-MW, 8-GeV proton beam at 50 Hz within a 20-T magnetic field [2]. The magnetic field is produced by a coaxial array of cryogenically cooled superconducting (SC) coils and water-cooled resistive magnets. The superconducting coils are protected from secondary radiation from the target by internal shielding of He-gas-cooled tungsten beads.

The design proton beam energy and power will be approached in stages [2], beginning with a 1-MW, 3-GeV proton beam. A solid carbon target can be used in the initial stage, and replaced with a mercury target module at a later stage when higher beam power is utilized.

The 20-T field on the target is reduced to 1.5 T in a tapering field profile over $\approx$ 5 m, beyond which is an $\approx$ 60-m-long, 1.5-T solenoidal Decay Channel where secondary pions decay to form the muon beam. Roughly 10% of the proton beam power is transported into the Decay Channel [3, 4], mainly via soft protons from breakup of target nuclei, and energetic protons scattered from the beam. These protons would be transported by the Decay Channel into subsequent components of the Muon Collider/Neutrino Factory Front End [5], the Buncher, Phase Rotator, and Ionization Cooling sections. To minimize radiation damage to these components, and to keep their activation low enough that hands-on maintenance is feasible, the secondary protons should be removed from the Decay Channel. This is to be accomplished via a bent-solenoid chicane [6], sketched in Fig.1, in which most proton of energy above 500 MeV are deflected out of the Decay Channel, and by a 10-cm-thick Be absorber which removes most protons of lower energy.

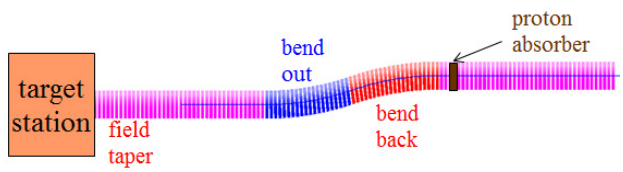

Figure 1: Sketch of the pion-production and Decay Channel, including a chicane to suppress energetic protons and an absorber for soft protons.

ENERGY DEPOSITION STUDIES

The higher-energy particles (mostly protons) which leave the beam in the chicane would pass through the coils of the bent solenoids unless the latter have adequate internal shielding. As for the superconducting coils of the target-system upstream of the chicane, we desire that the maximum energy deposition in the coils be less that 0.1 mW/g to permit an operational lifetime greater than 10 years of 10^7 s. This criterion is taken from studies [7] conducted for the ITER project.

To evaluate the amount of shielding required for the magnets of the Decay Channel chicane, we used a MARS15(2012) [8] simulation with field maps generated by G4beamline [9]. A preliminary version of these studies was reported in [10].

Given the complicated geometry of the chicane, adding tungsten shielding was not straightforward using only MARS extended geometry. However, a recently developed ROOT-based geometry framework [11] for MARS has made the task manageable with a wide variety of basic volumes provided by the ROOT TGeo module. The

TGeoCtub elementary volume (cut tubes with arbitrary entrance and exit angles) proved to be the most important for seamless shielding. The fact that the volume of each shielding or coil segment can be calculated precisely in ROOT removes the uncertainty intrinsic to MARS Monte-Carlo based volume calculation. Parts of the chicane as defined using ROOT are shown in Fig. 2.

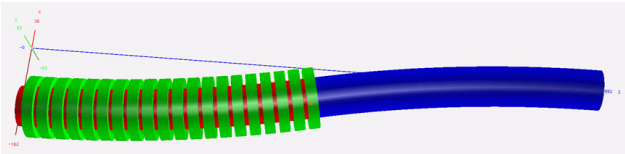

Figure 2: Chicane geometry as defined using ROOT. Red: shield, bend in; blue: shield, bend out; green: solenoidal coils of the bend-in.

In a straight solenoid with uniform field, particles move in helices about the (straight) trajectory of their "guiding center." The magnetic field of a bent solenoid, as in each half of the chicane, is toroidal, and the guiding center undergoes "curvature drift" perpendicular to the plane of the toroidal field [12]. For the 1.5-T field of the decay channel, whose beampipe has 30 cm radius, the curvature drift deforms the shape of the beam into an ellipse with semimajor axis of length 42 cm at the center of the chicane.

In a first study of possible shielding configuration for the chicane, the beampipe was assumed to have radius 42 cm, and the thickness of the tungsten-bead shielding was 35 cm. Figure 3 shows a "horizontal" section of the model of the chicane, together with contours of energy deposition as simulated by MARS15(2012).

The average power deposition in the superconducting coils of the chicane, averaged over azimuth, for the model of Fig. 3 is shown as the blue curve in Fig.4 as a function of position along the chicane, and is everywhere less than the "ITER" limit of 0.1 mW/g. To estimate the peak energy deposition in the coils, the MARS model was segmented azimuthally, leading to the results shown in the blue curve of Fig. 5, where the deposition in a few regions remains above the "ITER" limit.

In a second iteration of the study, only the central 4 m of the chicane was modeled with a beampipe of 40 cm radius, with the outer segments having a beampipe of 30 cm radius, as shown in Fig. 6. The thickness of the shielding in the central portion of the chicane was taken to have 40 cm thickness, while the thickness of the shielding was only 30 cm in the outer portions of the chicane. Contours of energy deposition in the midplane of the chicane are shown in Fig. 6, with the azimuthally averaged energy deposition, and the peak energy deposition, shown in red in Figs. 4 and 5, respectively. The thickness of the shielding downstream of the chicane was only 5 cm, which is not quite adequate, as shown in Fig. 5.

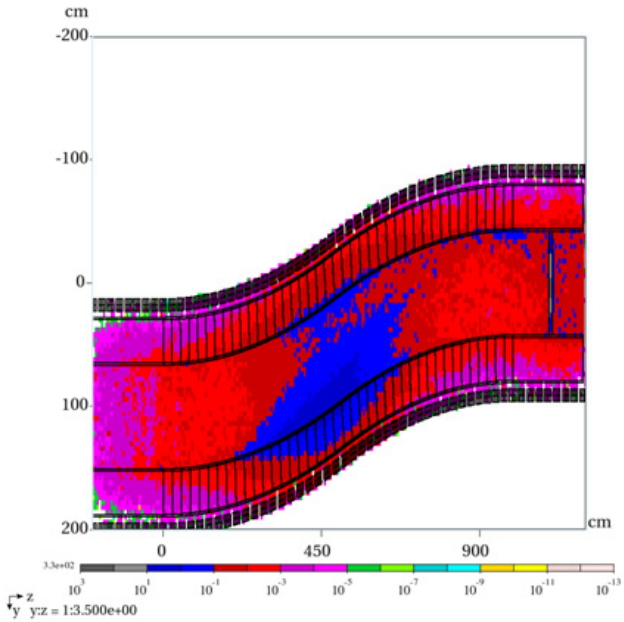

Figure 3: MARS15(2012) simulation of energy deposition in a model of the chicane with beampipe of 42 cm radius, surrounded by 35-cm-thick tungsten-bead shielding.

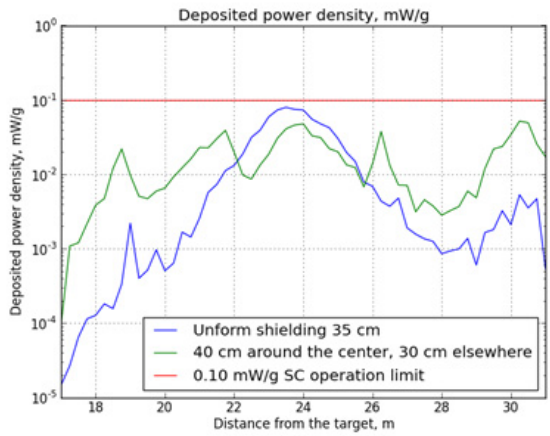

Figure 4: Simulated energy deposition in the superconducting coils of the chicane, average over azimuth.

SUMMARY

The models of shielding of the superconducting coils of the chicane investigated to date (based on MARS15(2012) simulations in the Default mode) appear to be close to providing sufficient protection against radiation damage for an operational lifetime in excess of 10 years. Simulations using MARS15 with MCNP data tables will be performed to evaluate better the energy deposition by low-energy neutrons, which may have been underestimated in the studies to date. Next steps in the studies are to introduce a beampipe which changes its cross section from circular to elliptical and back to circular along the chicane, along with shielding whose inner surface matches the beampipe

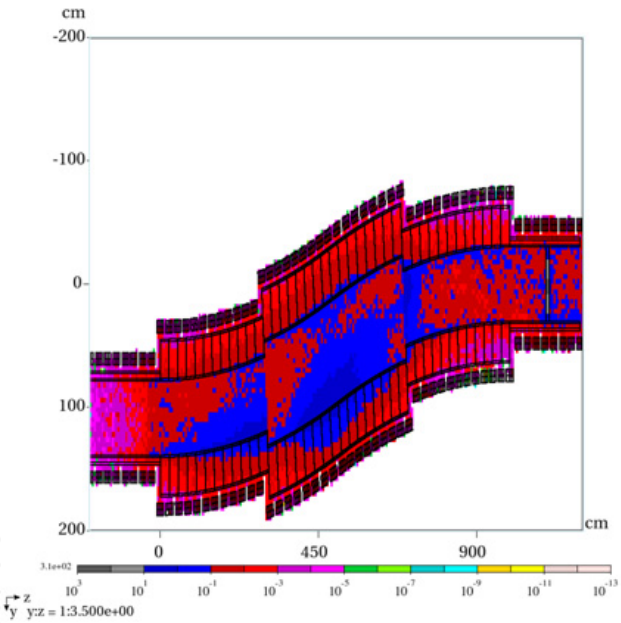

Figure 6: MARS15(2012) simulation of energy deposition in a model of the chicane with non-uniform beampipe of 42 cm radius around the central part of the chicane and 30 cm elsewhere, surrounded by 40 cm of tungsten-bead shielding around the central part of the chicane and 30 cm elsewhere.

and whose outer surface is circular, and with thickness that varies along the chicane.

Abstract

A first stage of a Neutrino Factory based on muon beams might use a pulsed 3-GeV proton beam with 1-MW average power. We report on optimization of particle production by a carbon target inside a solenoid magnet for this scenario.

INTRODUCTION

The ultimate option for the final stage of a Neutrino Factory (NF) in the Muon Accelerator Program [1] is to use a 8-GeV (or more) proton beam of 4-MW average power interacting with a free-flowing mercury jet to create copious amounts of pions that are captured in a high-field solenoid magnet system. Two capture systems, referred to as IDS120h and IDS120j, as sketched in Fig. 1 have been used for the present study. Figure 2 shows that the axial magnetic field for both the IDS120h tapers adiabatically from 20 T and the IDS120j tapers from 15 T around the target to 1.5 T at the end of the target system. The inner radius of superconducting coils (SC) in the region surrounding the mercury jet target region is 120 cm to permit sufficient internal tungsten shielding for a 10-year operational lifetime of the SC coils against radiation damage [2].

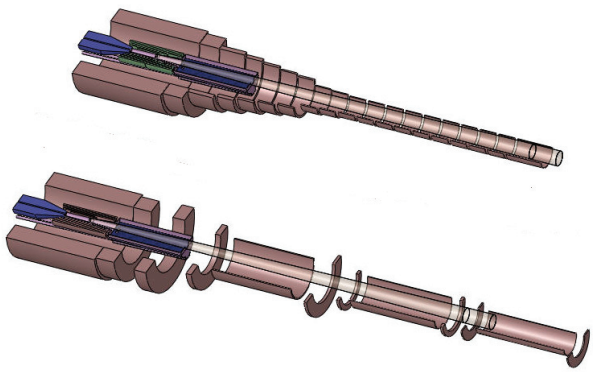

Figure 1: Lower half of the IDS120h (top) and IDS120j (bottom) target system.

A key feature in the staging scenarios [1] for a Neutrino Factory is initial operation of the proton driver at 3-GeV beam energy and 1-MW average beam power. As was noted in previous study, a radiation-cooled graphite target is a viable option for a 1-MW proton beam [3].

The particle production at the target depends on the target geometry as shown in Fig. 3, which illustrates the length and radius of the target, the radius of the proton beam, the orientation of the proton beam relative to the magnetic field, and the angle of the beam and target relative to each other (both of which lie in a vertical plane).

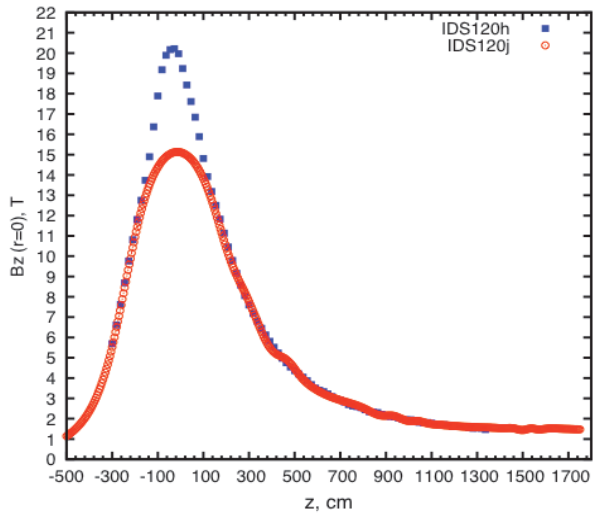

Figure 2: Longitudinal magnetic field along the solenoid axis of SC coils in the IDS120h (dashed line) and IDS120j (solid line) front-end channel.

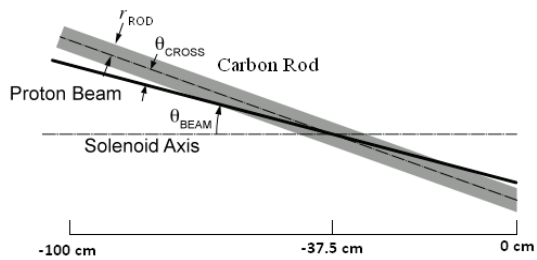

Figure 3: The carbon-target geometry. The proton beam and carbon target cross at z = -37.5 cm. The proton beam is launched at z = -100 cm.

In this paper, we report on the optimization of particle production (pion and muon yields) by a carbon target inside a solenoid magnet of IDS120h or IDS120j configuration. The pions and muons of interest for a Neutrino Factory are those with kinetic energies between 40 and 180 MeV, and we report rates of these at the transverse planes z = 0 m (downstream end of the beam/target interaction region) and z = 50 m.

We used four modes of the MARS15(2012) code [4] (denoted MARS15 below), as well as the FLUKA code [5]. The MARS15 modes used in this study were

Mode 1: MARS15 default mode (without either LAQGSM or the MCNP tables);

Mode 2: MARS15 with MCNPDATA (with the MCNP tables but without the LAQGSM mode);

Mode 3: MARS15 in LAQGSM mode (with the LAQGSM mode but without the MCNP tables);

Mode 4: MARS15 in LAQGSM mode with MCNPDATA (with both the LAQGSM mode and the MCNP tables).

OPTIMIZED TARGET PARAMETERS AND PARTICLE PRODUCTION OF IDS120H CONFIGURATION

Using the MARS15 default mode (Mode 1), our optimization started with a 3-GeV proton beam impinging on a carbon target with IDS120h configuration. The initial target radius was chosen as 0.75 cm and the target angle as 50 mrad to the solenoid axis of the SC coils [3]. The target and beam were tilted by the same angle with respect to the solenoid axis, while the beam radius (RMS spot size) was fixed to be either ¼, 1/3.5 or 1/2.5 of the target radius. Several runs were performed during each optimization cycle. In run 1 we varied the target length while keeping initial target radius, target angle fixed; in run 2 we varied the target radius using the new target length while keeping the target angle fixed; and in run 3 we varied the target angle with the new target radius. We repeated the above until convergence was achieved.

Figure 4 depicts the particle production as a function of target length, which shows that the target length corresponding to the peak of production is at 72 cm.

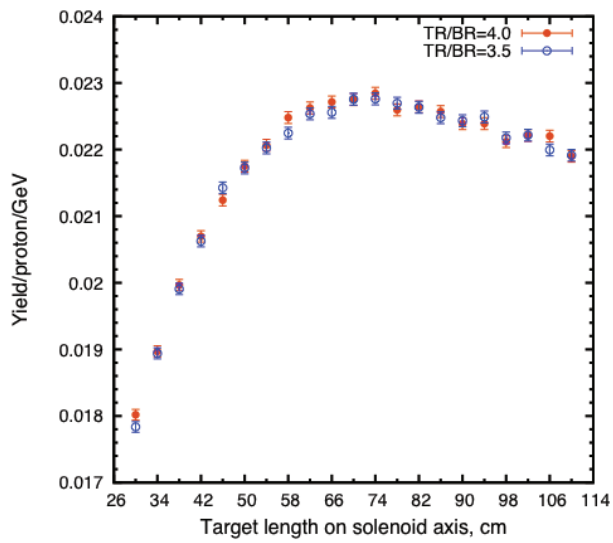

Figure 4: Particle production yields as a function of target length (TR/BR = target radius / beam radius).

Figure 5 shows the variation of particle production with target radius. The production is maximized when the target has a radius of 0.346 cm for a beam radius equal to 1/4 of this.

Figure 6 shows the particle production as a function of beam angle, with a peak around 42 mrad, when the beam radius is 0.0865 cm and the target has a length and radius of 72 cm and 0.346 cm, respectively. In comparison with the results of our initial setting in Fig. 4, the optimization has given a 15% increase in the peak of particle production (from 0.0228 to 0.0262 per proton per GeV).

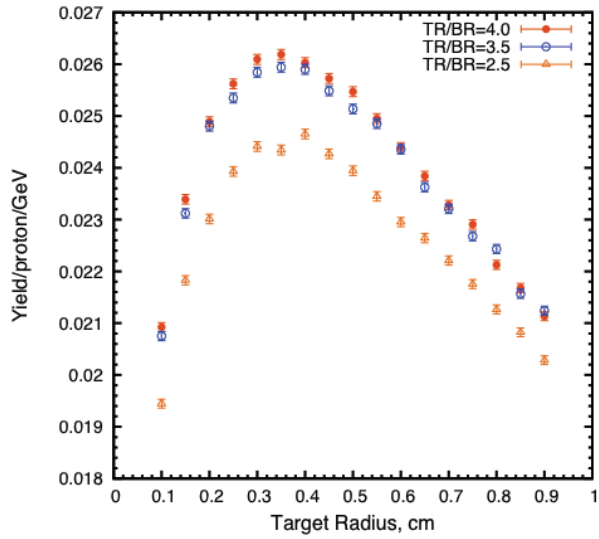

Figure 5: Particle production yields as a function of target radius.

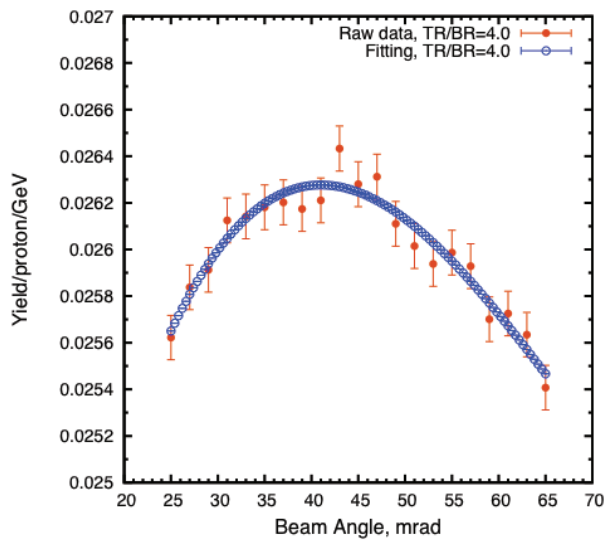

Figure 6: Particle production yields as a function of beam angle.

PARTICLE PRODUCTION AND ENERGY SPECTRA OF IDS120J CONFIGURATION

The above optimization of the carbon target in the IDS120h configuration for a 3 GeV proton beam was used as a starting point for studying particle production and energy spectra for the IDS120h configuration. Table 1 shows the particle production results using 10^5 incoming 3-GeV protons. The results using MARS 15 Modes 1 and 2 are similar, as are also those of Modes 3 and 4, which indicates that use of the optional MCNP mode in MARS15 does not play an important role in the particle production study.

Figures 7 and 8 show secondary-particle energy spectra from MARS15 Modes 1 and 4, respectively, and their

Copyright © 2013 CC-BY-3.0 and by the respective authors

comparison with FLUKA. A strange shape with both a peak and shoulder of soft pions at z = 0 m was observed using MARS15 Mode 1. However, this was not present when MARS15 was used in the LAQGSM mode, for which the results were more compatible with those from FLUKA.

Table 1: Particle Production Yields for the IDS120j Configuration using MARS15 and FLUKA

Running	Yield/proton/GeV z = 0 m	Yield/proton/GeV z = 50 m
MARS15 Mode 1	0.0341	0.0261
MARS15 Mode 2	0.0335	0.0254
MARS15 Mode 3	0.0299	0.0279
MARS15 Mode 4	0.0296	0.0273
FLUKA	0.0334	0.0298

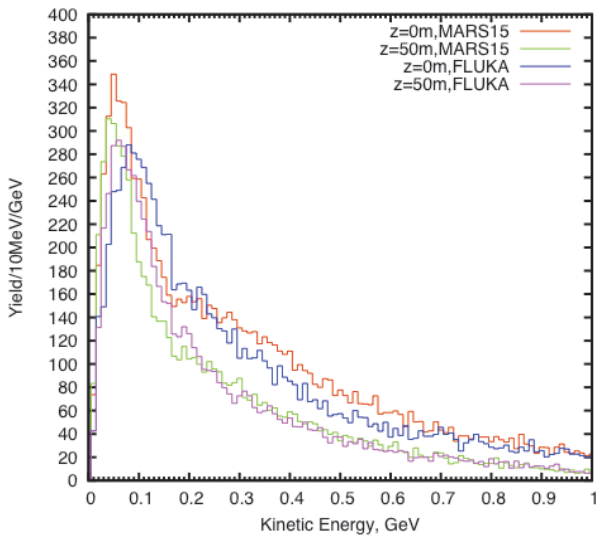

Figure 7: Energy spectra of all positive and negative pions and muons for 3 GeV protons at z = 0 m and z = 50 m for a carbon target from MARS15 Mode 1 and FLUKA.

CONCLUSIONS

With optimization of the geometric parameters for a carbon target impinged by a 3 GeV proton beam, particle production is around 0.0262 per proton per GeV when the target length is set at 72 cm, target radius at 0.346 cm, beam radius at 0.0865 cm and beam angle at 42 mrad for the IDS120h configuration. With these target parameters, we also studied four running modes of MARS15 for the IDS120j configuration and found energy spectra are comparable with those of FLUKA when the MARS15(2102) in LAQGSM mode with MCNPDATA was used. Production of negative pions from a carbon target with a 3-GeV proton beam is only about half that for positives in the energy range useful for a Neutrino Factory, which implies that there would be twice as many $\bar{\nu}_\mu$ (ν_e) as ν_μ($\bar{\nu}_e$) from a Neutrino Factory with these parameters.

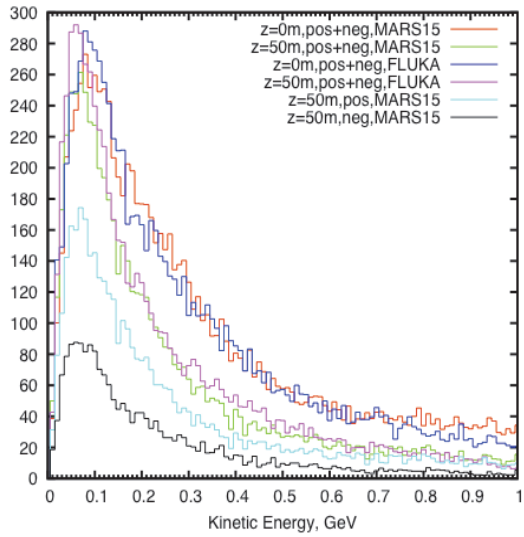

Figure 8: Energy spectra of all positive and negative pions and muons for 3 GeV protons at z = 0 m and z = 50 m for a carbon target from both MARS15 Mode 4 and FLUKA. Energy spectra of positive or negative pions and muons at z = 50 m from MARS15 Mode 4 are also shown.

ACKNOWLEDGMENT

We thank other colleagues from the Target Studies Collaboration for their help concerning this work.

A BUNCH LENGTH MONITOR FOR JLAB 12 GeV UPGRADE*

M. M. Ali, A. Freyberger, G. Krafft, J. Gubeli
Jefferson Lab, Newport News,VA 23606, USA

Abstract

A continuous non-invasive bunch length monitor for the 12 GeV upgrade of Jefferson Lab will be used to determine the bunch length of the beam. The measurement will be done at the fourth dipole of the injector chicane at 123 MeV using the coherent synchrotron light emitted from the dipole. The estimated bunch length is 333 fs. A vacuum chamber will be fabricated and a Radiabeam real time interferometer will be used. In this paper, background, the estimated calculations and the construction of the chamber will be discussed

INTRODUCTION

In recent days, many accelerators use short electron bunches. Measuring bunch length is important for operating and characterizing the accelerator. Bunch length measurement can be classified as invasive techniques such as zero-phasing [1] and deflecting cavity [2] or non-invasive techniques such as electro-optical sampling [3] and interferometers [4],[5]. In Jefferson Laboratory (JLab), we are going to measure the bunch length for the 12 Gev upgrade using the radiabeam Real time interferometer (RTI) [6]. The RTI is a solid state, compact and non-destructive. The experiment will be based on the Synchorotron light which will be emitted from the last bending magnet of the injector chicane. When the bunch length of the electron beam is shorter than the radiation wavelength, the electrons radiate in phase and the radiation power becomes proportional to the square of number of electrons per bunch (N^2) [7].

$$P_{total}(\lambda) = P(\lambda)[N + N(N-1)f(\lambda)] \quad (1)$$

where $P(\lambda)$ is the power radiated by single electron and $f(\lambda)$ is the form factor given by

$$f(\lambda) = |\int S(z) exp(\frac{-2\pi i z}{\lambda}) dz|^2 \quad (2)$$

where S(z) is the normalized longitudinal distribution function, z is the longitudinal position of the electrons and λ is the radiation wavelength. The form factor equals zero when the radiation is incoherent & equals one when the radiation is coherent.

COMPRESSION CALCULATION

In accelerator beam optics, the equation for an ellipse is normalized so ϵ the area of ellipse divided by π is on the right hand side. The general equation is given by

$$\gamma(\Delta\phi)^2 + 2\alpha(\Delta\phi)(\Delta E) + \beta(\Delta E)^2 = \epsilon \quad (3)$$

By compression, we desire to convert a horizontal upright ellipse to a tilted ellipse. The transformation array is given by

$$\begin{bmatrix} \Delta\phi' \\ \Delta E' \end{bmatrix} = \begin{bmatrix} M_{11} & M_{12} \\ M_{12} & M_{22} \end{bmatrix} \begin{bmatrix} \Delta\phi \\ \Delta E \end{bmatrix} \quad (4)$$

Equation(4) can be written as

$$\begin{bmatrix} \Delta\phi \\ \Delta E \end{bmatrix} = \begin{bmatrix} (M^{-1})_{11} & (M^{-1})_{12} \\ (M^{-1})_{12} & (M^{-1})_{22} \end{bmatrix} \begin{bmatrix} \Delta\phi' \\ \Delta E' \end{bmatrix} \quad (5)$$

Substituting by the values of it from eq.(5) into equation(3) and adding the terms of $(\Delta\phi')^2$, $(\Delta E')^2$ and $\Delta\phi'\Delta E'$, then the tilted ellipse twiss parameters will be

$$\gamma_1 = (M_{11}^{-1})^2\gamma_0 + 2(M_{11}^{-1})(M_{21}^{-1})\alpha_0 + (M_{21}^{-1})^2\beta_0 \quad (6)$$

$$\begin{aligned}\alpha_1 = {} & (M_{11}^{-1})(M_{12}^{-1})\gamma_0 \\ & + \left[(M_{11}^{-1})(M_{22}^{-1}) + (M_{12}^{-1})(M_{21}^{-1})\right]\alpha_0 \\ & + (M_{21}^{-1})(M_{22}^{-1})\beta_0 \end{aligned} \quad (7)$$

$$\beta_1 = (M_{12}^{-1})^2\gamma_0 + 2(M_{12}^{-1})(M_{22}^{-1})\alpha_0 + (M_{22}^{-1})^2\beta_0 \quad (8)$$

Assume that the longitudinal phase space distribution is a horizontal upright ellipse before compression with $\sigma_{\phi 0}$ and σ_{E0} as initial values for the bunch length and energy respectively. After the compression it will be $\sigma_{\phi,opt}$ and $\sigma_{E,opt}$ as shown in figure(1). let *M* be the magnification factor, so the bunch length will be compressed by a factor $\frac{1}{M}$ and to achieve the maximum minimum energy spread after compression, *M* must equal $\frac{\sigma_{\phi 0}}{\sigma_{\phi,opt}}$.

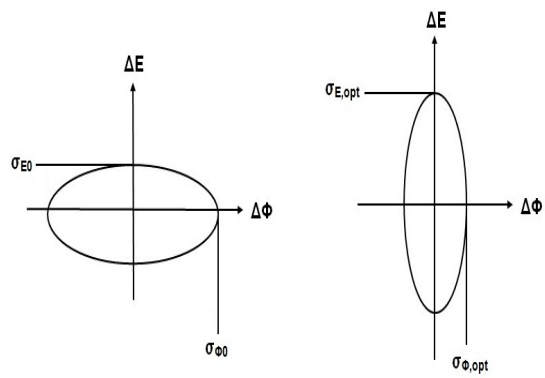

Figure 1: Phase space before & after compression.

* Work supported by the U.S. Department of energy under U.S. DOE Contract No. DE-AC05-06OR23177

Copyright © 2013 CC-BY-3.0 and by the respective authors

When there is a chirp, the horizontal upright ellipse will transform into a tilted ellipse and the transformation equation is given by

$$\begin{bmatrix} \Delta\phi_1 \\ \Delta E_1 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ -s & 1 \end{bmatrix} \begin{bmatrix} \Delta\phi_0 \\ \Delta E_0 \end{bmatrix} \quad (9)$$

Where $s = V \sin\phi$, V is the cavity offset voltage from the crest and ϕ is the offset phase from the crest in radians. Using the same technique as discussed before in equations [6,7 & 8] and notice that $\alpha_0 = 0$ when the ellipse was horizontal upright, then the new twiss parameters are

$$\gamma_1 = \gamma_0 + s^2\beta_0 \quad (10)$$

$$\alpha_1 = s\beta_0 \quad (11)$$

$$\beta_1 = \beta_0 \quad (12)$$

Since the amplification factor *M* is defined as "the new vertical distance divide by the old vertical distance" or "old horizontal distance divide by new horizontal distance", so $M = \sqrt{\frac{\gamma_1\epsilon}{\gamma_0\epsilon}}$.

Since $\epsilon = \sigma_{\phi 0}\sigma_{E0}$ $\quad \sigma_{\phi 0} = \sqrt{\beta_0\epsilon}$ $\quad \sigma_{E0} = \sqrt{\gamma_0\epsilon}$

$$\beta_0 = \frac{\sigma_{\phi 0}}{\sigma_{E0}} \quad (13)$$

$$\gamma_0 = \frac{\sigma_{E0}}{\sigma_{\phi 0}} \quad (14)$$

Square *M* and substitute by the previous values of γ_1, γ_0 and β_0

$$M^2 = 1 + s^2\frac{\beta_0}{\gamma_0} = 1 + s^2\frac{\sigma_{\phi 0}^2}{\sigma_{E0}^2} \quad (15)$$

The linear transfer matrix for the chicane is given by

$$\begin{bmatrix} \Delta\phi_2 \\ \Delta E_2 \end{bmatrix} = \begin{bmatrix} 1 & \frac{2\pi M_{56}}{\lambda E_{inj}} \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \Delta\phi_1 \\ \Delta E_1 \end{bmatrix} \quad (16)$$

Where λ is the RF wavelength and E_{inj} is the energy at which the compression is done. Again using the same procedure as mentioned before, the final twiss parameters will be

$$\gamma_2 = \gamma_1 \quad (17)$$

$$\alpha_2 = -K\gamma_1 + \alpha_1 \quad (18)$$

$$\beta_2 = K^2\gamma_1 - 2K\alpha_1 + \beta_1 \quad (19)$$

Where $K = \frac{2\pi M_{56}}{\lambda E_{inj}}$. Since the ellipse transforms into a vertical upright ellipse, so $\alpha_2 = 0$, and from eq.(18) the maximum compression condition becomes

$$K = \frac{\alpha_1}{\gamma_1} = \frac{s\beta_0}{\gamma_0(1 + \frac{s^2\sigma_{\phi 0}^2}{\sigma_{E0}^2})} \quad (20)$$

$$M_{56} = \frac{\lambda E_{inj}}{2\pi} \times \frac{s\sigma_{\phi 0}^2}{\sigma_{E0}^2(1 + \frac{s^2\sigma_{\phi 0}^2}{\sigma_{E0}^2})} \quad (21)$$

From equation(15) $\quad M^2 - 1 = \frac{s^2\sigma_{\phi 0}}{\sigma_{E0}^2}$ $\quad$ and finally

$$M_{56} = \frac{\lambda E_{inj}}{2\pi s}\frac{M^2 - 1}{M^2} \quad (22)$$

CALCULATIONS

The Jlab injector chicane consists of nine quads and four dipole magnets with bending radius 3.125 m, the magnetic field is 1.3128 kG, the length of magnet is 30 cm and the bending angle is 5.5^0 as shown in figure(2). One would like

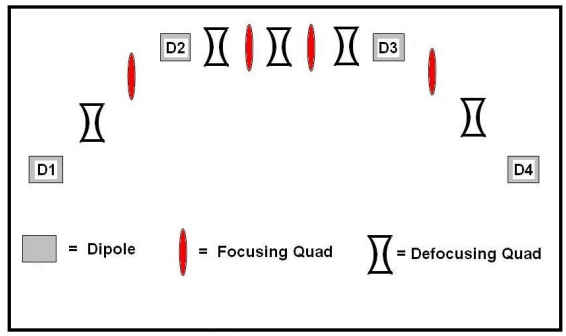

Figure 2: The Chicane.

to compare the bunch length at the third and fourth dipoles of the chicane in order to decide which place is better to do the experiment. Since the value of λ is 20 cm, E_{inj} is 67×10^6 keV and ϵ is 98.25 eV.rad then the bunch length will be calculated as follows.

For the fourth dipole, substituting with $M_{56} = 24$ cm in equation (21) and solving for s, one would find two values for s either 0.635×10^6 eV/rad or 8.256×10^6 eV/rad. Substituting from equations (10, 11 & 12) into equation (19), then

$$\beta_2 = K^2(\alpha_0 + s^2\beta_0) - 2Ks\beta_0 + \beta_0 \quad (23)$$

Substituting with s values, γ_0, β_0 and K value for $M_{56} = 24$ cm in equation (23), then β_2 is 0.031×10^{-6} rad/eV. Doing the same for $M_{56} = 12$ cm, then β_2 is 0.133×10^{-6} rad/eV. Substituting with the those values in $\sqrt{\epsilon\beta_2}$, the bunch length is 1.745×10^{-3} rad for ($M_{56} = 24$) and 3.6×10^{-3} rad for ($M_{56} = 12$). From these result, one can conclude that the bunch length will almost compress to its half value after the 3^{rd} dipole and compress fully after the 4^{th} dipole, then the best place to do the experiment is after the 4^{th} dipole.

A plane mirror will be used to deflect the synchorotron radiation to the RTI and it will confront a 3.25 degrees out of 5.5 degrees of the synchrotron radiation fan. The total energy per unit angular frequency emitted by a single electron moving on a circular orbit is given by [8]

$$\frac{dE}{d\omega} = \frac{9\sqrt{3}}{8\pi\omega_c}\frac{e^2\gamma^4}{3\rho\epsilon_0}y\int_y^\infty K_{5/3}(x)dx \quad (24)$$

where e is the electronic charge, γ is the relativistic factor, ρ is the bending radius, ϵ_0 is the free space permittivity, $K_{5/3}$ is the modified Bessel function and $y = \frac{\omega}{\omega_c}$, where $\omega_c = \frac{3}{2}\gamma^3\frac{c}{\rho}$ is the critical angular frequency. Since the radiation will be collected by a mirror at an angle $\Delta\theta = 3.25$ then

Copyright © 2013 CC-BY-3.0 and by the respective authors

the energy between two angular frequencies ω_1 and ω_2 is

$$E = \frac{3.25}{360}\frac{9\sqrt{3}}{8\pi}\frac{e^2\gamma^4}{3\rho\epsilon_0}\int_{y_1}^{y_2} y\int_{y}^{\infty} K_{5/3}(x)dxdy \qquad (25)$$

Since the repetition rate in JLAB is 500 MHz, power can be estimated by assuming the form factor is a Gaussian distribution, multiplying eq.(24) by $\frac{3.25}{360}$ and using equations (1), (2) then the estimated calculations for the power distribution as a function of wavelength for different bunch lengths is shown in fig (3).

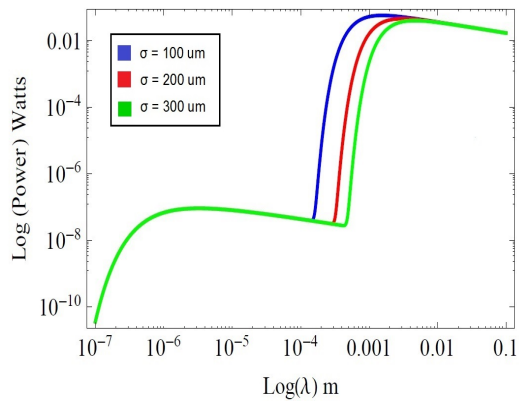

Figure 3: Power spectrum for different bunch lengths.

CONSTRUCTION OF THE CHAMBER

The old chamber and its component is shown in fig(4a) while the new one is shown in fig(4b). The new chamber is built with four additional ports, two of them are for the laser alignment assembly and the Synchorotron light (SL) assembly, while the other two is for the insertable mirror assembly. The difference between the new and old line is that the spool section is removed. The new chamber is made from 316 stainless steal with the same thickness as the old one so, it will have the same magnetic permeability. The chamber elastic limit is measured under vacuum and found to be 70 MPa which is much less than the elastic limit of the stainless steel.

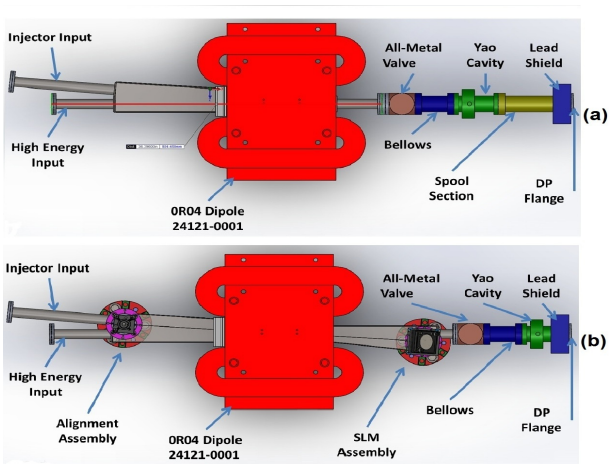

Figure 4: Old and new chamber.

The four assemblies are mounted on a rotatable flange with jacking screws to provide small angular correction as shown in fig(5). The alignment laser assembly has a cage

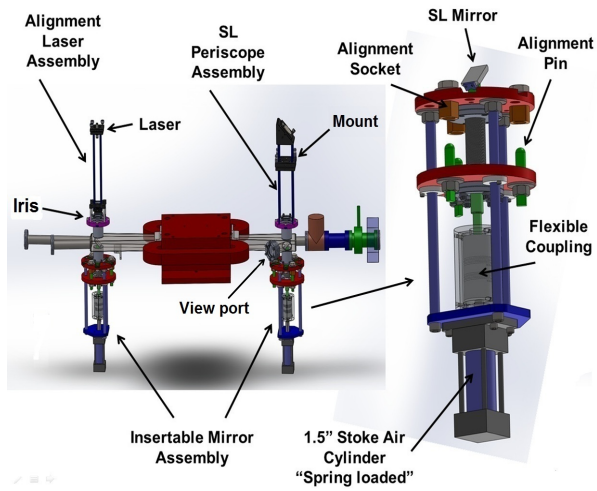

Figure 5: Chamber with laser & SL assembly.

system with a laser diode to help in the alignment. The insertable mirror assembly has a mirror in each one, one to help in the laser alignment while the other is to receive the synchorotron light and reflected upward to the RTI. Both assemblies are attached to stroke air cylinder which is a spring loaded to fail out in case losing air or electrical signals. Also, the chamber has a view port to make sure that the initial laser alignment is on the right spot.

CONCLUSION

The chamber will be installed by the end of the year and as the upgrade finishes, the RTI will be installed. The measurements will be taken in the second phase of the upgrade as JLAB will be operated for one cycle and the results will be compared to the zero-phasing technique used in the north linac.

A HIGH-INTENSITY NEUTRON PRODUCTION SOURCE BASED ON ROTARY VALVING*

B. Rusnak, P. Fitsos, J. M. Hall, R. Souza, P. Peaslee, LLNL, Livermore, CA 94550

Abstract

As part of the effort to develop a fast neutron imaging capability at LLNL, a novel windowless deuterium gas target was developed for use with high-intensity pulse deuteron beams to generate neutrons via the $D(d,n)^3He$ reaction. The system was designed to create high-velocity, cross-flowing gas to minimize rarefaction due to beam heating in the target gas. The system also employs a unique gas beam stop to minimize knock-on neutrons from implanted deuterons over time. A prototype system employing rotary valving to generate and modulate gas flow, and a rotating aperture to minimize gas back streaming into the beamline vacuum system, was designed and built. Design details and supporting analyses of the gas dynamics of the system are presented.

INTRODUCTION

Investigating low-density features and materials that are heavily shielded within high-density materials is a challenge for x-ray techniques due to the attenuation of the x rays in the high-Z outer materials. Using the high penetrability of fast neutrons to create radiographic images is an alternative technique demonstrated to be very effective at creating cubic-millimeter-scale resolution images in heavily shielded low-Z test objects [1]. Technology development in the pursuit of creating a fast neutron imaging capability as a complimentary non-destructive evaluation (NDE) diagnostic to x rays has been on going at LLNL for the last decade [2].

Neutron Source Requirements

To achieve high penetrability in a variety of potential high Z materials, a 10-MeV neutron energy was chosen. In addition, this energy would not create short-lived activation products in air due to the $^{16}O(n,p)^{16}N$ reaction, which has a threshold above 10 MeV. The rapid decay of ^{16}N produces a background of high-energy gammas that are not only a radiological hazard but can degrade image resolution. To minimize image degradation due to an excess of scattered lower energy neutrons, the source neutrons also needed to be quasi-monoenergetic. For this application, having the energy width be approximately 10% was acceptable. To achieve nominal cubic-millimeter resolution, the source spot size needed to be at most 1.5 mm in diameter. These requirements placed significant constraints on the system and have strongly influenced the technology development path.

*This work performed under the auspices of the U. S. Department of Energy by Lawrence Livermore National Laboratory under contract DE-AC52-07NA27344.

Production Target Resolution Requirements

Production of quasi-monoenergetic high-energy neutrons can be readily achieved by impinging a deuteron ion beam onto a fixed length of high-pressure deuterium gas via the $D(d,n)^3He$ reaction. The maximum final neutron energy is determined by the incoming beam kinetic energy plus the Q value of the fusion reaction of 3.3 MeV, and the energy width of the neutron beam is directly related to the ion beam energy loss as the beam subtends the length gas cell. For this application, the deuterium gas cell is nominally 1.5 mm in diameter and 40 mm long. A deuteron beam of 7 MeV will be used to create ~10 MeV neutrons with a nominal 1 MeV energy width with 90% of the beam being in a forward directed.

Production Target Intensity Requirements

The neutron source intensity desired is 10^{11} n/sec/st at zero degrees. This was set by the goal of realizing a full 256-image computed tomographic (CT) reconstruction of a heavily shielded object in a nominal work shift. To achieve this intensity, 300 uA of average beam current will need to interact with nominally 3-bar deuterium gas at ambient temperature in the gas cell volume.

The small source spot size required for high-resolution imaging will create very high deposited power densities on any materials the beam interacts with, including any solid-material window typically used for making deuterium-gas neutron targets. This is due to the high energy loss of ion beams in solids at these low energies. Operating such a windowed source lends itself to DC accelerators as these provide the lowest possible average power for a given spot size in the window compared to pulsed beam structures. A great deal of experimentation over the years has shown that most windowed gas cells with millimeter-scale focal spots only achieve ~20–30 uA of average current before failure [3]. Given the factor of 10 higher beam currents needed to make the intensity requirements, an alternate approach to windowed gas cells was needed.

Another significant challenge due to the small spot size was stopping and disposing of the unreacted beam after the gas cell. For any solid high-Z stop, since the beam loses only 10% of its energy and does not appreciably enlarge when interacting with the deuterium gas, the beam stop needs to absorb 90% of the beam power over a stopping range of tens of microns. While grazing incident and rotating stop ideas were considered to prevent melting, there was concern that the density variations produced for the neutron beam would result in unwanted shadows on the radiographs, that the solid material would be damaged over time due to the pulsed nature of the

Copyright © 2013 CC-BY-3.0 and by the respective authors

beam and subsequent cyclic heating and cooling, and that the build-up of implanted deuterium over time would lead to "knock-on" neutrons that broaden and soften the desired fast-neutron spectrum and degrade the resolution; therefore, such a solid stop was not pursued.

The team evaluated the option of placing quadrupoles and dipoles downstream of the gas cell to defocus and then divert the expanded beam to a solid beam stop further down stream and out of the imaging flight line. This approach was rejected due to the need to have massive steel electromagnets in a high-neutron-flux region for extended periods where they would become activated and produce unwanted scattered neutrons that degrade resolution. Permanent magnets were not seen as viable due to a large bore needed downstream of the gas cell to capture the beam (at least 3–4" diameter) and concerns over their sensitivity to high fluxes of neutron radiation and the longer lived activation products that would be produced.

In response to these issues, an argon gas beam stop was developed to use in conjunction with the deuterium gas cell. Stopping the beam in a high-pressure gas will remove the three main issues related to solid stops.

The array of target challenges due to the small source spot size and beam current needed also precluded using the 14-MeV neutrons from the D(t,n)^{4}He reaction. DT tubes are easily capable of achieving some combination of small-source spot sizes, high intensity, and long lifetimes but not simultaneously and reliably as is needed for neutron imaging.

WINDOWLESS APERTURE

As an alternative to a physical window separating the deuterium gas cell from the beamline vacuum, a rotating aperture system was studied that would allow passage of a low-duty-factor, pulsed beam into the cell but would then restrict gas flow back up the beamline. The rotating aperture approach exploits the pulsed nature of commercial accelerators that operate at ~1–2% duty factor and can reduce the gas load and the associated differential pumping system size and cost significantly [4]. The effectiveness of the technology is maximized by achieving precision tolerances of less than 0.001-0.002" in the gaps between sealing surfaces when closed.

To achieve accurate timing of the rotating aperture with the ion beam, a series of vignetting equations were created that modeled the aperture opening behavior as a function of overall diameter, rotational speed, hole size, and beam diameter [5]. These equations allowed designing the system to accommodate the operational range of the pulsed accelerator system.

Hydrodynamic modeling done as part of the analysis effort that looked at gas flow into the vacuum with and without the beam interaction showed that the large peak powers in the beam macrobunch (~110 kW) would significant rarefy the gas in the cell due to rapid heating. The team concluded that the gas in the gas cell could not remain static, as that would lead to a roll-off of neutron intensity for peak currents above ~1 mA. Cross-flowing deuterium gas moving at a minimum of 400 m/s in front of the beam was effective at maintaining the required gas density [6]. To achieve such high cross-flow velocities, various concepts were explored using either venturis or pulsed valves opening against a large pressure differential. The approach pursued was to extend the rotating aperture technique to be a rotating valve as well. By using a valve to modulate the gas, a smaller gas compressor could be used to circulate gas in the system than would be needed for a simple venturi.

The rarefaction predicted in the deuterium section of the gas cell will be even greater in the argon beam stop section, as 90% of the beam power is deposited there, and the energy deposition of the beam in the stopping gas per unit length is a factor of 9.1 greater. Calculations show that achieving high cross-flow velocities with argon will be more difficult than deuterium due to the lower sound speed in the heavier gas. The goal is to realize flow velocities in the 300 m/s range.

ROTARY VALVING APPROACH

Straightforward modifications were made to the rotating aperture vignetting equations to adapt them for rotary valving. These equations were then used to calculate the effective opening areas of the rotating aperture and the rotary valve, which can be compared to the beam pulse, as shown in Figure 1.

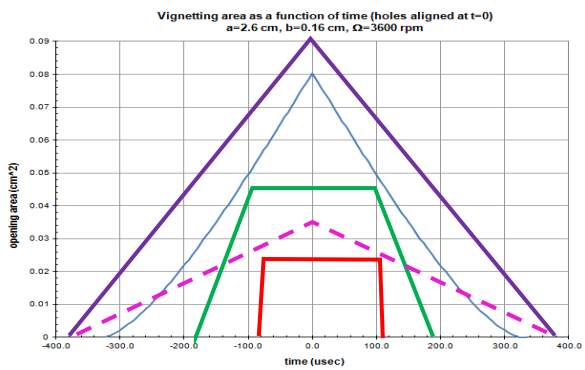

Figure 1: The plot shows the interrelation of the effective opening and the closing areas of the rotary valve gas inlet (purple), the aperture hole opening (light blue), the beam diameter opening (green), and representations of the gas pulse (purple dashed) and the deuteron beam (red).

Just as close tolerances were needed to reduce gas flow to the beamline when the aperture was closed, precision tolerances were also needed on the rotating valve portion of the assembly. The need to hold gap tolerances of less than 0.002" over the rotor length of nominally 14" drove many of the design choices. A system drawing is shown in Figure 2 and a finished system photo in Figure 3.

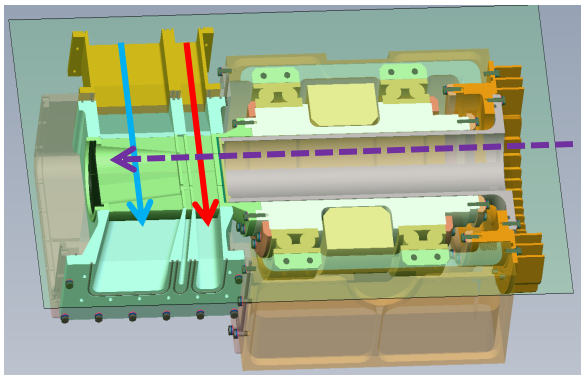

Figure 2: Cutaway of rotary valve system showing the ion beam (dashed) the cross-flowing deuterium gas (red), and the cross-flowing argon stopping gas (blue).

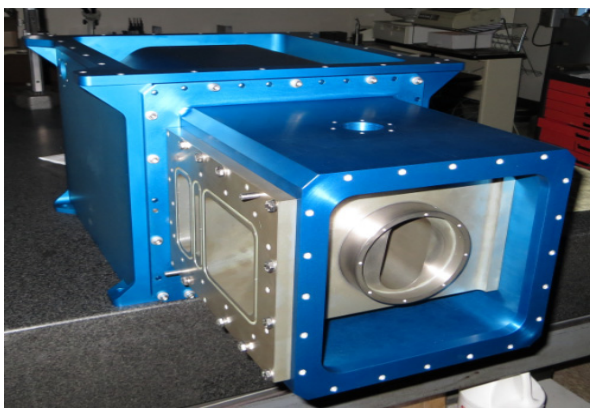

Figure 3: Photo of rotary valve being assembled, showing the central rotor inside the valve manifold (silver aluminium), and the outer aluminium case (blue anodized).

As the gas cell will ultimately need to operate in an intense neutron radiation field, design choices were made to improve reliability and ease disposal, including:

- Moving the motor ~12" away from the deuterium interaction point and being able to put in shielding
- Making as much of the assembly as possible out of 7075 aluminium to minimize longer lived activation products while maintaining good working strength and hardness
- Being able to use all metal seals on the assembly

GAS FLOW ANALYSIS

Extensive modeling allowed evaluation of the fluid flow of the gases in the cells. To simplify the studies and to better relate them to experiments, helium gas was used as a surrogate to deuterium, as it has comparable thermodynamic properties without the flammability hazard. Studies included:

- Helium (deuterium) cross-flow velocity and leakage with no beam
- Helium (deuterium) heating and density with beam energy present, shown in Figure 4
- Argon cross-flow velocity and leakage with no beam
- Argon heating and density with beam energy present
- Helium (deuterium) and argon intermixing with and without beam energy present
- Helium (deuterium) leakage down the beam line

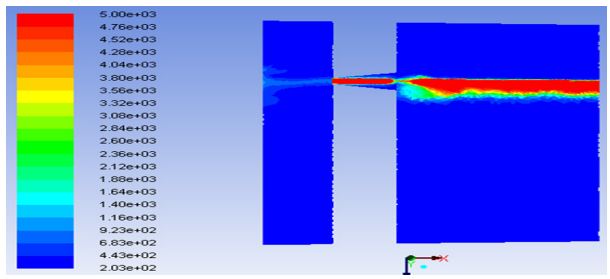

Figure 4: Temperature difference in Kelvin in the deuterium (left) and argon (right) streams due to variations in density and energy deposition with beam power present and the gases moving across the beam channel.

DESIGN DETAILS AND MACHINING

To sustain the tight tolerances needed to better seal the rotary aperture and valve sections, large-diameter bearing doublets were used successfully. To avoid the use of any type of rotary feed-through, which would be problematic at the 3600-rpm rotational speeds and the high radiation environment, a DC motor was installed in the chamber and attached to an aluminium heat sink. To reduce the risk of galling in the event the close-tolerance rotating surfaces contacted, those parts were coated with Ni-Lube, a nickel Teflon composite layer that significantly reduces friction.

ACKNOWLEDGEMENT

The authors would like to recognize the masterful machinist skills of Steve Reid and Peter Steinebrunner at the CHAMP Company, Campbell, CA, and their efforts to achieve the tight tolerances needed on this system.

ION-IRRADIATION RESPONSE OF GAFCHROMIC FILMS AND THEIR APPLICATION TO THE MEASUREMENT OF THE TRANSVERSE BEAM INTENSITY DISTRIBUTION

Yosuke Yuri, Tomohisa Ishizaka, Takahiro Yuyama, Ikuo Ishibori, and Susumu Okumura,
Takasaki Advanced Radiation Research Institute, Japan Atomic Energy Agency,

Abstract

The response of radiochromic films, Gafchromic HD-810 and EBT2, was investigated using MeV/u-class proton and heavy-ion beams to apply the films to a measurement technique of the transverse beam intensity distribution at an azimuthally-varying-field cyclotron of Japan Atomic Energy Agency. The optical density of the irradiated films increased linearly with the particle fluence of the beam in a low-fluence region. The linear-response range of the fluence strongly depended on ion species as well as on the film type. By analyzing the film response to absorbed dose, it was found that the sensitivity of the film decreased for a beam with higher linear energy transfer. Based on the linear response of the Gafchromic film, we measured the relative intensity distribution of a large-area ion beam focused with multipole magnets. It was demonstrated that the present technique was useful for evaluation of the size and uniformity of the ion beam.

INTRODUCTION

Precise, handy evaluation of the transverse intensity distribution of a large-area ion beam with various ion species is required for materials and biological researches at the accelerator facility TIARA of Japan Atomic Energy Agency (JAEA). Radiochromic films, Gafchromic HD-810 and EBT2 (Ashland Inc.) [1], were, therefore, adopted as a possible measurement technique of the transverse beam intensity distribution. Various properties of the film, such as high spatial resolution (below 1 mm), large size (over 100 cm^2), thinness (for the penetration of a low-energy ion beam), and easy handling, are advantageous to the present purpose.

A beam irradiation experiment was carried out systematically in order to determine the applicability of Gafchromic films to various ion beams at the azimuthally-varying-field (AVF) cyclotron in TIARA [2]. Their response characteristics were investigated in a wide fluence range. Furthermore, the optical-density response of the films was analyzed in terms of linear energy transfer (LET) and dose [3]. Based on the linear-response characteristics of the films, we measured the relative intensity distribution of a large-area beam focused with multipole magnets [4] and evaluated the size and uniformity of the beam.

FLUENCE RESPONSE

HD-810 and EBT2 films were irradiated uniformly with 10-MeV ^{1}H, 13-MeV/u ^{40}Ar, and 3.5-MeV/u ^{129}Xe beams from the AVF cyclotron. The irradiated films were read at a resolution of 127 dpi with a general-purpose flat-bed scanner, LiDE50 (Canon Inc.), to digitize them into TIFF-formatted images with 16-bit RGB color intensity values. The film scanning was performed in more than one day after irradiation to prevent short-term color variation after irradiation. The optical density d_X in each color channel X (red, green, or blue) was determined from the equation: $d_X = \log_{10}((2^{16}\text{-}1)/I_X)$, where I_X is the 16-bit intensity value.

The response of HD-810 films irradiated with the ion beams is shown as a function of the fluence in Fig. 1. The increment of the optical density depends on the color channels for each ion species. The optical density obtained from the red channel is the largest at a given fluence in the linear-response region, while that from the blue channel is the least sensitive. This reflects that the film absorption sensitivity is higher in the longer wavelength region. Thus, the intensity distribution of the beam can be measured in a wide fluence range with a moderate signal-to-noise ratio by choosing an appropriate color channel of the scanned image. The range of the response curves shifted drastically toward a lower-fluence region for heavier-ion beams, as clearly seen in Fig. 1.

For EBT2, the optical density only of the green channel exhibited the linear response in a low-fluence range. The linear-response range is one order of magnitude lower than that of HD-810.

DOSE RESPONSE

The strong dependence of the film response on ion species, as shown in Fig. 1, is probably due to the difference of the LET in the active layer of the film. To see this, the particle fluence F is transformed into the dose D using the following relation: $D = c\,(LET/\rho)\,F$, where ρ is the density of the active layer of the film and c is a constant. The LETs of the beams at each layer of the films can be determined using SRIM code [5]. For example, the average LETs in the active layer (ρ = 1.08 g/cm^3) of HD-810 are 5.0×10^0, 1.2×10^3, and 1.1×10^4 keV/μm for the H, Ar, and Xe ion beams in the present case, respectively.

The response curves of the three ion species are replotted as a function of the average dose in the active layer of HD-810 in Fig. 2. For the proton beam, the linear response in Fig. 2(a) is similar to those observed in previous studies in spite of the differences in proton energy and scanners [6-8]. Although the linear-response dose range has been partially overlapped with the manufacturer's specifications (10~400 Gy) of the film in

Copyright © 2013 CC-BY-3.0 and by the respective authors

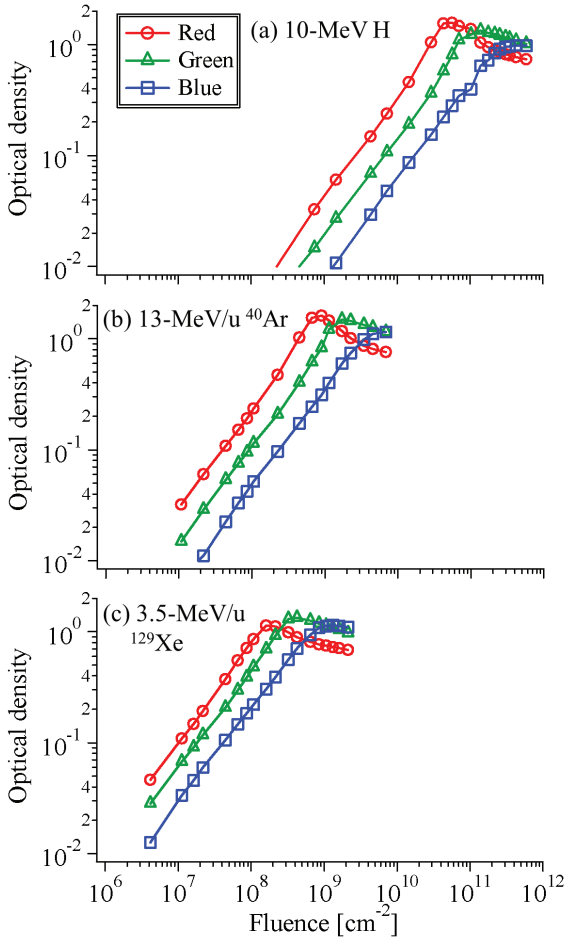

Figure 1: Response curves of the Gafchromic film HD-810 for three different ion beams as a function of the particle fluence.

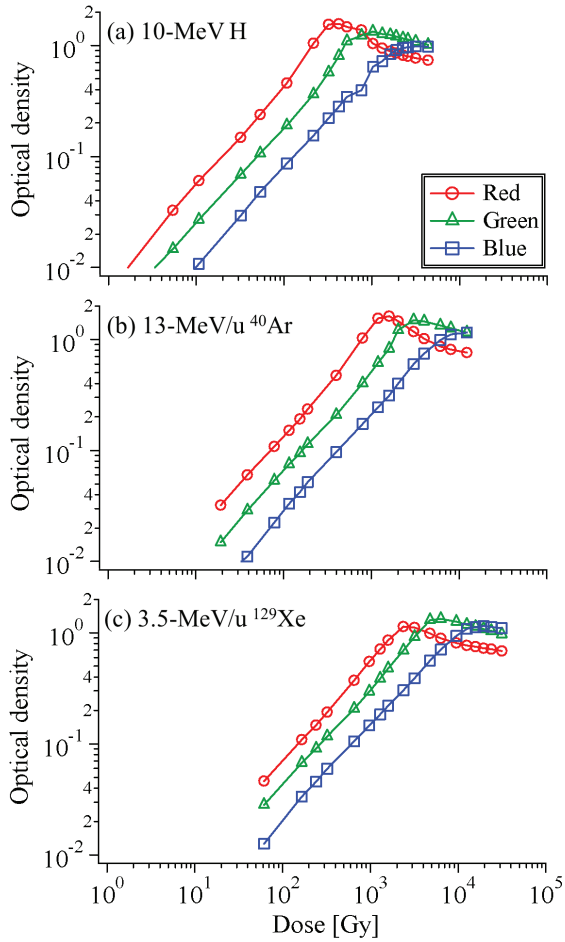

Figure 2: Response curves of the Gafchromic film HD-810 for three different ion beams as a function of the dose in the active layer of the film. The experimental data is the same as in Fig. 1.

all three ion species, the dose-response curves shift slightly to the right for heavier-ion beams and the film response seems still dependent on ion species. Therefore, the sensitivity of the film, defined here as a gradient of the linear-response region with respect to the dose, is evaluated for the three ion species and summarized as a function of LET in Fig. 3. The sensitivities of the EBT2 green channel for H and Ar beams are also plotted in Fig. 3. (The EBT2 film is not applicable to the 3.5-MeV/u Xe beam because the kinetic energy is too low for the beam to reach the active layer of the film.) It is clearly reconfirmed that the sensitivity is lower for heavier-ion beams and higher for EBT2. The sensitivity reduction for heavier-ion beams is probably because, for a heavy ion with a higher LET, the local dose along the ion's trajectory is very high and the coloration in the microscopic region becomes saturated: a large part of the deposited dose does not contribute to the film coloration. This tendency agrees well with previous studies [6, 9]. Similar sensitivity reduction of radiochromic films in a Bragg peak (where LET is large) is known as a quenching effect [10].

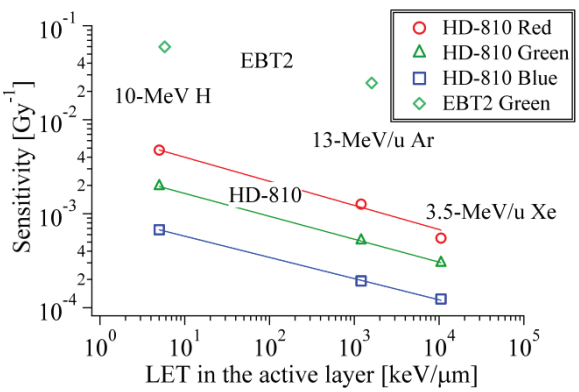

Figure 3: Sensitivity of the HD-810 and EBT2 films as a function of LET. For HD-810, the sensitivities of the red, green, and blue channels are fitted by power functions of $(\mathrm{LET})^{-0.26}$, $(\mathrm{LET})^{-0.24}$, and $(\mathrm{LET})^{-0.21}$ in the present case, respectively. For EBT2, the sensitivity of the green channel where the response is linear is plotted.

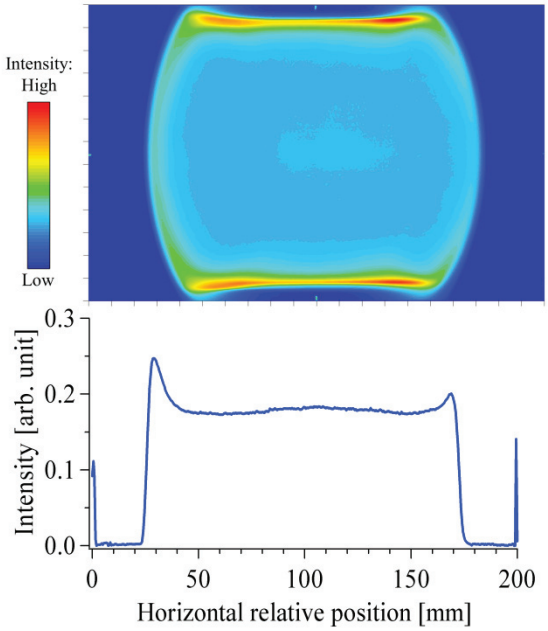

Figure 4: Relative transverse intensity distribution obtained from the optical density distribution of an HD-810 film. The film was irradiated with a 13-MeV/u Ar beam of 0.1 μA for 0.5 s, and scanned with the LiDE50 at a spatial resolution of 127 dpi. The 2D cross-sectional distribution is shown in the upper panel. In the lower panel, the 1D distribution is shown along the horizontal axis. The peaks appearing at both ends in the lower panel correspond to marks put on the film for indicating the central axial position.

INTENSITY DISTRIBUTION MEASUREMENT USING THE FILMS

As can be seen from Figs. 1 and 2, the response of the film is always linear in a low-fluence (low-dose) region where the optical density is well below unity. It is, thus, not always necessary to obtain the response curve in every experiment. This feature gives us a handy technique to measure the relative intensity distribution of the beam directly from the optical density. The relative distribution suffices for the evaluation of the size and uniformity.

Figure 4 shows the measurement result of the relative intensity distribution of a large-area ion beam, obtained from the optical density distribution of HD-810. As can be seen in the figure, the uniform intensity region is formed in the inner part of the profile. Such a beam was formed as follows: The ion beam from the cyclotron was first multiply-scattered with a thin foil to smooth the initial distribution into a Gaussian-like distribution and then focused by octupole magnets so that the intensity distribution could be made uniform on the target [11]. In this uniform-beam formation method, the intensity in the peripheral part of the beam can be very high due to overshooting the tail of the Gaussian-like beam focused by octupole magnets and thus the optical density of the high-intensity region may go beyond the available linear-response range of the Gafchromic film. Even in such a situation, the uniformity of the inner central region can be evaluated if the optical density in the uniform region is well below unity. In Fig. 4, the root-mean-square uniformity is evaluated as 7% in the 120-cm^2 flat-top region surrounded by a high-intensity peak. The uniformity is better (4%) in the inner 9-cm-square central region around the beam center, as predicted theoretically [4].

It is worthwhile to note that the beam uniformity, determined from the optical density of the Gafchromic film, is equal to that of the track-pore density distribution observed more microscopically through a track-etching technique [2, 12].

SUMMARY

The applicability of Gafchromic films HD-810 and EBT2 to proton and heavy-ion beams was investigated for the measurement and evaluation of large-area beam intensity distributions at the JAEA AVF cyclotron. The available fluence range was strongly dependent on ion species as well as on the film type. The sensitivity of the film was lower for a beam with higher LET.

Paying attention to the linear response of Gafchromic films, we developed a handy technique for obtaining the relative transverse intensity distribution of the beam. Using the technique, we confirmed that an ion beam with a uniform intensity distribution was formed by multipole magnets, and the size and uniformity of the beam was evaluated. Large-area proton and heavy-ion beams over 100 cm^2 can be realized at a uniformity of less than 10% and are applied to experiments for space [13] and materials science at TIARA.

SIMULATION OF X-BAND LINAC NEUTRON SOURCE

K. Tagi#, K. Dobashi, T. Fujiwara, and M. Uesaka, University of Tokyo, Tokyo, Japan
M. Yamamoto, Accuthera Inc., Kawasaki, Japan

Abstract

In Tokyo University, there is a plan of development of electron linac neutron source because the research reactor "Yayoi" was decommissioned and a new neutron source is required. This linac will be introduced in the core of the reactor, so measurement of nuclear fuel materials can be expected. The application of this research is to measure more accurate nuclear data of some atomic fuel materials. It is necessary for analysing debris in Fukushima 1st nuclear power plant.

30 MeV X-band linac is used and neutrons are generated by interactions between bremsstrahlung x-rays and materials. In this research, the thermal electron gun, the buncher and the target for the linac are optimized for generating as many neutrons as possible. Uranium can be used as target materials, so high neutron flux was gained from the calculation.

INTRODUCTION

Nuclear data, neutron cross section, is important because it can be applied to development of new reactor and analysis of debris in Fukushima 1st nuclear power plant. However, this data, especially the data of nuclear fuel materials, such as U, Pu, and Am, is not so correct. Figure 1 shows experimental data of total cross section of Pu-239 [1]. You can understand the accuracy of the peak at 1 eV is low. In addition, measurement of this data hasn't been done recently.

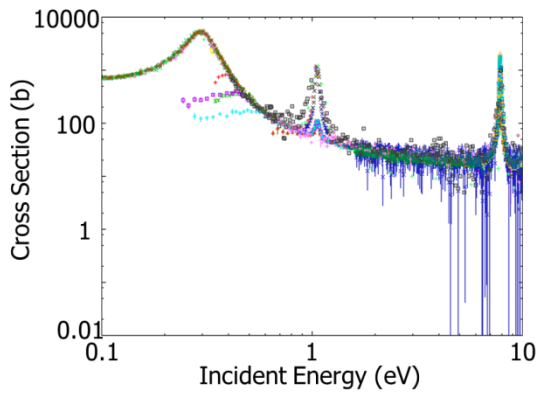

Figure 1: Experimental data of total cross section of Pu-239 [1].

Energy resolution is very important for the measurement of debris. The relation between time and energy is given by the equations

$$T[\mu s] = \frac{72.3L[\mathrm{m}]}{\sqrt{E[\mathrm{eV}]}}, \frac{\Delta E}{E} = -\frac{\Delta T}{T}. \quad (1)$$

For measuring data in 1% energy resolution, 1 μs is necessary when length of beam line is 5 m and beam energy is 10 eV, and 100 ns is necessary when length of beam line is 40 m and beam energy is 100 keV. So short pulse width is necessary for high energy resolution measurement. Pulse width of electron linac is much shorter than that of proton accelerator, so electron linac is suitable for our research.

PURPOSE

The purpose of my research is the development of electron linac driven neutron source for nuclear data measurement. Linac will be installed into the core of the "Yayoi" reactor which is now under decommissioning because in Yayoi, handling nuclear fuel materials are permitted. The reason why X-band linac is used for our neutron source is it enables us to set the accelerator in the core. But the klystron will be set out of the core.

COMPTON SCATTERING X-RAY SOURCE

For preliminary test of neutron source installation, 30 MeV X-band Linac has been tested. The Linac was originally designed for Compton scattering monochromatic X-ray source [2], shown in Figure 2. It is consisted of 3 MeV RF gun, alpha magnet, 30 MeV accelerator tube, and laser.

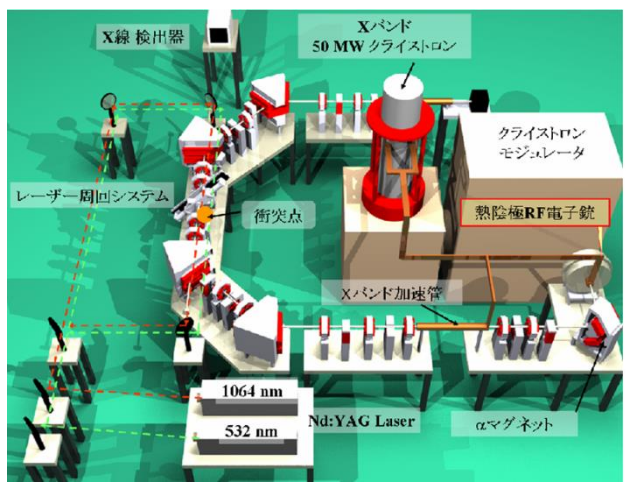

Figure 2: Compton scattering x-ray source.

In December 2012, the experiment of the RF electron gun was done. Figure 3 shows the current of it. The RF gun has is emittance, low current, and stability problem, so it is not suitable for neutron source.

Some part of this system, the RF source, the accelerator tube and the cooling system, will be used in the new neutron source. However, as I explained, RF gun is not suita-

Copyright © 2013 CC-BY-3.0 and by the respective authors

ble, so thermal DC gun and buncher is designed and will be installed. And neutron target is also designed.

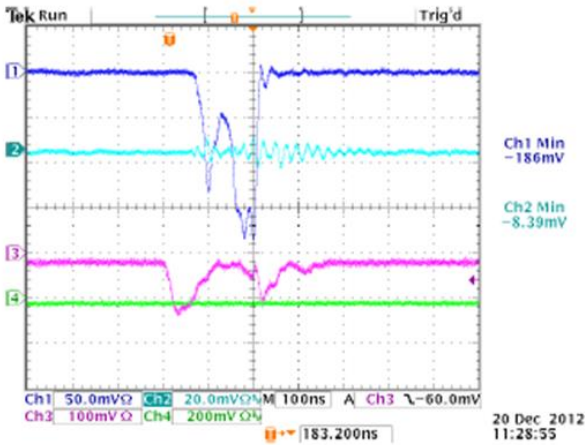

Figure 3: Current of thermal RF gun of Compton scattering x-ray source.

THERMAL ELECTRON GUN AND BUNCHER

Thermal Electron Gun

Stable current is expected to the thermal electron gun so it is suitable for our research. Electric field calculation by POISSON and beam transportation calculation by GPT was done [3-4]. The voltage of the gun was 20 kV. Figure 4 shows the result and Table 1 shows the gained parameters.

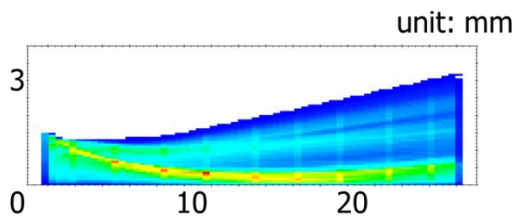

Figure 4: Simulation result of thermal electron gun.

Table 1: Parameters of Thermal Electron Gun

Parameter	Our Thermal Gun
Voltage	20 kV
Cathode Radius	1.5 mm
Beam size (σ) at z = 20 cm	0.224 mm
Emittance at z = 20 cm	0.674 mm-mrad

Buncher

The energy of thermal electron gun is 20 keV, so a buncher is necessary for smooth acceleration. The frequency is 11.424 GHz, the same as the accelerator tube of Compton scattering X-ray source and traveling wave mode is used. Electromagnetic field calculation by SUPERFISH and Beam transportation calculation by GPT was done.

Figure 5 shows the relation between the beam position and the internal diameter of the cavity to keep stable electric field. Figure 6 shows the relation between the electric field and the diameter at the gate of the cavity when the RF power was 5 MW. From this, we decided that the length of the buncher is 20 cm and accelerated energy is 4 MeV.

And from the electron gun and the buncher, the parameter shown in Table 2 can be expected.

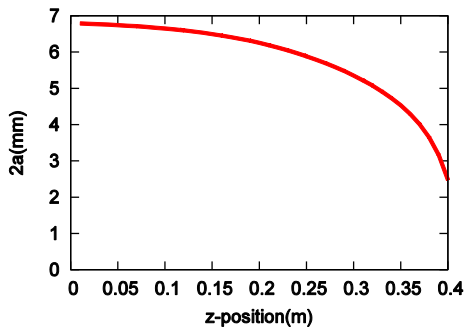

Figure 5: Relation between the beam position and the internal diameter of the cavity.

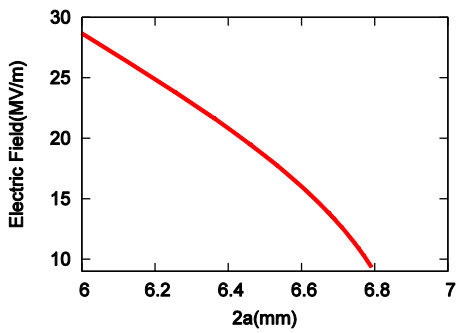

Figure 6: Relation between the electric field and the diameter at the gate of the cavity.

Table 2: Parameters of Electron Beam of Incident System

Parameter	Our Incident System
Energy	30 MeV
Max current	250 mA
Max pulse width	1 μsec
Intensity	50 pps
Max beam power	0.375 kW

NETURON TARGET

Electron linac neutron source has advantage of short pulse, but because of this, power of electron linac is lower than other neutron sources. Therefore, a high efficiency target should be developed for generating neutrons with high flux. Uranium target was simulated because it has photo fission effect and high flux can be expected [5].

Copyright © 2013 CC-BY-3.0 and by the respective authors

Linac will be set in the core of the plant, so nuclear fuel material can be used as the target. Figure 7 shows the neutron flux from various targets, calculated by PHITS, which was developed in JAEA [6]. The electron beam energy was 30 MeV. This shows that uranium target brings about twice as much flux as other target. And when beam energy was 30 MeV, beam power is 0.375 kW and uranium target was used, neutron flux of 3×10^{11} n/s was gained. However, way to treat fission product is important task.

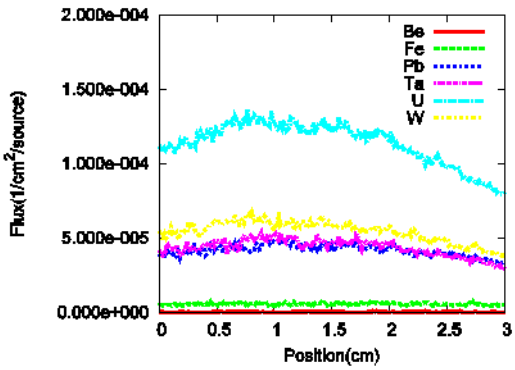

Figure 7: Comparison of neutron flux among several target materials.

CONCULUSION

Neutron source with 30 MeV X-band linac has been developed for measurement of neutron cross section. Thermal neutron gun and buncher were newly designed to combine with the existing accelerator tube. Various neutron target (including Uranium) was designed and neutron flux from target was calculated.In next years, electron beam and neutron beam is going to be measured.

DIRECT DIAGNOSTIC TECHNIQUE FOR A HIGH INTENSITY LASER BASED ON LASER COMPTON SCATTERING*

R. Sato†, Y. Yoshida, K. Nonomura, K. Sakaue, A. Endo, M. Washio
Waseda University, Tokyo, Japan

Abstract

In laser produced plasma (LPP) EUV source, high intensity pulse CO_2 laser is essential for plasma generation. To achieve high conversion efficiency and stable EUV power, we would like to measure laser profile in collision point and make feedback system. There is no way to directly measure a high intensity laser profile at the focus point. Therefore, we have been developing laser profiler based on laser Compton scattering. Laser profile can be measured by scanning focused electron beam while measuring Compton scattering signal. We use compact electron accelerator based on Cs-Te photocathode RF gun at Waseda university. Electron beam is focused by solenoid lens. We simulated beam size using GPT, obtained beam size of 10 μm rms. We measured beam size by Gafchromic film HD-810. We have succeeded in observing minimum beam size of about 20 μm rms. In this conference, we will report result of simulation, beam size measurements, and the present progress.

INTORODUCTION

Extreme ultraviolet lithography (EUVL) is the next generation lithography for integrated circuit fabrication at 22nm half pitch mode [1]. In EUVL, several 100W EUV light is based on Sn plasma produced by CO_2 laser. CO_2 laser is required more than 100 kHz repetition rate, 200 mJ, 100 μm spot size and 10 ns pulse duration. To achieve high conversion efficiency and stable EUV power, we would like to measure laser profile in collision point and make feedback system. However, there is no way to directly measure such high power laser profile.

We have been developing laser profiler based on laser Compton scattering (LCS). Laser profile can be measured by scanning focused electron beam while measuring Compton scattering signal. If both laser and electron beam have a gaussian distribution, the observed profile of Compton signal as a function of electron position is a gaussian distribution. Observed rms width can be written down as;

$$\sigma = \sqrt{\sigma_{\mathrm{laser}}^2 + \sigma_{\mathrm{electron}}^2} \qquad (1)$$

where σ_{laser} is the laser beam size, $\sigma_{\mathrm{electron}}$ is the electron beam size. If the electron beam size is much smaller than that of laser, the observed profile would be equivalent to the laser profile. To scan electron beam from various direction and reconstruct image used CT technique, we can obtain 2D laser profile.

Focused electron beam is a key issue of this method. The more electron beam is focused, the higher resolution laser profile we can obtain. To achieve small beam spot, we use low emittance electron accelerator and special design solenoid lens. In this paper, we discuss GPT simulation and results of beam size measurement by Gafchromic film.

ACCELERATOR SYSTEMS

A photocathode rf gun is one of the most high quality electron source. Because of high gradient electric field on the cathode, it can generate small emittance beam. At Waseda university, we have been performed the high quality electron beam generation and applied research experiments, such as laser Compton soft-Xray generation [2] and pulse radiolysis [3].

The cavity structure is based on the design of the BNL Type IV, which have 1.6 cell structure. The rf frequency is 2856 MHz. The cavity is able to produce low emittance beam with 5 MeV beam energy. We use Cs-Te photocathode which have a high quantum efficiency and achieve 1 nC / bunch. The seed laser is Nd:YLF mode lock oscillator with 119 MHz frequency. We use LN intensity modulator to pick pulse train, it chooses the number of pulses from 1 pulse to 100 pulses. The pulse trains are amplified by Yb fiber amplifier and LD pumped amplifier 4 pass system. After two amplifications, IR pulses are converted to UV pulses by two nonlinear doubling crystals.

The experiment set up is shown in Fig. 1. There are beam diagnostic instruments. A current transfer measure beam charge and pulse train stability. Alumina fluorescent plate (Demarquest Co.) beam profile monitor is located behind solenoid magnets. 45 degree bending magnet is used for energy measurement. Our accelerator system is characterized it's small structure, the total length is less than 3 m.

For this experiment, we designed new solenoid lens. The

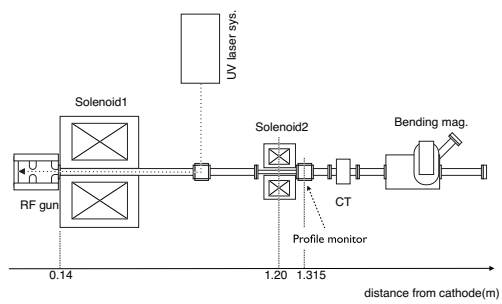

Figure 1: Schematic design of Waseda beam line.

lens shape and magnetic field was studied POISSON simulation code. The magnetic field calculated by POISSON and measured is shown in Fig. 2. Position is axis of beam traveling direction. To focus 5 MeV electron beam, we designed to achieve that a maximum magnetic strength is 0.6 T.

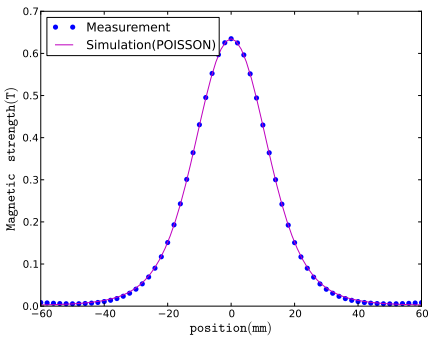

Figure 2: Magnetic field of Solenoid 2.

BEAM TRACKING BY GPT

We calculated focused electron beam by General Particle Tracer (GPT) [4]. The field of rf cavity and solenoid magnets were calculated by SUPERFISH and POISSON. Parameters of GPT are shown in Table 1. Number of particles seems very little, but there are no significant deference in results of beam size and emittance. Therefore, we used results of 1k data to optimize beam parameters and solenoid lens strength.

Figure 3 show beam size as a function of distance from cathode. The rf cavity accelerate the beam, and the emittance growth is controlled by Solenoid 1. The new solenoid lens, Solenoid 2, is placed 1.2 m downstream. It strongly focus the beam, Fig. 3 show the beam was focused to 15 μm at the position of 1.314 m.

Table 1: Parameters of GPT Simulation

Number of particles	1000
Space Charge	3D
Charge	50pC
Electric filed at cathode	100MV/m
Initial laser spot size	0.3 mm
Solenoid 1 strength	0.13 T
Solenoid 2 strength	0.5 T

Figure 4 show beam size at the focus point as a function of Solenoid 2 strength. The smaller beam spot is achieved as strong magnetic strength. On the other hand, a strong focusing make short focus distance and short focus spot. These characterization are obstacle to focus on the collision point.

Beam size and emittance versus beam charge is shown in Fig. 5. Smaller beam spot is also available by lower charge. 10 μm beam spot was achieved with 50 pC beam charge. In LCS, Compton signal flux depends on electron beam charge and laser intensity. Smaller beam spot and higher beam current are need, it is a contradictory demand. We plan to operate 50 $\sim$ 100 pC beam charge at LCS experiment. In this situation, calculated photon number is 8×10^4 photons / pulse, which is large enough for detecting LCS signal.

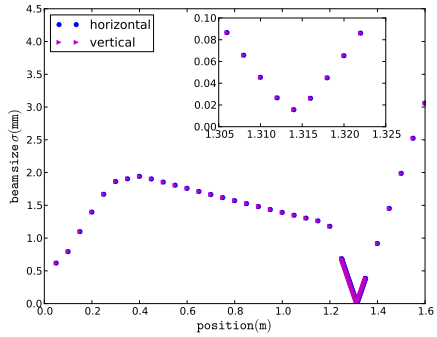

Figure 3: Beam size as a function of distance from cathode.

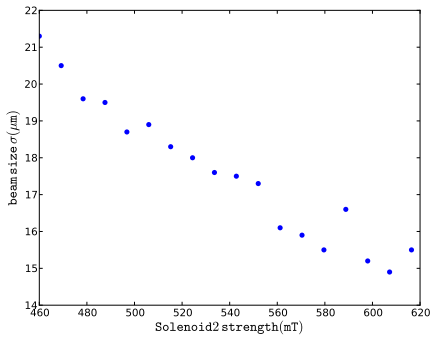

Figure 4: Beam size as a function of Solenoid 2 strength.

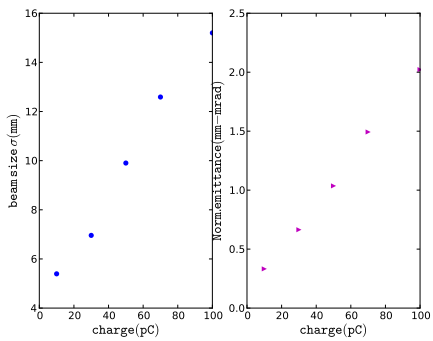

Figure 5: Beam size (left) and normalized eimttance (right) as a function of beam charge.

BEAM SIZE MEASUREMENT

Gafchromic Film

Gafchromic radiochromic film [5] is used for measuring a beam intensity distribution. The film is discolored by ionizing beam irradiation. We choosed HD-810, this film is commonly used for the measurement of absorbed dose of high energy photons. First, we calculated divergence of electron beam in HD-810 by Monte Carlo simulation code EGS5. The results show the beam was't expanded in active layer (6.5 μm thickness).

Optical density (OD) of HD-810 was measured by a cold CCD camera. For the dose calibration, we irradiated electron beam with various irradiation time. Figure 6 show the result, and we used this calibration curve for beam size measurements.

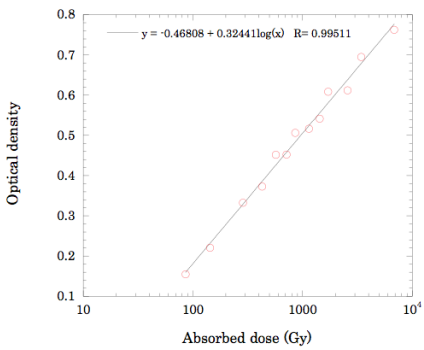

Figure 6: Calibration curve of HD-810 film.

Beam Size Measurement

We measured focused beam size by HD-810. The beam profile measured by HD-810 is shown in Fig. 7, focused beam size as a function of Solenoid 2 strength is shown in Fig. 8. The plots of Fig. 8 show average size of 3 measurements. In this experiment, the beam was 50 pC, 3.5 MeV and the irradiation time was 1 s. We achieved about 20 μm spot size. This results show our accelerator system fulfills the demand for high intensity laser profiler.

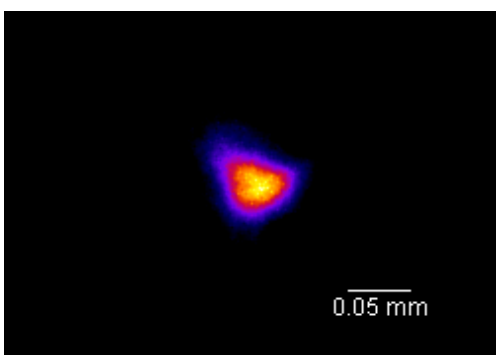

Figure 7: Beam profile measured by HD-810 film.

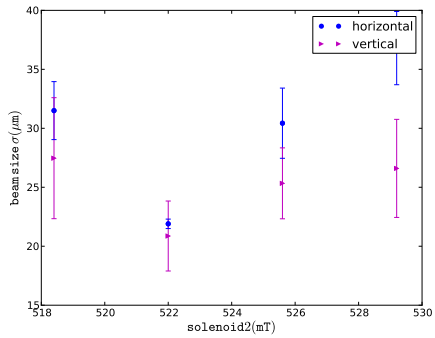

Figure 8: Beam size as a function of Solenoid 2 strength.

CONCLUSION

At Waseda university, we have been developing laser profiler based on LCS. Laser profile can be measured by scanning electron beam while measuring Compton scattering signal. Focused electron beam is a key issue of this method, so we designed new solenoid lens and measured beam size using HD-810. We achieved beam size of 20 μm, this is satisfactory beam size for laser profiler.

To produce small beam size, we have to operate with low beam charge. Therefore, we plan a multi bunch generation to 1 pulse of CO_2 laser. Our seed laser repetition rate is not satisfied this concept, so we will use optical delay line to change repetition rate. The UV pulse separate by PBS, and the pulse which is leaded to optical delay line return the initial line with 350 ps (2856 MHz) delay time.

We are preparing high repetition system, pulse CO_2 laser and the spectroscope to detect Compton scattering signal. In this winter, LCS experiments will be held to obtain CO_2 laser profile.

CONCEPTUAL PHYSICS DESIGN FOR THE CHINA-ADS LINAC

J.Y. Tang*, P. Cheng, H.P. Geng, Z. Guo, Z.H. Li, C. Meng, H.F. Ouyang, S.L. Pei, B. Sun, J.L. Sun, F. Yan, C. Zhang, Z. Yang, IHEP, CAS, Beijing 100049, China
Y. He, Y. Yang, IMP, CAS, Lanzhou 730000, China

Abstract

The China-ADS project was launched in 2011 to pursue the R&D on key technologies towards a final demonstration facility on ADS with the capability of more than 1000 MW thermal power. The driver linac is defined to be 1.5 GeV in energy, 10 mA in current and in CW operation mode. It employs the superconducting structures except the RFQs. To meet the extremely high reliability and availability, the linac is designed with much installed margin and fault tolerance, including hot-spare injectors and local compensation method for key element failures. The accelerator complex consists of two parallel 10-MeV injectors, a joint medium-energy beam transport line, a main linac and a high-energy beam transport line. The conceptual physics design including beam dynamics studies with multiparticle simulations is presented here.

INTRODUCTION

The C-ADS (or China-ADS) project is a strategic plan to solve the nuclear waste problem and the resource problem for nuclear power plants in China. With its long-term planning, the project will be conducted in three or four major phases with the final goal to build a demo transmutation facility by 2032.

The C-ADS accelerator complex is a large CW proton linac consisting of several sections and uses superconducting (SC) acceleration structures except the RFQs, which is under developing in collaboration at IHEP and IMP. The main design specifications for the proton beam at the ultimate stage are shown in Table 1.

Table 1: Specifications for the C-ADS Linac

Particle	Proton	Unit
Energy	1.5	GeV
Current	10	mA
Beam power	15	MW
RF frequency	(162.5)/325/650	MHz
Duty factor	100	%
Beam Loss	<1	W/m
Beam trips/year[1]	<25000 <2500 <25	1s<t<10s 10s<t<5m t>5m

*tangjy@ihep.ac.cn

DESIGN CONSIDERATIONS

The C-ADS linac is designed to have very high beam power and very high reliability, which surpasses those of the existing proton linacs by far. However, several proposed CW proton/deuteron linac projects such as Project-X [1-2], EFIT or MYRRHA [3], IFMIF [4] and EURISOL [5], etc. are good models for the physics design and technical design of the accelerator. In addition, some pulsed high power proton linacs and some CW heavy ion linacs using SC cavities also serve as good reference examples. Although most of the design philosophy for the linac has been addressed by previous literatures, we still list the main principles here: 1) the whole linac consists of SC cavities except the RFQ which is room-temperature; 2) installed redundancy for all the parts of the accelerator will be applied; 3) as low as possible beam losses along the linac, with an upper limit of 1 W/m in warm sections and even lower in cold sections; 4) the acceleration efficiency and the number of cavity types will be balanced; 5) different transverse focusing structures are used to follow the acceleration structures and beam properties in different acceleration sections; 6) tune depression will be controlled to stay in the emittance dominated regime preferably; 7) the growths in both the rms emittance and halo emittance should be controlled strictly, and the ratio of acceptance and rms emittance should be kept large to avoid severe beam beams; 8) the phase advance per period is controlled below 90° to avoid parametric resonances.

DIFFERENT ACCELERATION SECTIONS

The linac consists of two injectors, a special medium-energy beam transfer line (MEBT2), and the main linac, as shown in Figure 1. Two identical injectors will be operated in the mode of one as the hot-spare of the other to provide quick switch in case of failure of the one in delivering beam to the main linac, which is considered crucial to achieve very high reliability of the whole accelerator. MEBT2 is to transport and match the beam from either of the two injectors to the main linac. However, in the early developing phase two different approaches of injector will be developed in parallel by two different teams. At a later phase, a decision based on the R&D development will be made about which injector scheme will be used in the future phase. The main linac section that consists of different acceleration sections will be developed in phases.

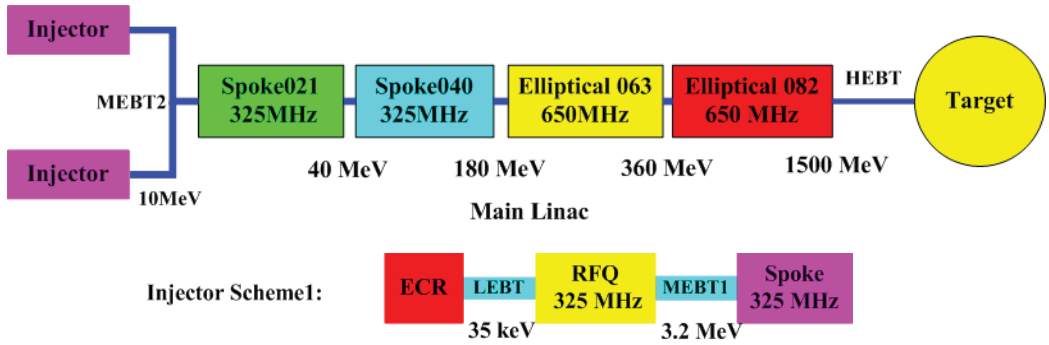

Figure 1: Layout of the C-ADS linac.

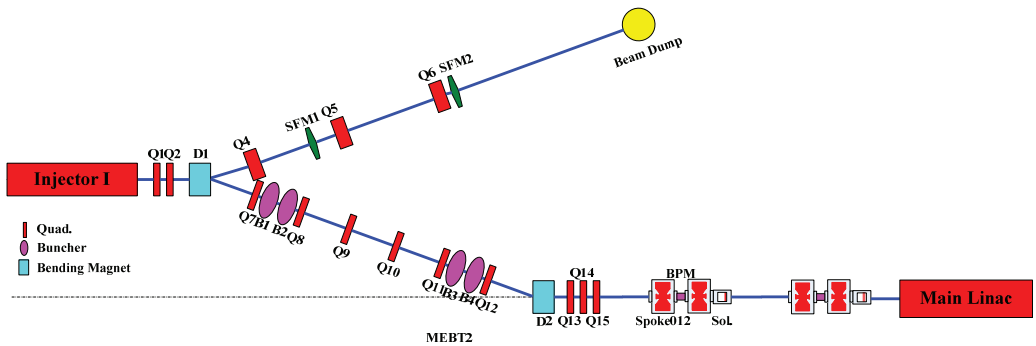

Figure 2: Schematic for MEBT2.

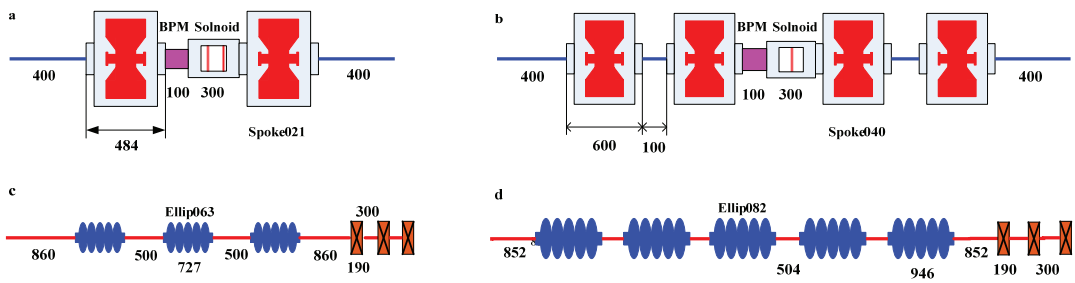

Figure 3: Lattice for the four sections in the main linac.

Injector

For the Injector-I scheme, a 325-MHz, 3.2-MeV, 4-Vane RFQ has been designed and a test stand is under fabrication. The inter-vane voltage is 55 kV, much smaller than the popular design, aiming to decrease the power density to a safe level. The injection energy of 35 kV is helpful in obtaining a relatively smaller output longitudinal emittance (0.16 mm.mrad in normalized rms), which is about 0.8 times the transverse one. The small longitudinal emittance is found very useful in designing the downstream SC sections. Then the MEBT1 [6] is to match the beam between the RFQ and the SC section of the injector. It is mainly composed of two bunchers, six quadrupoles and beam instrument devices.

The SC section of the injector has one long cryomodule (CM) of 8.5 m with twelve single spoke cavities [7] and eleven solenoids inside; it will accelerate the beam to 10 MeV. The geometry beta of the cavity is only 0.12 which is considered very small, and it increases the difficulty of developing the cavity. The compact lattice with short solenoid (150 mm) and larger absolute synchronous phase (-46 ~ -30°) is applied to improve the longitudinal beam dynamics.

MEBT2

It is a real challenge to design a merging beam line to connect the two injectors to the main linac, as this is a high-intensity beam requiring very strict control over beam loss and emittance growth. It is found difficult to control the emittance growths when a bending section is present, especially with the bunchers within the section. MEBT2 is also supposed to have a good collimation system to scrape the beam halo and non-trapped particles. The beam will be directed to a beam dump through an auxiliary beam line with a much reduced beam power when the injector is working in the hot-spare mode. The

Copyright © 2013 CC-BY-3.0 and by the respective authors

dump line is also used for the commissioning or beam setup of the injector.

As shown in Figure 2 [8], each of the mainstream lines of the MEBT2 consists of eight quadrupoles, two 20°-bending magnets and four 325-MHz single-gap normal conducting re-entrant type bunchers. In the common part, three quadrupoles, two Spoke012 cavities and two solenoids are used for the matching, while another two Spoke012 cavities serve as the back-ups.

Main Linac

To meet the strict requirement on stability and reliability, over-design, redundancy and fault tolerance strategies are implemented in the basic design. The fault tolerant design in the main linac is guaranteed by means of the local compensation and rematch method [9-10]. To cover the whole energy range from 10 MeV to 1.5 GeV in the main linac, at least four types of SC cavities are needed. We have chosen two single-spoke cavities working at 325 MHz with geometry β of 0.21 and 0.40, respectively, and two 5-cell elliptical cavities working at 650 MHz with geometry β of 0.63 and 0.82, respectively. For the nominal design, only 3/4 of the maximum available cavity voltage is used, whereas another 1/4 is reserved for the local compensation, and this redundancy is also beneficial to the cavity reliability.

There are four sections each consisting of one type of cavity, Spoke021 and Spoke040 for the lower energy part and Ellip063 and Ellip082 for the higher energy part. The lattice structures for each section are shown in Figure 3. The matching between two neighbouring sections is guaranteed by varying the parameters of the adjacent cavities and transverse focusing elements. With warm transitions between CMs, the replacement of failed CMs can be easily carried out; in addition, beam diagnostics and collimators can be arranged in the warm sections.

In total, thirty-eight Spoke021 cavities in seven CMs, sixty-four Spoke040 cavities in eight CMs, forty-two Ellip063 cavities in fourteen CMs and one hundred Ellip082 cavities in twenty CMs are used in the main linac. All the CMs have modest length of 5-10 m.

SOME SIMULATION RESULTS

End-to-end beam dynamics simulations are performed from the input of the RFQ to the end of the linac to verify the general beam dynamics and the matching between each part. The initial particle distribution at the entrance of the RFQ is assumed as 4D water-bag distribution with transverse rms emittance of 0.2 πmm mrad and the total particle numbers are 100000, and the optimized distributions at the RFQ exit are applied as the initial particle distributions for TraceWin.

The evolutions for both the rms emittances and halo emittance with different fractions are studied (see Figure 4). MEBT2 contributes to very important growth of the 100% emittance, almost 5 times in the transverse planes. It is expected that some halo particles can be collimated in MEBT2 with proper collimation schemes.

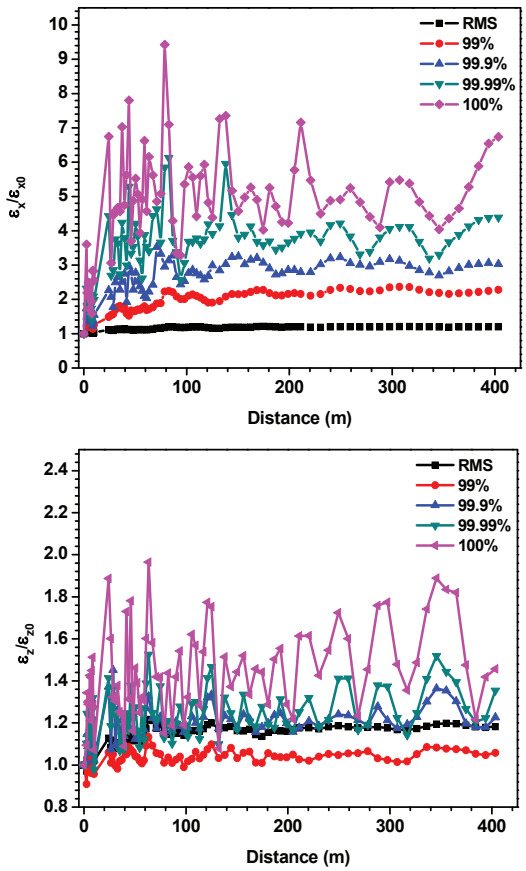

Figure 4: Halo development along the linac for different beam fractions.

ACKNOWLEDGMENT

The study is supported by the CAS Strategic Priority Research Program on ADS, and also by National Natural Science Foundation of China (Projects 11235012 and 10875099).

THZ BAND HORN ANTENNAS DESIGN

T.V. Bondarenko, S.M. Polozov, A.Yu. Smirnov,
National Research Nuclear University MEPhI, Moscow, Russia

Abstract

The report is concerned with the development of the irradiating antennas for THz radiation source. The THz radiation is irradiated by relativistic high brightness electron bunch traveling through the Cherenkov decelerating capillary channel [1]. Irradiation systems are built as horn antennas type with circular and rectangular cross-sections. Irradiating antennas are constructed directly to the open end of the capillary channel and are used for the THz radiation directivity enhancement after passing through the capillary output. The investigation of the horns directivities were performed using the far-field analysis of the emerging radiation. The antennas were also investigated to perform low values of the reflected power.

INTRODUCTION

High-power THz radiation source based on photoinjector and decelerating capillary channel is now one of the most discussable compact facilities providing monochromatic THz radiation of power high enough to be used for cargo introscopy [2].

Facility is based on two main parts: accelerating structure and decelerating radiating channel. Capillary is placed right after the accelerating structures and is made of copper with either dielectric coated inner surface or corrugated surface.

For effective irradiation of THz radiation from the capillary structure the high values of capillary RF matching with the open space and high directivity values are out to be fulfilled. Capillary that irradiates in the free space with its open end doesn't provide enough directivity that can be seen from the angular pattern shown in the Fig. 1. To enhance the directivity of the radiation the open end of the capillary must be attached to the irradiating antenna. As the capillary has a circular cross-section the optimal geometry of the horn is based on the horn antenna that is directly fitted to the metal parts of the capillary and is fabricated with it as a whole entity.

Main parameters of the antenna are the directivity, angle between the longitudinal axis and main lobe, main lobe angular width and horn power reflection coefficient. Angular width of the main lobe is the parameter defining the distance between two directions of the lobe with 3dB power decay between them. Important parameter is also bandwidth of the horn that is defined as frequency difference between horn working frequency (resonant frequency of the capillary) and the frequency of horn -20dB power reflection level.

There are several different types of horn designs. This article is concerned with the modelling of the horns with circular and rectangular cross sections. All antennas are discussed for the metal Cherenkov irradiating capillary with 300 μm aperture and 31 μm polytetrafluoroethylene coating on the metal surface. Resonant frequency of this type of capillary is 0.96 THz. Work band on the level of -3 dB of the maximal power transmission is 3.2%.

CIRCULAR HORN ANTENNA

Circular antenna is the most conventional type of antenna for such devices (Fig. 2). The model of the horn was built and calculated using the CST Microwave Studio [3]. To define the maximum effective horn parameters the electrodynamics characteristics were studied while varying the horn geometrical parameters. The opening angle was varied while the horn length was kept L=1 mm (fig. 3). After that with the angle equal 14.5 degrees (that corresponds to maximal directivity of the horn) length of the horn was varied (Fig. 3). The investigations were held in the frequency band of 0.7-1.1 THz.

The graphs in the Fig. 3 show that the increase of the horn opening angle decreases its directivity and bandwidth. Main lobe width is increased at the same time. Variation of the horn length leads to the enhancement of the directivity at the 4.8 mm length and then results in its reduction with higher values of the parameter. Inverse relationships are specific for main lobe direction and angular width.

Minimum of the reflection coefficient is defined at the 1 THz region for all discussed geometries. Opening angle enhancement leads to growth of the reflection on the resonant frequency value and bandwidth of the horn decreases. The frequency dependent values of the power reflection coefficients for varying geometrical sizes are depicted in the Fig. 4.

For more clearance the visualization of the horn directivity the directional diagrams are depicted in the Fig. 5. The diagrams are shown for the maximal directivity case of the horn antenna (length of the horn is 4.8 mm and 14.5 degrees opening angle). For maximal values of the mail lobe angular width the same graphs are shown in the Fig. 6. Antenna has corresponding parameters: 4.8 mm length and 57 degrees opening angle.

Characters of all dependences confirm the convention model of horn antennas modeling for lower frequency ranges.

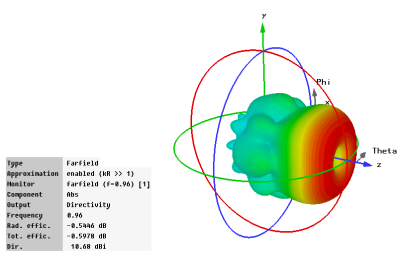

Figure 1: Directivity diagram of the open capillary end.

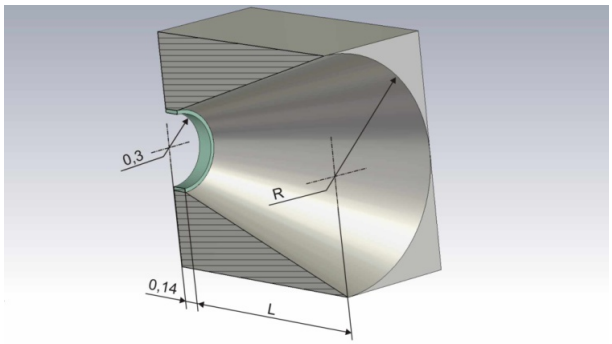

Figure 2: Circular horn antenna and the capillary.

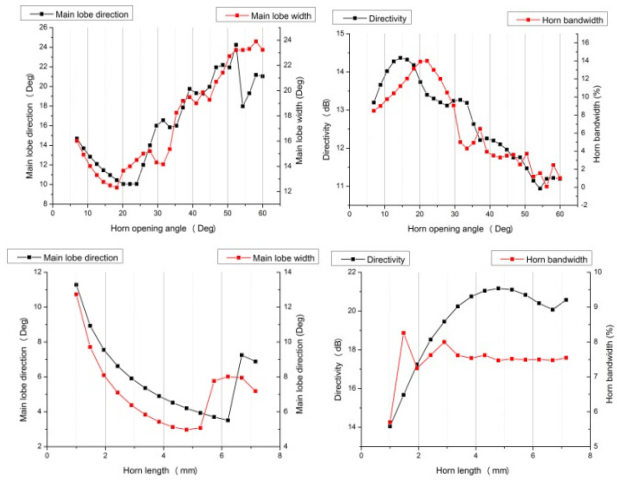

Figure 3: Dependences of electrodynamics characteristics vs. circular horn geometrical sizes.

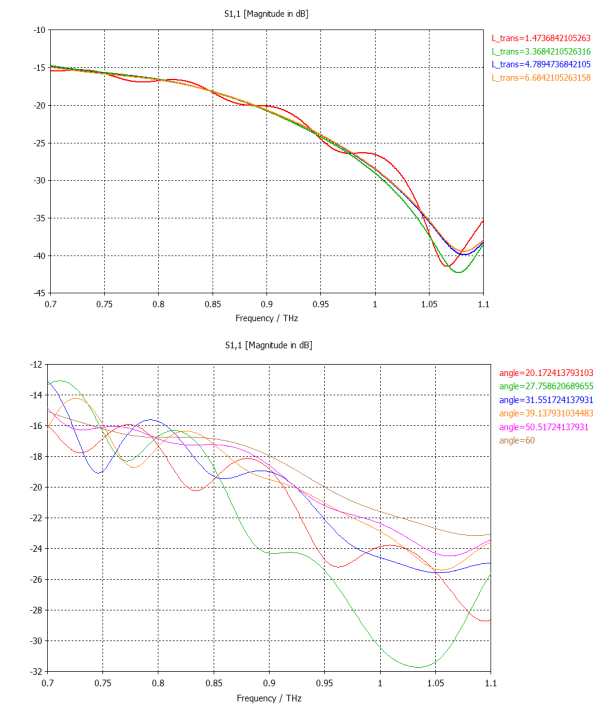

Figure 4: Reflection coefficients of the horn for different geometrical sizes of the horn.

At one definite point of horn opening it has maximal directivity and minimal value of main lobe angular width, minimal reflection coefficient and maximal bandwidth. Increasing of reducing of the angles leads to characteristics dramatic changing. Reduction of angular opening leads to unoptimized parameters levels and increasing – to enhanced values of phase distortions in its opening [3].

RECTANGULAR HORN ANTENNA

The second type of considered horns is the horn with variable cross-section (transition from circular to rectangular). The horn is attached directly to the coated capillary. The transition from circular to rectangular cross-section is done directly inside the opening (Fig. 7). To investigate the horn parameters the electrodynamics characteristics were tracked while changing the horn geometry.

The outstanding feature of this type horn vs. the circular horn is possibility to acquire the straightforward main lobe of the radiation. Dependences reveal the increase of horn directivity while opening angles reduction in both directions (Fig. 8). Increase of the openings in one of the planes leads to dramatic increase of the main lobe in this plane and a little less increase in another plane. Power reflecting coefficient of the horn increases if one of the opening angles equals zero. At even more increase of the parameter doesn't change. Horn bandwidth increases with opening increase and reaches the borders of investigated frequency region with the vertical opening angle equal 7.5 degrees [4].

For the case of maximal directivity of the horn (15 degrees opening angles in both planes) the length variation was held. The results of investigation consist in maximal directivity equal 22.5 dB with the horn length 2 mm. In whole band of 0.7-1.1 THz the reflection coefficient doesn't increased of -20 dB.

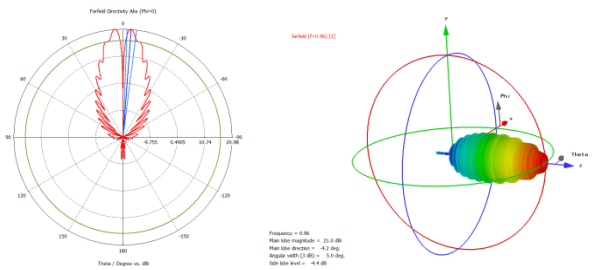

Figure 5: Circular pattern and 3D diagram for maximal directivity of circular antenna.

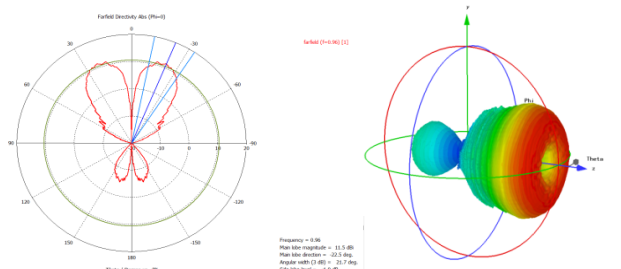

Figure 6: Circular pattern and 3D diagram for maximal main lobe angular width of circular antenna.

Copyright © 2013 CC-BY-3.0 and by the respective authors

For the horn with maximal directivity (2.71 mm length, opening angles 15 degrees) the circular patterns of the horizontal and vertical directions and 3D directivity diagram were acquired. The side lobes are practically absent and the main lobe is directed straight forward (Fig. 9). For the case of maximal main lobe angular width (7 mm length, 15 degrees vertical opening angle and 60 degrees horizontal one) the diagrams are represented in the Fig. 10.

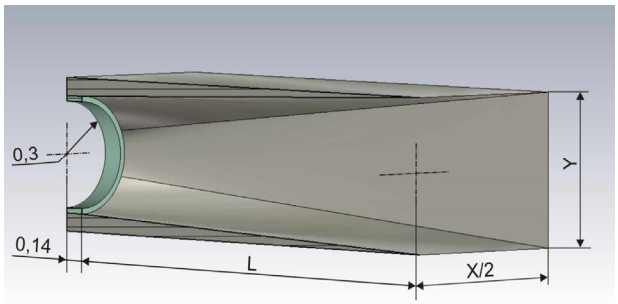

Figure 7: Horn antenna with circular to rectangular cross section transition and the capillary.

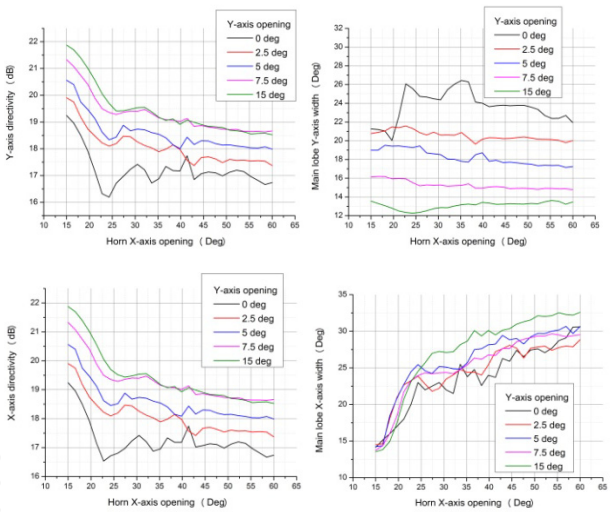

Figure 8: Dependences of electrodynamics characteristics vs. rectangular horn geometrical sizes.

CONCLUSION

By the means of the investigation results it turns out that to acquire high directivity of the THz radiation from the Cherenkov channel irradiating horn antenna can be effectively exploited. For the case when there is no need to irradiate the object placed directly on the axis of the channel the circular cross-section horn can be applied. If there is a demand for irradiation of the axis-aligned objects the rectangular cross section antenna can be used. Herein both types of the horns can be well-directed (~20 dB main lobe) after optimization and provide low levels of power reflection rates (<20 dB). Parameters and directivity diagrams of the both types of horns are declared for the cases of maximal directivity and for maximal main lobe angular widths.

ANALYSIS OF PROPAGATED EFFECTS IN PROTON DEPTH-DOSE DISTRIBUTION CURVES DUE TO INITIAL BEAM ENERGY SPREAD

S. Zalel*, J.F. Piech, UROP students, Imperial College London
M. Aslaninejad, P. A. Posocco#, Imperial College London

Abstract

Proton therapy treatment planning uses depth-dose distribution curves of single initial beam energies to create Spread spread Out Bragg Peaks (SOBP). These are used to target specific regions in the body. However, the initial energy spread of the beams leads to an uncertainty in beam energy, affecting the dose distribution. In this paper, previous work (M. Aslaninejad et al., 2011: 189–196) on the depth-dose distribution of proton beams using inelastic-collision cross sections of liquid water is extended into use with chromatic beams. The effect of the initial energy spread on depth-dose distribution curves, the distal dose and the SOBP are discussed. Limits on beam energy spread are suggested.

INTRODUCTION

Proton therapy is advantageous over conventional radiation therapy as particles lose most of their energy at a particular location, depending on their initial energy. This effect is usually represented by means of depth-dose distribution curves. These are characterised by the Bragg Peak (BP) where the relative dose reaches a sharp maximum. As the range and shape of the BP depends on initial beam energy, the energy spread of protons within a beam distorts the theoretical BP and potentially compromises the effectiveness of the treatment. In this paper we extend previous work to account for the energy spread within a therapeutic proton beam.

Depth-dose distribution curves are a useful tool indicating which region will be most affected by incoming radiation. In the code developed in [1] depth-dose distribution curves in water are created by modelling proton beams using a combination of semi-empirical models and the Bethe-Bloch theory. At energies below 1 MeV the cross section is defined by a combination of semi-empirical models, such as the model of ionization processes by Rudd et al.. The stopping cross section gives information on the energy transferred per unit length as a function of particle energy. The total stopping cross section is the sum of the stopping cross sections of all interactions contributing to energy. Nuclear processes are disregarded.

The Bethe-Bloch formula is a good approximation for calculating energy lost per distance travelled for fast charged particles (i.e. with energies higher than 1MeV). Equation 1 shows the Bethe-Bloch formula according to Groom and Klein [2]:

$$\frac{1}{\rho}\frac{dE}{dx} = Kz^2\frac{Z}{A}\frac{1}{\beta^2}\left[\frac{1}{2}\ln\frac{2m_e c^2\beta^2\gamma^2 T_{max}}{I^2} - \beta^2 - \frac{\delta(\beta\gamma)}{2}\right], \quad (1)$$

where z it the charge of the incident particle, Z and A are the atomic number and the atomic mass of the absorber, respectively. I is the mean excitation energy, $\delta(\beta\gamma)$ is the density effect correction to ionisation energy loss and β and c are the usual relativistic factors. T_{max} is the maximum kinetic energy which can be imparted to a free electron in a single collision.

Other considerations that were taken into account in the code are:

- Straggling model: range travelled by individual protons is governed by a Gaussian distribution.
- Fragmentation: effectively reduced fluence attributed to proton decay.

These lead to the broad-beam depth-dose curve characterised by increased peak width and reduced peak height. Multiple scattering was also considered; this changes the shape of the depth-distribution by changing the ratio of peak to entrance dose.

EXTENSION TO CHROMATIC BEAMS

In the discussion above proton beams of single defined energies are used. However, real beams are characterised by an energy spread. This is due to individual characteristics of the accelerator, beam transport, and collimation system [3]. The width of the initial energy spectrum is expressed as a percentage error in the initial beam energy and is estimated in the order of magnitude of ±1% [4]. In this paper a superposition of Gaussian probability weighted monochromatic beams was used to simulate chromatic depth-dose distribution curves and values of up to 2% sigma have been used for several initial beam energies. This analytical method is a good approximation for the peak itself, however the shape of the tail is affected largely by other factors and may vary further from the model used [3].

The Effect of Energy Spread on the Bragg Peak

The depth dose distributions curves created for single proton Bragg peaks as function of the initial beam energy spread were used to study the effect of the chromatic beam on the treatment. The depth dose distributions of the proton beams were modelled along a 1-D axis being the path of the proton. Effects of 3-D scattering were not included.

Depth-dose distribution curves of varying initial energy spreads were produced for 70, 100, 150, 200 and 250 MeV to cover the entire range of energies used for treatment, with energy spreads of 0.1%, 0.2%, 0.5%, 1% and 2% sigma.

Figure 1 shows the effects of increasing energy spread on the BP for a 200 MeV proton beam. Due to the

superposition of the BPs of different energy and therefore slightly different range, we can observe that:

- The peak's height decreases,
- The peak's depth decreases and
- The peak's width increases.

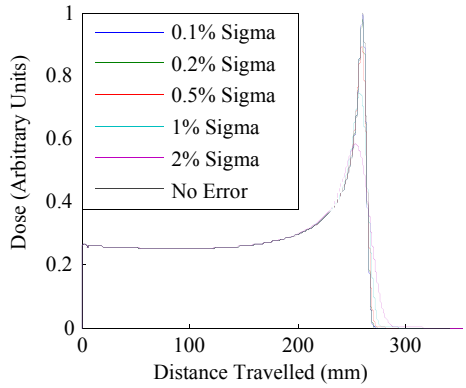

Figure 1: BPs (200 MeV) for different initial energy spread. Each BP has the same dose integral.

As the width of the Bragg Peak is of particular interest for the treatment, it was studied quantitatively. The peak width was defined as the distance from the peak's top to the distal point of a chosen percentage of peak's dose. Distal points of 95%, 50% and 5% of peak dose were used. Figure 2 shows the trend of 95% peak width for increasing energy spreads. As anticipated above, the distributed dose decreases less sharply for beams with a wider energy spread, meaning higher distal dose and more healthy irradiated tissue. While there is less of an effect in using lower energies, higher energy beams have a larger increase in peak width with increasing energy spread.

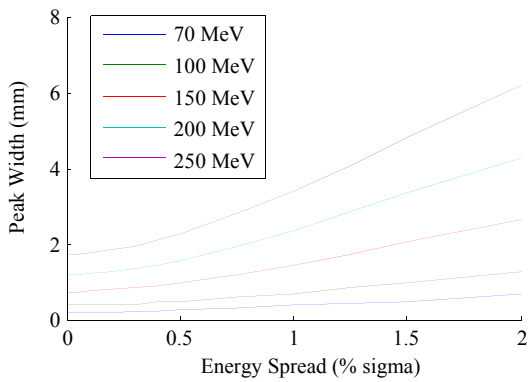

Figure 2: Peak width as distance between peak dose and distal 95%.

Investigations at all distal points found that the peak width is barely affected at energy spreads lower that 0.3% sigma. This is also the threshold point after which the distal dose rises significantly with energy spread. The distal dose encounters a 50% increase around 1% energy spread.

The Effect of Energy Spread on SOBPs

In clinical use, proton beams of initial energy between 70 to 250 MeV are superposed to create a plateau of uniform dose with the required width in order to treat a tumour effectively, depending on its shape, size and location. This is the Spread Out Bragg Peak (SOBP). The code was extended to produce this. As shown in Figure 3, the width of the plateau is called modulation width (from 90% proximal peak to 90% distal peak). The range is here defined as the distance from the entrance into the medium (zero distance travelled) to 90% distal peak.

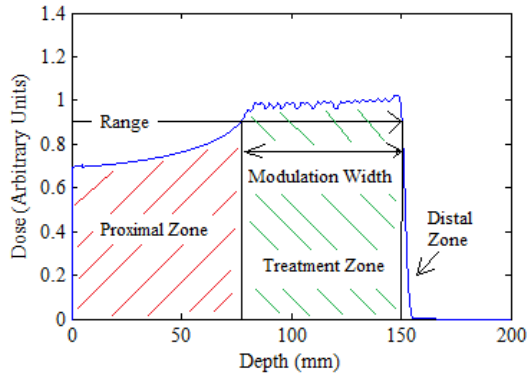

Figure 3: Sketch illustrating the different elements that were used to analyse the SOBP; proximal zone, treatment zone, modulation width, distal fall-off and range.

The shape (and uniformity) of the SOBP depends on the number of single peaks and their intensity. A common method in the literature [2, 4] uses a high intensity BP near the distal peak position and adding lower intensity peaks at regular intervals moving towards the proximal peak position. This creates a plateau characterised by a small peak at distal position and a sharp distal fall. Another method using different peak weighting produces a more uniform plateau but with a less sharp distal fall. The balance between the methods to create a smooth plateau with sharp distal fall is called distal-end optimization. Figure 4 shows an example of how to create a SOBP from its components: the most intense BP involved has most of the effect on the distal end.

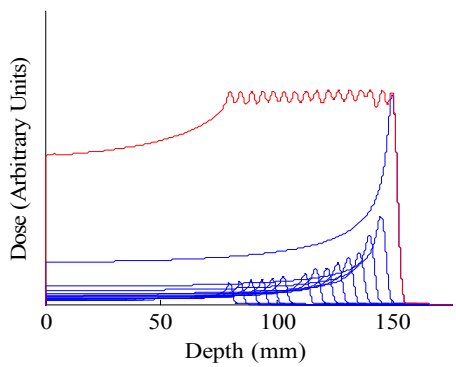

Figure 4: SOBP (80-150mm) using 15 BPs.

The chromatic beams were then used and their effect studied to learn to which extent the energy spread should be narrowed. The effect on the smoothness and uniformity of the peak were also studied.

Copyright © 2013 CC-BY-3.0 and by the respective authors

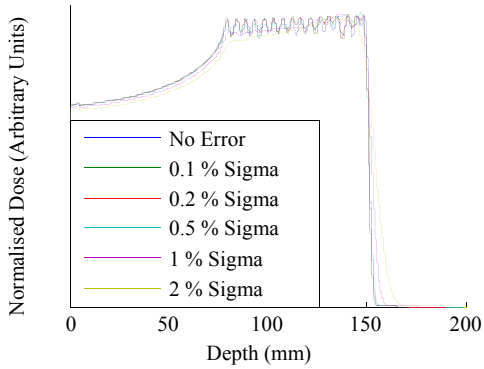

Figure 5: Same SOBP algorithm when using BPs of different initial energy spread (80-150 mm, 15 BPs).

Qualitatively, from investigating Figure 5 and similar SOBPs for different depths and widths, it was found that fewer single energy BPs were needed to create a smooth SOBP plateau when a higher energy spread was applied. Therefore a systematic study on the uniformity of the SOBP as function of the Energy Spread was launched varying the number of peaks for a SOBP 5 cm wide. The results plotted in Figure 6 show that above 0.5% sigma the reduction in the number of peaks needed for a given standard deviation is substantial. The drawback is that the distal falloff is less sharp, producing a higher distal dose.

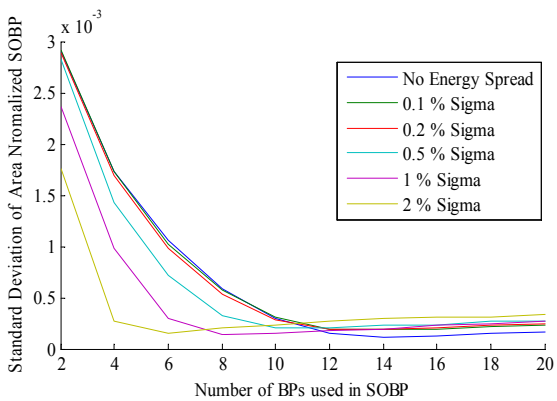

Figure 6: Standard deviation of the treatment zone as a function of BPs being used to create the SOBP. In this instance an SOBP between 10 and 15 cm was used.

Distal dose measurements were made at various modulation widths and depths. Figure 7 represents the results concisely. The distal dose is smaller for shallower and wider SOBPs because:

- For larger depths higher initial energies are needed making the distal BP wider (as shown previously in Figure 2).
- For smaller widths fewer BPs are needed and the contribution to the SOBP of the distal BP is higher, as there are a fewer components of lower energy BPs distal dose.

Below 0.5% sigma the energy spread has little influence (few percent) on the dose evaluated at 5 mm from the distal edge of the SOBP for low energy beams, whereas for higher energies the effect is significant.

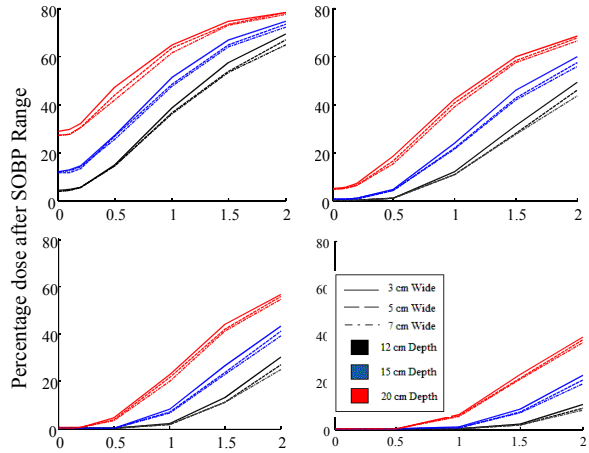

Figure 7: Graph showing the increasing distal dose at 3 mm, 5 mm, 7 mm and 10 mm (left to right, top to bottom) after the SOBP range. Different lines represent varying modulation widths while colours refer to differing ranges.

CONCLUSION

The energy spread of a proton beam causes a significant modification in shape of the Bragg Peak. This needs to be monitored and controlled in order to ensure the SOBP used in oncological treatments is modelled correctly so as to treat tumour efficiently and minimise damage to healthy tissue behind the tumour. Upper and lower limits on the beam energy spread are affected by considerations in the distal dose, the modulation width, the ratio between the zones and the shape of the resulting SOBP.

Taking into account the trade-off between the number of Bragg Peaks needed to ensure a uniform SOBP and the residual distal dose, from this work we can conclude that for beam energies:

- Lower than 100 MeV an energy spread greater than 0.5% sigma can be accepted.
- Greater than 150 MeV an energy spread lower than 0.5% sigma must be employed.

However, these considerations come from an over simplified 1-D geomet ry, where only water equivalent tissue is present, no interfaces between different tissues are simulated and a single-field treatment is applied. More work is needed to fill the gap between this study and the complex level of present-day treatment, however generalized, at a proton therapy centre.

A NOVEL SOLUTION FOR FFAG PROTON GANTRIES

J. Pasternak*, Imperial College London / RAL, STFC

P. A. Posocco, Imperial College London / The Cockroft Institute / Gunnar Nilssons Cancerstiftelse

Abstract

In the recent years FFAG gantries have been studied for medical applications, but none has so far been realised. The FFAG solution would reduce the complexity of beam line set-up, its weight and therefore the cost of the rotating support, in particular for heavy ions. The Imperial College London is using the experience gained in the Pamela Project and in the design and commissioning of EMMA to work on a solution of a non-scaling FFAG gantry, which could potentially fulfil the full requirements for the spot scanning - parallel beam treatment technique, and provides an easy interface to the upstream accelerator. The preliminary results will be presented in this paper.

INTRODUCTION

The research on Fixed Field Alternating Gradient (FFAG) accelerators was restarted after long period of silence in recent years, which triggered the successful construction and operation of several scaling machines in Japan and the world's first linear Non-Scaling one - EMMA [1] in the UK. Following these vigorous progress it was proposed to apply the FFAG principle for next generation hadron therapy machines [2] aiming to reduce the cost of treatment by utilising the very strong focusing and high repetition rate offered by FFAGs to make the machine dimensions more compact and the treatment time shorter.

In modern hadron therapy applications it is preferred to use the gantry as the final beam transport system, which allows to precisely vary the beam angle at the patient in the large range simultaneously allowing to carefully control the beam spot size and position in the spot scanning. Although the existing gantry solutions (non-FFAG type) have been constructed and are in operation, they consist of room temperature iron magnet system with a very large weight and overall dimensions, which is a significant fraction of the total cost of the facility.

FFAG solutions for proton and carbon gantries have been proposed [2, 3], which allow to greatly reduce the size and weight of the gantry by using superconducting magnets. Stable particle orbits exist in such gantry for the broad momentum range eliminating a need for magnets' ramp or requiring to ramp only between small number of operational regimes, which offers an opportunity to reduce the treatment time. Thus FFAG gantries will contribute in decreasing the cost of modern hadron therapy facilities. It may be fed by any conventional medical accelerator including cyclotron or by a future medical FFAG.

* j.pasternak@imperial.ac.uk

FFAG gantries studied so far were based either on linear non-scaling magnets, scaling ones or such that break only partially the scaling law. This paper describes a novel gantry type using nonlinear non-scaling FFAG magnets, which explicitly violates the scaling law maintaining the zero-chromatic condition.

NONLINEAR NON-SCALING FFAG GANTRY DESIGN

Requirements and Assumptions

As the starting point of the study the classical shape of the gantry is assumed, in which the beam is firstly deflected outwards from the common incoming beam/patient axis, which also serves as gantry axis of rotation. Secondly the beam is deflected in opposite direction cancelling the initial negative angle and finally bending by the final 90° pointing at the patient. If this configuration is rotated using the incoming beam as the axis of rotation, it allows for the full flexibility in the choice of the treatment angle in a very broad angular range.

As the goal a gantry for proton therapy was chosen as it allows an easy comparison with other existing gantries and can be further extrapolated to a carbon case. It was also decided that the operation energy range of 100-200 MeV is potentially interesting especially for applications in paediatrics and is also quite ambitious at the start.

To simplify the orbit matching in the presence of rotation for different energies, zero dispersion condition is preferred at the input of the gantry. To avoid any correlations between the beam position and energy, zero dispersion at the patient is also required. The identity matrix is needed as the total betatron transfer map through the gantry, which will allow to set the particular condition required for treatment downstream the gantry in the non-rotating part and transparently reproduce it at the patient position simplifying the gantry operation.

Linear Optics Design

In order to minimize the orbit excursion in an FFAG many short cells are required with a very strong focusing. As the compromise between the orbit excursion, the maximum value of the magnetic field and space constraints in the magnet design, the design of the first bend consists of 8 identical FDF triplet cells, with the total deflection angle of -72°. As the preliminary studies showed that zero dispersion is preferred also at the end of the negative bend section as it minimises the orbit distortion downstream, the phase advance of $\pi/2$ rad per

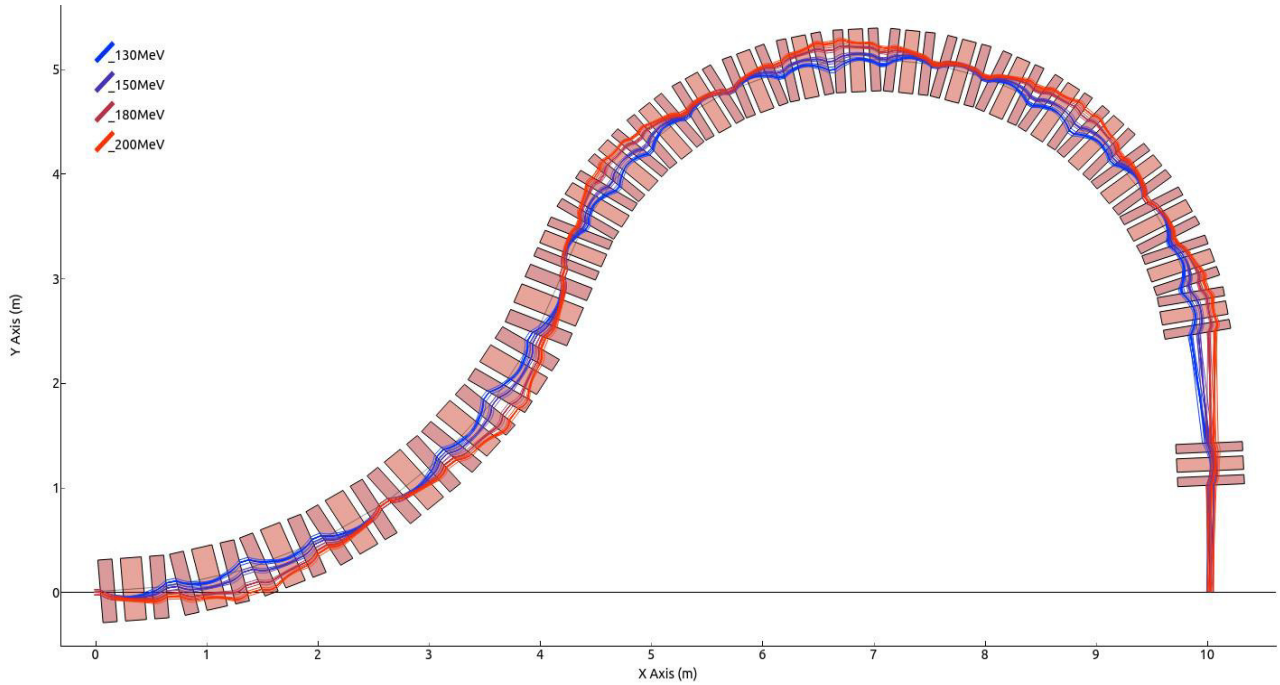

Figure 1: The layout of the novel FFAG gantry. The orbits for different energies and magnets have been 10 times enlarge for visibility. The zero dispersion condition can be clearly seen at the end of the first bending section and at the end.

cell was set in the bending plane to allow this condition; 3π/8 rad per cell was chosen in the non-bending one.

The next downstream bend section deflects the beam by 156.6° and consists of 17 identical FDF triplet cells. The value of deflection angle and the choice of the phase advances per cell (1.339 and 0.609 rad in bending and non-bending planes, respectively) have been adjusted to take into account the need to accommodate the final cell focusing the beam to the patient position, providing space to place scanning magnets and diagnostic tools, and allowing the magnetic field to practically decrease to zero at the patient position. The final cell is also of FDF triplet structure and it accommodates long straight sections of 1m in length. The additional constraints are such that the symmetric betatron functions and dispersion need to be the same as in the downstream section to assure the correct matching of the dispersion and the transparent character of the entire gantry. It sets the values of the phase advances in the final cell and together with the need for the total deflection of the gantry to be equal 90°, it fixes the value of the deflection in the final cell.

The layout of the gantry with all three cell types and long straight sections in the final cell are shown in Figure 1.

Nonlinear Optics Design

In order to avoid ramping the magnets optical conditions described in the previous section need to be preserved in a broad momentum range. In order to achieve it, the chromaticity correction is performed adjusting the phase advances in three points: at the central energy and two points close to the boundaries of the selected range (100-200 MeV) both in the bending and non-bending planes. In fact all 3 cell types are considered as periodic and the symmetry condition for the orbit is assumed. Multipole field components: dipole, quadrupole, sextupole and octupole ones are found numerically in the triplet magnets to fulfil the zero-chromatic condition in a broad momentum range. In addition the central orbit is controlled in two symmetric points to keep it centred in the vacuum chamber and to improve the stability of the numerical procedure. The resulting phase advances per cell are shown in Figure 2. The required total magnetic field obtained by summing all multipole components inside the transverse aperture, which was estimated to be about 6 cm is presented in Figure 3. The magnets assumed in the gantry would be of the superconducting type and rectangular in shape with the maximum field strength up to 4 T. Although the shortest magnet required would be only of 8.5 cm in length, it seems to be feasible. Table 1 shows the summary of the main parameters of the novel nonlinear non-scaling gantry.

Table 1: Main Gantry Parameters

Parameter	Value
Radius of the main arc [cm]	300
Proton energy range [MeV]	100-200
Max B field [T]	4
Betatron phase advance (H, V)	(12 π, 7 π)
Total number of magnets	78
Min magnet length [cm]	8.7
Magnet radius [cm]	~3

Copyright © 2013 CC-BY-3.0 and by the respective authors

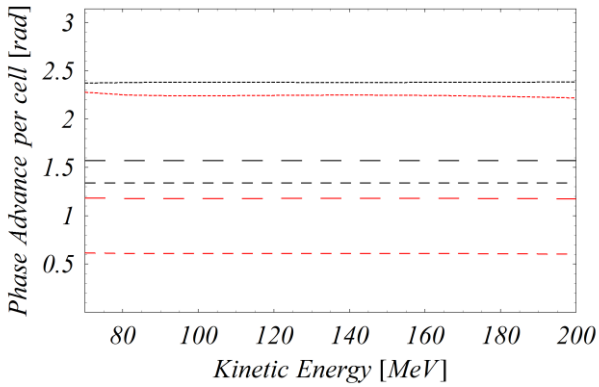

Figure 2: Phase advances per cell after correction for the first, middle and the final lattice cell types as a function of proton energy are shown using lines with decreasing order of dashing. The black and red lines correspond to bending and non-bending planes.

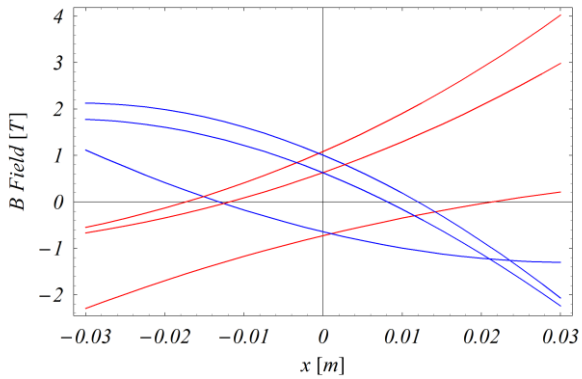

Figure 3: Total magnetic fields in all 3 lattice cell types (all 6 magnet types) within estimated aperture. Red and blue lines correspond to F and D magnets, respectively. The strongest field is required in the middle section, a bit weaker in the final cell. The different sign of deflection angle can also be seen in the magnets with the lowest fields. All magnets violate the scaling FFAG law.

TRACKING STUDIES

Tracking studies were performed in the designed gantry using Zgoubi [4, 5] and Elegant [6] codes. Results obtained with Zgoubi are presented in Figure 1, showing the orbits for different energy, while Figure 4 and 5 are showing the final phase spaces. The gaussian particle distribution with rms normalized emittance of 5π.mm.mrad was assumed. Some nonlinear distortions have been observed especially in the vertical plane, which are present only after beam passes the final cell, which may be due to a specific choice of the phase advance in that cell.

The results obtained using Elegant agreed on the middle momentum, however certain discrepancies have been observed for the off-momentum motion. It was identified for instance, that the current version of the code does not support octupole components in the combined function elements, while Zgoubi has this capability.

CONCLUSIONS

These results show that a nonlinear non-scaling FFAG gantry could be suitable for use in proton therapy. The principles of the design: the transparent beta propagation, zero dispersion and good beam transmission have been obtained. Further optimization to decrease the size and improve the final cell configuration will be performed. The gantry shown here would require superconducting magnets, which design needs still to be addressed.

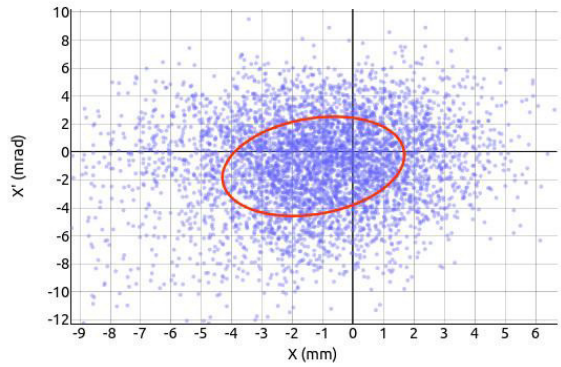

Figure 4: X-X' phase space at the end of the gantry obtained using Zgoubi at 150 MeV. Red ellipse corresponds to the rms geometrical emittance.

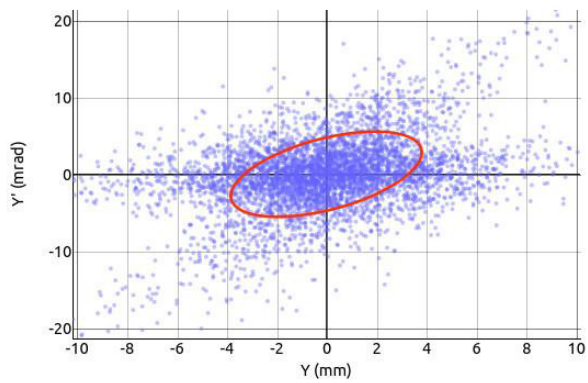

Figure 5: Y-Y' phase space at the end of the gantry obtained using Zgoubi at 150 MeV. Red ellipse corresponds to the rms geometrical emittance.

A READY-TO-USE APPLICATION OF LASER-PLASMA ACCELERATORS USING GABOR LENSES

R.M. Nichols*, UROP student, Imperial College London
M. Aslaninejad, N.P. Dover#, Z. Najmudin, J.K. Pozimski, Imperial College London
P. A. Posocco, Imperial College London / The Cockcroft Institute / Gunnar Nilssons Cancerstiftelse

Abstract

A realistic particle distribution for a proton beam generated by laser-plasma interaction is required in order to simulate its transport through a Gabor lens system intended for use in radiobiology experiments. A stack of radiochromic films were exposed to a laser-driven proton beam of 25 MeV at the Vulcan Petawatt Experiment at Rutherford Lab and subsequently analysed to find the energy deposited per film and therefore the energy spectrum of the beam. Combined with the information on the radial profile of the dose in the films, it was possible to generate an idealised particle distribution. This distribution was sampled and used as a realistic proton source in a simulation through the Gabor lens system published at IPAC'13, scaled down to 4 MeV to fit the radiobiology experiment requirements.

INTRODUCTION

An intense beam of ions is generated when a solid target, several microns thick, is irradiated by a high intensity laser pulse [eg. 1, 2]. In such a scheme, the laser ionises the surface of the target and accelerates electrons to high energies. These electrons travel through the target and upon exiting the target result in the generation of huge quasi-static electric fields, due to charge separation. This field accelerates the ions at the target surface, which are often protons, carbon and oxygen ions from the typical hydrocarbon layer on the target surface [3, 4].

Ion beams accelerated in this way have attracted interest in recent years due to their potential for use in radiotherapy and a number of other applications [5]. There has been considerable investment in recent years into hadron therapy, which can provide more targeted therapy for deep-seated tumours than conventional x-ray or electron radiotherapy. Current systems for proton therapy are extremely costly and laser-accelerated beams could offer in the long-term simple and compact treatment devices and therefore significantly reduce treatment costs. Meanwhile, while still requiring further development before being suitable for treatment, they are sufficient to allow biologists to study the effect particles produce in cells, and are already far more convenient than electrostatic accelerators commonly used for this purpose. Experimental radiobiology with particles is an area that has been only partially explored and with a strong impact on the modalities of particles delivery to patients and treatment outcomes.

We believe that laser-plasma accelerators of the current generation combined with a novel optical system based on Gabor lenses [6] is an ideal candidate for this application. If proven effective, Gabor lenses can be scaled to higher energies and thus easily applied to future laser-driven particle sources in a clinical environment.

THE PARTICLE DISTRIBUTION

The Vulcan Petawatt laser was focused to a focal spot of 4 μm (FWHM) at 45 angle of incidence onto a 100 μm thick Al target. The resultant accelerated proton beam was diagnosed using a film stack positioned 7.4 cm from the target. The stack itself is 0.66 cm thick and consisted of Al shielding followed by layers of RadioChromic Films, which darken when exposed to dose, alternated with spacers of either Fe or Al.

The set of RCFs (data taken in 2012) were scanned and the intensity value for each pixel was converted to dose by calibrating with pixel intensity values of images of RCFs exposed to known doses of radiation.

Calibration of the Films

Calibration images were obtained by scanning RCFs that had been exposed in three separate experiments when films were exposed to known doses of radiation using the Scanditronix MC 40 cyclotron at the University of Birmingham. In the area selected, the median pixel value is found for each of the colour channels of the image. A median is used rather than a mean as it will not be affected by outliers (caused by, for example, dust on the film). These values are then compared to the dose known to have irradiated the calibration films.

The results of the calibration are shown in Figure 1, in which the pixel intensity values are plotted as function of their known doses. The red channel is more sensitive than the green or blue channels and so it reaches its saturation point at a much lower dose. Therefore the red channel was used for the lower doses and the blue channel for the higher doses. The calibration switch point between the two channels was chosen at 200 Gy.

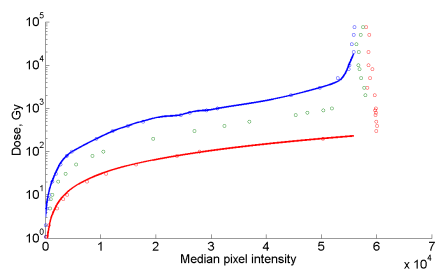

Figure 1: Calibration of how the red, green and blue channels of images of RCF respond to irradiation.

Image Conversion

For each processed image (an example in Figure 2), the image was disregarded if the mean intensity value over the entire film was less than twice the noise in the scanned image. Using this rule, only the first four RCF layers for this particular shot were used.

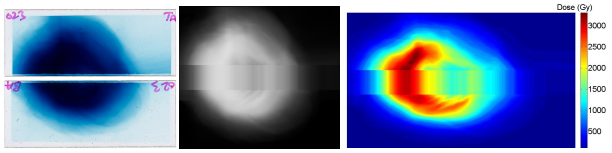

Figure 2: Scanned image of the first RCF (left), blue channel after processing (centre), dose map (right).

Reconstruction of the Energy Distribution

The dose deposited in each pixel of the scan of each RCF layer was calculated using the calibration. The mean dose in the layer was then converted to total energy deposited in the film's active layer, using the active layer density and thickness. For each of the four RCFs a profile of how much energy is deposited per proton in the active layer as a function of proton energy is generated using a series of TRIM Monte Carlo simulations [7].

The proton energy that dominates the energy deposition in each RCF is therefore found from the peak of the curves. To convert from energy deposited to the estimated proton number in the spectrum, the following initial assumptions were made:

- the area around the peak of the profile is selected using the 1/e width of the peak;
- inside this area protons of all energies deposit an equal amount of energy;
- protons with energies outside this area do not deposit any energy.

Therefore the energy deposited per proton is calculated by taking the average across this width. The number of protons in the beam depositing energy in each film is then given by the energy deposited in the film divided by the average energy deposited per proton in this peak. Hence the number of protons per MeV (dN/dE) is found by dividing the number of protons depositing energy by the width of the peaks in Figure 5. The number of protons at energies higher than 25 MeV, where the proton signal was below the noise, was set to zero.

Although the above assumptions give a good first estimate of the spectra, a large assumption is made by disregarding the dose deposited by the higher energy protons which could cause an overestimation of the particle numbers. Therefore, an iterative technique was used in which the initial spectral guess is convolved with the curve obtained with TRIM and the energy deposited in each film recalculated. The ratio of this new energy deposition value compared to the actual measured value is then found. The initial spectral guess is then modified by this ratio at each film layer, and this process is iterated until the energy deposited in each RCF calculated from the RCFs and the reconstructed energy spectrum was within 0.01%.

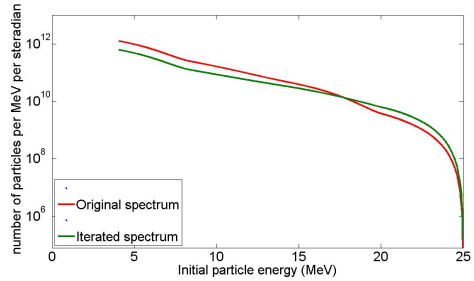

Figure 3: Comparison between the initial energy spectrum and the spectrum after iteration.

Reconstruction of the Transverse Distribution

The spreading of the beam in the direction transverse to the beam axis was assumed to be negligible over the depth of the stack (6.6 mm), as the distance between the films is less than 2% of the total distance travelled by the protons after the target. The mean transverse scattering within the stack was estimated from TRIM Monte Carlo simulations and was found to be $\sigma \approx 0.2$ mm for 35 MeV protons, negligible compared to the beam size.

The particle distribution was generated assuming that:

- the particles are emitted with cylindrical symmetry;
- the particles are emitted from a point like source;
- the particles are emitted at the same time, but with different energies;
- the particle distribution at each RCF is represented by a 2D Gaussian.

These assumptions reduce the 6D particle distribution to a 2D distribution (energy and radius). For each proton energy the particle number was first scaled with respect to the energy spectrum previously calculated. Then, a further modification depending on the spatial position was calculated by fitting a 2D Gaussian to the proton beam dose deposition profile (Figure 4). Below 5 MeV the distribution was given a spread similar to that of the first RCF in the stack.

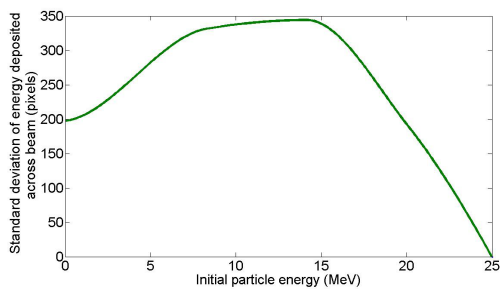

Figure 4: Spread of the dose distributed in the films as function of proton energy.

SIMULATION OF BEAM TRANSPORT

The particle distribution was converted into the GPT file format and used as input for the particle tracking simulations with GPT [8] using the lattice suggested in [6]. The preliminary results looked very unfavourable because the beam divergence is about 6 times larger than assumed and the number of particles above 10 MeV is too low for sufficient statistics (see Figure 5).

Copyright © 2013 CC-BY-3.0 and by the respective authors

Therefore a new Gabor lens with the radius of anode and cathode increased from ~20 to 35 mm was designed and the lattice setup updated (Figure 6), increasing the acceptance angle by a factor of 3. Only 200 particles are initially available for the original distribution (see Figure 5-E red scale) in the lowest energy bin considered for experiments (4 MeV) at twice the divergence angle (~240 mrad half cone angle) compared with the angular acceptance (~120 mrad) of the improved lattice: the transmission is therefore below 25% (~50 particles at start). In order to boost the statistical significance of the results an artifical particle distribution (120 mrad divergence angle and 2100 particles per energy bin) was used for comparison.

The beam trajectory behind the aperture shown in Figure 6 is well defined after energy selection. For the artificial distribution ~80% of the particles in this energy bin are transmitted. The distribution derived from experiment show similar characteristics, but the overall transmission is 7.5%, equivalent to a 33% transmission through the aperture. Both distributions (see Figure 7) show a sharp peak at the chosen energy of 4 MeV with a FWHM below the bin width of 93.8 keV, which should be fine for most applications.

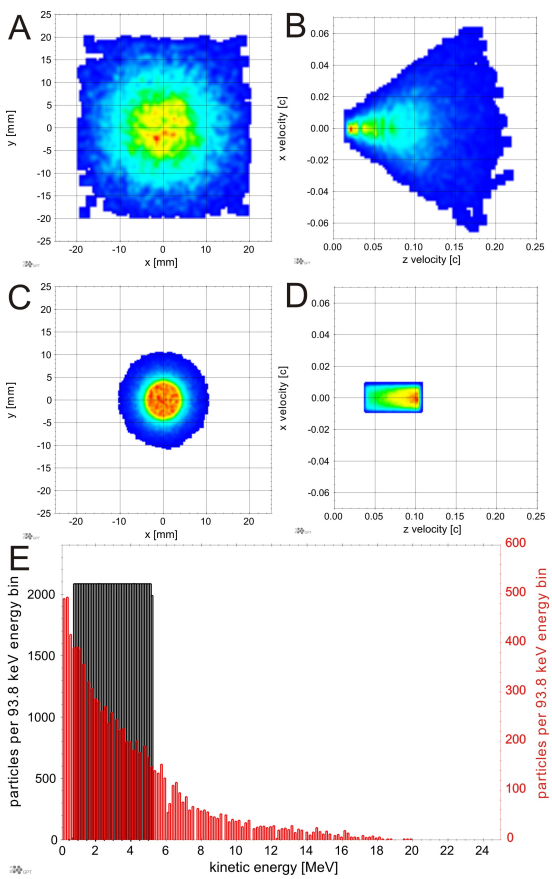

Figure 5: Graph A: transversal phase space (x,x') of the initial particle distribution and B the x-z velocity space both for the distribution generated experimentally; Graphs C and D: artificial distribution with reduced divergence angle and energy spread for comparison; Graph E: the particle number per energy bin for both distributions.

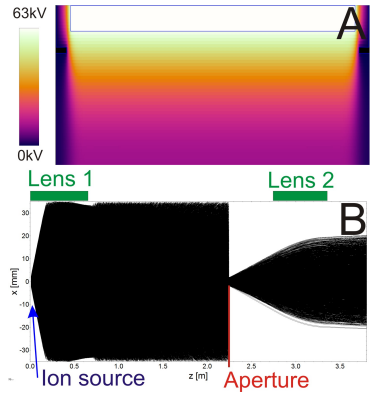

Figure 6: Lattice setup and a trajectory plot using a beam with ~120 mrad input divergence.

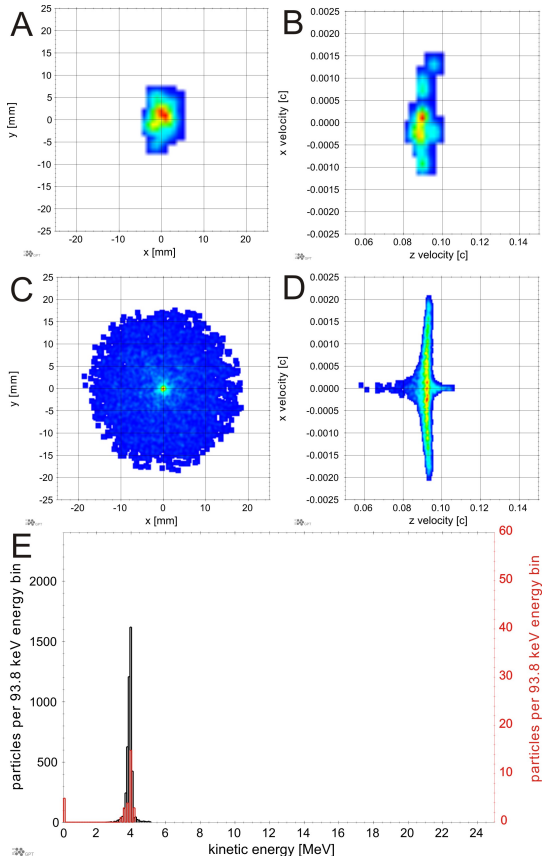

Figure 7: Graph A: transversal phase space (x,x') and B the x-z velocity space for the experimentally determined distribution after the aperture at 3.1 m; Graphs C and D: same plots for the artificial distribution.; Graph E: the particle number per energy bin for both distributions.

CHARACTERISATION OF NITROGEN CLUSTERS AND GAS JET TARGETS UNDER VARIED NOZZLE GEOMETRIES

C. Hughes, N.P. Dover*, Z. Najmudin, P.A. Posocco, Imperial College London

Abstract

Gas jets are widely used for targets in laser-plasma driven article acceleration experiments. Optimising the mechanism requires tailored gas jet density profiles. Therefore, high density gas profiles have been investigated and characterised using different types of nozzles: sonic, supersonic, slit and supersonic slit. Gas jet profile optimisation was examined using nozzles of different diameters while varying gas pressure between 0 and 100 bar and valve opening duration. Gas jets produced by the nozzles were characterised using an optical probe laser. The gas jet density profile was measured through interferometry which was captured using a CCD camera. A second camera was used to record the Rayleigh scattering from the laser to confirm the presence clustering in nitrogen at high pressures.

INTRODUCTION

Recent research into laser-plasma ion acceleration has demonstrated beams with various characteristics from a number of different target types. The use of solid targets presented two widely investigated mechanisms: target normal sheath acceleration (TNSA) and radiation pressure acceleration (RPA) [1]. For applications that require high energies and monoenergetic beams, RPA is seen as the more desirable mechanism for acceleration due to the characteristics of the accelerated beams, though has been difficult to achieve in experiments [2][3]. Solid targets can add complications to the ion source as they require very high laser contrast to avoid their destruction, create debris, result in multispecies beams, and may cause difficulty for high repetition rate systems for applications.

Gas jet targets have been seen to offer a solution to these issues. Gas jet targets have been widely used for laser wakefield electron acceleration [4], and some more recent studies for ion acceleration. For example, recent experiments have demonstrated monoenergetic proton beams from the interaction of a CO2 laser with gas jets [5], generated from the laser radiation pressure acting on a low density, but opaque, plasma. Interest in gas targets has led to the development and subsequent optimisation. The acceleration mechanism can be optimised via tailored gas jet density profiles through altering nozzle geometry (Figure 1).

Under high pressure and specific conditions a range of gases have been found to form small grouping of atoms which are loosely bound to each other through their Van der Waals forces. These are known as gas clusters. The formation of clustering in supersonic gas jets is a concept that has been observed for many years, along with their dependency on pressure and nozzle size [6]. Clustering gases are of interest in targetry mainly in relation to high intensity laser-plasma interaction as they provide very high absorption of laser energy [7]. It has also been shown that high pressure gas clustering can be utilised as targets in ion acceleration [8]. More recently, an experiment has been reported investigating a selection of nozzle geometries: sonic, supersonic, slit and supersonic slit (Figure 2).

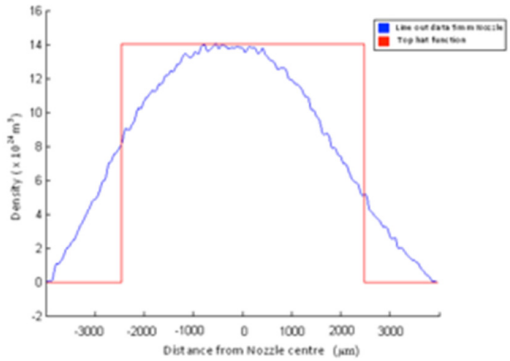

Figure 1: Ideal gas jet would possess a density profile that follows the shape of a top hat function. Actual jets do not produce such a steep density gradient.

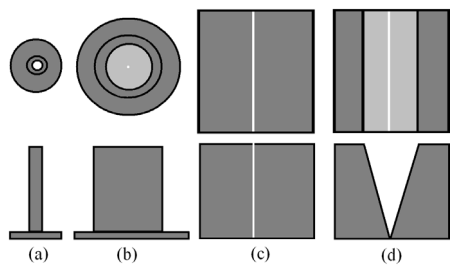

Figure 2: Examples of nozzle geometries for (a) sonic nozzle (b) conical nozzle (c) slit nozzle (d) supersonic slit nozzle.

EXPERIMENTAL SET-UP

Nozzles

A selection of nozzles was used to produce gas jets bearing different characteristics due to their geometries. Additionally, the effect of placing an insulator before the nozzles was investigated (Figure 3). These included a 10 mm diameter conical supersonic nozzle with an entrance aperture of 2 mm, a 2 mm diameter conical sonic nozzle and a slit nozzle. The slit nozzle was shaped with pliers from a 2 mm sonic nozzle to approximate the properties for this geometry. The slit dimensions were verified the CCD camera. This set up was found to be able to observe clusters in argon gas through a probing laser and the resulting Rayleigh scattering [9].

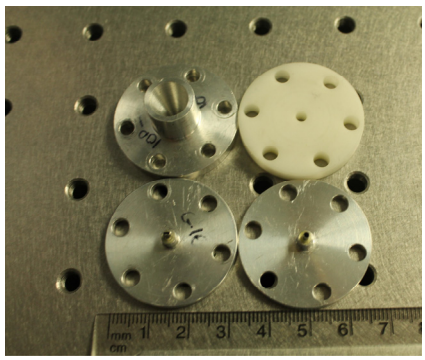

Figure 3: Nozzles used (diameters given). From left: (top) 10 mm conical nozzle, insulator (bottom) 2.5 mm by 1 mm slit nozzle, 2 mm conical nozzle.

The introduction of an insulator should reduce the likelihood of discharge onto the nozzle from the laser-plasma area. Discharge can lead to degradation of the nozzle or could obscure or completely obstruct the plasma feature that is being observed or, potentially, influence laser-plasma interactions differently.

Mach-Zehnder Interferometry and Rayleigh Scattering

High-pressured nitrogen gas was passed through nozzles inside a controlled vacuum chamber where the gas was then characterised using an optical probe laser. The laser used was a ~1 mW CW Helium-Neon 632.8 nm laser .The gas jet density profile was measured using a Mach-Zehnder interferometer (see Figure 4). After both paths were recombined, the fringe shift was captured using a high frame rate CCD camera, allowing measurement of the time evolution of the gas jet as well as the spatial properties. A second camera (Qimaging camera) was used to record the Rayleigh scattering from the laser to confirm the presence clustering.

For each of the nozzles, pressure, valve opening duration and gas jet-time evolution were investigated. Gas jet pressure was varied between 0 and 100 bar and valve opening duration between 6 ms and 150 ms with the fringe shift being taken at a time where the jet was deemed stable. The gas jet evolution to reaching this point of stability and after was also viewed.

Image Processing

Images produced through interferometry were analysed using a method earlier used to review gas jet density profiles of needle nozzles [10]. The processing script was written using Matlab.

Phase shift maps were compared with a reference (control) image to obtain the net phase shift experience under the gas evolution. Region containing shift - found above the nozzle - was then selected to reduce redundant processing and thus reduce computing time. The sampled region selected was Fourier filtered around the frequency space of the interferometry fringes to remove noise. This is then used to produce a 2D image of the phase shift as a function of space. Lastly, the geometrical conditions are applied resulting in a density profile that accounts for nozzle shape and symmetry. The Abel inversion was used for nozzles which possessed cylindrical symmetry (conical nozzles). Gaussian smoothing is also applied to remove noise and achieve main characteristic.

The area of interest from the density profiles was selected as 0.7-1 mm height above the nozzle exit, which is where the laser will be focussed on the high intensity laser experiments the gas targets, will be used for. This position is a chosen compromise between achieving the best density profile at the nozzle exit while avoiding any possibilities of ablating or melting of the nozzle caused by intense laser contact.

Scattered light from clusters will be visible in the images without any processing [9].

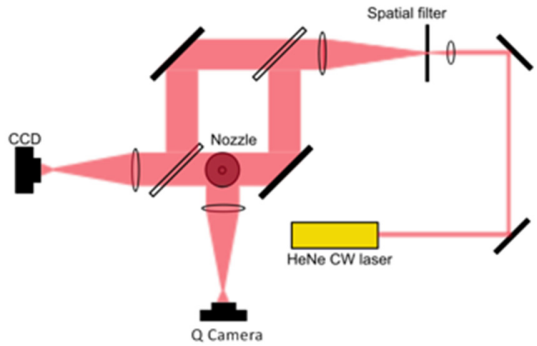

Figure 4: Experimental set up used. Combining Mach-Zehnder interferometry with an additional focussing lens and camera to image Rayleigh Scattering from the probing laser due to clusters within the gas medium.

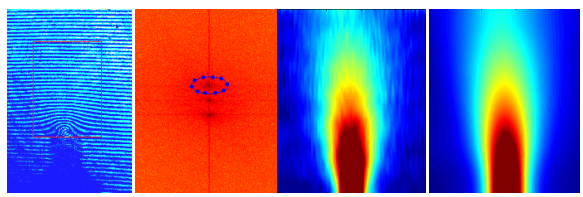

Figure 5: Interferometry image processing (from left): 1 showing region selected for transforming (red box), 2 showing Fourier transformed phase map with sample area highlighted (blue ring), 3 gas jet density profile, 4 smoothed density profile with geometric compensations.

CLUSTER FORMATION

From analysing the images taken by the Qimaging camera, Rayleigh scattering from the probing laser was not observed. This is believed to be resulting from: low camera resolution, light lost in path to camera and the intensity of the laser not being high enough to produce a measureable scatter when accounting for losses. The experimental set up will be amended to resolve these issues.

Density Profiles of Nozzles

Analysis of the phase maps indicates that both transverse (Figure 7) and parallel (Figure 8) of the slit nozzle have a different characteristic shape to that of the sonic nozzle (Figure 6) across the range of pressures. Throughout the phase line outs for the transverse slit, a

Copyright © 2013 CC-BY-3.0 and by the respective authors

plateau is visible around the region of highest phase shift, on the axis of the nozzle centre. This accounts for the wider diameter of the nozzle. A distinct, sharp peak is visible where the phase shift is at maximum for those when the slot nozzle is parallel to the probing laser (Figure 8). This was also expected due to its decreased diameter.

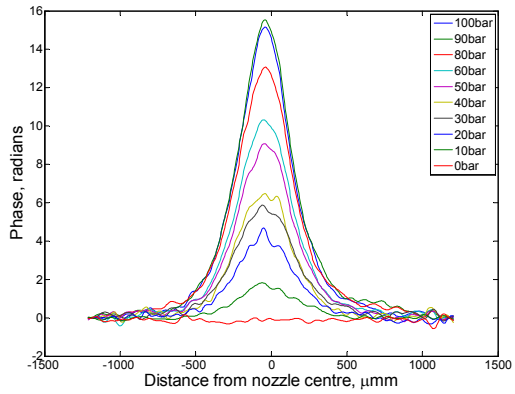

Figure 6: Phase line out 1 mm above nozzle normal to laser and gas jet for 2 mm diameter sonic nozzle.

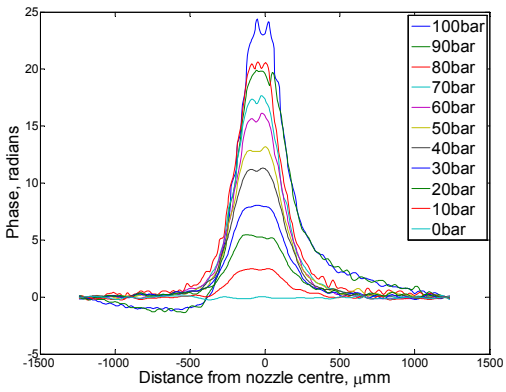

Figure 7: Phase line out 1 mm above nozzle normal to laser and gas jet for 2.5 mm x 1 mm slit nozzle at normal incidence.

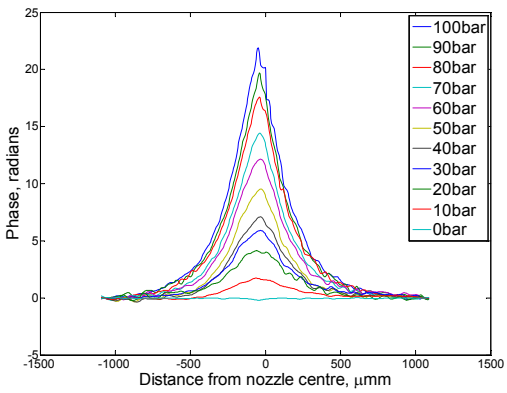

Figure 8: Phase line out 1 mm above nozzle normal to laser and gas jet for 2.5 mm x 1 mm slit nozzle at normal incidence.

Both orientations of the slit nozzle achieved higher phase shift than those achieved at the same pressures for sonic nozzle. This is a result of the decreased area at the exit of the nozzle.

The phase shift at the centre of the nozzle was found to be higher throughout the range of pressures when the slit was orientated normal to the laser. It was expected that greater phase shift would be observed when the slit of placed parallel as this would present a longer gas medium, more laser interaction and thus, greater phase shift. This could be a result of the experimental set up, i.e. slit on parallel to incidence or may suggest that the gas diverges differently from the slit nozzle to predictions.

CONTINUATION OF THE EXPERIMENT

A higher power laser will be incorporated in the set up. This should lead to a greater amount of Rayleigh scattering from the laser which should be detectable by the camera. An improved imaging system will be introduced to increase the scattering solid angle being captured by the imaging system. Coning and casing around the path between nozzle and camera may be added to reduce noise. Lastly, a lens will be placed before the nozzle to focus down the laser at the gas jet-laser interface.

New slit and supersonic slit nozzles have been designed (Figure 9) and these will be tested, following the same method and experimental set up as before.

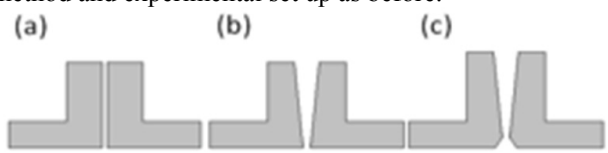

Figure 9: Supersonic slits: These are formed from two pieces as opposed to the single piece structure of the originals allowing the entrance aperture and nozzle diameter to be varied. Shown are the prism faces of each and all have a depth of 35 mm: (a) 15 mm x 15 mm (b) 15 mm x 15 mm with wall angle of 2° (c) 18 mm x 15 mm with wall angle 2° and lower of 65°.

CONSTRUCTION AND TESTING OF THE DUAL SLOT RESONANCE LINAC*

N. Barov, D. Newsham, R.H. Miller, FAR-TECH, Inc., San Diego, CA 92121

Abstract

The dual slot resonance (DSR) linac is a novel method of providing enhanced coupling to a coupled cavity linac system, resulting in very strong coupling. For the 11-cell, 2856 MHz structure described here, the acceleration mode bandwidth is about 650 MHz, which is an order of magnitude greater than many traditional side-coupled and axis-coupled linacs. The strong coupling promotes phase and amplitude stabilization, and offers decreased sensitivity to fabrication errors. We describe the construction, tuning, and RF conditioning of the prototype structure.

INTRODUCTION

The basic concept of the DSR linac was reported in [1], and that article contains a more in-depth explanation of this linac type. FAR-TECH was granted a patent for this technology [2]. The geometry of a pair of linac cells is shown in Figure 1, which shows a half-geometry of the vacuum region inside the linac structure. A group of two resonant slots connect two adjacent linac cells through an intervening swept triangular volume which we refer to as a "void". The void region serves to provide RF coupling between the two slots. Each group of two slots has two collective resonant modes: a mode at around 1 GHz, and the working mode at the target operating frequency of 2.856 GHz. The mode split between these collective modes is so large that the pair of slots can effectively be considered a single oscillator at 2.856 GHz. The two slots serve the same purpose as a coupling cell in a side coupled linac. The advantages of the DSR linac include: a very large coupling with about 22% bandwidth, a compact geometry, no additional radial space required for the coupling cells, and shunt impedance competitive with a side-coupled linac. Simulations with HFSS [3] and with Omega3P [4] predict a shunt impedance ZT^2 of 85 $\mathrm{M\Omega/m}$. This is competitive with other linac designs featuring large coupling such as the PWT design [5], and is slightly less efficient than an equivalent side-coupled linac, which might have about 8-10% higher ZT^2 with the same basic cavity and nose cone shape. The linac is designed for the UCLA Pegasus laboratory to aid in ultra-short electron bunch experiments [6] by boosting the beam energy by a design 10 MeV. The linac can also be operated in bunching phase, which will further shorten the bunch length and enable better resolution for experiments such as electron diffraction studies. It is hoped that the DSR linac design will also find uses in industrial and medical applications.

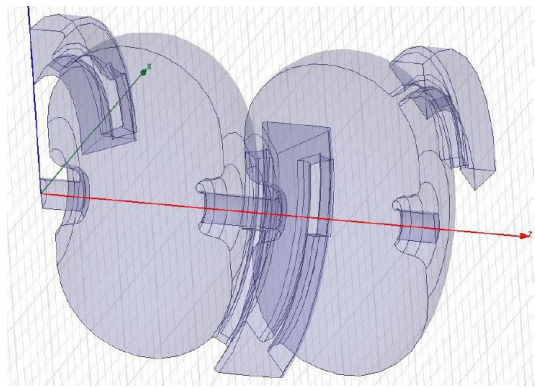

Figure 1: HFSS geometry used to model two cells of the DSR linac.

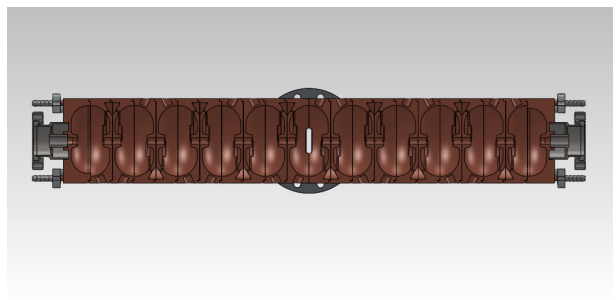

Figure 2: A cross section view of the 11-cell DSR linac.

DESIGN AND CONSTRUCTION

Design

An 11-cell DSR linac was designed with HFSS and Omega3P, as shown in Figure 2. End cells were transversely displaced in order to limit dipole kicks, and the central coupling cell shape was designed to minimize the mode pull due to the RF coupler. The linac is cooled with four cooling tubes running the length of the structure. The RF connection is via a WR284 waveguide and Skarpaas flange, and vacuum connections to the beamline are made with 2.75 inch ConFlat flanges. The beam clear aperture diameter is 8 mm. The band surrounding the accelerating mode extends from 2.513 to 3.153 GHz, making the frequency spacing from the accelerating mode to the closest nearby modes 45 MHz in our 11-cell structure. In a linac with $\pi/2$ phase advance per cell, the dispersion curve should be closed by tuning the even and odd oscillators to the proper frequency. The tolerance for the amount of closure depends on the overall bandwidth, and we have estimated that a residual stop band of as much as 3 MHz will not harm the electrical properties of the structure. Time

Figure 3: A finished half-cavity copper part.

dependent studies simulating the RF fill transient, as well as steady-state field balance sensitivity studies, reveal that a larger stop band, beyond 10 MHz, does indeed start to affect performance.

Construction

The copper components for a half cell were made with a combination of lathe and 5-axis milling processes, which is more complicated than what is required for other linac types. We estimate that components for this linac type are 50-100% more expensive to machine than for conventional linac types, but this added cost is only a small fraction of the overall cost of producing the structure, and is offset by the simplified tuning method discussed below. Figure 3 shows a finished half-cavity part. The full linac was brazed with Au/Cu alloy in a dry hydrogen atmosphere using three braze steps.

TUNING AND BEAD PULL

The purpose of bead pull and structure tuning is to close the dispersion curve, achieve the correct operating frequency, and properly balance the field gradient in each cell. Tuning steps were interspersed with bead pull measurements and data fitting to a matrix model. A matrix description used one oscillator for each linac cell and one oscillator representing the collective mode of a pair of slots. The full eigenvalue equation has the form:

$$\mathbf{M}\mathbf{V} = \frac{1}{f^2}\mathbf{V} \qquad (1)$$

with $\mathbf{V}$ describing the voltage in each oscillator, and $\mathbf{M}$ for an example five-oscillator system is given by:

$$\mathbf{M} = \begin{bmatrix} \frac{1}{f_1^2} & \frac{k_{ac}}{2f_1^2} & \frac{k_{aa}}{2f_1^2} & & \\ \frac{k_{ac}}{2f_2^2} & \frac{1}{f_2^2} & \frac{k_{aa}}{2f_2^2} & \frac{k_{cc}}{2f_2^2} & \\ \frac{k_{aa}}{2f_3^2} & \frac{k_{ac}}{2f_3^2} & \frac{1}{f_3^2} & \frac{k_{ac}}{2f_3^2} & \frac{k_{aa}}{2f_3^2} \\ & \frac{k_{cc}}{2f_4^2} & \frac{k_{ac}}{2f_4^2} & \frac{1}{f_4^2} & \frac{k_{ac}}{2f_4^2} \\ & & \frac{k_{aa}}{2f_5^2} & \frac{k_{ac}}{2f_5^2} & \frac{1}{f_5^2} \end{bmatrix}, \qquad (2)$$

where the matrix for the full 21-oscillator system follows the same pattern, f_i is the natural frequency of the i^{th} oscillator, k_{ac} is the coupling coefficient from the cell to the coupling slots, and the remaining coupling terms are the next nearest neighbor coupling terms from one accelerating cell to another (k_{aa}) and from one set of coupling slots to another (k_{cc}).

The tuning procedure is significantly different for the DSR structure than for a conventional side-coupled structure. Adjustments made to a single slot in a two slot system are capable of adjusting the field balance of the structure, and these adjustments can be performed after the final braze. The effect of such tuning is shown in Figure 4, which shows the slope of the before and after plots to be mostly consistent, except between cells 7 and 8 where the adjustment was made. Adjustments to both slots also have an effect on the resonant frequency of the surrounding cells, and can be used to tune the structure frequency as a whole, as long as the dispersion curve tolerance is adhered to. Although the structure was built with dimple tuners in each cell and deformable wall push-pull tuners at the end cells, these did not have to be used to arrive at the final tune, and all tuning was performed entirely by slot adjustments. The tuning method consisted of tightening a two-piece aluminum collar around the linac while monitoring the mode frequencies. In the final field balance measurement, all cells were within $\pm 1.9\%$ of the average. The dispersion curve was closed to within 400 kHz, much better than the initial goal.

We believe this tuning method, together with relaxed tolerances afforded by the large bandwidth, can simplify the production of a DSR linac structure. RF measurements of the as-machined half cell components were consistent enough that we believe it may be possible to machine the components to their net final shape in one machining pass with no additional tuning cuts. It may also be possible to eliminate any stack-up and bead pull tests performed ahead of the brazing operation. In this scenario, the only difficult stage would be the final tuning, which can be guided by a computer model.

POWER DISTRIBUTION

For the installation at the Pegasus laboratory, we have acquired or built the major waveguide components to distribute the power to the linac, including a high-power phase shifter, directional coupler, power divider, and several adapters between different flange types. The power divider, shown in Figure 5, was designed and built by FAR-TECH following the idea of the variable tap-off (VTO) device developed for ILC [7]. The device has four waveguide ports including an input port, an isolated port, and two output ports. In order to change the power split, the fastening bolts must be loosened and the central cartridge rotated to the new position. The device was designed for infrequent changes to the power ration, as the adjustment also de-pressurizes the SF_6-filled waveguide. A challenge for the power divider RF design was to optimize the RF

Copyright © 2013 CC-BY-3.0 and by the respective authors

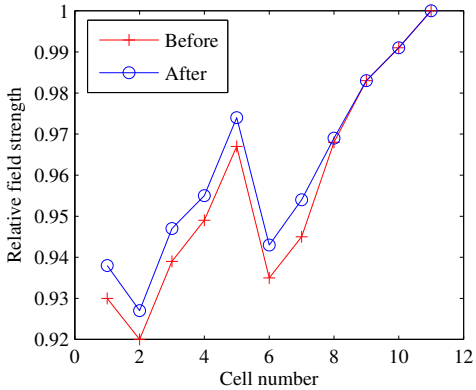

Figure 4: Effect of tuning slots balance between cells seven and eight.

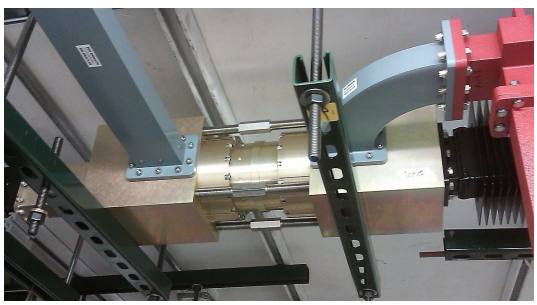

Figure 5: The waveguide variable power divider.

parameters (return loss, isolation, range of power split adjustment) while keeping the device as compact as possible, at just over 22 inches in length. The device was optimized with a computer-based minimization procedure, which resulted in a measured isolation and return loss of better than 24 dB for any power split setting, and adjustment of the power split between 0% and >98% from the input to the #2 port. The power divider was able to transmit the full klystron output of 12 MW under 1 atm of SF_6 pressure.

RF CONDITIONING AND TESTING

The linac was brought to the UCLA Pegasus laboratory for conditioning. After two days of conditioning, the input power was consistent with a 9.3 MeV energy gain through the structure using the calculated shunt impedance. The cavity field estimate should be considered imprecise because the lack of a flat top on the input RF pulse had the effect of the system never reaching steady-state, and the number was obtained by averaging the net input power over the last half of the pulse. Figure 6 shows the linac installed in the Pegasus beamline, just ahead of the spectrometer magnet. The testing of the linac with beam is reported by R. Li [8]. In actual operation, the linac reached 7.5-8.0 MeV energy gain with 1.8 MW power input. The energy gain was limited by the power divider setting, and with more power as well as slightly better vacuum ($< 3 \times 10^{-8}$ Torr), the full design energy gain of 10 MeV would likely be realized. The linac is used to boost the energy of the Pegasus laboratory gun, as well as to perform bunch compression through velocity bunching. This has allowed the facility to achieve < 100 fs electron pulses which are needed for ultrafast electron diffraction experiments.

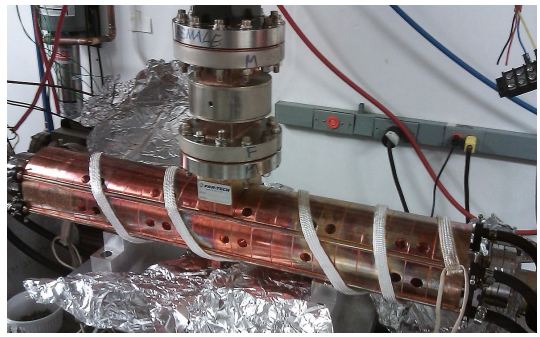

Figure 6: The DSR linac as installed in the Pegasus beamline at UCLA.

CONCLUSIONS

We have conceptually developed, built, and tested a linac structure based on dual slot resonance coupling. The linac was installed at the Pegasus laboratory at UCLA, where it is used to boost the beam energy and perform velocity bunching to achieve < 100 fs bunch length for ultrafast electron diffraction microscopy applications. The new linac design is more compact than a side-coupled structure and the large bandwidth, combined with the unique properties of the structure, results in simplified manufacturing.

Abstract

Recently, the Advanced Accelerator and Ultrafast beam Lab (AAUL) at Idaho State University (ISU), has been developing an X-band linac for the medical CyberKnife project by collaborating with Korean Atomic Energy Research Institute (KAERI) and Radiation Technology eXcellence (RTX) [1–3]. The medical CyberKnife is essentially an X-band linac, which is attached to a robotic arm for precise cancer treatment. The X-band linac has considerable advantages in cancer treatment over C-band or other RF linacs, partly due to its compact size and light weight. These qualities make the X-band linac easier to attach to a robotic arm, thus making it more maneuverable. Other advantages include a higher accelerating gradient and a higher shunt impedance. Since high mobility is necessary for precise cancer treatment, the compact X-band RF linac was selected for the CyberKnife project. This paper describes detailed design processes of the X-band linac structure, which was done with 2D SUPERFISH and 3D CST MICROWAVE STUDIO (CST MWS) electromagnetic simulation programs.

INTRODUCTION

Recently, ISU AAUL, KAERI, and RTX have been developing an X-band Standing Wave (SW) RF linac for the CyberKnife robotic radiosurgery system. CyberKnife is a non-invasive cancer treatment technique, which can be used for a multitude of cancers or tumors in the human body [4]. By adjusting a robotic arm housing the X-band linac precisely, CyberKnife can target with pinpoint accuracy. The X-band linac is used to deliver high doses of radiation directly to the cancer or tumorous areas. This process is a major improvement over older and harsher cancer treatment techniques and has the potential to save thousands of lives. The expected parameters of the X-band linac for the CyberKnife project is summarized in Table 1. The X-band linac consists of a π-mode SW linac structure with 15 cells and a coupler as shown in Fig. 1. By using the π-mode, a higher shunt impedance and a higher gradient can be obtained [5]. For the RF power source of the linac, an X-band coaxial pulsed magnetron manufactured by L-3 Communications was selected [6]. Therefore, the linac was optimized to make an RF resonance at 9.3 GHz.

* cryptoscientia@gmail.com

Table 1: Parameters of an Optimized X-band Linac

Parameter	Value	Unit
length of the linac	0.25	m
initial beam energy from gun	20	keV
maximum beam energy at linac exit	6	MeV
RF frequency	9.3	GHz
maximum RF input power	2.36	MW
shunt impedance	78	MΩ/m
maximum energy gain per cell	400	keV
unloaded quality factor	8306	·
external quality factor	7099	·

By knowing the RF resonant frequency, the cell lengths and cell radii of the linac structure can be calculated in advance. The cell length l of the π-mode SW linac structure is given by

$$l = \beta \frac{\lambda_{RF}}{2}, \quad (1)$$

where β is the relativistic velocity of electrons, and λ_{RF} is the RF wavelength of the linac structure [1]. In our linac design, the bunching cells in the linac structure correspond to the cells where β is smaller than 0.95. All these initial conditions were used in 2D SUPERFISH simulation to find a basic geometry of the linac structure. A MATLAB program was developed to work in conjunction with the 2D SUPERFISH program to design basic geometries of each bunching cell and nominal accelerating cell. These individual cells are then combined in series to form a full linac structure with good electric field symmetry. Therefore, we can save our working time to find full geometry of the X-band linac structure with good electric field symmetry by using the homemade MATLAB and SUPERFISH combined program. Then, 3D CST MWS was used to optimize the linac structure and coupler by starting with the full geometry generated by the MATLAB and SUPERFISH combined program. Once the design is completed with CST MWS, it will serve as a blueprint for an actual working model.

2D SUPERFISH SIMULATION

SUPERFISH is a 2D electromagnetic field solver created and distributed by the Los Alamos National Laboratory to evaluate cylindrically symmetric RF accelerator cavities [7]. The cells in the X-band SW RF linac structure

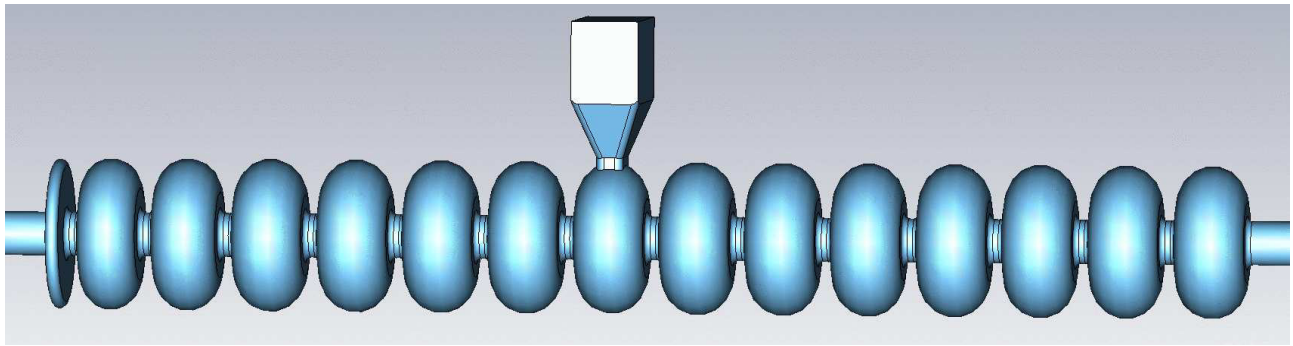

Figure 1: 3D CST MWS simulation result for an X-band linac structure with 15 cells summarized in Table 2.

were individually modeled using the SUPERFISH elliptical cavity tuning program ELLFISH. ELLFISH tunes an elliptical cell for explicit beam parameters and geometric constraints by making slight adjustments in the geometry of the cell. The geometric constraints are determined by the parameters of the electron beam. In this case, unbunched electron beam enters the linac structure with kinetic energy of 20 keV from the electron gun. Then, the bunching will be developed at bunching cells in the linac structure. The linac accelerates the electron beam through each cell in the structure and exits with a total energy of 6 MeV.

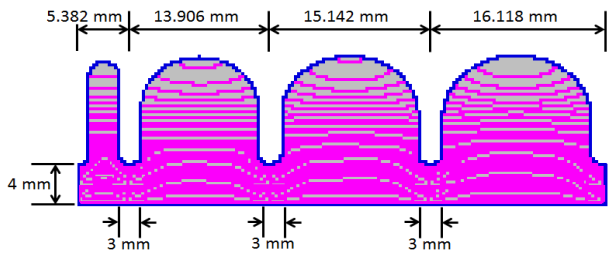

Figure 2: 2D SUPERFISH simulation result for a linac structure with four bunching cells.

The field symmetry along the linac cells is dependent upon the radius of the linac cells as summarized in Table 2. The semi-major and semi-minor ellipses of the elliptical cells can be calculated from the cell length, cell radius, and the desired septum thickness and iris radius. ISU AAUL has developed a MATLAB program to expedite the modeling of the linac structure with several bunching and nominal accelerating cells. The boundary constraints for the SW π-mode in the linac are hard coded into the program. The program allows for the user to input a desired frequency, the β values for the bunching cells and nominal cells with $\beta = 1$, and the desired iris radius. The program also offers an option to specify the mesh size and to add an extended beamline to the structure. The MATLAB program writes the geometrical parameters, calculated from the data input by the user, to several ELLFISH control files. ELLFISH executes each control file, optimizes the geometry for each cell, and writes the optimized geometries to a set of output files. The MATLAB program splices the individually optimized cell geometries, writes the multi-cell geometry to a single control file, and executes the control file in Autofish. Autofish performs an electromagnetic analysis of the multi-cell linac structure as shown in Fig. 2. WSFplot displays the longitudinal electric field. The shunt impedance, power dissipation, and transit-time factor are located in the PMI output files for the multi-cell linac structure.

Table 2: Detailed Geometry of the X-band Linac Cells

Cavity	Radius (mm)	Length (mm)
1^{st} bunching cell	13.680	5.382
2^{nd} bunching cell	13.850	13.906
3^{rd} bunching cell	13.906	15.142
4^{th} cell	13.949	16.118
5^{th} cell	13.950	16.118
6^{th} cell	13.950	16.118
7^{th} cell	13.951	16.118
8^{th} coupling cell	13.790	16.118
9^{th} cell	13.950	16.118
10^{th} cell	13.951	16.118
11^{th} cell	13.950	16.118
12^{th} cell	13.950	16.118
13^{th} cell	13.949	16.118
14^{th} cell	13.949	16.118
15^{th} cell	13.929	16.118

DESIGN OF RF COUPLER

The RF input is channeled through a WR-112 waveguide with an inside dimension of 28.4988 mm $\times$ 12.6238 mm with an allowable frequency range of 7.05 GHz to 10.0 GHz. Using these waveguide dimensions, the coupler design could be developed for the structure. Placing the coupler in the central location in the accelerating structure provides greater separation of modes [8]. The waveguide dimensions needed to be reduced to an appropriate size to couple with the X-band structure. This was accomplished by tapering the X-band waveguide to the RF power input window of the 8th coupling cell as shown in Fig. 1. The RF power input window to the coupling cell has the di-

Copyright © 2013 CC-BY-3.0 and by the respective authors

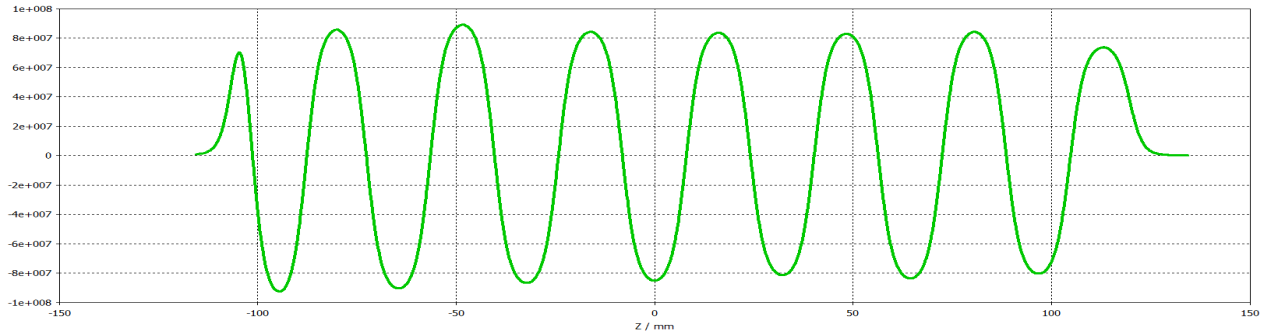

Figure 3: Electric field along the axis of the X-band linac structure summarized in Tables 1 and 2.

mensions of 10.7 mm $\times$ 5.0 mm and comes straight up out of the cell 1.0 mm. The waveguide, tapered area, coupler window and the coupling cell were tuned as a single cell, apart from the full structure. This single cell was given the proper boundary conditions in CST MWS as shown in Fig. 1. The dimensions of cell radius and coupler window have been tuned to obtain a coupler coefficient $\beta = 15$, which is the same as the total number of cells at the resonance frequency of 9.3 GHz. This coupling coefficient of $\beta = 15$ provides the maximum RF power coupling to each of the 15 cells in the full structure [8]. After this coupler is tuned individually, it is then placed into the full structure and tested once more. Experience shows that this coupler still will need an adjustment before it will work properly in the full linac structure.

3D CST MWS SIMULATION

CST MWS provides 3D manipulation and a more in-depth testing ground for the X-band structure [9]. To get a higher shunt impedance, generally, we may choose cell geometries with the nosecones. However, as shown in Figs. 1 and 2, all cells of the X-band linac structure have the bell shapes instead of the nosecone ones for easy fabrication. To obtain the symmetric electric field for the whole linac structure, the radius of each cell was individually modified by small increments [5]. These small increments were determined by the physical machining tolerances, which are ± 2 μm. Even small changes in the cell radius generate big impacts on the symmetry of the electric field. The cavity radius and the iris radius of each cell are inversely proportionally to the global frequency and the local electric field strength. Since the iris radius is directly related to the frequency separation between electromagnetic modes, we chose 4 mm for the iris radius of the linac structure to keep the mode separation larger than 5 MHz. Any shape made in CST MWS is carved from a default background of uniform conducting solid material and the carved shape is assumed to be vacuum. Once the cells, irises, and a coupler are connected into one solid structure, the electric fields can be optimized. The electric field was optimized for π-mode in CST MWS using the *Eigenmode Solver Parameters* tool to produce the desired field as shown in Fig. 3. This tool uses one of two solvers: the Advanced Krylov Subspace method (AKS) and the Jacobi-Davidson method (JDM). AKS measures modes with the lowest resonant frequencies, whereas the JDM measures modes at arbitrary positions specified by user input; this X-band structure used JDM [9]. The specifications of *Eigenmode Solver Parameters* tool were shown to be the first five modes above the frequency of 9.295 GHz. To help alleviate the calculation time, the *Boundary Conditions* toolbox has an option under the *Symmetry Planes* tab to cut the structure into symmetrical sections for calculation purposes. This process of optimizing the electric field was the most time consuming part of the X-band linac design.

SUMMARY

An X-band SW linac structure was successfully designed with SUPERFISH and CST MWS. The linac will be operated in π-mode to generate 6 MeV electron beam for the CyberKnife. The central RF coupler was designed and optimized to produce a symmetric electric field for the X-band structure as shown in Fig. 3. The final optimized geometry of the X-band linac structure is shown in Fig. 1 and its parameters are summarized in Tables 1 and 2. The next steps in the process are to simulate the X-band linac with a copper shell and design the heat dissipation method for the structure. Then it will be built and tested as an electron beam source for the medical CyberKnife project. Independently, we also have been optimizing a longer X-band linac structure with 25 cells.

COMPACT SCHEME FOR LASER-FREE THZ-SUB-THZ SOURCE*

A. V. Smirnov#, RadiaBeam Technologies Inc., Santa Monica, CA 90404, USA

Abstract

Undulator-free schemes based on resonant Cherenkov radiation in a small insertion device driven by a few MeV RF electron injector and alpha-magnet are considered. S- and C-band RF guns are compared to X-band multi-cell microlinac. Preference is given to planar radiator and wide quasi-flat sub-ps bunches that can be obtained with alpha magnet. It is shown that up to a milli-joule of sub-THz energy can be produced within a macropulse.

INTRODUCTION

Relatively insignificant number of facilities such as synchrotron radiation sources and free electron lasers (FELs) around the world are dedicated specifically to the THz range to deliver substantial power to users. Obviously, more facilities are needed to cover the rapidly growing demand in dedicated sources for THz science and technology [1]. However, conventional radiation facilities based on FELs, electron storage rings, and/or energy recovery linacs (ERLs) are too large, expensive, and not readily available for a broader community of researchers, investigators, scientists and commercial applicants to operate it on a flexibly customized, on-demand, independent base. For narrow bandwidth radiation generation, resonant Cherenkov resonant radiation is an attractive alternative to undulator radiation due to relative frequency independency from the beam energy (for relativistic beams) and due to the much higher equivalent shunt impedance. Coherence is provided by the Cherenkov synchronism between the microbunches and fundamental (or one of the lowest) eigenmode(s) along the interaction space hundreds of wavelengths long.

THE CONCEPT

This source concept illustrated in Fig. 1 can be utilized for container inspection, screening, safe imaging, cancer diagnostics, surface defectoscopy, and many other applications. Substantial average power can be provided by using thermionic, plasma [2], field [3] or secondary emission [4] that can be perfectly combined with RF cavity.

The THz radiation is generated by beam pre-bunching and chirping in the RF gun, followed by microbunching in a magnetic compressor and resonant Cherenkov radiation of an essentially flat beam in a robust, planar, structure with mm-sub-mm gap. The proof-of-principle has been successfully demonstrated recently on a 5 MeV beam driven by an L-band thermionic injector [5].

We calculate the energy radiated by a single microbunch using the modal energy loss found analytically with the eigenmode excitation theory applied in time domain [6] for matched outcoupling without trapped modes as follows:

$$W_{lb} \approx \frac{\omega}{4}\frac{rL}{Q}\frac{(q|\Phi|)^2}{|1-\beta_{gr}/\beta|}\left(\frac{1-\exp(-\alpha L)}{\alpha L}\right)^2, \qquad (1)$$

where $\omega = 2\pi f = h(\omega)v$ is the circular frequency of the resonant Cherenkov radiation, $h(\omega)$ is the wavenumber defined by the structure dispersion, q is the bunch charge, $r = E_z^2/dP/dz$ is the shunt impedance, $\beta = v/c$, Q is the Q-factor, $Q|\beta-\beta_{gr}|>>1$, $\alpha = \pi f/Qv_{gr}$ is the attenuation, and $\Phi = \exp\left(-(\omega\sigma_t)^2/2\right)$ is the formfactor for a Gaussian bunch having rms duration σ_t. Note Eq. (1) applied to, e.g., the 270 GHz setup [7], gives 9 μJ energy which is the same as measured [7].

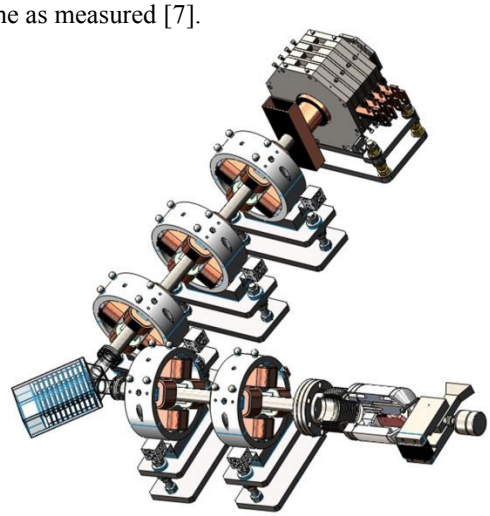

Figure 1: Schematics of the THz source beamline composed by quadrupoles, PM α-magnet, Cherenkov radiator, dipole magnet, and THz beam output.

Below we consider only briefly key features of beam dynamics, slow-wave structure, and general beamline design.

PLANAR CHERENKOV RADIATOR

Electromagnetic and mechanical engineering of a planar radiator [5,8,9] is used here as a prototype for a 0.67 THz radiator design shown in Fig. 2. The structure parameters are the following: r/Q=8 kΩ/m at 3 mm width of the grating, 0.6 mm interaction gap and 42 μm grove height; Q=1410, and 1" structure length.

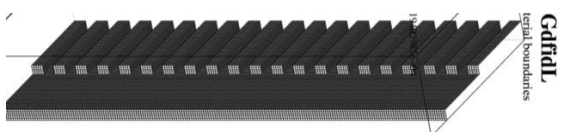

Figure 2: 20-period, bottom-half fragment of the planar radiator structure in GdfidL model (antenna horn is not shown).

Results of time domain GdfidL code [10] and analytical [6] simulations are in a good accordance and given in Figs 3-5 for 50 pC charge, 200 fs rms duration (60 μm rms length) bunch having ~0.7 formfactor Φ.

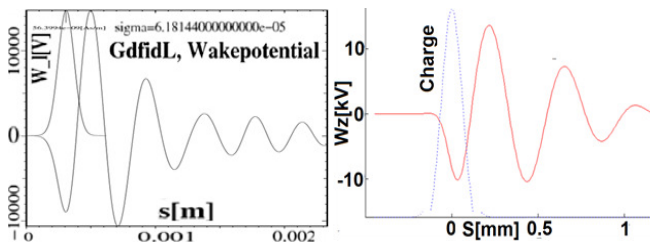

Figure 5: Wakepotential calculated numerically (left) and analytically (right) for 70 pC charge in the 40-period structure.

BEAM DYNAMICS SIMULATIONS

Performance features of the rugged, high group velocity, planar radiator imply forming of sub-mm long, sub-mm tall, and mm-cm wide bunches to efficiently utilize the low-energy beam having substantial emittance (compared to photoinjector not used here). We simulated with ASTRA code [11] 1.6 cell thermionic RF guns producing 1.8 MeV energy-modulated beam in S- and C-bands using BNL/UCLA/SLAC cavity shape. Field profiles used for S- and C-band RF gun simulations are shown in Fig. 6 to produce 1.8 MeV, 90 pC bunch with ~11μm normalized emittance. Cathode radius is 1 mm, for S-band and 0.5 mm for C- band (with cathode loading~17 and 86 A/cm2 respectively).

The beamline with the alpha-magnet have been optimized with ELEGANT for minimum vertical and longitudinal bunch dimensions in the radiator. The results are exemplified in Figs 7, 8 for C-band variant with 5 quadrupoles.

For X- band variant we considered here a biperiodic, 45-cell, tapered, side-coupled, 2 MeV microlinac designed and developed at RadiaBeam [12]. The microlinac structure was modified by using slightly longer regular cells to provide energy chirp simulated with PARMELA code [13] (see Fig. 9).

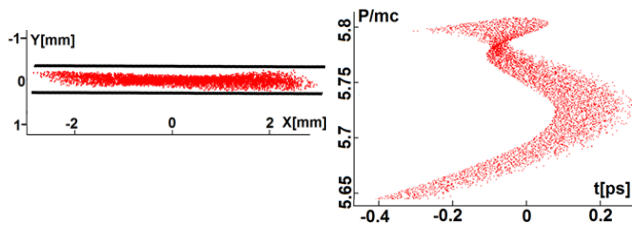

Figure 8: LEFT: Transverse beam profile in the 0.6mm interaction gap for C-band variant with 5 quadrupoles. RIGHT: Longitudinal phase space of the beam in the gap.

The beamline with 3 quadrupoles and α-magnet was optimized with ELEGANT code [14]. Benefit of energy filtering related to formfactor (see Eqn. (1)) is shown in Fig. 10. The ELEGANT results are compared to the GPT code [15] simulations with taking into account space charge in the beamline (see Fig. 11).

40	2.5	2	132	2.4	23	2.3	23

CONCLUSION

Alpha magnet and quadrupoles can produce flat beams with a moderate aspect ratio ~10 making a good match to the gap of planar radiator. C-band RF gun is very promising configuration for the system and capable to produce a kW power within a macropulse.

ADAPTATION OF THE ISIS INDUCTION-CELL DRIVER TO A LOW-IMPEDANCE *X*-PINCH DRIVER

R.V. Shapovalov, W. Beezhold, V.I. Dimitrov (deceased), and R.B. Spielman
Idaho Accelerator Center, Pocatello, ID 83201, USA

Abstract

In this paper we summarize the work done to design a system to non-destructively convert the Idaho State Induction System (ISIS) induction cell driver (ICD) to a low impedance pulse power driver for *x*-pinch applications. The simulation results show that such a driver can supply about 300-kA peak current with about 70-ns rise time (10-90%). However, simulations also show that the negative reflective wave is formed, which can cause the destruction of the ISIS ICD's pulse forming line (PFL). Particular attention was taken to simulate the effect of misfire of one of the PFLs. To reduce the amplitude of this destructive wave, high power damping resistors should be placed after the output of each PFL. This would result in the maximum current achievable by this driver to be limited to about 200-kA peak value.

OVERVIEW

ISIS is a high-intensity, pulsed-power electron accelerator able to supply about 80 GW of power in a 35-nanosecond pulse [1]. It was donated to the Idaho State University by Titan Pulse Sciences, Inc. in 2002, and its primary purpose has been to serve as a radiation source for radiation effect testing in biological and semiconductor systems [2]. The power supply of ISIS [3] is composed from a Marx generator and five separate PFLs. Forty oil-filled, 77-ns-long cables connect the power supply to each acceleration unit (AU) of ISIS. The power supply of the ISIS is shown in Fig. 1. Each PFL produces a perfect 84-ns long, flat-topped 300-kV pulse which is directly used to accelerate electrons inside each AU.

In order to convert the ISIS power supply to a low-impedance *x*-pinch driver, an impedance transformer was designed [4]. The impedance transformer is the most important part of the *x*-pinch driver and serves to combine five, 300-kV outputs of the ISIS' induction cell driver (5 Ω each) into one, low-impedance (<1 Ω), 40-80 kV output to be fed to the *x*-pinch chamber. Analysis of the ISIS induction-cell driver showed that the most suitable spot for tapping its output pulse is at the end of the water-filled PFLs before the oil-filled connectors to the high-voltage cables [4].

We present the electrical circuit simulation results of proposed ISIS' based *x*-pinch driver. LTspice [5] simulations show that after directly connecting the output of each PFL to the impedance transformer and feeding the output pulse to *x*-pinch load, such a *x*-pinch driver can supply about 300-kA peak current with about 150-ns rise time (Fig. 3a). However, simulations also show, that the negative reflective wave is formed, which can cause the destruction of the ISIS PFL. Particular attention was taken to simulate the effect of misfire of one of the PFLs (Fig. 3b). To reduce the amplitude of this destructive wave, a high-power damping resistor should be placed after the output of each PFL. This would result in the maximum current achievable by this driver to be limited to about 200-kA peak value (Fig. 4a).

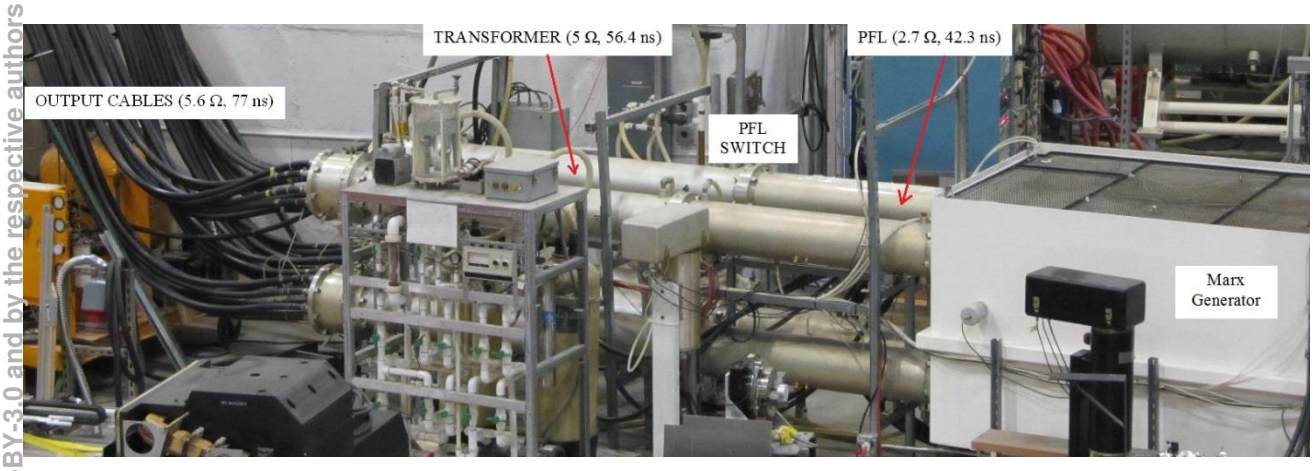

Figure 1: ISIS power supply.

Copyright © 2013 CC-BY-3.0 and by the respective authors

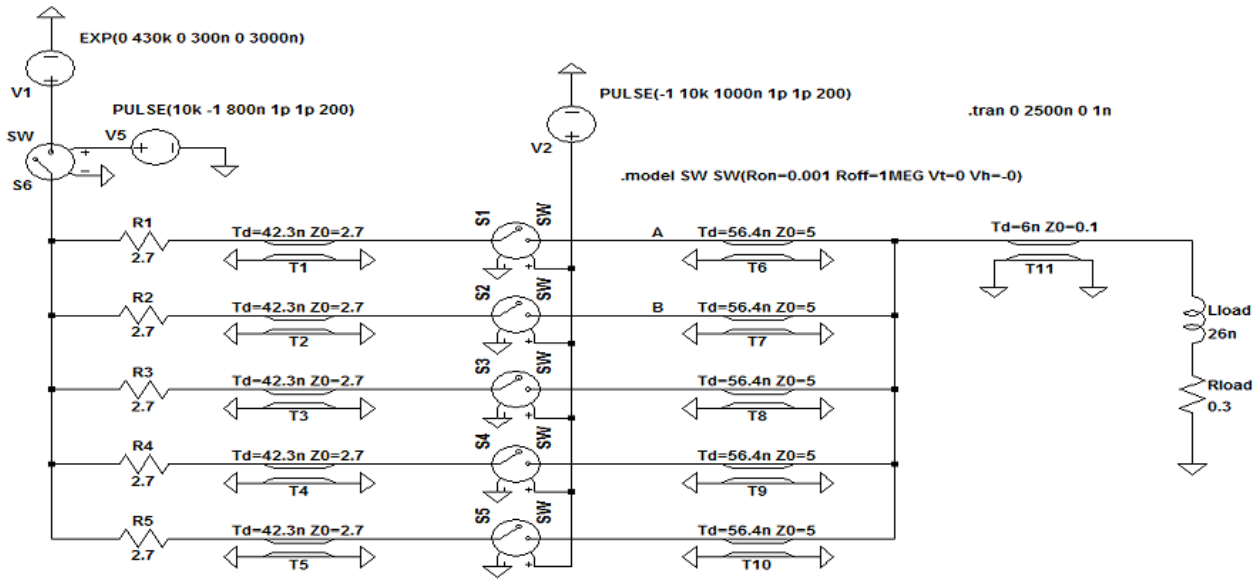

Figure 2: Electrical circuit of an ISIS-based *x*-pinch driver.

LTSPICE SIMULATIONS: 300-KA *X*-PINCH DRIVER

Figure 2 shows the electrical circuit of the ISIS' based *x*-pinch driver. The impedance transformer (represented by the transmission line element T11) is directly attached to the output of each PFL and the output of the impedance transformer is fed to the *x*-pinch load located in the middle of the vacuum chamber. The total inductance of the *x* pinch and all connection lines (header, lower feed, upper feed, etc.) can be roughly approximated to be equal to about 26 nH [6].

Simulation of current pulse as it propagates through the *x*-pinch load is shown in the Fig. 3a. After optimization of the impedance transformer parameters (6-ns long, 0.1 Ω), it was found that such a driver can supply about 320-kA peak current with 70-ns rise time (10-90 %).

Because the impedance transformer is necessary to transform down the impedance of PFLs by a factor of about 10, a reflective negative wave is formed traveling back to the PFL switch. This reflective wave will become even worse, if one or more PFL switches are not fired. Fig. 3b shows simulations of the voltage behaviour at the exit of PFL switch for two cases: the black line represents the scenario when all PFL switches are fired simultaneously (fire), and the red line represents the scenario when one PFL switch is not fired (misfire). As can be seen, the negative reflective wave with the maximum amplitude of about 150 kV is formed at the switch location for the normal regime of operation (fire). In the case of misfire of one of the switches, this reflective negative wave reaches the maximum amplitude of about 250 kV.

It is known [7], that such a high-voltage negative reflective pulse will probably destroy the PFL switch. Although the maximum current of about 320-kA peak value is achievable by this design, such a driver will probably not survive for a large number of shots due to possible damage to the PFL switches. As a result, a costly repairs would be necessary in the future.

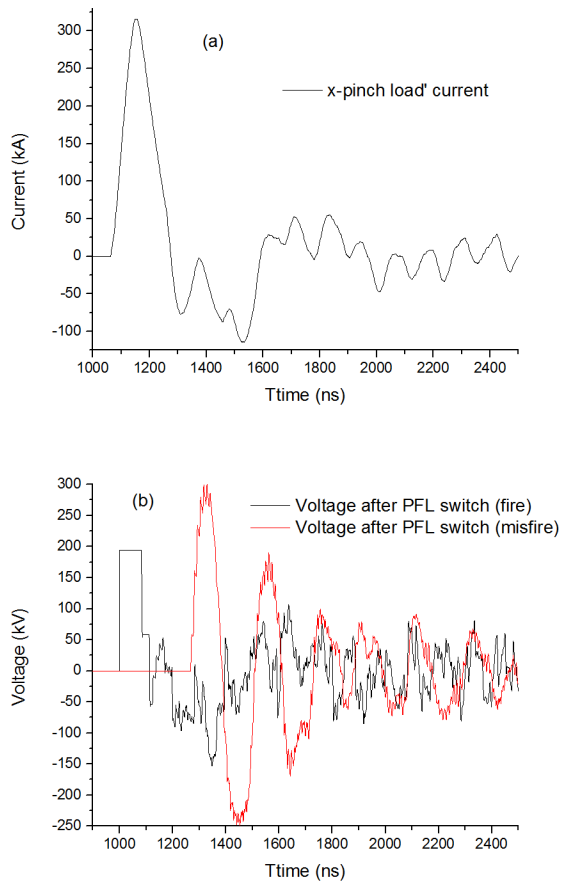

Figure 3: LTspice simulations of an ISIS-based *x*-pinch driver: (a) current measured at the *x*-pinch load (b) voltage measured after PFL switch.

Copyright © 2013 CC-BY-3.0 and by the respective authors

LTSPICE SIMULATIONS: 200-KA *X*-PINCH DRIVER WITH DAMPING RESISTORS

To reduce the amplitude of this destructive negative wave, high-power damping resistors (4.7 Ω) are placed after each PFL before the impedance transformer. This will reduce the amplitude of the reflective negative wave at the PFL switch location to the appropriate value, so the *x*-pinch driver can be safely operated.

As shown in Fig. 4a, such a modified *x*-pinch driver can supply about 200-kA peak current with 60-ns rise time (10-90%). The simulation results of the voltage behavior at the exit of the PFL switch for two cases, fire and misfire, as described above, are shown in Fig. 4b. In the normal regime of operation (fire), the amplitude of the negative reflective wave is almost reduced to the zero value. In the case of misfire of one of the switches, a negative reflective wave is still formed of maximum amplitude of about 25 kV, but the total duration of this wave is only about of 100 ns. This small negative reflective wave will probably not damage the PFL switches.

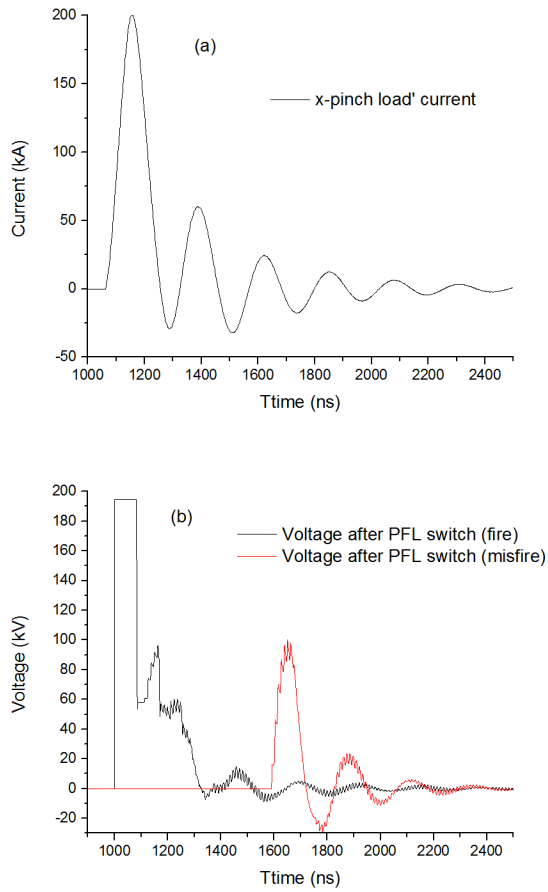

Figure 4: LTspice simulations of the ISIS-based *x*-pinch driver with a damping resistor placed after each PFL: (a) current measured on the *x*-pinch load (b) voltage measured after PFL switch.

CONCLUSION

In this report, we presented electrical circuit simulation results of a proposed ISIS-based *x*-pinch driver. LTspice simulations show, that after directly connecting the output of each PFL to the impedance transformer and feeding the output pulse to *x*-pinch load, such a *x*-pinch driver can supply about 300-kA peak current with about 70-ns rise time (10-90%). However, simulations also show, that the negative reflective wave is formed which can cause damage to the ISIS PFLs. Particular attention was taken to simulate the effect of misfire of one of the PFL switches, which causes the negative reflective wave to become even worse.

To reduce the amplitude of this destructive wave, a high-power damping resistor must be placed after the output of each PFL before the impedance transformer. This will to reduce the amplitude of the reflective negative wave at the PFL switch location to the appropriate value, so the *x*-pinch driver can be safely operated. But as a penalty, the maximum current achievable by this driver will be limited to about 200-kA peak value.

Taking into account these results and other considerations (time, effort and cost-needed to switch between the *x*-pinch operation mode and the normal operation mode of ISIS), the decision was made to design a new stand-alone, compact and portable pulse-power *x*-pinch generator [6].

TRANSVERSE BEAM TRANSFER FUNCTIONS VIA THE VLASOV EQUATION*

M. Blaskiewicz†, V.H. Ranjbar
BNL Upton NY 11973 USA

Abstract

A semi-numerical method of integrating the Vlasov equation to obtain beam transfer functions directly as a function of frequency is presented. The results are compared with beam transfer functions calculated via particle tracking and excellent agreement is shown. The technique works well with both transverse wakes and detuning wakes from space charge.

INTRODUCTION AND THEORY

The stability and response properties of particle beams are encapsulated in beam transfer functions (BTFs) [1, 2, 3]. BTFs are relatively easy to measure making their accurate calculation of great practical interest. In this paper we will present two independent ways to calculate bunched beam transverse beam transfer functions, and show their agreement for some challenging parameters. To begin let θ denote azimthh, which increases by 2π each turn. Let t be clock time and let τ denote particle arrival time with respect to the synchronous particle so that $\theta = \omega_0(t-\tau)$, with ω_0 the synchronous angular revolution frequency. We use θ as the time-like variable and, to make a precise cross check possible, take linear rf so that

$$\frac{d\tau}{d\theta} = Q_s\epsilon \qquad \frac{d\epsilon}{d\theta} = -Q_s\tau, \tag{1}$$

where Q_s is the synchrotron tune and ϵ is the energy variable. with We consider a single transverse variable x and uniform focusing. Collective forces are taken in the continuum approximation with $dx/d\theta = p$ and

$$\begin{aligned}\frac{dp}{d\theta} &= -Q_\beta^2(\epsilon)x + F_e(\theta,\tau)\\ &+ 2Q_\beta\Delta Q_{sc}(\tau)[x-\bar{x}(\theta,\tau)]\\ &- \frac{q}{2\pi P_0\omega_0}\int_0^{2\tau_b} W_\perp(\tau_1)D(\theta,\tau-\tau_1)d\tau_1,\end{aligned} \tag{2}$$

where $Q_\beta(\epsilon) = Q_0 + Q_s\epsilon\omega_0\xi/\eta$ is the betatron tune, with chromaticity ξ and frequency slip factor η, $F_e(\theta,\tau)$ is the external driving force, $\Delta Q_{sc}(\tau)$ is the space charge tune shift as a function of longitudinal position in the bunch, and $\bar{x}(\theta,\tau)$ is the average beam offset. The wall induced forces are due the the transverse wake potential $W_\perp(\tau)$ and driven by the instantaneous dipole moment $D(\theta,\tau) = \bar{x}(\theta,\tau)I(\tau)$ with $I(\tau)$ the bunch current, q the particle charge, and P_0 the synchronous momentum. The force is limited to a single bunch of full length $2\tau_b$ but can be extended to uniformly filled rings.

To solve (1) and (2) using the Vlasov equation first introduce amplitude angle variables defined by $\tau = a\sin\psi$ $\epsilon = a\cos\psi$. Since all particle have constant a,

$$\frac{\partial F}{\partial\theta} + p\frac{\partial F}{\partial x} + \frac{dp}{d\theta}\frac{\partial F}{\partial p} + Q_s\frac{\partial F}{\partial\psi} = 0, \tag{3}$$

where $dp/d\theta$ is given by Eq (2). We normalise F so that $F dx dp a da d\psi$ is the number of particles in the phase space volume. To continue we define 3 transverse moments [4],

$$\{X(\psi,a,\theta),P,\Psi\} = \int dxdpF(x,p,a,\psi,\theta)\{x,p,1\}. \tag{4}$$

This gives

$$\frac{\partial X}{\partial\theta} + Q_s\frac{\partial X}{\partial\psi} = P(\psi,a,\theta), \tag{5}$$

$$\begin{aligned}\frac{\partial P}{\partial\theta} + Q_s\frac{\partial P}{\partial\psi} &= -Q_\beta^2(\epsilon)X + F_e(\theta,\tau)\Psi\\ &+2Q_\beta\kappa\left[X\int d\epsilon\Psi - \Psi\int d\epsilon X\right]\\ &-\frac{q\Psi}{2\pi P_0\omega_0}\int_0^\infty d\tau_1 W_\perp(\tau_1)q\int d\epsilon X(\epsilon,\tau-\tau_1)\end{aligned} \tag{6}$$

where $\Delta Q_{sc}(\tau) = \kappa\int d\epsilon\Psi$, $\bar{x}(\tau)\int d\epsilon\Psi = \int d\epsilon X$ and, for example,

$$\int d\epsilon X \equiv \int a_1 da_1 d\psi_1\delta(a\sin\psi - a_1\sin\psi_1)X(\psi_1,a_1,\theta),$$

and the occurences of τ and ϵ in (6) are understood to be shorthand for the amplitude angle representations. Next we substitute (5) in (6) and drop second partial derivatives with respect to ψ. We take $F_e(\theta,\tau) = F_0(\tau)\exp(-iQ\theta)$, and we take $X = X_1\exp(-iQ\theta - i\xi\omega_0\tau/\eta)$, with $Q = Q_0 + \Delta Q$. This yields

$$\left\{\Delta Q + iQ_s\frac{\partial}{\partial\psi} + \Delta Q_{sc}(a\sin\psi)\right\}X_1(\psi,a) = \tilde{F}(\tau)\Psi(a), \tag{7}$$

where

$$\begin{aligned}\tilde{F}(\tau) &= \frac{-e^{i\xi\omega_0\tau/\eta}F_0(\tau)}{2Q_0} + \kappa\int d\epsilon X_1\\ &+q^2\int_0^\infty d\tau_1\frac{W_\perp(\tau_1)e^{i\xi\omega_0\tau_1/\eta}}{4\pi Q_0 P_0\omega_0}\int d\epsilon X_1(\epsilon,\tau-\tau_1).\end{aligned} \tag{8}$$

The strategy is to solve (7) for $D_1 = q\int d\epsilon X_1$ resulting in a one dimensional integral equation for D_1 which will be solved numerically. To proceed let $\Delta Q_{sc}(a\sin\psi) = \lambda(a) + d\Lambda/d\psi$ where $\Lambda(a,\psi) = \Lambda(a,\psi+2\pi)$. Substitute $X_1 = X_2\exp(i\Lambda/Q_s)$ yielding

$$\left\{\Delta Q + iQ_s\frac{\partial}{\partial\psi} + \lambda(a)\right\}X_2 = e^{-i\Lambda/Q_s}\tilde{F}\Psi. \quad (9)$$

Multiply both sides by the integrating factor $\exp(-i\psi(\lambda+\Delta Q)/Q_s)$ and integrate from ψ to $\psi+2\pi$ employing the periodicity of X_2. Backsubstitute X_1 giving

$$X_1 = \frac{\Psi e^{iG(a,\psi)}}{Q_s R(a)}\int_{\psi}^{\psi+2\pi} d\psi_1\tilde{F}(a\sin\psi_1)e^{-iG(a,\psi_1)} \quad (10)$$

where $R(a) = 1-\exp(-2\pi i(\lambda+\Delta Q)/Q_s)$ and

$$G(\tau,\psi) = \int_0^{\psi} d\psi_1\frac{\Delta Q + \Delta Q_{sc}(a\sin\psi_1)}{Q_s}.$$

To proceed note that

$$D_1(\tau) = q\int adad\psi\delta(\tau - a\sin\psi)X_1(a,\psi)$$

yielding

$$D_1(\tau) = \int\hat{G}(\tau,\tau_1)q\tilde{F}(\tau_1)d\tau_1 \quad (11)$$

where

$$q\tilde{F}(\tau) = \frac{-e^{i\xi\omega_0\tau/\eta}qF_0(\tau)}{2Q_0} + \kappa D_1(\tau)$$
$$+\frac{q^2}{4\pi Q_0P_0\omega_0}\int_0^{\infty} d\tau_1 W_\perp(\tau_1)e^{i\xi\omega_0\tau_1/\eta}D_1(\tau-\tau_1) \quad (12)$$

and

$$\hat{G}(\tau,\tau_1) = \int_0^{\infty} ada\int_0^{2\pi} d\psi\delta(\tau - a\sin\psi)\Psi(a)e^{iG(a,\psi)}$$
$$K(a)\int_{\psi}^{\psi+2\pi} d\psi_1\delta(\tau_1 - a\sin\psi_1)e^{-iG(a,\psi_1)} \quad (13)$$

where $K = i\Psi/Q_sR$. To proceed assume $D_1(\tau)$ is defined at a set of equidistant points $\tau_k = k\Delta$ and that D varies linearly between these points. Then

$$q\tilde{F}(\tau) = \sum_{k=-N}^{N} a_k T(\tau - k\Delta),$$

where $T(x)$ is a triangle function of height 1 and half width at base Δ. For smooth bunches $D(\tau)$ is zero at the ends of the bunch so we take $\Delta = \tau_b/(N+1)$ where τ_b is the half bunch length. Next we do the integral over ψ in (13). For any smooth function $h(a,\psi)$,

$$\int_0^{2\pi}\delta(\tau - a\sin\psi)h(a,\psi)d\psi = \sum_{p=1,2}\frac{h(a,\psi_p)}{\sqrt{a^2-\tau^2}},$$

where the two angles satisfy $\sin\psi_{1,2} = \tau/a$ and the integral vanishes for $|\tau| > a$. Next we define a new radial variable u defined by $u^2 = a^2 - \tau^2$ so $udu = ada$. The dipole density is defined at the same set of lattice points as $\tilde{F}$ so

$$D_1(m\Delta) \equiv D_m = \sum_{n=-N}^{N} a_n M_{m,n}, \quad (14)$$

where

$$M_{m,n} = \int_0^{\sqrt{\tau_b^2-m^2\Delta^2}} duK(a)\sum_{p=1,2}e^{iG(a,\psi_p)}$$
$$\int_{\psi_p}^{\psi_p+2\pi} d\psi_1 T(n\Delta - a\sin\psi_1)e^{-iG(a,\psi_1)}. \quad (15)$$

In integral (15) $a = \sqrt{u^2+m^2\Delta^2}$ and $\sin\psi_p = m\Delta/a$. We have written a program which solves (14) with matrix element (15) and a_n from (12),

$$a_n = \frac{-e^{i\xi\omega_0 n\Delta/\eta}qF_0(n\Delta)}{2Q_0} + \kappa D_n$$
$$+\frac{q^2}{4\pi Q_0P_0\omega_0}\sum_{k=0}^{2N+1}\Delta W_\perp(k\Delta)e^{i\xi\omega_0 k\Delta/\eta}D_{n-k}. \quad (16)$$

SIMULATIONS

The solution of Equations (1) and (2) using particle tracking is straightforward [5, 6, 7, 8]. Before considering a sinusiodaly drive BTF we consider forces of the form $F_0(\tau,\theta) = f(\tau)\cos(Q\theta)\exp(gQ)\delta_p(\theta)$ where δ_p is the periodic delta function, Q is the real part of the drive tune, g is the imaginary part of the drive tune and $f(\tau)$ is nonzero only over the full bunch length, $2\tau_b$. Suppose $D_f(\theta,\tau)$ is the dipole response to a kick $f(\tau)$ given at $\theta = 0$. Then the response from all the kicks is

$$D(\theta,\tau) = \sum_{m=-\infty}^{\infty} D_f(\theta-2\pi m,\tau)\cos(2\pi mQ)\exp(2\pi gm). \quad (17)$$

To obtain a scalar we take the inner product

$$\hat{D}(\theta) = \int_{-\tau_b}^{\tau_b} d\tau f(\tau)D(\theta,\tau)$$
$$= \sum_{m=-\infty}^{\infty}\hat{D}_f(\theta-2\pi m)\cos(2\pi mQ)\exp(2\pi gm)$$

For a pickup at a fixed location one obtains the time series $\hat{D}(0), \hat{D}(2\pi), \hat{D}(4\pi), \ldots$, these values may be obtained with a single simulation. As long as $\hat{D}_f(\theta)$ does not grow more quickly than $\exp(g\theta)$ we will have

$$\hat{D}(2\pi k) = [A_Q\cos(2\pi kQ) + B_Q\sin(2\pi kQ)]\exp(2\pi gk)$$

Copyright © 2013 CC-BY-3.0 and by the respective authors

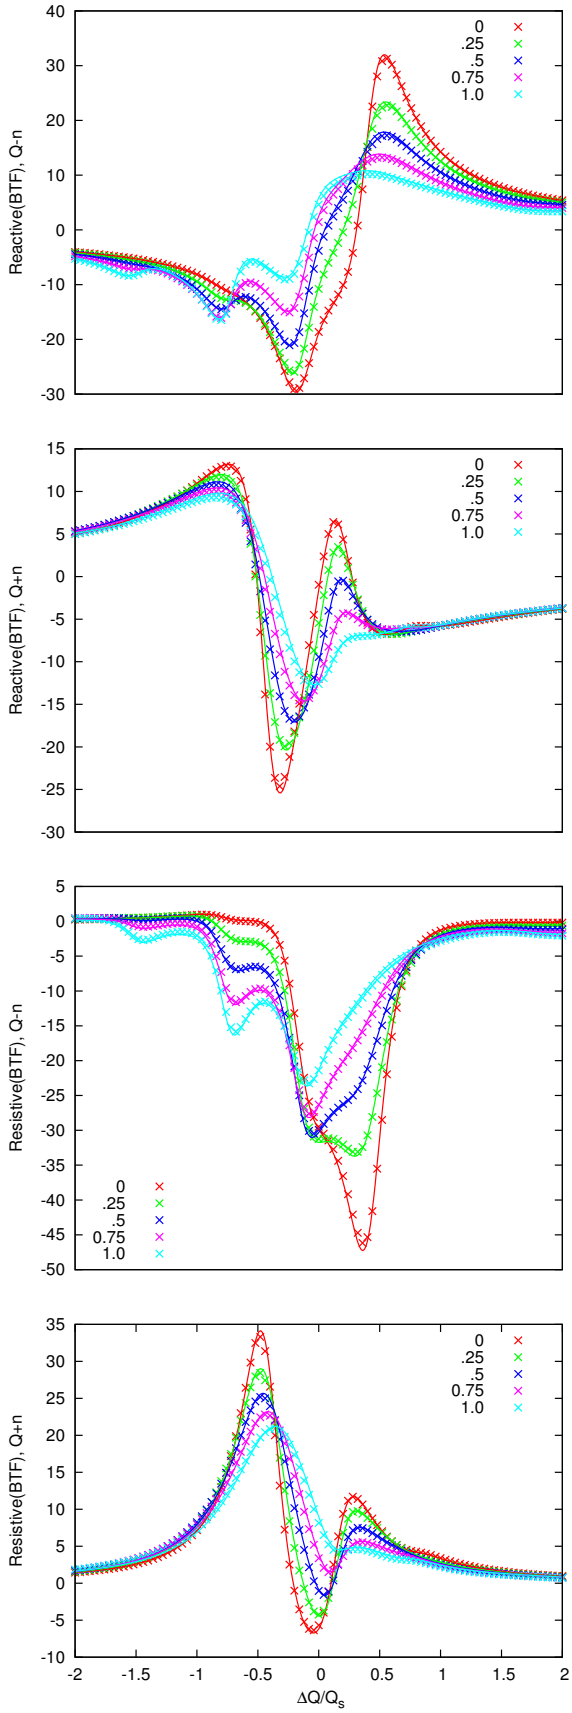

Figure 1: Simulated BTFs (solid lines) and those following from Eq (14) (crosses).

with

$$A_Q + jB_Q = \sum_{\ell=0}^{\infty} \hat{B}_f(2\pi\ell)\exp(2\pi\ell[jQ-g]) \qquad (18)$$

Hence, the entire BTF can be obtained with one simulation. For a real beam transfer function the force at the pickup is sinusiodal. We assume the frequency is $n\omega_0+\omega_1$ where n is an integer, $|\omega_1| \le \omega_0/2$. Then the driving force is given by

$$\begin{aligned} F_e(\theta,\tau) &= \delta_p(\theta)\cos[(n\omega_0+\omega_1)t], \\ &= \delta_p(\theta)\cos[(n\omega_0+\omega_1)(\tau+\theta/\omega_0)], \\ &\approx \delta_p(\theta)\cos(n\omega_0\tau)\cos(\omega_1 k(t)T_0) \\ &\quad -\delta_p(\theta)\sin(n\omega_0\tau)\sin(\omega_1 k(t)T_0) \end{aligned} \qquad (19)$$

where $T_0 = 2\pi/\omega_0$ and $k(t) = \mathrm{nint}(t/T_0)$. In a real BTF only the response at the drive frequency is measured so, with a sinusiodal kick one needs to run two simulations. One with a kick proportional to $\sin(n\omega_0\tau)$ and another with kick $\cos(n\omega_0\tau)$. During each simulation one takes inner products of the response with each sinusoid every turn. One finds

$$BTF(\omega_1) = \sum_{m=0}^{\infty}(C_m + jS_m)e^{-(j\omega_1+\epsilon)mT_0}$$

with

$$C_m = \int_{-\tau_b}^{\tau_b} d\tau D_{cos}(2\pi m,\tau)e^{-jn\omega_0\tau},$$

where $D_{cos}(\theta,\tau)$ is the response to a cosine kick at $\theta = 0$, and similarly for S_m. In these equations we have used the electrical engineering convention with $j = -i$ and allowed for an exponentially growing drive $\propto \exp(\epsilon t)$. The driving terms in the Vlasov approach are given by $F_0(\tau) = \exp(\pm jn\omega_0\tau)$ for the $Q \mp n$ sidebands, respectively. Figure 1 shows upper and lower sideband BTFs with $n\omega_0 = \pm\pi/2\tau_b$, varying chromaticity and a step function wake of size comparable to what is needed for a mode coupling instability. The peak space charge tune shift is 4 times the synchrotron tune. For more extreme parameters the disagreement increases and we continue to look for errors.

Abstract

The feedback control of intra-bunch instabilities driven by electron-cloud or strong head-tail interaction requires bandwidth sufficient to sense the vertical position and apply correction fields to multiple sections of a nanosecond-scale bunch. These requirements impose challenges and limits in the design of the feedback channel.

We present experimental measurements taken from the CERN SPS machine development studies with an intra-bunch feedback channel prototype. The performance of a 3.2 GS/s digital processing system is evaluated, quantifying the effect of noise and limits of the feedback channel in the bunch stability as well as transient and steady state motion of the bunch. The controllers implemented are general purpose 16 tap FIR filters and the impact on the bunch stability of controller parameters are analyzed and quantified. These studies, based on the limited feedback prototype, are crucial to validate reduced models of the system and macro-particle simulation codes, including the feedback channel. These models will allow us to predict the beam dynamics and controller limits when future wideband hardware is installed in the final prototype to stabilize multiple bunches.

INTRODUCTION

Intrabunch instabilities induced by electron-cloud (ECI) and strong head-tail interactions (TMCI) limiting factors to reach the maximum beam currents in the SPS and LHC rings [1]. Feedback techniques can stabilize bunch instabilities induced by electron cloud and strong head-tail interactions. The application of feedback control to stabilize the bunch is challenging because it requires large bandwidth to sense the transverse position and apply correcting fields to multiple sections of a nanosecond-scale bunch. These requirements impose technology challenges and limits in the design. The goal is to design a feedback control channel and to develop the hardware of a control system prototype to prove principles and evaluate the limitations of this technique by stabilizing a few bunches in the CERN SPS machine. This paper presents results from measurements conducted at SPS and validation studies of models of the feedback system using those measurements.

FEEDBACK SYSTEM

A single bunch wideband digital feedback system has been developed to explore new technology and control techniques. The implementation of this system is based on a reconfigurable FPGA and ADC/DAC operating at 3.2 GS/s. The system is synchronized with the SPS RF clock and is able to perform diagnostic functions, set feedback parameters and record the bunch motion at selected intervals [2]. The present studies were conducted using an existing stripline device as a kicker with 160 MHz bandwidth. Future tests will be conducted using new wideband kickers, which are currently under development [3]. The four-electrode kicker is driven by 4- 90W amplifiers of 1GHz bandwidth. The pickup signal is equalized to compensate the frequency response of the device and the cables. The controller is implemented using a bank of simple FIR filters, processing each individual ADC samples across the bunch. The prototype is capable of setting 16-tap filters, and during the test 5-taps and 7-taps were used. Additionally, the filter parameters can be changed during the run, allowing to vary the controllers in the feedback system to process the bunch motion signals.

Feedback Model

The block diagram of the feedback system including noise sources and external signal perturbations is depicted in Fig. 1. The main blocks in this figure are modeled in both macro-particle simulation codes and tools where the bunch dynamics is represented by reduced order models to assess the stability margins of the system and study the bunch performance under the influence of noise and external perturbations. These models have to be validated

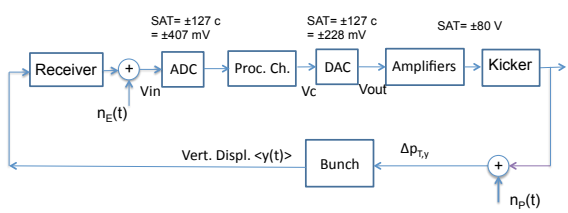

Figure 1: Block diagram feedback system.

with measurements in the SPS to be able to predict future operation conditions and evaluate the impact of limitations and non-linearities in the feedback hardware on the bunch stability and performance. The frequency response of the receiver and the RF power stage have been measured and appropriated models are included in the simulation tools [4].

ANALYSIS OF MD DATA

In January 2013, several machine developments (MDs) where conducted to test the 3.2 GS/s digital processing prototype. The feedback system was evaluated driving and stabilizing the transverse motion of a single bunch in the SPS ring. Multiple tests were performed changing main parameters of the beam and the controller. The main goal was to evaluate the performance of the new hardware - firmware and collect data to validate simulation models and explore the limits of the feedback technique in the stabilization of the intrabunch dynamics. It will allow to predict future tests and define new hardware-firmware for operation with multiple bunches.

To quantify the overall feedback loop gain tests were conducted using the feedback system to stabilize an unstable bunch. To generate the unstable bunch, the chromaticity was changed from positive to negative after injection. The beam becomes unstable in the vertical plane, mainly with mode 0 motion. The bunch with slight positive chromaticity is injected in the machine with the feedback system in open loop and 3500 turns after injection the chromaticity is set negative decreasing slightly as a function of the turn number. If the feedback system remains in open loop, the bunch becomes unstable. Figure 2 depicts the spectrogram of the vertical motion of the centroid showing the unstable motion and the shift in the fractional vertical tune due to lost of charge. Figure 3 shows the motion of a similar bunch when it is stabilized by the feedback system. In this case, the feedback loop is closed 2000 turns after injection and the beam is stabilized. This test was repeated for different loop gains, exhibiting stable motion for gains above a certain minimum value. Using the results of these tests with unstable beam and the feedback system operating in either open loop or closed loop, it is possible to characterize the overall loop gain of the system. It allows setting the gain of the different blocks in Fig. 1 combining additional information related to the transfer function of the feedback stages. To quantify the loop gain, the growth rate of the unstable motion of the bunch centroid was measured with the feedback system in open loop or in closed loop with low gain. The time interval to measure the growth rate was limited to make sure the measurement is conducted preserving the bunch charge. A summary of these measurements and the results of the growth rate estimation based on a simplified model of the feedback loop are shown in Fig. 4. Given the direct proportionally between the chromaticity and the number of turns, the growth time constant is plotted vs. the turn numbers or the chromaticity. The blue points depict the growth time constant measured when the feedback is in open loop and in closed loop with gains equal to 2 and 4 (unstable cases). The estimated time constants based on a simplified model for the damping are shown by the red circles. The green curve is a fitting to the growth time constant of the bunch vs. chromaticity if the feedback loop is open. The growth time constant (inverse of growth rate) decreases as a function of the number of turns because the chromaticity decreases slightly after switching from positive to negative. Assuming the simplified model for the damping bunch damping $\sigma_f(\xi) = 1/\tau_f(\xi) = 1/\tau_{OL}(\xi) - \sigma_D$, with ξ chromaticity, $\sigma_D = \sigma_1 G$ and G the controller gain, the constant is $\sigma_1 = 5.47 \times 10^{-4}$ turns^{-1}. This estimation defines the critical gain to stabilize the vertical mode 0 motion of the bunch. For example, to stabilize an unstable bunch with a growth rate $\sigma_{OL} = 0.01$ turns^{-1} ($\tau_{OL} = 100$) turns a gain $G > 17$ is necessary. More precise analysis of this motion was conducted via simulation using macro-particle simulation codes and a reduced models of the bunch dynamics. Using a reduced model of the bunch and representative model of the feedback system, the results depicted in Fig. 4 can be reproduced. For that case, motion of the bunch centroid was studied, with a 5-tap FIR filter and appropriated gains for the receiver and RF power stage. Figure 5 shows the results for the feedback system in open loop when the parameters of the bunch are set to define a growth time constant equal to $\tau_{OL} = 200$ turns. Figure 6 shows the unstable motion of the bunch centroid with the

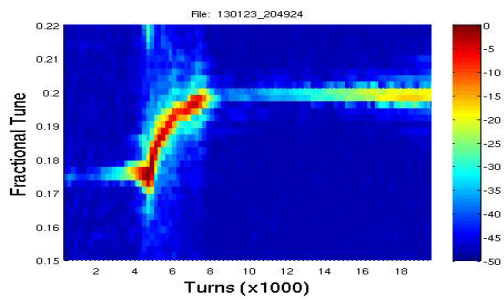

Figure 2: Spectrogram unstable bunch.

feedback gain $G = 4$, giving a $\tau_f = 360$ turns. Similar agreement of the final growth rate with the results depicted in Fig. 4 were obtained when the gain was set to $G = 2$.

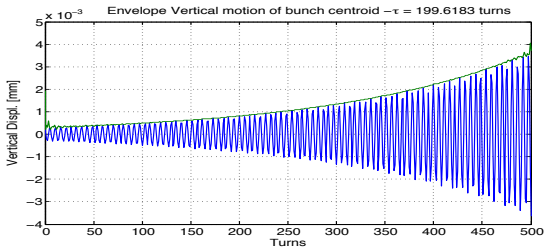

Figure 5: Unstable motion of the beam corresponding to $\tau_{OL} = 200$ turns in Fig. 4 - Open loop feedback - Reduced model simulation

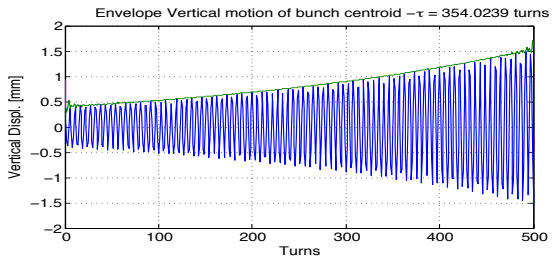

Figure 6: Unstable motion of the beam with feedback in closed loop and gain $G = 4$. - $\tau_f = 360$ turns in Fig. 4 - Reduced model simulation

Using macro-particle simulation codes and appropriated models for the receiver and RF power stages, the damping behavior can be reproduced as well.

Several parameters in the controller have been changed and the response of the bunch motion has been measured to quantify the robustness of the feedback system. Furthermore, this data displays how well the models are able to predict the effect of those variations in the stability and performance of the feedback system. The controller is parameterized by two variables, the gain G and the phase ϕ. Additionally, another important parameter in the feedback loop is the timing between the bunch position and both the ADC samples and the kicker signal. Other important parameters for the design of the overall system are the kicker-amplifier bandwidth and amplifier maximum power, and their impact in the feedback stability and performance are evaluated using simulations and reduced models for the system. In this paper, we show results of the impact on the stability of changes in the controller parameters G and ϕ. The nominal controller is set with a phase $\phi = 70^o$ giving a almost pure damping without changing the betatron tune. When the phase of the controller is set to $\phi = 30^o$ the tune frequency is changed for increasing gain. Figure 7 shows the fractional tune for different samples across the bunch when the feedback is in open loop around turns 0-2000, while Fig. 8 depicts the closed loop case with $G = 64$ and $\phi = 30^o$ for turns 4000-6000. It can be observed the tune shift from $f_\beta = 0.177$ to $f_\beta = 0.183$. Similarly, if the gain is set to $G = 16$ with $\phi = 30^o$ the fractional tune changes from $f_\beta = 0.177$ to $f_\beta = 0.178$. Figure 9 summarizes these measurements and compares them to the values of the complex dominant eigenvalues for the feedback system calculated from a simplified model of the bunch.

codes and reduced models. We presented some results from these studies and the matching with the estimated parameters given by the simulation tools. Further analysis is in progress to analyze the bunch dynamics and quantify the models based on data collected when the bunch was driven by different excitations.

SIMULATION STUDY ON TRANSVERSE LASER COOLING AND ORDERING OF HEAVY-ION BEAMS IN A STORAGE RING

Yosuke Yuri, Takasaki Advanced Radiation Research Institute, Japan Atomic Energy Agency,
1233 Watanuki-machi, Takasaki, Gunma, Japan

Abstract

The formation of three-dimensionally ultralow-temperature ion beams by means of laser cooling in a storage ring is studied with the molecular dynamics approach in which stochastic interaction between laser photons and ions is incorporated. The transverse motion of a coasting beam is cooled indirectly through horizontally-displaced lasers and resonant coupling at several different operating points. The indirect transverse cooling rate depends on the displacement and detuning of the lasers as well as on momentum dispersion. In the ultralow-temperature equilibrium state, a 3D ordered (but not crystalline) structure can be formed depending on laser-cooling conditions. The characteristics of the Coulomb-ordered beam are discussed in contrast to a 3D crystalline beam.

INTRODUCTION

Three-dimensional (3D) beam cooling is essential in order to generate an ultralow-emittance beam in a storage ring. It is expected that, at ultralow emittance, the beam is Coulomb-ordered where the relative particle configuration is arranged in order and, in the zero-emittance limit, Coulomb-crystallized where the betatron and synchrotron oscillations are fully suppressed [1]. A longitudinal, one-dimensional (1D) ordering phenomenon was already observed experimentally in ultralow-current (about 10^3 ions in the ring) ion beams using electron cooling [2-4]. It has been found, by theoretical studies, that ions in the ordered beam do not pass through each other longitudinally [5-7]. As to crystalline beams, however, even a 1D string crystal has not been realized up to now in spite of a laser-cooling experimental effort at a cooler storage ring S-LSR in Kyoto University [8]. It is actually very difficult to observe phase transition of a very low-intensity (about 10 ions per bunch) bunched beam clearly although the feasibility of 1D and 2D crystalline beams was predicted with a molecular dynamics (MD) simulation [9, 10].

We have recently demonstrated the feasibility of the three-dimensionally ordered state of an ion beam with 3D laser cooling for the first time [11]. In these proceedings, more detail MD simulation results are given on transverse laser cooling and the ordered state of heavy-ion beams. The stress is put on various characteristics of the Coulomb-ordered beam.

SIMULATION PARAMETERS

A dedicated MD simulation code CRYSTAL, in which stochastic interaction between laser photons and ions is incorporated, is employed for the present study [9]. An actual beam and lattice parameters of S-LSR (see Fig. 1) has been considered. The superperiodicity of the ring is six. The ring can fulfill the following requirements to reach an ultralow-temperature state of an ion beam [1, 12]: First, the storage ring must be operated below transition energy. Second, the bare betatron tune $\nu_{x,y}$ must be less than 0.35 per lattice period to avoid linear resonances at ultralow temperature. More desirably, it must be below 0.25 to avoid linear resonance crossing in the cooling process [13].

A coasting beam of 40-keV $^{24}Mg^{+}$ ions is assumed. The space-charge force is calculated efficiently by imposing a periodic boundary condition in the longitudinal direction. The initial transverse rms emittance and longitudinal rms momentum spread of the beam have been chosen from the recent experimental observation [8].

One co-propagating and one counter-propagating Gaussian cooling lasers with the waist radius of 5 mm are applied along one of the straight sections in the ring. The direct longitudinal laser-cooling force is extended to the horizontal direction through momentum dispersion by horizontally displacing the two Gaussian laser beams [14, 15, 10]. Moreover, the vertical direction is coupled with the horizontal one through a weakly-excited solenoid magnet by applying a resonant coupling scheme [16]. Three different operating points ($\nu_x = \nu_y = (\nu_0 =)$ 1.44, 1.60, and 1.90), which fulfil the above tune requirement, are chosen for comparison. To reduce the longitudinal momentum spread, the frequencies of the lasers are

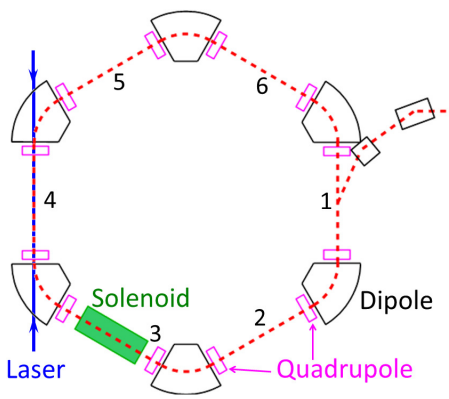

Figure 1: Schematic drawing of S-LSR. The circumference of the ring is 22.56 m. Six bending dipole and 12 quadrupole magnets have been excited so that the six-fold lattice superperiodicity can be realized. Numbers (1 to 6) in the figure express the number of straight sections for convenience. Two cooling lasers are injected along the fourth straight section. A solenoid magnet, installed in the middle of the third straight section, is excited for horizontal-vertical coupling.

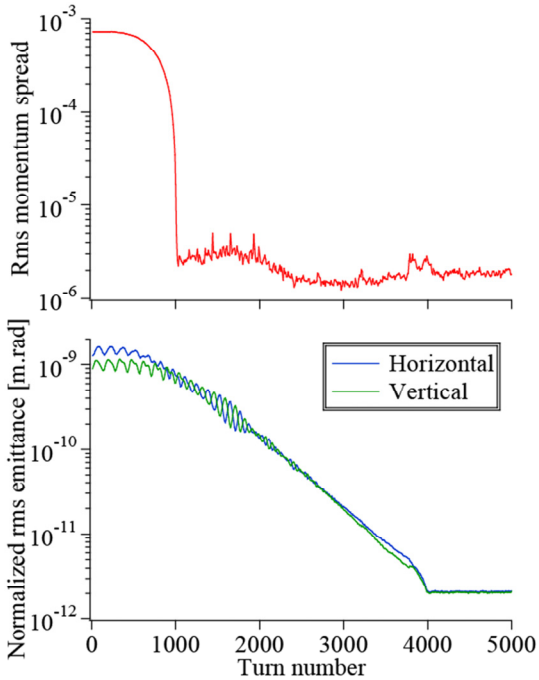

Figure 2: Time evolution of the longitudinal momentum spread and transverse emittance of the 40-keV $^{24}Mg^{+}$ ion beam during laser cooling. The bare betatron tune ν_0 is 1.44. The line density of the beam is 2.4×10^4 m^{-1}. The laser detuning is scanned in 1000 turns. The horizontal displacement and final detuning of the lasers are 3 mm and -81 MHz, respectively.

scanned from an initial detuning of -4.3 GHz to a final detuning on the order of -10 MHz in 1000 turns.

SIMULATION RESULTS

In the following, the result on ν_0 = 1.44 is mainly shown unless otherwise noted. A typical time evolution of the momentum spread and normalized rms emittance of the beam during laser cooling is shown in Fig. 2. The average dispersion function is 2.1 m in the laser cooling section for ν_0 = 1.44. The longitudinal momentum spread is decreased rapidly down to the order of 10^{-6} with the laser frequency scanning. The transverse emittance shrinks exponentially after the scanning is ended because the transverse cooling rate is higher at a smaller detuning. The 1/e cooling time is 20 ms after the laser scan in the present case. Similarly at the other higher tunes, beams with a line density on the order of 10^4 m^{-1} are laser-cooled down to the same order of the momentum spread and emittance. The cooling time is longer for higher tunes because of smaller dispersion. However, the dependence of the cooling rate does not always agree the linear theory that the transverse cooling rate is proportional to the dispersion [17].

Figure 3 shows the 3D ordered profile of the laser-cooled beam. Such ordered states of the laser-cooled beams can be generated also at ν_0 = 1.60 and 1.90, depending on the line density of the beam and the displacement and final detuning of the lasers. Although

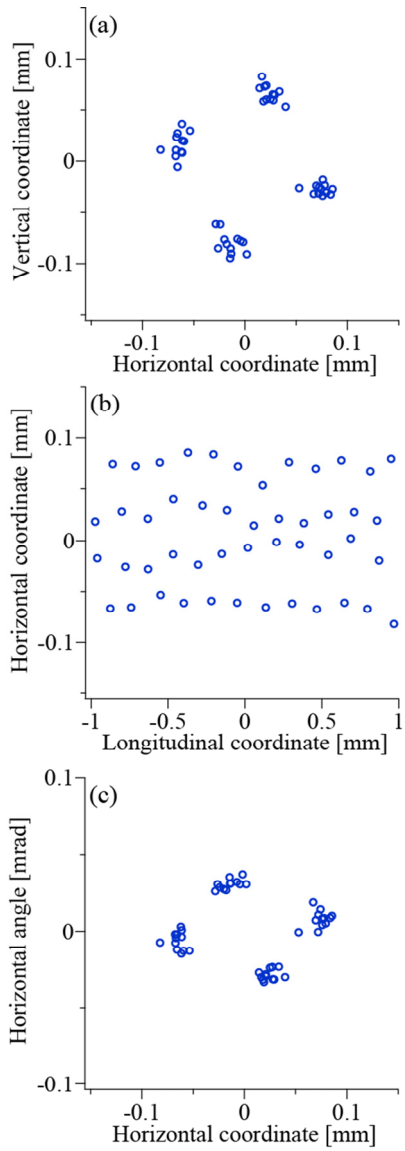

Figure 3: Real-space and phase-space configurations of the laser-cooled beam in Fig. 2. Each blue circle corresponds to a single $^{24}Mg^{+}$ ion.

the snapshot views of the real-space configuration in Figs. 3(a) and 3(b) are similar to those of a single-shell crystal, the phase-space profile is very different. According to Ref. [18], the transverse phase-space configuration in an ideal crystalline beam is always linear. On the other hand, the phase-space configuration of the ordered beam is not linear but square in the present case, as clearly seen from Fig. 3(c).

Another difference is the time evolution of the single-particle orbit and the cross-sectional profile. The transverse orbits of three ions arbitrarily picked out from the ordered beam are plotted in Fig. 4. Unlike a crystal, the orbits are not periodic with the six-fold superperiodicity of the ring, and the ions are still executing betatron oscillation, as shown in Fig. 4(a). The betatron tunes have been depressed from 1.44 to 1.20 in the equilibrium due to the space-charge effect. The trajectories of the ions in the beam cross-section are

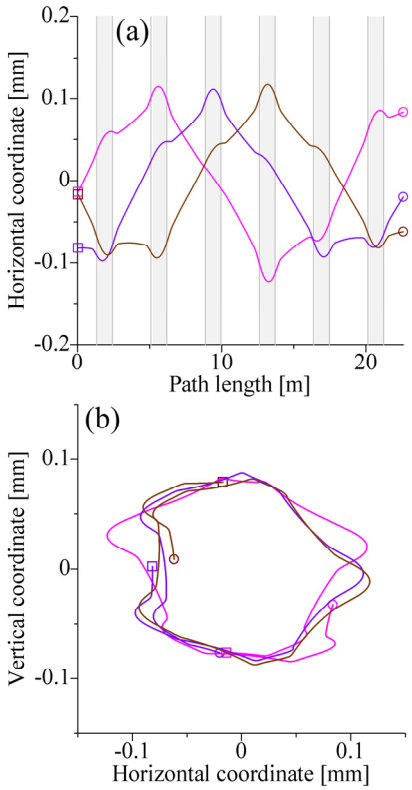

Figure 4: (a) Single-particle orbits of the beam in Fig. 3 while the beam circulates the storage ring once. The horizontal orbits of three ions arbitrarily picked out from the ordered beam are shown. The six gray shaded areas indicate the bending-magnet sections. (b) The trajectories of the three ions in the cross-sectional view are shown. In both panels, the square and circle symbols represent the initial and final coordinates of the ions during one turn, respectively.

shown in Fig. 4(b). It is obvious that the ions are rotating around the central axis. The rotation frequency while the beam goes around the ring once is 1.20, the same as the depressed betatron tune. Similarly, the ions rotate in both transverse phase planes. The dependence of the depressed tune and tune depression on the bare tune ν_0 is summarized in Fig. 5. It is worthy to note that an ordered beam is formed with a rather large tune depression at a high tune.

Since the longitudinal motion is almost frozen out by direct laser cooling, the longitudinal relative position does not change in the straight section. However, the relative position is changed due to the shear effect, depending on the horizontal coordinate in dipole bending magnets. In spite of this shear effect, the ordered configuration is stabilized: the shear effect is compensated because the horizontal coordinates of outer rotating ions are randomly changed every time the ions pass through the bending magnets.

The strength of the correlation in a beam can be estimated from a Coulomb coupling constant Γ [19]. The average temperature of the ordered beam in Fig. 3 is 3 mK in the longitudinal direction and 0.3 K in the

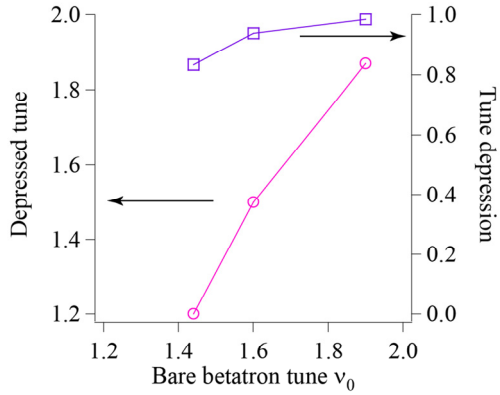

Figure 5: Depressed tune and the tune depression of 3D ordered beams formed at different operating points.

transverse direction. The longitudinal direction is sufficiently in a liquid phase ($\Gamma_{long} \sim 70$) while Γ of the transverse direction is relatively small ($\Gamma_{trans} \sim 0.7$) due to the rotation of ions.

SUMMARY

We studied 3D laser cooling of heavy-ion beams and the formation of the ordered structure in ultralow emittance with the MD simulation technique. The indirect transverse cooling worked well, depending on various laser and lattice parameters. The 3D ordered beams were formed by 3D laser cooling and exhibited unique characteristics such as the cross-sectional rotation unlike a crystalline beam. We have found that the 3D ordered beam is established in an excellent balance in spite of such anisotropy of the state.

ELECTRON CLOUD MEASUREMENTS USING A SHIELDED PICKUP IN A QUADRUPOLE AT CESRTA*

J.P. Sikora†, M.G. Billing, J.V. Conway, J.A. Crittenden
J.A. Lanzoni, Y. Li, CLASSE, Ithaca, New York 14853 USA

Abstract

We have recently constructed a shielded pickup in a quadrupole magnet for time-resolved detection of electron cloud. Cloud electrons pass into the detector through an array of small holes in the wall of the beam-pipe that shield the collecting electrode from the direct beam signal. There are two collectors, each aligned on a pole face: one near the longitudinal center of the quadrupole, the other in the fringe field. The signals from the collectors are recorded with a digital oscilloscope. We present a summary of the design, construction and commissioning of this device, as well as initial beam measurements. This work was performed at the Cornell Electron Storage Ring which has been reconfigured as a test accelerator (CESRTA) with positron or electron beam energies ranging from 2 GeV to 5 GeV.

INTRODUCTION

Investigation of electron cloud (EC) growth and decay is an important part of the CESRTA program. Shielded pickups (SPU) in two field free regions have been in use since 2009 and significant progress has been made in connecting simulations with data from these detectors [1]. Parameters used in simulation of the electron cloud are tuned to match the data, including modeling of the detectors . The introduction of dipole or quadrupole fields makes this connection more difficult, mostly in accurate modeling of the detectors rather than modeling of the electron cloud. There was an interest in constructing a simple device that would give time-resolved information about the EC density in a quadrupole field since there is some evidence and modeling that electron cloud could be trapped there [2, 3, 4].

The quadrupole shielded pickup (QSPU) is based on the successful design of the SPU. An important part of that design is the array of holes that connect the vacuum space to the detector. The 1:3 diameter to depth ratio of the holes provides significant attenuation of the direct beam signal [5]. This is important, since a typical direct beam signal will be tens of volts, while the largest (unamplified) electron cloud signals that we have seen are tens of millivolts. Even with this attenuation, some direct beam signal is visible in the detector output.

QSPU DETECTOR

The QSPU has two collectors, both aligned with a pole face as shown in Fig. 1: one in the longitudinal center of the quadrupole , the other is located in the fringe field. This paper contains data only from the centered detector.

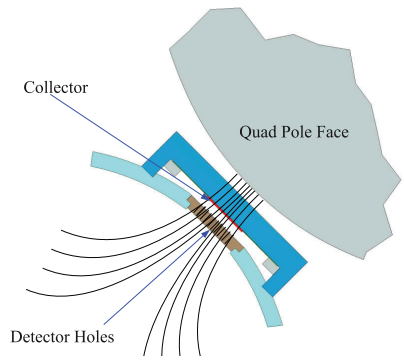

Figure 1: The QSPU detector is centered on one of the quadrupole pole faces. The rectangular collector is 10 x 100 mm copper on kapton centered longitudinally along the pole face behind an array of holes in the beam-pipe wall.

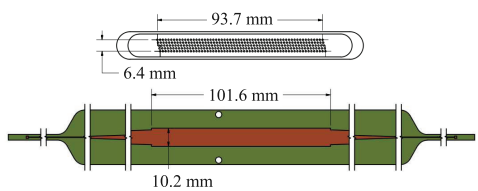

Figure 2: The 5 x 60 array of 0.79 mm diameter holes allow cloud electrons in the beam-pipe to enter the detector. The wall thickness is 2.4 mm. Electrons are collected on the copper flex circuit and the signal routed to feed-throughs at either end of the quadrupole chamber (not shown).

In the QSPU, the collector is an approximately 10 x 100 mm copper rectangle on a 0.13 mm thick kapton flex circuit with a ground plane shown in Fig. 2. Tapered striplines on the flex circuit couple the signal to SMA vacuum feed-throughs approximately 1 m apart at either end of the quadrupole chamber. For comparison, the collector in the field free SPU, is a 1.7 cm diameter button of the type used for beam position monitors.

Copyright © 2013 CC-BY-3.0 and by the respective authors

The collectors for both the QSPU and SPU and biased at +50 V to ensure the capture of incident electron current. The collector signals are AC coupled to a cable that is routed to two cascaded 20 dB amplifiers (ZFL-500 from Mini-Circuits) that give a total voltage gain of 100. The signals are digitized with an oscilloscope that uses a timing system trigger and provides signal averaging.

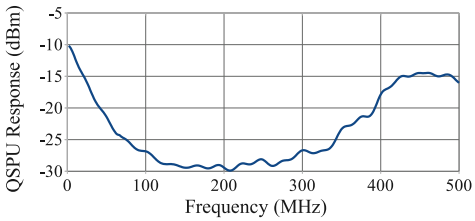

Figure 3: The response of the collector flex circuit was measured with a spectrum analyzer. There is a low-pass feature due to the collector capacitance with a -3 dB point at about 13 MHz and a high-pass feature above 300 MHz.

The QSPU collector has fairly high capacitance due to its construction on the thin kapton flex circuit. As shown in Fig. 3, it acts as a low-pass filter with a -3 dB rolloff at about 13 MHz. At frequencies above 300 MHz, the circuit has a high-pass characteristic that results in significant direct beam signal from the detector.

BEAM SIGNALS

Witness bunch measurements with the field free SPU have provided useful comparisons to simulations of EC density build-up using ECLOUD [1]. Most of these measurements have been carried out with pairs of bunches, where (roughly speaking) the first bunch generates a cloud and the second bunch accelerates this cloud into the detector. The revolution period at CESRTA is 2562 ns which is long compare to the expected EC decay time of about 100 ns. So with short trains of bunches, the EC density is taken to be zero with the arrival of the first bunch. The signal from the first bunch is dominated by photo-electrons and is much smaller than that of the second bunch, where electrons near the beam are accelerated to hundreds of electron volts into the detector.

Although the array of holes in the QSPU provides significant attenuation of the direct beam signal, it is still visible in the detector output. Figure 4 shows the output from a 20-bunch train of positrons with 14 ns spacing and a bunch population of 1.36×10^{11} (8.5 mA). The raw data is digitally filtered by convolving it with a 12 ns impulse response.

Figure 5 shows an overlay of witness bunch measurements with a field free SPU where a 10-bunch train of 5.3 GeV positrons is followed by a witness bunch with delays from 28 to 140 ns. All of the bunches have the same population of 1.36×10^{11} positrons/bunch. As witness bunches are placed at various distances after the bunch

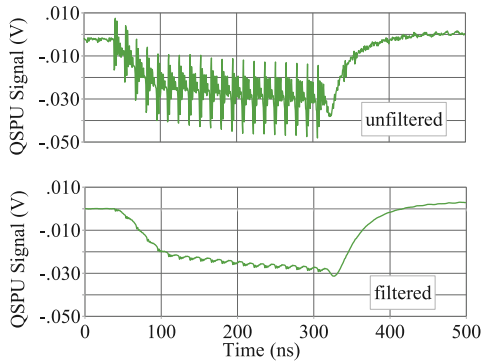

Figure 4: The signal from the QSPU with a 20-bunch train of 5.3 GeV positrons at 1.36×10^{11} positrons/bunch shows significant direct beam signal (upper). The data is filtered by convolving with a 12 ns impulse response (lower).

train, they map the decay of the cloud that the train produced. Also, the signal from the first bunch of the train is quite small, about 0.2 V or less, while the signal from the second bunch is roughly 1.7 V. This is consistent with EC density decaying to zero in the 2.5 μs beam revolution time.

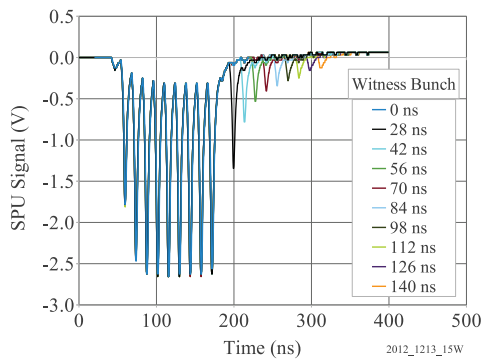

Figure 5: Signals from a field free SPU are overlaid, for a 10-bunch train that is followed by witness bunches at various spacings. The decreasing signals from the witness bunches show the decay of the cloud.

A similar measurement was made with the QSPU, where a 10-bunch train of 5.3 GeV positrons was followed by witness bunches from 28 to 84 ns. All bunches are at 8 mA (1.28×10^{11} positrons/bunch) and a 6 ns filter was applied to the data before plotting. The plots overlaid in Fig. 6 show a decrease in signal amplitude that is on a time scale similar to that of the field free SPU. An expanded detail in Fig. 7 shows the time delay between the direct beam signal and the peak in collection of electrons. This delay of about 18 ns is considerably longer than that observed in the field free region. The beam-pipe geometries are somewhat different – the field free SPU is in oval pipe with a height of 5 cm, whereas the quadrupole SPU is in round pipe that is 9 cm diameter. But it is likely that the presence of the

Copyright © 2013 CC-BY-3.0 and by the respective authors

7.4 T/m field is responsible for most of the time delay since the cloud electrons have more complicated trajectories.

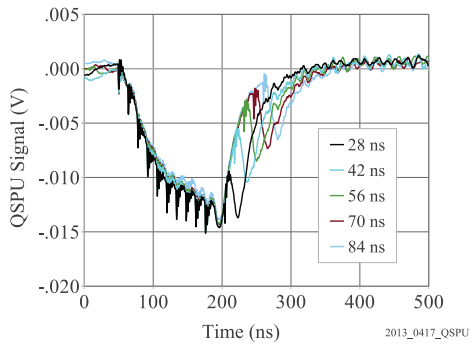

Figure 6: With the QSPU in a 7.4 T/m field, a 10-bunch train of positrons spaced by 14 ns is followed by a single bunch spaced at intervals from 28 to 84 ns. An overlay of these measurements shows a decrease in the witness bunch signal.

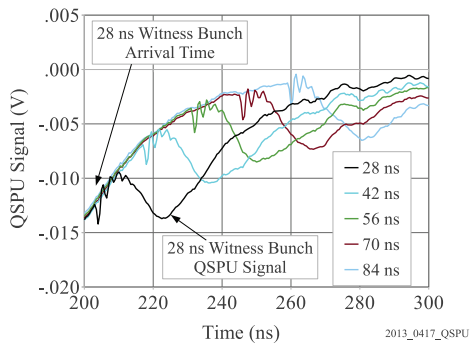

Figure 7: In this detail of the QSPU witness bunch signals, the direct beam signal is seen about 18 ns before the arrival of electrons in the detector.

Data was also taken with both the SPU and QSPU with a 20-bunch train of 14 ns spaced 5.3 GeV positrons. The bunch currents ranged from 4.3 to 10.4 mA/bunch which corresponds to 0.69×10^{11} to 1.67×10^{11} positrons/bunch. The overall shape of the signal from the field free SPU is an amplitude that increases quickly, then reaches an equilibrium value as can be seen in Fig. 8. The shape is similar over a range of bunch charges.

The overall shape of the QSPU signal with the same 20-bunch train (Fig. 9) changes with bunch charge. At higher bunch charge the signal never reaches an equilibrium value. There are also two slopes to the data: a rapid rise at the beginning followed by a more gradual increase out to the end of the bunch train.

CONCLUSIONS

We have constructed a device to make time-resolved measurements of electron cloud in a quadrupole. Witness bunch measurements after a train of ten bunches in the 7.4 T/m quadrupole field gives an electron cloud decay

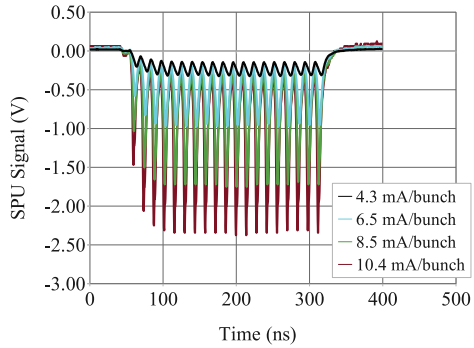

Figure 8: The SPU signal with a 20-bunch train of positrons at 5.3 GeV reaches an equilibrium value early in the train independent of bunch current.

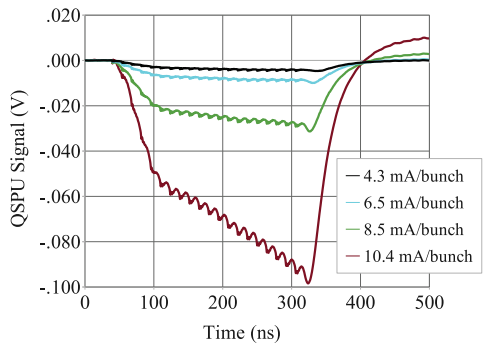

Figure 9: The QSPU signal with a 20-bunch train never reaches an equilibrium value and appears to have two slopes at the highest bunch charge of 10.4 mA/bunch (1.67×10^{11} positrons/bunch).

time that is similar to that obtained in a field free region. A 20-bunch train has a signal with a somewhat different character in the two types of detectors. The signal in the quadrupole does not reach equilibrium at the highest bunch currents. Further experiments and simulations are needed to better understand these initial measurements.

EXPERIMENTAL STUDY OF HALO FORMATION IN SPACE CHARGE DOMINATED BEAM*

H. D. Zhang#, B. L. Beaudoin, R. A. Kishek,
University of Maryland, College Park, MD 20742, USA

Abstract

Beam halos are a group of particles with low density that are far away from the well-defined central beam core and have large transverse velocities. Beam losses from halos can require a larger aperture and impose restrictions on the beam current. Several theoretical techniques have been applied to analyze and understand halo formation, including the particle-core model, the free energy model as well as particle in cell (PIC) simulations. However, few experiments on beam halos have been carried out. Here, we describe an experimental study at the University of Maryland to understand and characterize space-charge induced halo formation. The experiments are conducted on the University of Maryland Electron Beam (UMER) and the results are compared with PIC simulations using WARP.

INTRODUCTION

Halo is generally understood as a population of particles that do, or will reach large transverse radii relative to a more intense, centralized beam core. It is associated with emittance growth, degradation of beam quality and particle loss [1]. Several analytic models such as the particle-core model [2] and the free energy model [3] are derived either to depict the process of halo formation or to describe the associated emittance growth. Many theoretical and simulation studies developed these ideas and discussed various mechanisms for halo formation. However, fewer experimental studies have been performed as it is hard to obtain a halo free beam, a crucial component to identify different mechanisms or sources for halo formation. The LEDA experiment [4] is an example for demonstrating agreement with the particle-core model. But its propagation length is limited and it is no longer operational. In this paper, we discuss a method to get a halo-free beam though envelope match and skewness correction. Based on the matched beam, we perform a mismatch experiment as well as a skewness test to verify the sources of halo formation in UMER. Then, we generate a pure breathing mode mismatch, and compare experiments with simulations to confirm this mode.

EXPERIMENT SETUP

UMER

UMER [5], is small compact electron ring with a low energy (10 keV) but relatively high beam current (0.6-100 mA). It is designed to study the physics of electron beams from the emittance dominated regime to space charge dominated regime. The results can be scaled to higher energy beams with higher mass. Fig. 1 shows a schematic of the UMER layout, and Table 1 lists its key parameters and Table 2 lists the beam parameters we will use in this discussion.

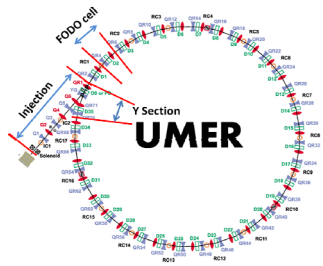

Figure 1: Diagram of UMER.

Table 1: UMER Design Parameters [5]

Parameter	Value
$\beta = v / c$	0.2
Pulse Length	20-120 ns
Beam Energy	10 keV
Current	0.6-100 mA
Ring Circumference	11.52 m
Lap Time	197 ns
Pulse Repetition Rate	10-60 Hz
FODO Period	0.32 m
Zero-current Phase Advance	0.760

Table 2: Beams in UMER [5]

Aperture#	r_0 (mm)	I (mA)	ε (μm)	χ
1	0.875	6	16.8	0.605
2	1.5	21	30.0	0.901

Image System

An imaging system was designed and dedicated for this work utilizing Ethernet cameras, in order to take and process images quickly. A system illustration is shown in Fig. 2. The cameras are connected to a control PC through a gigabyte Ethernet switch. The camera control PC can also control the magnets though the main control PC by sending an appropriate command. The whole system is integrated by a Matlab GUI code. It includes a camera control panel, Magnet control panel, image display and calculation panel, and the Auto picture scan panel. It allows one to change camera settings and take beam images, in order to calculate transverse beam parameters; such as centroid, size and rotation angle. This system can also be used for injection scan (empirical method discussed later) and phase space tomography.

ENVELOPE MATCH

Match Description and Fitting

We use a tracking code Trace3D to get a match solution. There are 3 different sections in UMER when we discuss beam envelope match, including injection, Y-section and ring section. Ring section contains 34 equivalent FODO cells, and the matched periodic envelope solution is defined by the emittance from Table 2 and the predefined lattice setting, specially the ring quadrupole strength. In UMER, the ring quadrupoles are setting to 659.0 G/m with positive and negative value alternating. Y-section contains a regular FODO cell, YQ and QR1, where the later two are pulsed Panofsky quadrupoles. Because the pipe for injection and recirculation go through YQ, the center line of YQ is off the ideal beam path by 10°, which results a slightly difference in peak gradient. We use Type 8 fitting procedure in Trace3D to find the quadrupoles setting for Y-section. Next step is to find appropriate injection quadrupole settings with the YQ and QR1 strength determined from last step. The lattice of injection starts from the aperture and ends at the entrance of a regular FODO cell. The final beam parameter is predefined by the ring FODO cell. Here, Q1 is usually small to avoid large ratio of two transverse sizes. The initial Twiss parameter at aperture is from Table 2. Using a Type 8 matching procedure in Trace3D, we will finally get a series of quadrupole setting either Q2-Q5 or Q3-Q6.

Empirical Matching

In practice, many factors, such as beam initial properties, lattices imperfection, vacuum condition and etc., will affect calculations and simulations, and make them deviate from experiments. The magnets strength obtained though calculation and simulation does not necessarily yield a good matching condition. A further empirical method will be used to achieve the final match. The idea here is to scan 4 injection quadrupoles and to take the envelope responses in more than 4 screens. The optimal solution can be obtained in a least square sense, i.e. $\Delta I = (R^{T}R)^{-1}R^{T}E$, where ΔI is the difference between current and updated quadrupole setting, R is response metrix, E is the envelope of current settings. An updated injection setting is given by I-ΔI. Details for this method can be referred to [6].

Correction for Skewness

Due to fringe field of solenoid and rotation error of injection quadrupoles, there is a beam rotation in each chamber inside the ring which also can be a source for halo formation. Here we use two skew quadrupoles in Q3 and Q6 to correct this rotation. The skew quadrupole is a type of UMER quadrupole with a normal pair of printed-circuits [6] and a 45-degree rotated pair as in Fig. 3. Each pair is powered by different current supplies, so the normal and skew components can be independently adjust. By scanning the skew quadrupoles and comparing the rotation angle of beam images in each chamber, we can minimize the rotation in least square sense similarly to the empirical matching.

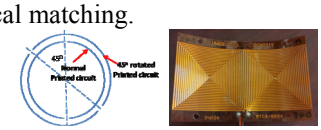

Figure 3: Schematic diagram of skew quadrupole (a) and piece of printed circuit (b).

Matching Result

After going through the process mention above, we obtain match beams of 6mA and 21 mA. The image of the beam for the first turn is shown in Fig. 4. The beam sizes in each chamber are plotted in Fig. 5. Note that, the screen is 28.6 mm ahead of ring chamber center and we also have a small difference of edge focusing in two transverse directions from dipole. Therefore, beam images in the screen are not round. Here, we calculate the average sizes are 3.55 mm, 2.79 mm for 6mA and 6.00 mm, 4.81 mm for 21mA and the standard derivations are 0.17 mm, 0.16 mm for 6mA and 0.30 mm, 0.17 mm for 21mA, which proof that we match the beam quite well. Meanwhile, the rotation angle is small, the average and standard derivation of which is only 0.4 degree and 8.3 degree for 6mA, and -1.4 degree and 7.7 degree for 6mA.

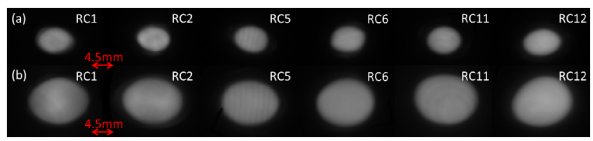

Figure 4: Matched beam images at different ring chamber: (a) 6mA; (b) 21mA.

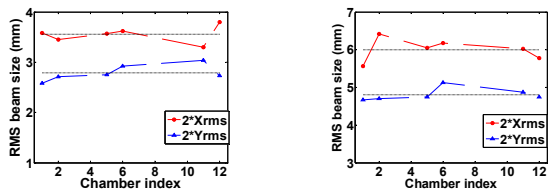

Figure 5: Plot of matched beam size 6mA (left); 21mA (right).

MISMATCH EXPERIMENT

Halo Related to Mismatch and Skewness

From the matched 6 mA beam, we mismatch the beam simple by reduce one of the quadrupole in the injection, e.g., Q5 by 20%, which is a huge error in realistic sense. We compared the beam images in RC5 between matched and mismatched case in Fig. 6. The phase space x-x' plot and y-y' plot is from phase space tomography. From the configuration space, it is clear that there are large amount of halo generated due to mismatch. From the phase space plot, there are also two hot spots in x-x' plot and large

Copyright © 2013 CC-BY-3.0 and by the respective authors

spikes in y-y' plot, which indicate an emittance growth related to that halo.

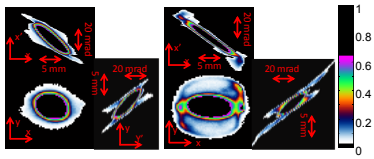

Figure 6: Comparison of matched (left) and mismatched (right) beam at RC5 in x-y, x-x', y-y' plots.

Beam rotation is also a driving source for halo formation. In order to see the halo generated in first turn, we intentionally introduce a 22.3° rotation in RC1 by setting the skew component of Q6 by 0.4 A (or 144.4 G/m peak gradient). The beam images are shown in Fig. 7. It is obvious from images in RC1 to RC5 that there is a wobbling mode related to beam rotation. When the beam finally gets close to equilibrium state (see in RC11 and RC12), the wobbling energy will be transfer to particles to form halo.

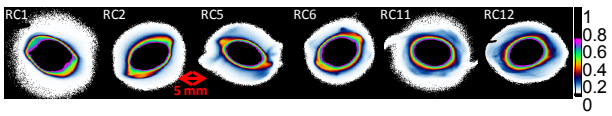

Figure 7: Halo generation from the rotation of the beam.

Pure Breathing Mode Generation

To generate quadrupole solutions that produce a pure breathing mode mismatch beam, we need to go back to the matched ellipse parameters at a little downstream of the screen in RC1, where two *beta functions* are equal. A breathing mode mismatch solution is obtained by scaling α_x, β_x, α_y and β_y there by a common factor μ^2, where μ is the mismatch parameter. From previous aperture condition and lattice settings in Trace3D, we change the setting of the final condition as the scaled twiss parameters, use a Type 8 matching procedure, and we can find the settings of quadrupole Q2-Q5, or Q3-Q6.

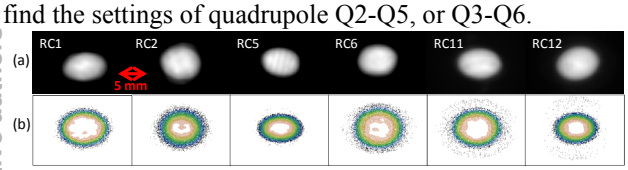

Figure 8: Breathing mode mismatch comparison between (a) experiment and (b) WARP simulation with mismatch parameter μ=1.3.

Here is an example of breathing mode mismatch using 6mA beam in Fig. 8 (a) where the mismatch parameter μ=1.3. Since the screen is offset from the center of each chamber, the breathing of beam envelope is not obvious from the images. To testify the mode we generate, we perform a PIC simulation using Warp [7]. The same emittance and current of 6mA beam are used and the breathing mismatch mode is generated the same way by scaling the α_x, β_x, α_y and β_y by a common factor μ^2 at the point when two *beta functions* are equal. The difference in simulation is we only use the ring section instead of starting from the aperture. The simulated images are shown in Fig. 8 (b). We plot the envelopes of this mismatched beam in Fig. 9 with dotted line from simulation and red dot representing the experimental data from each screen. From the plots, the experimental data lie on the simulation curve quite well which confirms a good agreement.

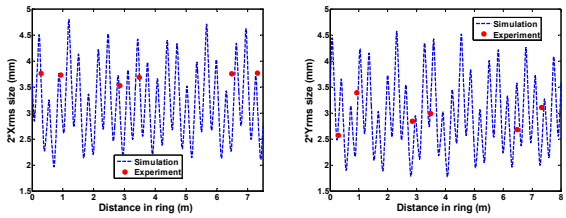

Figure 9: Envelope of the breathing mode mismatch: x (left) and y (right).

Next, we perform a FFT analysis to the envelope curves of breathing mode mismatch from simulation (see Fig. 10). We got a single strong peak for each direction with peak wave number 5.561 m^{-1} and 5.561 m^{-1} separately. This wave number is close to the result from analytic model 5.775 m^{-1}, which verifies that we generate a pure breathing mode.

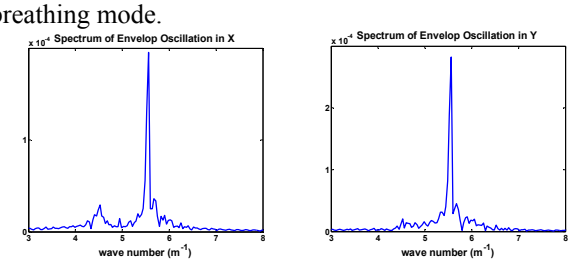

Figure 10: FFT analysis of the envelope for breathing mode mismatch: x (left) and y (right).

CONCLUSION

In this paper, we discussed a method in UMER for beam match which can be performed generally in any accelerator. We identified the sources for halo formation in UMER are from envelope mismatch and beam rotation. We generated a pure breathing mismatch mode in UMER and verified it. The pure mismatch mode has simpler dynamics, which will allow us study the halo formation related to mismatch quantitively. For near future, we will continue to study the breathing mode mismatch, especially compare beams in different space charge region.

SNS PERFORMANCE AND THE NEXT GENERATION OF HIGH POWER ACCELERATORS*

J. Galambos#, on behalf of the SNS team, ORNL, Oak Ridge, TN 37830, USA

Abstract

The SNS accelerator at ORNL has been operating near the MW level for several years now. This presentation discusses the successes and challenges, new insight gained and lessons learned with regard to the operation of a modern high power accelerator. In particular, issues with the RFQ, the target and the superconducting RF linac are discussed. Also future high power proton accelerator plans and development needs are discussed.

RECENT SNS OPERATIONAL EXPERIENCE

The Spallation Neutron Source (SNS) accelerator reached the 1 MW operational power level in 2009. Over the past two years beam power has been run between 0.85 MW and 1 MW, as indicated in Fig. 1, with reduced power operation driven by considerations beyond accelerator components. For example the past year of operation, beam power was reduced to preserve target lifetime due to a target spare shortage. However, for the past few weeks, the operational power level has been increased up to 1.2 MW.

Extended running periods without power increase in 2010 – 2011 coincided with increased accelerator availability, as shown in Figure 2. After steady rises in operational hours and beam availability through 2011, the past 2 years show decreases in both these figures. These are due to target failures at the end of FY 2012, and the start of 2013 that severely reduced operational hours and negatively impacted the beam availability. The target issue is discussed in more detail below. Discounting the target failures, the accelerator availability for the years 2011-2013 was 92%, 94% and 89% (YTD) respectively.

RFQ Issues

The SNS RFQ experienced 2 detuning incidents in 2003 and 2009, which required retuning of the RFQ in order to operate. From the period mid-2011 through mid-2012 a reduction of beam current measured downstream of the RFQ was observed for all ion sources [1] (see Figure 3). This prompted a measurement of the field profile in the RFQ, and yet another perturbation was observed (see Figure 4). Interestingly, this field disturbance did not prevent operation of the RFQ, only a reduction in beam transmission. The first extended outage that allowed for retuning the field was summer of 2013. However, while there are suspected causes of the first two detuning incidents, this latest incident remains unexplained.

The field profile changes discussed above are likely specific issues related to the manufacturing of this RFQ. However, another perhaps more generic RFQ issue has been observed. This is the issue of discharge heating in the RFQ (in addition to the normal RF induced copper hearting [2]. The discharge related heating can be significant (~ 10% of total heat load) and is not constant, but rather dependent on the gas load history into the RFQ. Also it can change suddenly, complicating the cooling system and resonance control, which is designed for slower heat load changes. To accommodate this complication the low level RF control has been modified to provide fast modulation of the RFQ pulse length to help control the resonance error. However the additional pulse length margin used for this function is becoming limited as we reach the design pulse length of the machine (1 ms), and a new mitigation technique is being sought.

Errant Beam

Machine protection has always been a major concern for high power operation at the SNS accelerator. Beam shut-off times were prescribed to protect the machine from prompt damage. Generally a 10-20 μs beam shut-off time has been accepted (damage can occur faster at lower beam energies where the stopping length is shorter). However, we have learned that the superconducting RF linac (SCL) cavities can be susceptible to performance degradation with beam loss periods lower than that required to actually approach melting temperatures [3]. In particular, beam trips caused by anomalies upstream of the SCL result in beam loss in the SCL, until the machine protection shuts off the beam. We refer to the beam lost in the SCL during these trips as "errant beam". Even if each individual errant beam pulse does not harm the SCL, we have noticed degraded cavity performance after prolonged exposure to repeated errant beam pulses. A suspicion for the degradation cause is that the slight local heating (a few K) caused by errant beam pulses may initiate the migration of trapped gas in the cavity surface, to a more vulnerable region of the cavity. Figure 5 shows the history of the operational beam energy. Following an beam energy increase in 2009 resulting from cryomodule equipment fixes, during 2009-2011 operation, a slow energy degradation occurred, raising concern about errant beam.

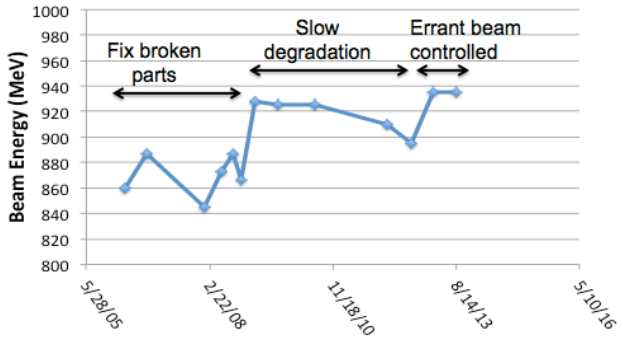

Figure 5: Operational linac output beam energy, indicating a period of performance degradation in 2009-early 2011.

An effort was initiated to identify and rectify causes of errant beam pulses. Two primary causes were identified: 1) pulses formed in the ion source with non-standard waveform shapes, and 2) pulses with premature upstream warm linac RF truncation. The first class constitutes < 10% of the trips and are caused by arcs in the source and electrostatic LEBT. Over 90% of the trips were caused by the RF faults, and the majority of effort was focused on these. We note that while the RF faults were damaging SCL performance, the actual down-time caused by the RF faults themselves was small (~ 30 trips per day each lasting < 1 minute).

One weakness identified, that contributed to increased RF fault rates, was insufficient attention to the vacuum quality which increased the frequency of arcs (hence RF trips). A more rigorous approach to vacuum maintenance improved this situation. Another reduction in fault frequency was reducing the number of trips allowed per second before requiring operator intervention from 2 to 1. Finally we also addressed a shortcoming the beam shutoff response time of the machine protection system. Namely, filters introduced to mitigate noise induced false machine trips also cased delays in the response time (up to > 300 µs in some cases). Even though electrical noise sources had been mitigated, the filters had not been removed. Eliminating these reduced the beam shut-off time to the design level of 10-20 µs and additional fast differential current systems are being deployed [4]. With these implementations the RF fault frequency was greatly reduced as shown in Figure 6. Also, the linac output beam energy has stabilized since instituting these changes, as indicated in Figure 5.

Target Issues

High power accelerators require high power target systems. SNS uses a liquid mercury target system that has the advantage of combining the spallation material and coolant [5]. However the very short beam on target pulse (< 1 μs) introduces a complication of shock waves that cause cavitation damage. The target system includes a stainless steel vessel that contains the flowing mercury, and requires regularly scheduled replacement, using robotic, remotely controlled equipment. Until Sept. 2012, of the five target vessels used, there had been only one unplanned target replacement. However, in Sept. 2012 there were two target failures in rapid succession [6], which depleted the supply of spare targets, and resulted in the reduction of operating power (~850 kW) for almost one year, as seen in Figure 1. Investigation of the target failure mechanism resulted in identification of poor welds in a region of reduced stress that had not received adequate manufacturing oversight. Fabrication QA has subsequently been improved, but there is a time lag of ~ one year to manufacture these complicated, first of a kind structures, and replenish the target spare inventory.

In addition to the need to survive high power density, radiation damage effects, and intense pulsed stress levels the cavitation issue mentioned above introduces considerable uncertainty in target lifetime. Figure 7 shows a typical cavitation induced damage pattern, in sections of the upstream portion of the target vessel. There are 4 separate containment walls, and the inner-most bulk mercury facing wall is shown (this is the wall most subject to the cavitation damage). These cut-outs are part of an on-going target Post Irradiation Examination (PIE) effort. The cavitation pitting seen here is observed in a similar pattern as this on all targets. Especially pronounced is the narrow "cut-through" along the target mid-plane. The narrow line of cavitation damage is much more focused than the proton beam power distribution and is not well understood. Even if this layer is compromised, target operation is not limited. The following wall must also be compromised to produce a leak that halts operation, and to date this second wall does not show extensive damage. However PIE efforts are limited to date, we cannot see the entire second surface, and there is uncertainty in this area. New target designs include modified mercury flow patters to eliminate mercury stagnation near the region of observed pitting, and a removable outer shroud (outer vessel walls) to allow better PIE efforts. Targets with these changes are expected to be introduced into operation sometime in mid 2014.

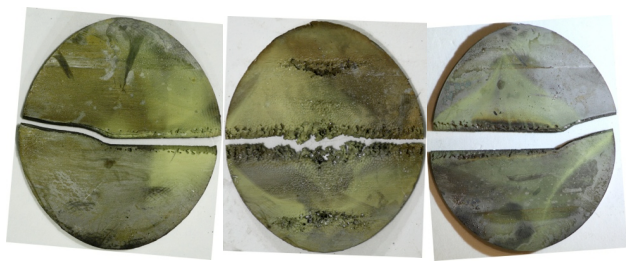

Figure 7: Three circular cross section cut-outs of the inner, front facing surface of target number 4 vessel – with a clear cavitation induced cut-through on the mid-plane.

A general lesson is that attention needs to be placed on the design and analysis of the target system, in addition to the accelerator. These systems are critical for operation of high power accelerators, and require development along side the accelerator components. Changes in this area require significant lead-time, and possibilities are limited due to the complete robotic maintenance approach that must be used.

NEXT GENERATION HIGH POWER PROTON ACCELERATORS

Recently the high power proton accelerator capabilities, planned upgrades and future facilities were surveyed [7], as part of the 2013 High Energy Physics Community Summer Study. Other facilities have high power proton accelerators in operations and in plans, and theses are summarized here. A more exhaustive facility list and explanation of R&D needs is explained in Ref. 7.

Existing Accelerators

There are many high power proton accelerators in operation today, in addition to SNS, as listed in Table 1. There are a number of different types of accelerators running at 100 kW or more today. Many of these involve rapid cycling synchrotrons (RCS) as part of the acceleration chain. Many of these operate, or have operated, as part of a higher energy collider chain. There are two accelerators that operate at the MW level: the PSI cyclotron chain and the SNS linac.

Table 1:Parameters of Existing High Power Proton Accelerator Facilities

Facility	Max. Power (kW)	Energy (GeV)	Time Structure	Accelerator Type
TRIUMF	100	0.52	CW	cyclotron
LANSCE area A	80-120	0.8	120 Hz	linac
ISIS	200	0.8	40 Hz: TS1, 10 Hz: TS 2	linac + RCS
J-PARC MR (FX)	240	30	0.4 Hz x 5 us	3 GeV into RCS
J-PARC RCS	300	3	25 Hz x 1 us	181 MeV linac + RCS
FNAL MI	400	120	9.4 us every 2.2 s	Linac + RCS
CERN SPS	470	400	4.4 s cycle length	linac + 2 stage RCS
SNS	1,200	0.94	60 Hz	linac + accumulator
PSI	1,300	0.59	CW	2 stage cyclotron

Table 2: Parameters of Planned Upgrades for Existing Accelerator Facilities

Facility	Max. Power (kW)	Energy (GeV)	Time Structure	Accelerator Type
FNAL MI + ANU	700	120	9.4 us every 1.33 s	Linac + RCS
J-PARC MR (FX)	750	30	0.4 Hz x 5 us	3 GeV into RCS
CERN SPS	750	400	4.4 s cycle length	linac + 2 stage RCS
LANSCE area A	800	0.8	120 Hz x 625 us	linac
J-PARC RCS	1000	3	25 Hz x 1 us	181 MeV linac + RCS
SNS	2800	1.3	60 Hz	linac + accumulator

Table 3: Future High Power Proton Accelerators

Facility	Max. Power (kW)	Energy (GeV)	Time Structure	Accelerator Type
ESS	5	2.0	50 Hz x 2.5 ms	SRF linac + accumulator
CERN with SPL	4	5	50 Hz x 6 bunches	SRF linac + RCS
Project-X (stage 1+2)	3	3	CW linac /accumulator	CW SRF linac + accumulator
Project-X (stage 3)	2.3	60-120	10^{-5} duty factor	+ pulsed 8 GeV SRF linac + RCS
MYRHHA	2.4	0.6	CW	SRF linac
Daedalus	3	0.8	60 Hz	2 stage cyclotron

Planned Upgrades

Many of the existing accelerator facilities have plans for further power increases, and these are shown in Table 2. Here we consider upgrades being considered in the next 5-10 years with some active development effort. There are several MW class applications appearing, with the J-PARC upgrade, and several of the high-energy (> 10 GeV) RCS chains approaching the 1 MW level.

Future Facilities

Finally, future proton accelerators with at least 1 MW beam power and an on-going design or development effort are shown in Table 3. Interestingly, superconducting RF linacs play a prominent role in all cases, except Daedalus. Also, the beam energy in most cases is lower than those in Tables 1-2.

R&D Needs

Each specific high power project and application has unique development needs, but there are certain overarching common needs. A key consideration is management of beam loss to very low fractional levels when operating at or above 1 MW. The rule of thumb for hands-on maintenance (a necessary condition to make these accelerators affordable) is keeping beam loss below 1 W/m, which translates to < 1 part in 10^6 for 1 MW at full energy. Measuring beam profiles and emittance in the full 6-D phase space to this level is beyond present day capabilities. Improvements are needed in increased

Copyright © 2013 CC-BY-3.0 and by the respective authors

dynamic range for instrumentation and novel methods to measure the multi-dimensional phase space. Also, simulations cannot predict beam behaviour to this level. At present tuning for beam loss mitigation is largely an empirical exercise in high power facilities [8]. Significant advances in simulation are needed to directly use modelling tools for loss tuning (beyond machine design). As mentioned above, even low loss that does not introduce machine activation at SNS can cause equipment damage.

Another common area of concern for high power proton accelerators is designing a survivable target. Generally the targets are made as small as possible to provide an intense secondary beam, but this necessarily forces high hear loads, high radiation damage rates etc. As mentioned above for the pulsed SNS case there are cavitation issues. These high power targets require remote maintenance techniques for replacement and repair, and the possible activities are thus quite limited. In addition, construction and operation costs (e.g. spent target disposal) are considerable and need to be considered up front, along with the accelerator.

For the superconducting RF accelerators there are RF development needs. Generally the beam energy is quite low compared to linear collider applications, so the need to increase gradients to reduce the linac length is not as severe. However for the pulsed SRF applications, development of high power coupler and reduced cost high availability high peak power RF power sources are needed. For the CW applications, production of cavities with low Q is needed to minimize cryogenic loads.

For cases with ring injection, new charge exchange injection techniques need to e developed. Typically 10^{-4} of the beam is lost in an optimized foil stripping injection. As the beam powers increase, this localized beam loss may become intolerable. Also for cases with long injection times, the foil scattering in the circulating beam can cause intolerable emittance growth. Laser stripping [9] is an attractive alternative, but requires significant development.

Chopping beam gaps at low energy is needed for some multi-purpose accelerator applications to facilitate beam transfer to different targets / accelerator chains and to provide user desired timing characteristics. The chopping is planned for the micro-bunch time-scale at low energy for the Project-X case [10], and must be done at an extremely high efficiency to guarantee low loss at higher energy. These techniques remain to be proven.

Finally, for some applications high reliability is a major consideration. Traditional nuclear and high energy physics high power accelerator applications can tolerate short outages (hours – days), as they typically have single purposes with long collection periods (years). However the neutron scattering and accelerator driven systems (ADS) have more stringent reliability issues. Areas such as automatic recovery from failed RF stations and dual front-end systems are discussed, but remain to be demonstrated in operational conditions.

THE EUROPEAN SPALLATION SOURCE

Mats Lindroos*, Mohammad Eshraqi and David McGinnis, ESS AB, Lund, Sweden

Abstract

The European Spallation Neutron Source project includes a 5 MW superconducting linac, and aims for initial operation at 1.5 MW in 2019 with 5 MW capacity installed for 2023. Design considerations including the work done to find the minimum cost for preserved beam power will be discussed. This will include discussions on lessons learnt from SNS regarding e.g. superconducting RF performance and RF power sources. The design and construction plans and status will be described.

NEUTRON USAGE AND HISTORICAL BACKGROUND

The neutron beams are being used extensively in science and industry to investigate the properties of matter. The beams of neutrons are used to monitor the structure of the matter in atomic levels using scattering methods. These methods give a high precision information about matter and the high penetration property of neutron makes it the only probe for these measurements.

Most existing neutron sources in Europe are based on nuclear reactors. This approach has been taken to its limits set by both technical issues such as cooling but also by licensing which is non-trivial for any facility using fissile material. Compared to existing spallation sources ESS will be 30 times brighter and it will be the first spallation source with a time averaged flux of neutrons as high as the best research reactors. Europe has today over 5000 researchers who use neutrons and this community is asking for a new intense source of neutrons.

The need for the European Spallation Source (ESS) [1] was articulated 20 years ago but a decision to build it in Lund in Sweden was only taken in May 2009. A series of meetings organized in 1991 and 1992 by Forchungszentrum Jülich (FZ-J) and Rutherford Appleton Laboratory (RAL) explored the basis for an advanced accelerator driven pulsed spallation source, which later formed the basis for the specification for ESS [2]. The decision to site it in Lund was the final stage of a process initiated by the European Commission and steered by the European Strategy Forum on Research Infrastructures (ESFRI). ESFRI was created in 2002 and is a strategic instrument of EC to develop the scientific integration of Europe and to strengthen its international outreach [3].

* mats.lindroos@esss.se

THE ESS FACILITY

The spallation cross section for protons on heavy nuclei increases as a function of proton energy up to several tens of GeV [4]. Nonetheless it is generally agreed that a kinetic proton energy between 1-3 GeV is optimal for practical target and moderator designs, and in order to keep the shielding requirements reasonable.

The ESS accelerator design has gone through several evolutions. In 2002 a fully normal conducting design was proposed [5] in parallel to a pre-dominantly superconducting design derived from the CONCERT project [6]. In 2003 a new design was presented [2] with two front-ends consisting of ion-source, Radio Frequency Quadrupole (RFQ) and a Drift-Tube Linac (DTL) up to 20 MeV. The beams of the two front-ends were merged at 20 MeV and further accelerated in normal conducting structures up to 400 MeV and superconducting structures up to 1334 MeV. The facility had both a long pulse target station and a storage and accumulation ring for a short pulse target. To enable low loss injection into the accumulator ring H^- ions were proposed to be accelerated at a total beam power of 10 MW. In 2009, the competing ESS-Bilbao [7] team and the ESS-Scandinavia [8, 9] team both proposed a simplified 5 MW design with protons accelerated to 2.5 GeV by a mostly supercondcting linac with only one front-end to avoid the complex merging stage and higher beam energy to lower the required beam current. The requirement for a short pulse target station was also dropped to reduce cost. This makes it possible to accelerate H^+ ions, which should reduce losses due to intra-beam stripping of H^- ions and simplifies the ion source design.

The last design iteration was undertaken after cost objectives were set in autumn 2012. The main changes were: i) the implementation of energy staging to ease installation and commissioning, ii) the removal of cryomodules with RF systems and compensate by using operational experience from SNS and run the linac more aggressively, iii) the removal of additional cryomodules with RF systems and compensate by increasing the peak field in the cavities from 40 MV/m to 45 MV/m and iv) introducing new Multi Beam (MB) IOT technology for the high beta linac RF system in the baseline. For the staged commissioning the plan is to start with 1.5 MW in 2019 and complete remaining installation of linac to 2.0 GeV to provide 5 MW of beam by 2022. The staging doesn't only leave more time for installation but it also creates more time for the development of MB-IOTs.

As a result of this series of optimization and iterations the ESS linac beam current is proposed to be 62.5 mA and the final energy is fixed to 2.0 GeV to provide 125 MW of

Copyright © 2013 CC-BY-3.0 and by the respective authors

peak power to the target. More than 95 % of acceleration is done in superconducting structures. The linac accelerates a 2.86 ms long pulse with a repetition rate of 14 Hz, resulting in a 4 % duty cycle and giving an average beam power of 5 MW with a high demand on availability of the facility (>95 %). The former two parameters are set by the experiments, instrument design and scientific performance of ESS.

The ESS has the ambitious goal of becoming a sustainable research facility with zero release of carbon dioxide. This will be achieved through a combination of actions, but with the linac being the most energy hungry part of ESS, the energy efficient design of the RF power sources, the cryogenics systems and high-Q cavities are important issues.

THE ESS LINAC

The configuration of the current baseline linac is shown schematically in Fig. 1, and selected linac parameters are listed in Tab. 1 [10].

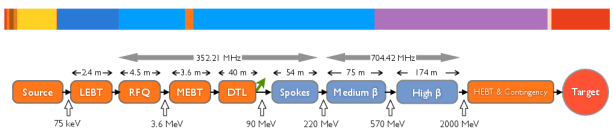

Figure 1: Top: Scaled Layout of ESS. The normal conducting structures are indicated by warm colors and the blue themes sectors indicate the superconducting structures. From left: Ion source, LEBT, RFQ, MEBT, DTL, Spoke, Medium β, High β, and HEBT (consisting of Contingency and beam transport, Dogleg, and Expander). Bottom: blob layout of the ESS linac.

The warm linac design has been done in a collaboration consisting of ESS, INFN Catania, CEA Saclay, ESS-Bilbao and INFN Legnaro, the superconducting cavities and their cryomodules are developed at IPN Orsay and CEA Saclay, and the HEBT is designed by ISA in Aarhus.

A proton beam of less than 80 mA is produced in a pulsed microwave-discharge source on a platform at 75 kV. A low-energy beam transport, LEBT, with two solenoid magnets as focusing elements brings the beam to the entrance of the RFQ. The LEBT has a chopper that cuts away the beam while the proton pulses from the ion source stabilize, preventing a beam with off-nominal parameters from being accelerated in the RFQ and lost at high energy. The 4-vane RFQ accelerates the beam to 3.6 MeV with small losses and a minimal emittance growth. It is designed specifically for ESS but it is based on the IPHI RFQ at Saclay. The RF frequency of the RFQ and the warm linac is 352.21 MHz. After the RFQ there is a medium-energy beam transport, MEBT, with three buncher cavities and 11 quadrupole magnets. The MEBT has several different functions: it has optics to match and steer the beam from the RFQ into the drift-tube linac, it has a comprehensive set of beam-instrumentation devices, it has a chopper which acts faster than the LEBT chopper since space-charge neutralization is not an issue in the MEBT, and it allows collimation of the transverse particle distribution. A drift-tube linac, DTL, with five tanks which each are $\leq$8.0 m long takes the beam from 3.6 MeV to 90 MeV. It has a FODO structure with permanent-magnet quadrupoles. Every second drift tube is empty or used for steering magnets and beam-position monitors.

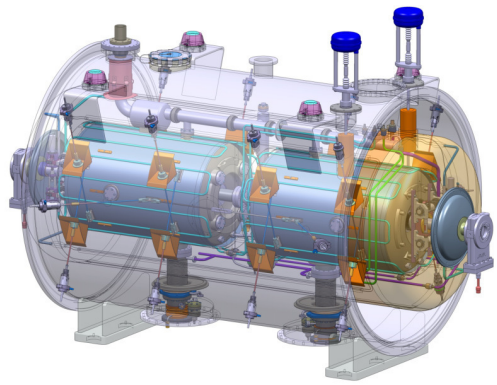

Figure 2: Spoke cavity cryomdoule for ESS

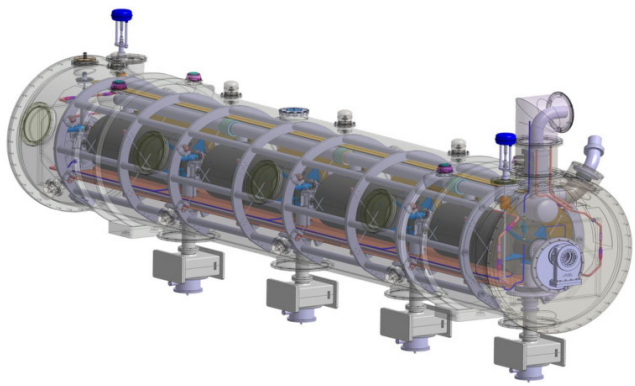

Figure 3: Elliptical cavity cryomdoule for ESS

The superconducting linac has three types of cavities: double-spoke resonators, six-cell medium-beta elliptical cavities and five-cell high-beta elliptical cavities. The linac has 13 spoke cryomodules (see Fig. 2) with two double-spoke resonators in each, and between the cryomodules there are warm quadrupole doublets. The spoke resonators operate at 352.21 MHz like the warm linac, but then there is a frequency doubling to the 704.42 MHz at the elliptical cavities. There are a total of 30 elliptical cavity cryomodules (see Fig. 2) with 9 medium-beta cryomodules with four cavities in each and 21 high-beta cryomodules with four cavities in each. There are quadrupole doublets between every cryomodule. The period length in the medium-beta and high-beta section is exactly the same to allow swapping the cryomodules in case of low performing medium-beta cavities.

HEBT	2000	–	0	–	$\sim$ 300	Not fixed

* β_{opt}

All accelerating structures will be powered by klystrons or IOTs, except the spoke resonators where tetrodes might be used. The possibility of using Solid State Amplifiers is still under study. With one klystron per elliptical cavity plus a few for the warm linac, there will be more than 120 large tubes and more than 60 modulators depending on how many tube each modulator is feeding. A tube could be a klystron, an IOT or a tetrode. The density of components in the klystron building would become too high if these were to be positioned linearly. Instead they will be located in groups of eight klystrons and four modulators across the klystron building Fig. 4.

After the last cryomodule there is the contingency and upgrade section where additional cryomodules can be installed to compensate for a shortfall in linac performance and/or a power upgrade of the facility. The additional tunnel would also make it possible to bend the beam out for a second target station.

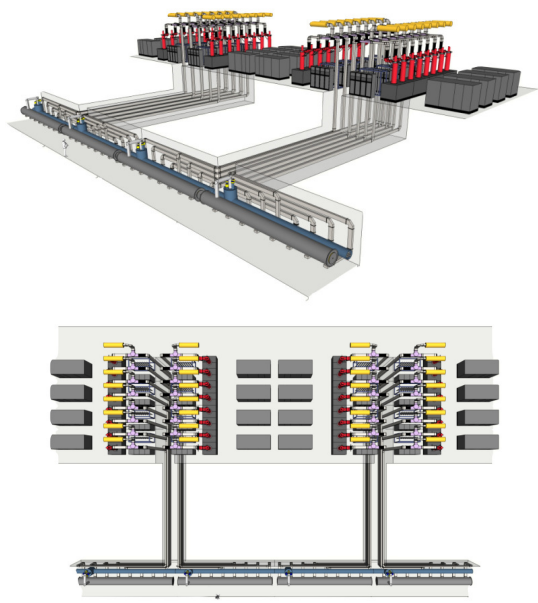

Figure 4: The ESS RF sources in and the RF waveguide stub lay-out. The 3D view on top and the view from top on bottom.

Then the beam is brought from the tunnel to the spallation target at the surface through two vertical bends and an expansion section. A raster scanning system is used to blow the beam up onto the desired profile of the proton-beam window and the target window.

RF SOURCES

The vast majority of structures in the ESS linac are superconducting cavities, therefore the dominant feature of the ESS RF system is the number of RF stations. The enormous gradients in the superconducting cavities is strong enough to deform the 4 mm thick niobium cavities by exerting a significant radiation pressure. This deformation is called Lorentz detuning and must be compensated, otherwise the deformed cavity will resonate at a different frequency which will destroy beam quality and induce losses. To handle variations in cavity coupling and Lorentz detuning there is one RF power amplifier per superconducting resonator; totaling 146 individual RF stations for the superconducting cavities. The core of each RF station is an RF power amplifier which is typically a klystron. For the high beta section of the linac consisting of 84 stations, the peak power required for the cavities is 1100 kW, Fig. 5.

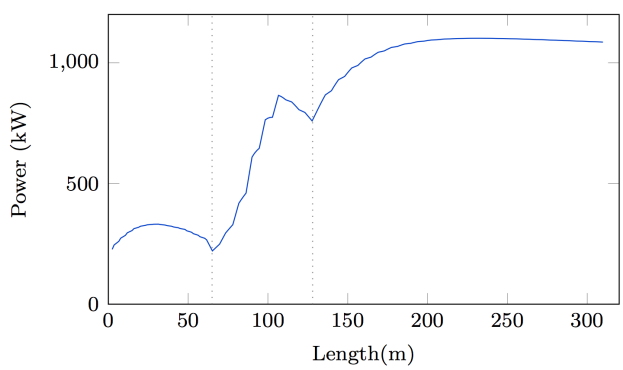

Figure 5: Power profile in the superconducting linac of the ESS, the three section divided by vertical dotted lines are the spoke, medium beta and high beta section.

Even though the loaded Q of the cavities is quite low (7×10^5) to compensate for heavy beam loading, the Lorentz detuning for ESS can be quite severe. Without any Lorentz-detuning compensation, the resonant frequency of the cavities could shift up to 400 Hz. The bandwidth of the cavity in the absence of the beam, the unloaded cavity bandwidth, is 0.07 Hz, and the bandwidth in the presence of beam is almost 1 kHz. Comparing to the number of oscillation of the RF wave during the 2.86 ms of pulse length one can calculate that even this small difference in frequency can shift the RF wave with respect to bunches by more than one whole RF period. In addition, the beam pulse for the ESS linac is very long and is about a factor of three longer than the mechanical response time of the cavity to the Lorentz detuning. Other methods like predetuning of the cavity as done in the SNS linac is not sufficient in the case of ESS. To save on RF power overhead and maintain the beam quality, all superconducting cavities will be equipped with fast piezo-electric tuners to negate the Lorentz detuning of the cavities.

The klystrons are operated 30 % below the maximum saturated power so that variations in the RF system such as modulator droop, cavity coupling, residual Lorentz detuning, and power loss in the waveguide distribution system can be compensated. Also part of the overhead is used for stable regulation of the feedback loop. The target efficiency of the klystrons at maximum saturated power is 60 % which will give an operational efficiency of about 45 %. The required maximum saturated power for the klystrons is 1.5 MW. For stability, reliability and economic reasons, the klystrons will be powered in the pulsed cathode configuration.

The klystrons are energized using modulators. The modulators must supply a 3.5 ms long pulse at a rate of 14 Hz. The cathode voltage for each klystron is about 100 kV with a peak current of about 20 Amperes. For a modulator efficiency of 90 % and a power factor of 0.9, 120 kVA will be required for each klystron. For economical and space reasons, it has been decided to power two klystrons per modulator which limits the required power per modulator to 240 kVA. To handle the long pulse length of 3.5 ms, the modulators will implement solid-state switches at relatively moderate voltages and the output voltage pulse will be stepped up by a pulse transformer or equivalent technology.

The regulation of each RF system will be done independently with the low level RF system. Using modern digital technology, most of the regulation will be done with adaptive feed-forward algorithms. Feedback regulation will play a secondary role to the adaptive feed-forward so the required power overhead can be minimized.

With the large number of RF systems, it will be uneconomical for the high power waveguide of each RF system to have its own penetration to the tunnel. ESS will use a "stub" concept for distributing 16 RF systems into the tunnel as shown in Fig. 4. The stubs will provide access to additional conventional services such as water and power as well. In addition, the radiation shielding issues are best handled with the stub concept.

ESS is also considering the use of Inductive Output Tubes (IOTs) in place of klystrons for the high beta section of the linac. IOT shows the promise of high efficiency and much lower capital cost. IOTs can be thought of as a cross between klystrons and tetrodes. As in tetrodes, IOTs employ a grid to control electron flow from cathode to collector. These grids are very robust with the advent of pyrolithic carbon technology. Since IOTs are gridded tubes, no pulsed modulation system is needed to energize the cathode. This eliminates costly high voltages switches in the power supply for the IOT. Also a gridded tube can be run in deep class C that can produce very high efficiencies (less than 70 %). Also IOTs do not exhibit the severe saturation effect of klystrons. This permits the operation of IOTs at the maximum rated power in feedback loops which increases the efficiency of the RF system significantly. It is estimated that 3-4 MW of power consumption can be saved if klystrons are replaced by IOTs. Like klystrons, IOTs use a resonant output cavity to efficiently couple power from the electron beam at high frequencies. However the gain of an IOT is much lower than a klystron because an IOT uses a single output cavity while a klystron may employ 4-5 stages of cavities. With the advent of low cost solid stage RF amplifiers as pre-drivers, the high gain provided by multi-cavity klystrons is not required. Because of this low gain, IOTs require cathode voltages on the order of 35 kV as compared to 100 kV for high gain klystrons. The lower cathode voltage also reduces the cost of the power supply that energizes the IOT. Current estimates for a power supply for an IOT is 60 % the cost of a klystron modulator of comparable power. Currently there are no commercially available IOTs for the ESS power range. However there has been very good progress made in higher order mode multi-beam IOTs in which power levels of 1 MW have been achieved [11]. For a more detailed discussion on the ESS RF system and the potential of IOTs we refer to [12, 13].

SUMMARY

The European Spallation Source to be built in Lund will be the most powerful linac worldwide. Design and construction of ESS is done through an international collaboration and benefits from the experiences of the similar facilities. The construction of the ESS will start in 2014 and the accelerator will be operational in 2019. The beam power will be increased after the start up and will reach its nominal value of 5 MW by 2025 and scientists will be welcomed to perform experiments at the facility.

Abstract

The Facility for Rare Isotope Beams (FRIB) is based on a continuous-wave superconducting heavy ion linac to accelerate all the stable isotopes to above 200 MeV/u with a beam power of up to 400 kW. At an average beam power approximately two-to-three orders-of-magnitude higher than those of operating heavy-ion facilities, FRIB stands at the power frontier of the accelerator family - the first time for heavy-ion accelerators. To realize this innovative performance, superconducting RF cavities are used starting at the very low energy of 500 keV/u, and beams with multiple charge states are accelerated simultaneously. Many technological challenges specific for this linac have been tackled by the FRIB team and collaborators. Furthermore, the distinct differences from the other types of linacs at the power front must be clearly understood to make the FRIB successful. This report summarizes the technical progress made in the past years to meet these challenges.

INTRODUCTION

During the past decade, facilities like the Spallation Neutron Source (SNS), the Japan Proton Accelerator Research Complex (J-PARC) and the PSI accelerator advanced the frontier of proton beam power by an order of magnitude to 1 MW level (Fig. 1) [1]. On the other hand, facilities for heavy ions has been at the 1 kW level of average beam power. FRIB currently designed and ready for civil construction at the Michigan State University will advance the frontier of heavy-ion beam power by two-to-three orders-of-magnitude to 400 kW.

On August 1, 2013, the Department of Energy's Office of Science approved Critical Decision-2 (CD-2), Approve Performance Baseline, and Critical Decision-3a (CD-3a), Approve Start of Civil Construction and Long Lead Procurements, for the FRIB construction project. The Total Project Cost for FRIB is $730M, of which $635.5M will be provided by DOE and $94.5M will be provided by Michigan State University. The project will be completed by 2022. "When completed, FRIB will provide access to completely uncharted territory at the limits of nuclear stability, revolutionizing our understanding of the structure of nuclei as well as the origin of the elements and related astrophysical processes."

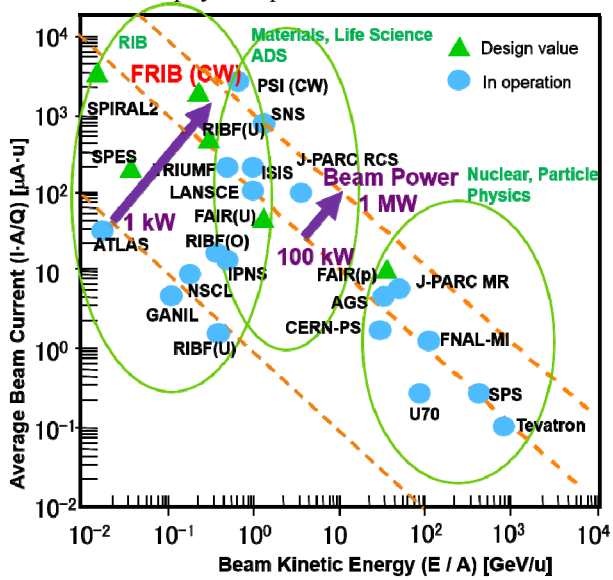

Figure 1: Average beam power as a function of the kinetic beam energy for various operating and proposed proton and heavy-ion accelerator projects.

The FRIB driver accelerator is designed to accelerate all stable ions to energies > 200 MeV/u with beam power on the target up to 400 kW (Table 1) [2]. As shown in Fig. 2, the driver accelerator consists of Electron Cyclotron Resonance (ECR) ion sources; a low energy beam transport containing a pre-buncher and electrostatic deflectors for machine protection; a Radiofrequency Quadrupole (RFQ) linac; linac segment 1 (with Quarter-wave Resonators (QWR) of β_0=0.041 and 0.085) accelerating the beam up to 20 MeV/u where the beam is stripped to higher charge states; linac segments 2 and 3 (with Half-wave Resonators (HWR) of β_0=0.29 and 0.53) accelerating the beam > 200 MeV/u; folding segments to confine the footprint and facilitate beam collimation; and a beam delivery system to transport to the target a tightly

focused beam. The reaccelerator (ReA) consists of similar β_0=0.041 and 0.085 accelerating structures [3].

Table 1: FRIB Accelerator Primary Parameters

Parameter	Value	Unit
Primary beam ion species	H to ^{238}U	
Beam kinetic energy on target	> 200	MeV/u
Maximum beam power on target	400	kW
Macropulse duty factor	100	%
Beam current on target (^{238}U)	0.7	mA
Beam radius on target (90%)	0.5	mm
Driver linac beam-path length	517	m
Average uncontrolled beam loss	< 1	W/m

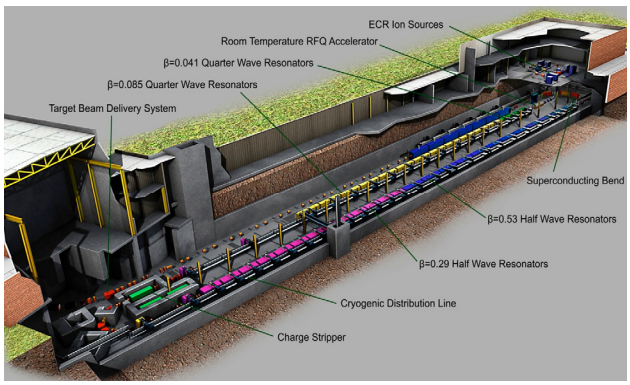

Figure 2: Layout of the FRIB driver accelerator.

DESIGN PHILOSOPHY

Full-energy linac technology is chosen to deliver primary beam that can meet the FRIB requirements of rare-isotope productivity and separation accuracy. Up to 400 kW of beams are focused to a diameter of 1 mm (90%), energy spread of 1% (95% peak-to-peak), and bunch length of < 3 ns (95%) on the target.

Superconducting (SC) technology is the energy-efficient choice for the CW linac. SC acceleration of heavy-ion beams is feasible from low energy (500 keV/u) with practically sized cavity bores by housing both the cavities and solenoids in a cryomodule. A two-gap scheme is chosen throughout the entire linac providing both efficient acceleration and focusing. Developments of digital low-level RF control and solid-state RF amplifier technologies have made individual cavity powering and control reliable and cost efficient.

Furthermore, high availability, maintainability, reliability, tunability, and upgradability are especially required for the FRIB accelerator to operate as a national scientific user facility.

- Availability: The accelerator is designed with high beam-on-target availability accommodating normal, alternative, and fault scenarios. In the normal scenario, a liquid lithium stripper is used to raise the average charge state of ^{238}U beam to 78+ for efficient acceleration. Alternatively, helium gas confined by plasma windows with differential pumping can be used to strip the ^{238}U beam to a lower average charge state of 71+. Fault scenarios include the situation when superconducting (SC) cavities underperform by up to 20% of the design gradients. Furthermore, key components and subsystems are implemented with spares and design redundancies.
- Maintainability: The average uncontrolled beam loss is limited to below 1 W/m level for all ion species from proton to uranium, to facilitate hands-on maintenance. For a proton beam at high energy, this level corresponds to an average activation of about 1 mSv/h measured at a distance of 30 cm from the beam chamber surface, 4 hours after operations shutdown. For heavy ions like uranium at low energies, activation and radiation shielding is of less concern; the 1 W/m limit addresses concerns in damage on superconducting cavity surfaces and in cryogenic heat load. To facilitate maintenance of individual cryomodules, warm interconnect sections are used between cryomodules, and U-tubes with bayonet connections are used for cryogenic distribution. Furthermore, identical, interchangeable cryomodules are used for each β type of the cavities.
- Reliability: A Machine Protection System (MPS) minimizes component damage and operational interruption caused by both acute (fast) and chronic (slow) beam losses. Upon acute beam loss, the MPS response time is 35 μs (including diagnostics, signal processing, and residual beam dumping). MPS responding to slow beam loss is complicated by low sensitivity of conventional ion chamber loss detection to low-energy heavy ions and beam-loss signal background from adjacent linac segments with which beam energies are significantly different. Beam-halo-monitor rings in the warm interconnect sections and possible thermal sensors at cold regions are planned for more sensitive loss detection [4].
- Tunability: The accelerator is designed to be easily tunable during both beam commissioning and operations. In linac segment 1, where beam transverse-phase advance is large, cold beam-position monitors (BPM) are implemented in the cryomodules. Efforts are made in establishing beam-tuning strategies based on virtual accelerators and on-line models under normal and fault conditions.
- Upgradeability: Space is reserved in linac segment 3 to house another 12 cryomodules to readily increase the energy of ^{238}U beam > 300 MeV/u. If cavities with 35% higher accelerating gradient are used in linac segments 2 and 3, the beam-on-target energy can be raised > 400 MeV/u for ^{238}U. The linac tunnel allows future expansion so that a dedicated light-ion injector can be added supporting rare isotope production using the isotope separation on-line (ISOL) method [2]. Using an RF deflector cavity and a Lambertson septum magnet, ^{3}He^{+} beam supplying protons to the ISOL target can share cycle with the

Copyright © 2013 CC-BY-3.0 and by the respective authors

^{238}U beam feeding the fragmentation target; thus simultaneous users are supported. Furthermore, space is reserved to house instrumentations including non-destructive diagnostics and sub-harmonic buncher that are compatible with future user demands of experiments.

ACCELERATOR PHYSICS CHALLENGES

The FRIB accelerator design combines the complexity of heavy ion accelerators with the engineering challenges of high-power accelerators. Due to the low charge-to-mass ratio, heavy ion acceleration is often not efficient. Uncontrolled beam loss, which usually is not an issue for low-power heavy ion machines, is of primary concern for the FRIB accelerator. Comparing with high-power proton machines like the SNS linac where apertures of the elliptical SC cavities are large and beam amplitude reaches maxima in the warm locations of the focusing quadrupole magnets, the apertures of the FRIB QWR and HWR accelerating structures are small and beam amplitude reaches maxima in the cold solenoid locations inside cryomodules. Requirements on beam halo prevention, detection and mitigation are stringent.

To maximize beam intensity on the target, beams of multiple charge states are accelerated simultaneously (2 charge states of 33+ and 34+ before stripping, and 5 charge states of 76+ to 80+ after stripping for ^{238}U). Bends of second-order achromatic optics are used to fold the beams, and cavity phases are adjusted so that beams are longitudinally overlapping at the charge stripper.

Conventional charge strippers like solid carbon foils are not sustainable at the power of a ^{238}U beam at 17 MeV/u during normal operations. FRIB accelerator lattice needs to accommodate beam acceleration of different charge states resulting from various stripping methods including liquid lithium and helium gas (average charge state from 63+ to 78+ for ^{238}U). Buncher cavities of fundamental (80.5 MHz and 322 MHz) and double (161 MHz) linac RF frequencies are strategically placed in the folding segments to preserve beam quality.

Due to the short stopping distance in surrounding materials, uncontrolled beam loss of the low-energy heavy ions can cause damage to the surface of accelerating structures much more easily than a proton beam. On the other hand, due to the low level of radio-activation, losses of low-energy heavy-ion beams are difficult to detect [4]. Beam-loss detection and machine protection often rely on beam scraping. On the other hand, scraping of partially stripped ions may lead to higher ionization further complicating beam collimation and machine protection.

Due to requirements of frequent transverse focusing in the superconducting acceleration structure, solenoids are placed inside cryomodules adjacent to cavities. Alignment tolerance of these solenoids is ±1 mm under cryogenic conditions. Horizontal and vertical steerers are needed to thread the beam and correct the beam orbit.

Stringent beam-on-target requirements demand tight optical control, error control, and advanced beam diagnostics. The primary beam of 400 kW needs to be focused into a diameter of 1 mm with below ±5 mrad transverse angular spread. The desired range of beam power variation on target is 8 orders of magnitude. Orbit stability needs to be controlled at 0.1 mm level.

TECHNOLOGY CHALLENGES

Charge Stripper

The FRIB baseline design of charge stripping is a liquid lithium film moving in front of the beam at high speed of about 50 m/s. During the last couple of years the stability of a thin liquid film with the correct thickness for the FRIB stripper was achieved at ANL. Tests with a proton beam produced by the LANL LEDA source were conducted in 2013 demonstrating that power depositions similar to the FRIB uranium beams could be achieved without destroying the liquid film (Fig. 3) [5].

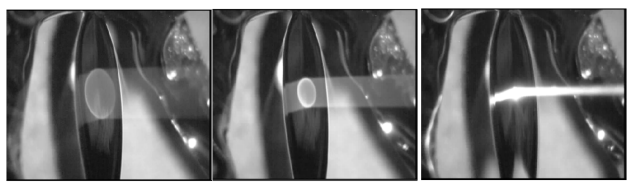

Figure 3: Liquid lithium film flowing at high speed (~ 50 m/s) intercepting a proton beam of about 60 kV at ANL. The test produced power deposition densities similar to the FRIB uranium beams.

An alternative option for the stripper consisting of a helium gas cell enclosed by plasma windows was considered. The BNL work has demonstrated that a conductance reduction of about 10 can be obtained with an aperture of 6 mm diameter [6].

Superconducting RF

FRIB driver linac is the first full-size SC linac using a large number (340) of low-β cavities. Cavity design is optimized not only for optimum performance but also for low production cost. This requirement guided the choice of the cavity geometries, materials and mechanical solutions, avoiding complicated shapes, minimizing the amount of electron beam welds, eliminating bellows, optimizing construction and surface treatment procedures. All FRIB cavities work with superfluid helium at 2 K. This innovative choice in a low-β linac allows operation of cavities in stable pressure conditions with high safety margin on the maximum surface fields.

After several years of development, the 2nd generation QWR prototypes are used in the ReA3 (7 of β_0=0.041 in operation and 8 of β_0=0.085 in construction). This cavity type underwent modifications including the displacement of the RF coupler from the bottom plate to the resonator side and an increased distance between the tuning plate and the inner conductor tip to remove a critical thermal problem in the design. The new tuning plate includes slots and undulations to increase its maximum elastic

Copyright © 2013 CC-BY-3.0 and by the respective authors

displacement and thus its tuning range, and a "puck" whose length can be adjusted for cavity tuning before final welding [7]. The 11 2nd generation prototypes of β_0=0.085 QWR have been tested in vertical dewars at 2 K exceeding FRIB design specifications (Fig. 4a).

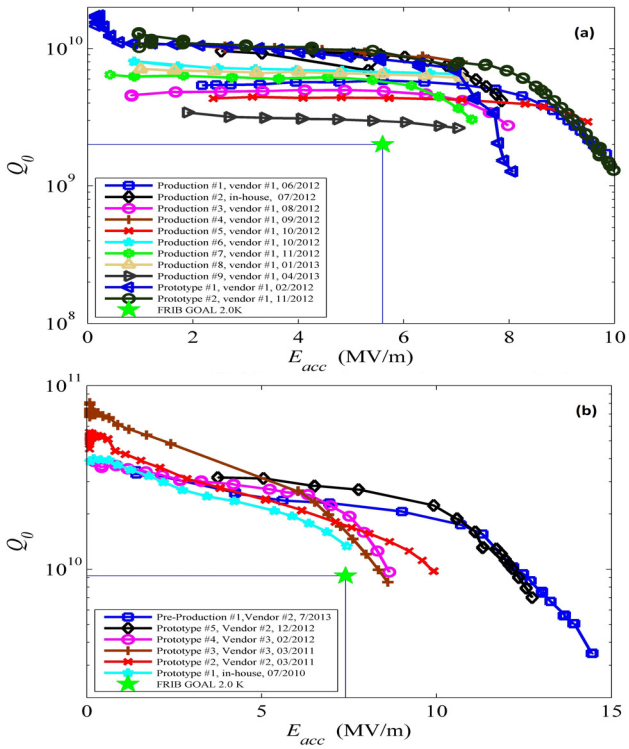

Figure 4: Q_0 vs. E_{acc} performance tested at 2 K for (a) β_0=0.085 QWR prototypes used in the ReA3, and (b) the prototype and pre-production β_0=0.53 HWR.

After testing 5 units of 2nd generation HWR prototype, the first production-design, 3rd generation β_0=0.53 HWR fabricated by an industrial supplier was tested in vertical dewars at 2 K exceeding FRIB design specifications (Fig. 4b). The 3rd-generation design optimization resulted in significant improvement of peak fields E_p/E_{acc}, B_p/E_{acc} and shunt impedance R_{sh}, with consequent reduction of the overall linac cost and operational risk. E_p and B_p in operation are below the safe values of 35 MV/m and 70 mT in all cavities. The apertures of all QWRs were enlarged from 30 to 36 mm, and their bottom rings were modified for efficient tuning-plate cooling using a low-cost design. In all cavities, the helium vessel is made of titanium to avoid brazed Nb-to-stainless-steel interface.

A "Technology Demonstration Cryomodule" was developed consisting of 2 β_0=0.53 HWRs operating at 2 K and a 9 T solenoid operating at 4.5 K arranged in a "top-down" configuration. The cryomodule was demonstrated excellent cryogenic and LLRF control stabilities. Local magnetic shielding was verified and adopted [8].

The FRIB cryomodule design has evolved significantly from the "top-down" ReA3 style to a "bottom-up" design (Fig. 5) [9]. An "Engineering Technology Cryomodule" containing the rail and support, vacuum, cryogenics for liquid nitrogen cooling and wire-position monitor was fabricated and successfully validated alignment requirements. Presently, the full-scale "bottom-up" prototype (ReA6 cryomodule) is under development starting with 2 production-design β_0=0.085 QWRs, a solenoid, 2 K cryogenics and full shieldings.

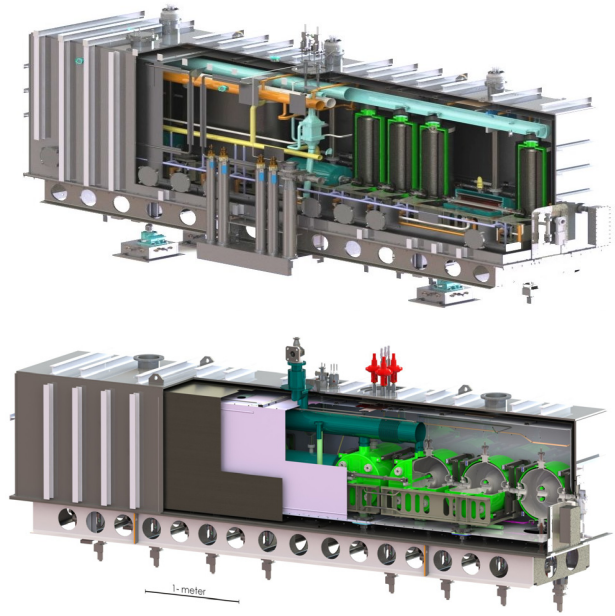

Figure 5: FRIB "bottom-up" cryomodule designs. The top cryomodule contains 8 β_0=0.085 QWRs, 3 solenoids, and 3 cold beam position monitors; the bottom cryomodule contains 8 β_0=0.53 HWRs and a solenoid.

ACQUISITION

After project baseline, the FRIB project entered into its final design phase when detail-engineering designs are performed. While critical processing and assembly are to be performed in house, mass production by industrial providers is facilitated as much as feasible. The FRIB accelerator project plans to place more than 100 procurements valued at more than $50k each. A procurement strategy is implemented for the best value to the FRIB project:

- For most procurements multiple providers are identified and competitions encouraged through strategic Request for Information/Proposal processes.
- FRIB evaluates how the project fits into the supplier's total capabilities and long-term business plans to gauge supplier management's commitment meeting production challenges. We develop long-term supplier relationships for mass production. Phasing of procurements from prototypes to production sensitizes vendors to be able to successfully produce the unique components at reasonable prices.
- Both FRIB technical and business staff works directly with the vendors' understanding their individual risk concerns and proposing mitigations. Weekly teleconferences and frequent site visits are maintained for most active procurements.

Copyright © 2013 CC-BY-3.0 and by the respective authors

So far, we have implemented this strategy to some major procurements including all the SRF material [8], the production of 174 β_0=0.53 HRWs [9], part of the liquid helium refrigerator [10], and the RFQ [11].

COLLABORATION & PARTNERSHIP

FRIB accelerator systems design has been assisted under work-for-others agreements by many national laboratories including ANL, BNL, FNAL, JLab, LANL, LBNL, ORNL, and SLAC, and in collaboration with many institutes including BINP, KEK, IMP, INFN, INR, RIKEN, TRIUMF, and Tsinghua University.

The cryogenics system is designed in collaboration with the JLab cryogenics team. The refrigeration process incorporates the cumulative experience from both JLab and SNS cryogenic systems. The recent experience gained from the JLab 12 GeV cryogenic system design is utilized for both the refrigerator cold box and the compression system designs. The Floating Pressure Process – Ganni Cycle is to be implemented to provide efficient adaptation to the actual loads.

The charge stripping system is under development in collaboration with the ANL Physics Division. We borrowed the LEDA ion source and LEBT from LANL to modify the optics to obtain a 3 mm diameter beam spot on the liquid-lithium film at MSU. Once the new optics is checked on a new platform that is matched to the ANL lithium loop, the device will be moved to ANL for the integrated test. BNL collaborated on the development of the alternative helium gas stripper.

The SRF development benefited greatly from the expertise of the low-β SRF community. FRIB is collaborating with ANL on the coupler and tuner developments, and assisted by JLAB on cavity processing and cryomodule developments.

FUTURE PERSPECTIVES

The FRIB accelerator design is advanced towards beginning technical construction in 2014. Early procurements before 2014 is strategically planned to establish the front end test stand to demonstrate critical components of the ECR ion source and the fully powered RFQ, to contract on long lead-time cryogenic refrigeration subcomponents, and to acquire SRF components to be assembled in the pre-production cryomodules. Upon fabrication, installation, and integrated tests, early beam commissioning will be staged from 2018 to 2020. The facility is scheduled to meet key performance parameters supporting user operations before 2022. We plan to reach full design capability in 4 years after the beginning of operations. Science driven upgrade options may be pursued at any stage of the project.

Abstract

The Facility for Rare Isotope Beams (FRIB) is currently in the preliminary design phase at Michigan State University (MSU) [1]. FRIB consists of a driver linac for the acceleration of heavy ion beams, followed by a fragmentation target station and a ReAccelerating facility (ReA). While FRIB is expected to start commissioning in 2018, the first stage of ReA called ReA3 is already under commissioning [2, 3]. ReA was connected to the Coupled Cyclotron Facility at MSU in 2012 and has delivered its first radioactive ion beam to the experimental hall in 2013. An overview of the facility will be discussed. In addition, this paper focuses on the technical progress and first commissioning results with radioactive ion beams.

INTRODUCTION

Nuclear science research requires reaccelerated radioactive isotope ion beams in a range of kinetic energies from thermal energies to near 20 MeV/nucleon. Isotope Separation On-line (ISOL) and Projectile Fragmentation (PF) are the two most common methods used to produce high quality radioactive ions beams (RIBs) for the various nuclear science experiments. In the ISOL technique the RIBs are produced in a thick target from which they have to diffuse out before they can be ionized and used as radioactive beams. While this technique offers unmatched yields for a number of isotopes, chemically reactive isotope are more difficult and slow to extract.

Projectile fragmentation on the other hand can be used for a broad range of interesting nuclei, since the reaction products recoil out of the target in forward direction, which makes the production method chemically indifferent. In order to separate the desired isotope from the bulk of the other reaction products, in-flight fragmentation facilities are often combined with a high acceptance fragment separator [4]. This combination offers a versatile method to develop a wide range of isotopes in a short time. As an example, in the 10 years of operation of Coupled Cyclotron Facility at Michigan State University more than 1000 rare isotope beams have been produced and more than 870 have been delivered to users for experiments [5]. The energy however of those radioactive beams are close to the primary driver beam energy (80-150MeV/nucleon) which can be too high for some nuclear physics experiments.

The physics reach can be further enriched if such a facility is combined with a gas stopper and a re-accelerator. Then in addition to the fast RIBs of 50 to a few 100MeV/u, high quality beams can be provided from the lowest energies of a few 10s of keV/nucleon (for trapping and spectroscopy experiments) to an energy range between a few 100 keV/nucleon and 20

MeV/nucleon. The recently commissioned re-accelerator facility ReA is the first rare isotope post accelerator coupled to a projectile fragmentation facility. An overview of the Coupled Cyclotron Facility and the ReAccelerator Facility is shown in Figure 1 and a detail layout of ReA is shown in Figure 2.

FACILITY OVERVIEW AND STATUS

The first stage of the re-accelerator facility ReA3 consists of a rare isotope beam stopping area, a transport section, a charge breeder, a compact SC-linac and a beam distribution system. In the stopping area, the rare isotopes are thermalized by using a combination of solid degraders with a linear gas cell [6]. After extraction, a low energy beam line [7] transports the 1+ or 2+ ions or molecules to the trapping areas and laser spectroscopy experiments, or to an Electron Beam Ion Trap (EBIT) [8, 9] for charge breeding and subsequent acceleration. The linac consists of a second off-line stable ion beam injector, a multi harmonic buncher, a room temperature RFQ, a buncher cryomodule (CM) and two low beta cryomodules with a total of fifteen superconducting cavities [2]. The last of the three cryomodules, designed for a beta equal to 0.085, is currently being assembled and is expected to be installed in July of 2014, after which phase 1 (ReA3) will be completed.

ReA3 is nominally capable of accelerating ions with a charge-to-mass ratio Q/A=0.25 from 300 keV/u to 3 MeV/u and for Q/A=0.5 from 300 keV/u to 6 MeV/u. In its final configuration ReA will consist of three buncher cryomodules, one β_o=0.041 and four β_o=0.085 accelerating CMs with a total of 41 superconducting quarter wave cavities (funding proposal submitted). In this configuration, ReA will nominally provide heavy ion beams from 0.3 MeV/u to 12 MeV/u for the heaviest ions and energies from 0.3 MeV/u up to 20 MeV/u for light ions. Figure 3 shows the nominal energy range of the facility in the first phase, and the high energy upgrades with the three additional beta=0.085 cryomodules. The first of the three high energy cryomodules is currently under design (see section below) and is expected to be completed in 2015.

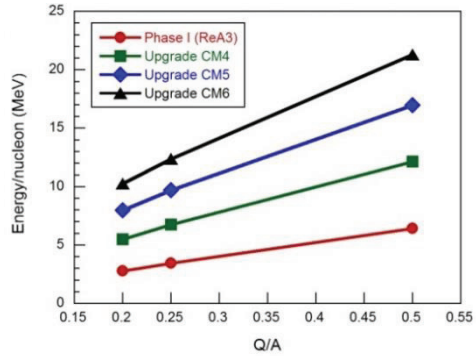

Figure 3: Energy range of the ReAccelerator facility [4].

The current facility was commissioned using stable beams between 2011-2012 [2, 3]. The linear gas stopper and low energy beam transport lines were commissioned with rare isotopes and stable beams in 2013[7]. The first of the three transport lines into the low energy beam hall was commissioned in summer of 2013 [3] and the first radioactive ion beam was delivered to users in August of 2013 (see below). The remaining two beam lines are under construction and are expected to be completed by December of 2013.

PILOT BEAM DEVELOPMENT

One of the challenges of radioactive post accelerators is the wide dynamic range that the beam diagnostics need to cover [10, 11]. Due to the low rate of the injected radioactive ions (10-10^6 pps), the front end and the linac must be phased and pre-tuned using stable (pilot) beams (10^9pps or more). Therefore in preparation for the radioactive ion beam commissioning experiment, stable pilot beams from the off-line injector ion source (H_2 and He)

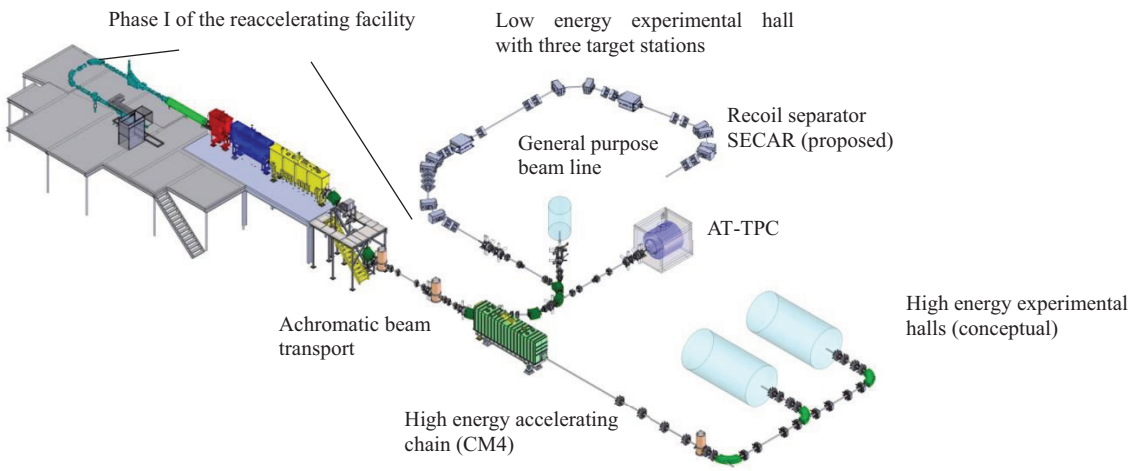

Figure 2: Layout of the ReAccelerator facility and the transport lines into the low energy experimental hall. In addition, the first cryomodule of the high energy section of the linac is shown.

Copyright © 2013 CC-BY-3.0 and by the respective authors

and heavy ion beams pilot beam from the EBIT were established. In order to scale from one A/Q to the next the injection voltage into the RFQ must be well matched to ensure efficient acceleration. For this purpose the energy acceptance of the RFQ was measured by varying the injection energy of the EBIT beam. Figure 4 shows the results of the calibration. An absolute energy acceptance of ±250V FWHM or ±0.75% relative was measured. This value is slightly lower than the simulated RFQ energy acceptance of ±2% for a 1.4nsec (±20 degree) long beam bunch [12] which will be further investigated.

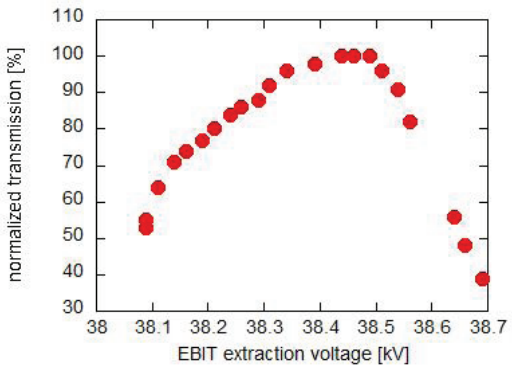

Figure 4: RFQ energy acceptance in dependence of the EBIT extraction voltage for a $^{16}O^{5+}$ beam.

In addition, the full acceleration scheme for radioactive ions was tested by injecting 1+ ^{85,87}Rb ions from the gas stopping area into the EBIT, charge breeding the rubidium ions to high charge states and subsequently accelerating $^{85}Rb^{27+}$ as well as $^{87}Rb^{28+}$with the linac. Figure 5 shows the superposition of four spectra measured with a scattering-gold foil silicon detector mounted at 30 degrees [10]. The first peak is recorded when the detector is retracted from the beam line and depicts the energy spectra of ^{241}Am α-calibration source (5.486 MeV). The second, third and fourth peaks are recorded as the beam line, the RFQ injection voltage, and RFQ vane voltage were scaled from the $^{16}O^{5+}$ pilot beam settings to the $^{40}Ar^{13+}$ beam (third peak) and finally to the $^{87}Rb^{28+}$beam (fourth peak). As the maximum A/Q scaling was only 4%, the linac settings were kept unchanged for this test. For the radioactive ion beam online experiment the linac was scaled using fixed velocity beam energy profiles in order to achieve the desired beam parameters and energy on target.

RADIOACTIVE ION BEAM COMMISSIONING

^{37}K Beam Production

To produce ^{37}K ($T_{1/2}$=1.23s), a primary beam of ^{40}Ca was extracted from the Coupled Cyclotron Facility at an energy of 140 MeV/nucleon, fragmented in a thin beryllium target, and separated in the A1900 fragment separator[5]. The ^{37}K was then transported to the beam stopping area, which consists of a high energy beam momentum compression beamline, a degrader and wedge

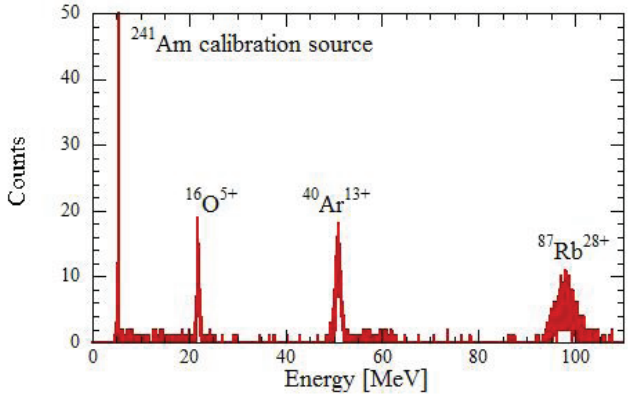

Figure 5: Energy spectra obtained using the scattering-foil silicon detector for three heavy ion tunes.

section, and a 1.2 m long linear gas cell operated at about 100Torr [6].

After the fragments are slowed down to less than one eV in the helium gas of the gas cell, they are extracted as singly or doubly charged ions and singly or doubly charged molecular ions, mass-analyzed and transported to the EBIT charge breeder.

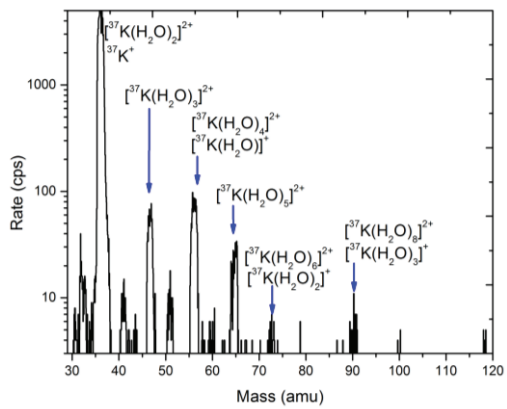

Figure 6: Scan of the extracted beam from the gas cell after the analyzing magnet in the low energy beam line.

As an example, Figure 6 [11] shows the mass (activity) scan of the beam extracted from the gas cell using a β-decay counter/Faraday cup assembly after the analyzing magnet in the low energy RIB injection line [11]. For potassium, the low energy beam consists mostly of ^{37}K ions (≈ 94%) and a few small peaks of weakly bound molecular 1+ and 2+ ions which are formed with one to a few water ligands from residual contaminates in the gas cell. In the preliminary commissioning tests this summer, ion beams with intensities of up to 10^5 particles per second have been thermalized and total extraction efficiencies of up to 14% have been achieved. Further increases of the efficiency are expected once the vacuum is improved in the cell. After mass analysis, the RIBs are injected into the EBIT charge breeder and charge bred to $^{37}K^{17+}$.

Post-Acceleration

An important design choice for the ReA accelerator was the selection of an EBIT as charge breeder. With the expected rates of radioactive ions from the reaccelerator of 10 to 10^6 ions per second, minimizing the stable ion beam contamination from residual gas ions is an important factor. The ReA EBIT has a cryogenic ion trapping structure [9] to minimize the beam contamination from residual ions. As expected, the intensity levels for beam other than the typical residual gas ions such as nitrogen, helium, and oxygen are very low. As an example, Figure 7a shows the charge state spectrum of background ions from the EBIT where the positions of various ^{37}K charge states are indicated. Due to the energy required by the experiment of 2.4 MeV/nucleon, charge state of 15+ and higher were needed for the linac. Figure 7b shows a high resolution Q/A scan of the 16+ to 19+ region.

In addition to possible beam contaminations the charge breeding efficiency was considered as well when $^{37}K^{17+}$ (helium like ion) was selected as the best choice for the experiment. During off-line charge breeding tests, an efficiency of 4 to 5% into K^{17+} using stable potassium 1+ ions was achieved [9]. A similar efficiency was measured with radioactive ions with a repetition rate of 6Hz (≈167 ms charge breeding time). The efficiency was slightly lower (≈2%) when the repetition rate was increased to 20 Hz due to the shorter breeding time.

After the beam was extracted from the EBIT and mass analyzed, it was subsequently accelerated with the RFQ and the superconducting linac to an energy of 2.4 MeV/u using the first two cryomodules during the 80 hours of beam delivery. In order to achieve the required energy for the experiment several cavities were operated at twice the original specified gradients and all of them well beyond specification. Overall the cavity amplitudes were set at 170% of the nominal values and ran stable without any issues throughout the experiment. The overall transport efficiency from the EBIT through the linac was about 60% during the experiments (close to the maximum expected transmission through the MHB and the RFQ of about 70%). The linac and injection lines were pre-tuned using a $^{16}O^{7+}$ beam, and then scaled to $^{15}N^{7+}$ while maintaining a fixed velocity tune in the linac. Finally during the $^{37}K^{17+}$ delivery the linac and the injection line were scaled for the remaining 1.5%. Only minor corrections were necessary after scaling to deliver the beam to the experimental station [3]. Several decay counters along the beam line were installed to monitor the activity during the tuning process and optimize the transmission. Beam impurities were analyzed using in-beam silicon detectors and the ionization chamber mounted in the experimental station. In addition to the $^{37}K^{17+}$ ions, about 1000 ions/sec $^{13}C^{6+}$ and about 100 ions/ sec of $^{37}Cl^{17+}$ were identified as impurities in the accelerated beam.

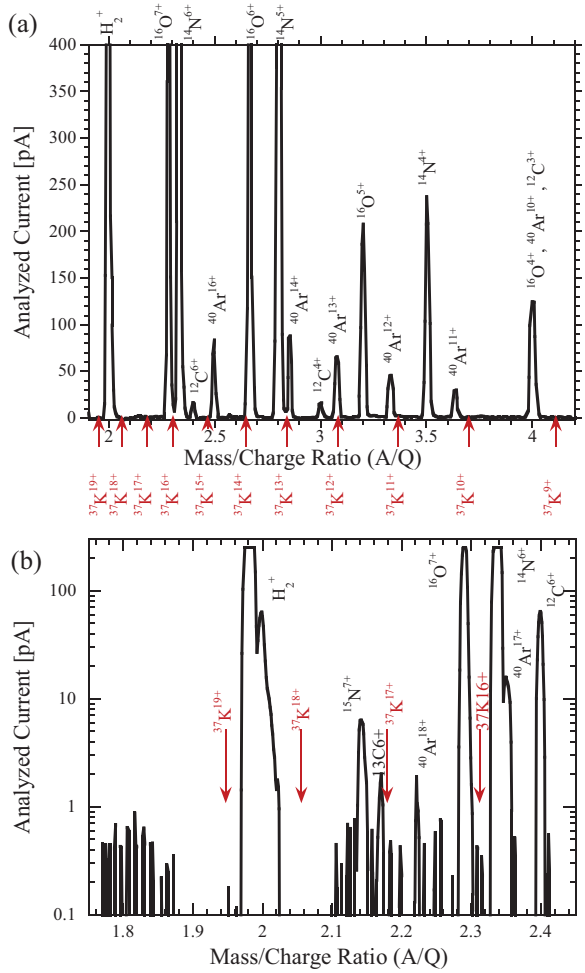

Figure 7: (a) Charge state distribution of the residual ion beam from the EBIT where the position of various $^{37}K^{n+}$ ions are indicated. (b) High resolution, high sensitivity A/Q scan, charge states for $^{37}K^{16+\ -\ 19+}$ ions are indicated.

Figure 8 shows two dimensional PID (particle identification) plots of the energy in the first segment (partial beam energy loss, delta-E) versus total energy (total beam energy loss) in all segments of the ionization chamber, in arbitrary units. This figure is provided courtesy of the ANASEN collaboration. The top panel shows the particle identification without injection of the ^{37}K into the EBIT, and the bottom panel with injection. The separation of mass 13 from 37 is evident, and it was for this reason that $^{37}K^{17+}$ was chosen for transport to the experiment. The small background rate of ^{37}Cl was relatively low and separated from the ^{37}K.

FUTURE DEVELOPMENTS

The third cryomodule with a design β=0.085 is currently in its final assembly stage. It consists of eight quarter - wave SRF cavities and three superconducting solenoids for focusing. Once it is installed in the beam line it will add nominally 8.4 MV acceleration voltage to the accelerating chain. Eleven cavities have been successfully tested, all of which achieved a performance well above the nominal required accelerator gradient and Q-value (see figure 9) [2, 13]. A detailed description of the cavity design and its development can be found elsewhere [13]. Figure 9 shows the final acceptance test of the eight cavities mounted in the cryomodule.

In parallel the first cryomodule of the high energy accelerator chain is under development. It will consist of additional eight cavities and three solenoids, providing a nominal total accelerating voltage of 14.24 MV. Additionally one cold beam position monitor will be mounted after each solenoid. Contrary to the top-down cryomodule design of the first three cryomodules, where the coldmass is mounted on a strongback and supported from the top flange of the cryomodule, the new cryomodule is based on a modular bottom-supported design, which is optimized for mass-production and efficient precision assembly [14]. This cryomodule serves also as prototype cryomodule for the eleven FRIB β=0.085 cryomodules of linac section 1 [1].

Abstract

New developments at HIMAC include a superconducting carbon gantry, a new therapy area with three new treatment rooms, and substantial enhancements to the synchrotron extraction system to enable energy-variation through multiple flattops within a synchrotron cycle to match characteristics of the gantry and three-dimensional raster scanning. The carbon gantry consists of ten combined-function superconducting magnets, allowing a very compact geometry – the length and the radius of the gantry are approximately 13 and 5.5 m, respectively, comparable to the dimensions of existing proton gantries. Further, these superconducting magnets are designed for fast slewing of the magnetic field to follow the multiple flattop operation of the synchrotron. In this paper, the recent developments of HIMAC are presented.

INTRODUCTION

Heavy-ion cancer-therapy using the Heavy-Ion Medical Accelerator in Chiba (HIMAC) has been carried out since June 1994. The successful cancer treatments have led us to construct a new treatment facility [1]. The new treatment facility equips with three treatment rooms; two of them have both horizontal and vertical fixed-irradiation-ports, and the other is a rotating gantry port as schematically shown in Fig. 1. For all the ports, the three-dimensional raster-scanning irradiation method with pencil beam will be employed [2].

In raster-scanning irradiation, a target is directly irradiated with high-energy carbon-ions, after being accelerated by a synchrotron ring. Since the position of the focused beam on a target is controlled by the fast horizontal and vertical scanning-magnets, the lateral dose distribution is determined by these scanning magnets. On the other hand, the depth dose-distribution is determined by beam energy. To control the depth dose-distribution, it is preferable to change the beam energy directly by the accelerators, instead of using energy degraders, since energy degraders may broaden the spot size of the beam on a target, and concurrently produce secondary fragments, which could adversely affect the depth dose-distribution.

To quickly change the energy of the beam, as provided by the synchrotron ring, we developed a multiple-energy operation with extended flattops [3]. The proposed operation enables us to provide carbon ions having various energies in a single synchrotron cycle; namely, the beam energy would be successively changed within a single synchrotron pulse. With this operation, the beam range could be controlled without using any energy degraders.

To further obtain precise dose distributions, we developed an isocentric superconducting rotating-gantry for carbon therapy [4]. This rotating gantry is designed to transport carbon ions having 430 MeV/u to an isocenter with irradiation angles of over ±180 degrees, and is further capable of performing the fast raster-scanning irradiation. The combined-function superconducting magnets will be employed for the rotating gantry. Use of the superconducting magnets with optimized beam optics allow a compact gantry design with a large scan size at the isocenter; the length and the radius of the gantry will be approximately 13 and 5.5 m, respectively, which are comparable to those for the existing proton gantries. This rotating gantry is currently under construction, and will be installed in the room G of the new treatment facility.

We report the recent developments of the multiple flattop operation as well as the superconducting rotating-gantry.

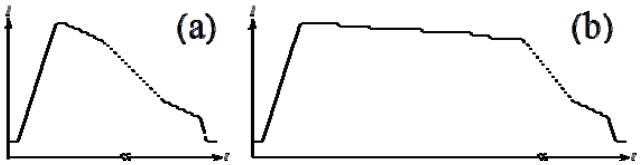

Figure 2: (a) Schematic drawing of synchrotron pattern for multiple-energy operation. (b) The same pattern as (a), but with the extended flattops. The beam is extracted from the synchrotron ring during these extended flattops.

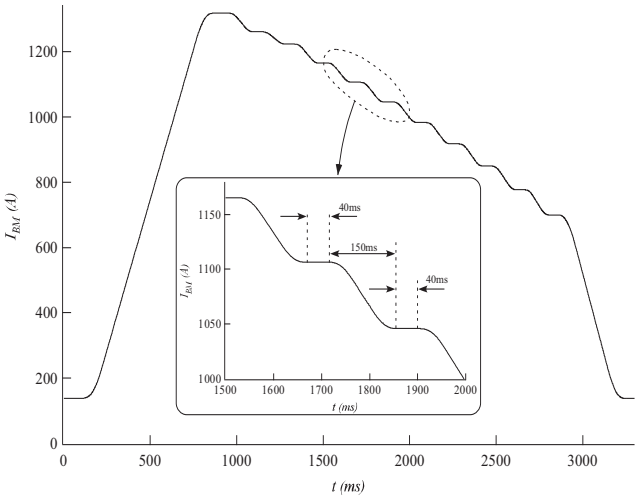

Figure 3: A current pattern for the main-bending magnets in the ring as a function of time. The currents of the 11 flattops correspond to the beam energies of 430, 400, 380, 350, 320, 290, 260, 230, 200, 170, and 140 MeV/u.

MULTIPLE FLATTOP OPERATION

The multiple-energy operation employs operation patterns having a stepwise flattop, as schematically shown in Fig. 2(a). With these operation patterns, the carbon ions injected in the ring are initially accelerated to the maximum energy, and then successively decelerated to lower energies. Although the stepwise pattern only has short flattops, where the beam can be extracted from the ring, we can extend the flattop and extract the beam during the extended flattop.

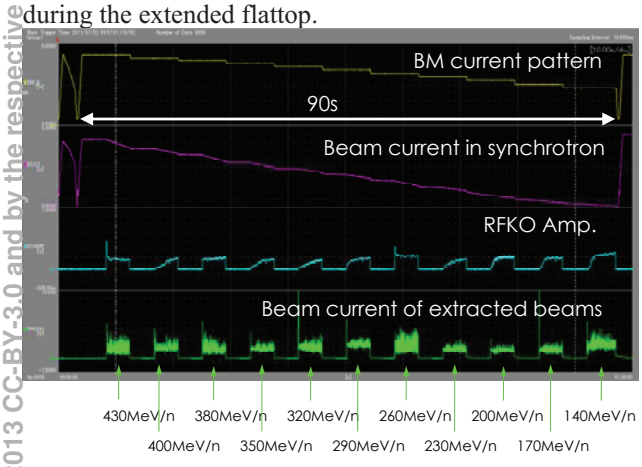

Figure 4: Current patterns for the main bending magnets, beam current in the synchrotron ring, RFKO amplitude, and the beam current of the extracted beam.

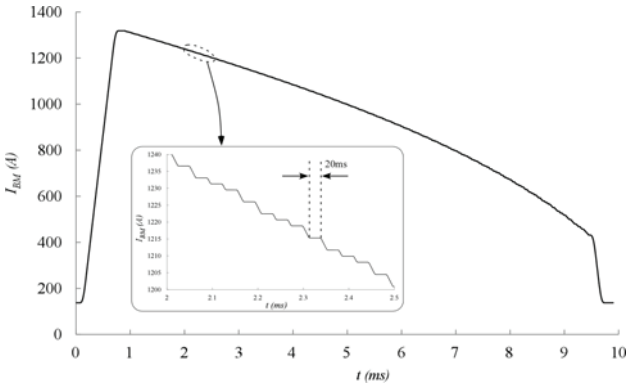

Figure 5: A current pattern for the main-bending magnets in the ring. This pattern has 201 flattops.

Having consecutively extended the flattops, as illustrated in Fig. 2(b), the beams having various energies can be extracted from the ring within a single synchrotron cycle, and hence the total irradiation time can be considerably reduced.

11-flattop pattern

To prove the principle of multiple-energy operation with extended flattops, we have performed beam acceleration and extraction tests using the stepwise operation pattern. In the tests, a current pattern for the main bending magnet having 11 short flattops, corresponding to 11 beam energies, was prepared as shown in Fig. 3. Further, similar patterns were prepared for other devices, such as the main quadrupole, sextupole magnets, the RF-acceleration cavity, and the beam-extraction devices in the extraction channel. By using the prepared operation patterns, the beam will be initially accelerated to 430 MeV/u, and then consecutively decelerated down to 140 MeV/u at an energy step of 20 MeV/u or 30 MeV/u. Results of the beam test are shown in Fig. 4. As can be seen in the figure, beams having 11 different energies were successively extracted from the synchrotron ring. The multiple-energy operation using this pattern was successfully commissioned, and has been used for scanning treatments since FY 2012.

Full energy-scan with 201-flattop pattern

The final goal of this project is to control the depth dose-distribution by varying the beam energy from the accelerators, namely, *full energy scanning*. To accomplish

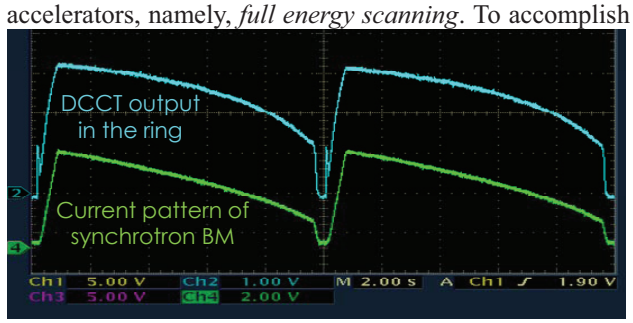

Figure 6: Current patterns for the main bending magnets, DCCT output in the synchrotron ring during beam acceleration tests using the 201-flattop pattern.

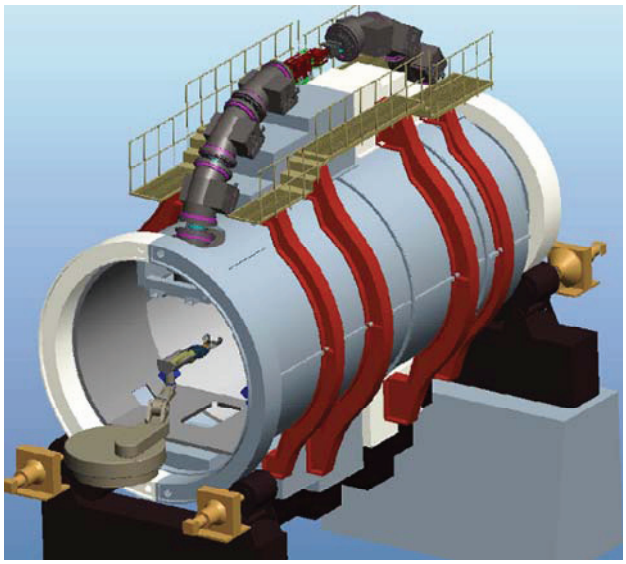

Figure 7: Three-dimensional image of the superconducting rotating gantry for carbon therapy.

this, it is required to change, the beam energy successively by an energy step corresponding to the water range of 1 or 2 mm. Since the maximum and minimum energies, as used in the raster-scanning irradiation, are 430 and 56 MeV/u, respectively, the synchrotron patterns having the 201 flattops will be needed to cover the entire energy range. Fig. 5 shows a current pattern of the main bending magnets having the 201 flattops.

Beam acceleration and extraction tests using the 201-flattop patterns were successfully made as shown in Fig. 6. In the test, we found that any of the 201 flattops can be extended, and that the beam can be extracted during the extended flattop. Hence, with this operation pattern having the 201 flattops - *the universal pattern*, the depth dose-distribution could be controlled without using any energy degrader.

SUPERCONDUCTING ROTATING-GANTRY

A three-dimensional image of the isocentric rotating gantry for the new treatment facility is presented in Fig. 7. This rotating gantry has a cylindrical structure with two large rings at both ends. The end rings support the total weight of the entire structure, and are placed on turning rollers so as to rotate the beam line on the rotating gantry along the central axis over ±180 degrees. Carbon beams, provided by the HIMAC, are transported with ten sector-bending magnets, mounted on the gantry structure through each of their supporting structures; they are directed on a target located at the isocenter. In the treatment room, a tumour in a patient is precisely positioned to the isocenter by using a robotic couch.

Layout and beam optics

A layout of the compact rotating-gantry is presented in Fig. 8. The rotating gantry has ten superconducting magnets (BM01-10), a pair of the scanning magnets (SCM-X and SCM-Y), and two pairs of beam profile-monitor and steering magnets (ST01-02 and PRN01-02). A total length and radius of the rotating gantry is 13 m and 5.45 m, respectively. All of these devices are installed and mounted on the cylindrical structure. Since beam focusing can be made only with the combined-function

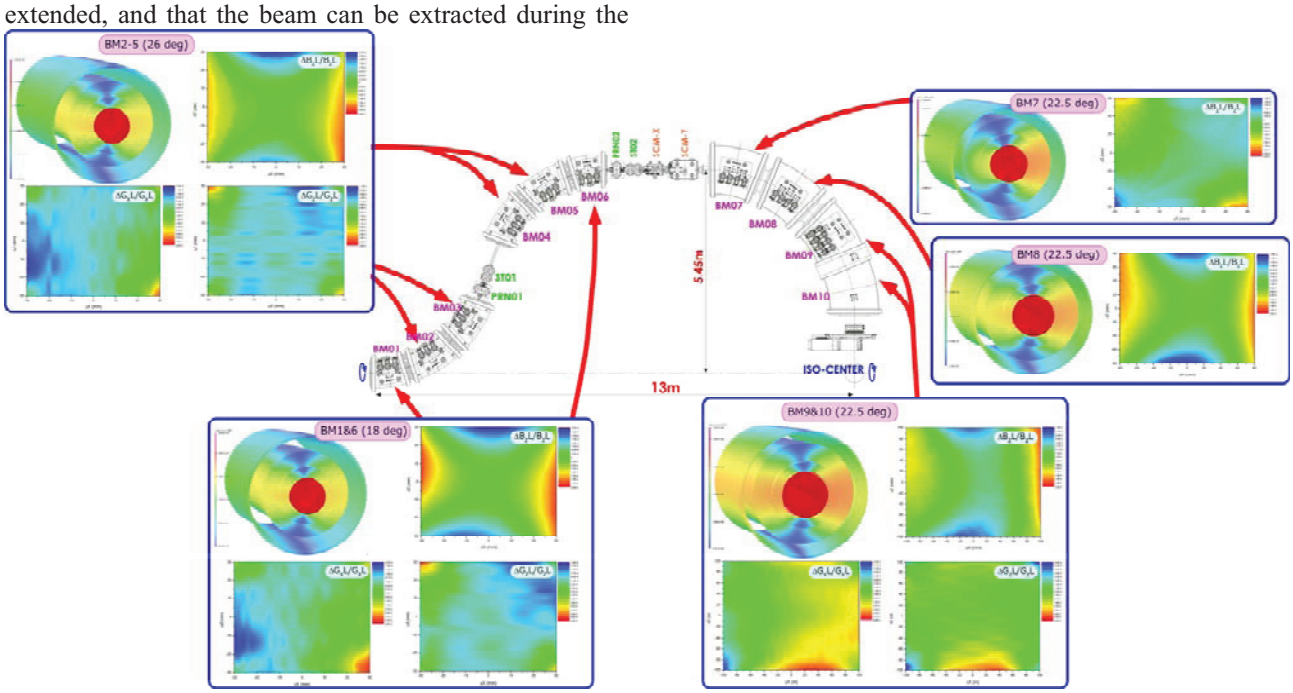

Figure 8: Layout of the superconducting rotating gantry. The gantry consists of ten combined-function superconducting magnets (BM01-10), a pair of the scanning magnets (SCM-X and SCM-Y), and two pairs of beam profile-monitor and steering magnets (ST01-02 and PRN01-02). Representative results of 3D magnetic field calculations for the five kinds of the superconducting magnets are also shown.

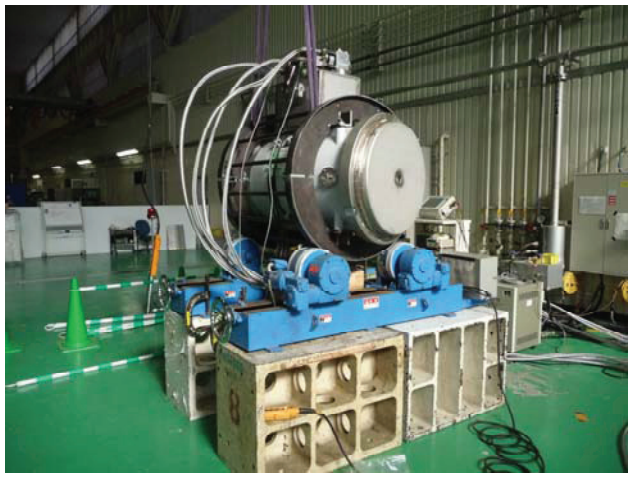

Figure 9: Picture of the test bench during rotation tests of the model superconducting-magnet.

superconducting magnets, no quadrupole magnets are needed to install in the rotating gantry, and thus we could design the compact rotating gantry. Details of the beam optics are provided in Ref. [4].

Field calculations

Based on the design of the beam optics, specification of the superconducting magnets was determined. According to their apertures, the magnets are categorized into five kinds. All the magnets have the surface-winding coil structure, and were designed by using a 3D electro-magnetic field-solver, the Opera-3d code [5]. In the code, the curved superconducting coils, having typically a few thousand turns per pole, as well as the cold yoke and vacuum chamber were precisely modelled, and a three-dimensional magnetic field was calculated. Representative results of the calculations are shown in Fig. 8. Having optimized the conductor position, we obtained the required uniformity of the calculated field.

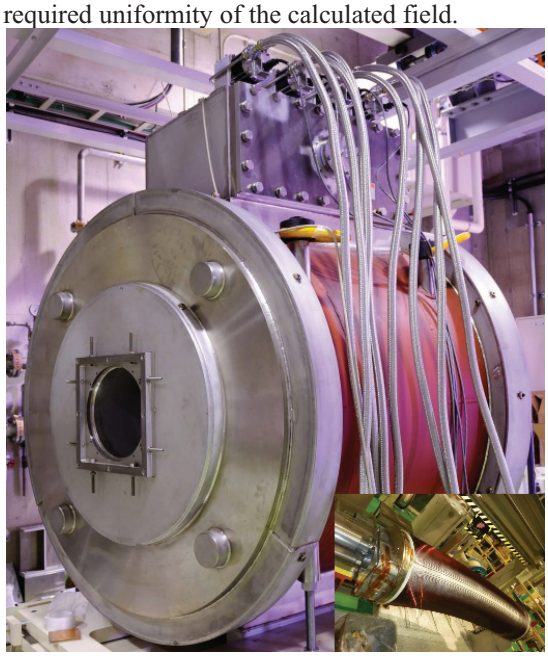

Figure 10: Picture of BM10 and its superconducting coil.

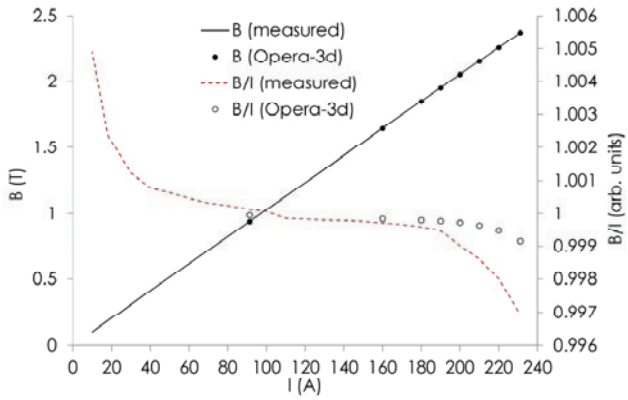

Figure 11: Measured magnetic field, *B*, and magnetic field as divided by coil current, *B/I*, as functions of coil current, *I*, for BM10. For comparison, calculated magnetic field is shown by the filled and open dots.

Rotation tests

Since the superconducting magnets on the rotating gantry are to be rotated over ±180 degrees during treatments, an unexpected quench of the superconducting magnets, as caused by rotations, is a concern. To verify this, a model superconducting magnet was developed and tested by Toshiba Corporation. This model magnet has a similar magnet structure as that of BM01-06, although this model magnet only has a dipole coil. Fig. 9 shows a picture of a test bench during rotation tests. Prior to the tests, the coil of the model magnet was cooled down to below 4K by cryocoolers, installed on the magnet. While exciting the superconducting coil with the maximum current, the model magnet was rotated by ±180 degrees, and the coil temperatures in the magnets were monitored. As a result, no unexpected temperature increase, which may cause quench problems, was observed.

Magnetic field measurements

The five superconducting magnets of BM01-BM04 and BM10 (Fig. 10) were constructed, and the rest of the five will be constructed within a year. Firstly, we measured central magnetic field by using an NMR probe. The NMR probe was installed in the middle of the magnet, and current of between *I*=10-240 A was applied for the dipole

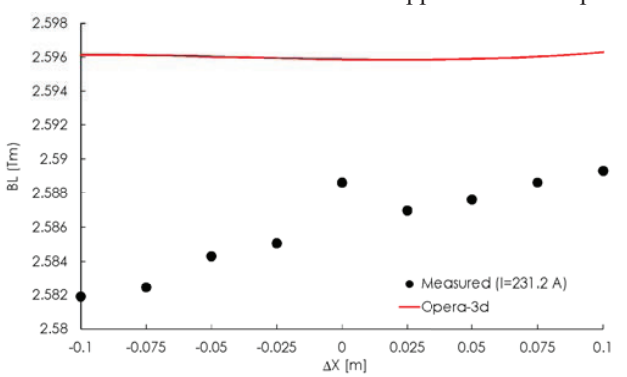

Figure 12: Measured BL products as a function of ΔX. Current for the dipole coil is *I*=231.2A. The solid curve show calculated result with the Opera-3d code.

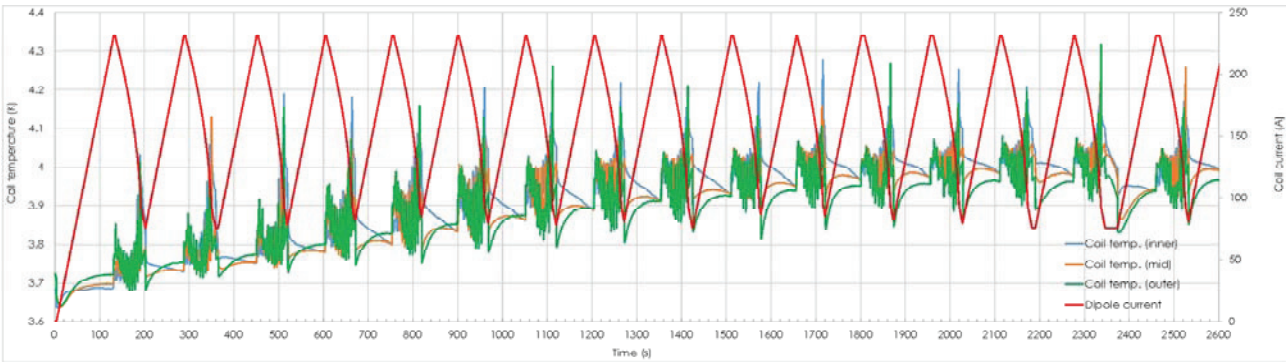

Figure 13: Results of the fast slewing tests for BM10. Average coil temperatures were converged below 4K.

coil of BM10. The measured magnetic field, B, and magnetic field as divided by the coil current, B/I, are shown by the solid and dashed curves in Fig. 11, respectively. For comparison, calculated results of B and B/I using the Opera-3d code are also plotted by the filled and open dots in Fig. 11, respectively. We found that the measured and calculated magnetic field agreed with each other, although the measured B/I curve at the maximum current slightly differs with the calculated curve. This discrepancy might be attributed to a difference in estimation of a packing factor for the laminated cold yoke.

Secondarily, measurements of magnetic field distributions along beam trajectories were performed. Measured-magnetic field distributions along the central beam trajectory were measured and integrated over the beam trajectories to determine a BL product and an effective length. The same analysis was made for the calculated distribution with the Opera-3d code. Fig. 12 shows the BL products of various beam trajectories, as shifted horizontally by ΔX, for the dipole current of I=231.2A. Here, the values of the BL products are normalized, so as to have the same effective length of $L=\rho\theta$=2.8m×22.5° for all the trajectories. Corresponding results, as calculated by the Opera-3d code, are also shown by the solid curves in the figures. The absolute values of the measured BL agreed with the calculated values within accuracy of a few times 10^{-3}; however we clearly see the quadrupole component of approximately GL~3.8×10^{-2} T for the measured field in Fig. 12. We presume that this unexpected quadrupole component might be attributed to an alignment error between the superconducting coil and cold yoke. However, since this magnet has the quadrupole coil, this quadrupole component can be corrected by adding or reducing current for the quadrupole coil by approximately ΔI=5 A from the applied quadrupole current of I~200 A.

Fast slewing tests

To simulate the multiple flattop operation, fast slewing tests were made. In the tests, currents of both the dipole and quadrupole coils were maximized to initialize the magnet, and then were decreased by 201 steps. In each step, coil currents were kept for 0.3 s, where carbon beams would be extracted from accelerators and transported through a beam-transport line including the rotating-gantry during this constant-current region. Further, the coil temperatures were measured with resistance temperature sensors, installed in the inner, middle and outer sides of the coil. A representative result for BM10 is provided in Fig. 13. Although the coil temperature gradually increases, we found that the average coil temperatures were converged around 4 K, while the critical temperature is approximately 6.8 K.

SUMMARY AND FUTURE PLAN

Recent developments of the HIMAC accelerator complex are reported. To take advantage of the fast raster-scanning irradiation, the multiple energy operation was developed. This operation using 11-flattop pattern was successfully commissioned, and is presently used in scanning-treatment operations. Furthermore, we successfully made beam acceleration and extraction tests with 201-flattop pattern, which enables us to perform the full energy scanning; this operation will be used for treatment operation in near future.

A compact superconducting rotating-gantry for carbon therapy is being developed. Having optimized the layout using the combined-function superconducting magnets, we could design the compact rotating-gantry. The design study as well as major tests of the superconducting magnets was completed, and the construction of the superconducting rotating-gantry is in progress. The rotating-gantry will be completed at the end of FY2014, and be commissioned in FY2015.

ADVANCES IN SUPERCONDUCTING UNDULATORS *

Y. Ivanyushenkov#, Advanced Photon Source, ANL, Argonne, IL 60439, USA

Abstract

Superconducting technology could be employed for building undulators with enhanced parameters for synchrotron light sources and free-electron lasers. Expected and measured performance of superconducting undulators will be presented. Although superconducting technology is already working in superconducting wigglers, the development of superconducting undulators was slowed down by a variety of challenges that will be discussed. Possible solutions with examples will be presented. Finally, an overview of recent developments in superconducting undulators is presented in this paper.

INTRODUCTION

Insertion devices (IDs) are essential parts of modern and future light sources. The trends for IDs of future light sources are reviewed in [1]. Until now most IDs have been built using permanent magnets as a source of magnetic flux. At the same time, there is a growing interest in electromagnetic devices that use superconducting windings. As a matter of fact, superconducting wigglers are a well-established technology; such IDs are being used in many synchrotron light sources [1]. In comparison, the development of superconducting undulators is lagging behind the progress being made with superconducting wigglers.

This paper follows the review of developments in superconducting insertion devices given in [2] and concentrates on superconducting undulators (SCUs). The motivation of developing SCUs is first discussed, followed by a list of challenges. Examples of recent developments towards finding the solutions are then given. Finally, an overview of activities in superconducting undulators is presented.

SCU MOTIVATION

Interest in SCUs is stimulated by the fact that the SCUs can reach, for the same vacuum gap and period length, higher field events with respect to cryogenic permanent magnet undulators (CPMUs)—the state-of-the-art of permanent-magnet-based undulators. The undulator peak field for both technologies is compared in Table 1 [3]. In this table, NbTi-APC refers to a NbTi-superconductor with artificial pinning centers (APC).

A similar comparison is given in [4]. A careful analysis of CPMU and SCU technologies concludes that above the period length of 10 mm SCUs produce the highest fields. For the smaller period lengths, CPMUs can compete with NbTi SCUs, whereas Nb_3Sn or NbTi-APC devices are still superior.

Table 1: CPMU and SCU Comparison [3]

	CPMU PrFeB	SCU NbTi	SCU NbTi-APC
Undulator period, mm	15	15	15
Magnetic gap, mm	5.2	6	6
Undulator peak field B, T	1.0	1.18	1.46
Undulator parameter K	1.40	1.65	2.05

SCU CHALLANGES

Development of SCUs is progressing relatively slowly due to several challenges. The first one concerns the requirement of high quality field from an undulator magnet. The second one is operating the SCU magnet coils at high current densities and providing adequate cooling in the presence of beam heating.

The first and second field integrals should be kept at a minimum to avoid electron beam position deviation by the undulator magnetic field. To achieve the highest performance of an undulator at higher harmonics, the phase error should also be kept at a level of a few degrees RMS. Those requirements are not easily achievable for multipole magnetic structures.

Cooling complex multi-coil superconducting magnetic structures of SCUs in the presence of heating by an electron beam is another challenging task. The possible solutions are discussed below.

SCU MAGNET

Magnet Design

A planar SCU generates a periodic magnetic field in a plane. For this, a set of linear currents is required as a minimum [5]. For practical reasons, a set of small racetrack coils (with dimensions of few a cm in height by a few cm in length) is used forming a multi-coil structure supported by a magnet former. The coils are usually vertically oriented due to a relatively short (15-30 mm) period length in the undulators. One undulator period contains two coils with the currents going in opposite directions. A magnet former, or a core, can be made of magnetic or non-magnetic material. A complete SCU magnetic structure is then made of two such magnets separated by a magnetic gap where a beam vacuum chamber can be located [6].

Such a magnetic design is adopted in the SCUs for the National Synchrotron Radiation Research Center (NSRRC), Taiwan [7], Advanced Photon Source (APS), USA [8], Diamond Light Source (DLS), UK [9], and Shanghai Synchrotron Radiation Facility (SSRF), China [10]. In the SCU for ANKA there is no beam vacuum

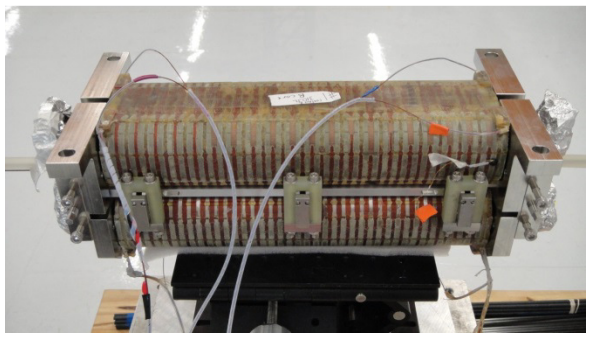

Figure 1: Magnetic structure of the test superconducting undulator SCU0 at the APS [8].

chamber, but a thin liner is used to shield SCU coils from the electron beam [11].

The above scheme is suited for winding SCU coils with the low-temperature superconductor (LTS) wires although the exact designs could vary. Both NbTi and Nb_3Sn superconductors were successfully used for making SCU magnet prototypes, but NbTi has been used so far in the completed devices.

There also have been attempts to use high-temperature superconductors (HTSs) for SCU magnets. The idea of making a zigzag-like pattern on the HTS YBCO ($YBa_2Cu_3O_7$) tape is suggested in [12]. An SCU magnet could then be built as a stack of such tapes. The expected field of this undulator could exceed 1 T for a period length of 7 mm and beam aperture of 2 mm. An undulator with such a small pole gap is targeted primarily at free electron lasers.

A prototype of an HTS magnet was built and tested by the ANKA group and Babcock Noell GmbH [13]. The achieved field was lower than the field of a NbTi-based magnet. This is due to a very low packing factor in a winding made of the HTS tapes, where a superconductor layer is very thin and occupies only about 1% of the tape overall thickness.

Magnetic Shimming

Magnetic and mechanical shimming is usually used to tune conventional undulators to achieve the required field integrals and phase errors. It is a common perception therefore that magnetic shimming should also be employed for SCUs. In the case of superconducting devices where a magnetic structure is enclosed in a cryostat, such an approach requires development of new shimming techniques.

One possibility for planar SCUs is to add extra iron pieces to a magnetic pole as described in [14]. The measured maximum field compensation is 2.43% for a shimming piece of height 25 mm in a 130-pole undulator magnet with period length of 15 mm and a 5.6-mm pole gap. An additional magnetic flux could be injected into a pole when a trim coil is mounted directly on the outer faces of the iron pole with a trim iron piece [15].

A concept of passive shimming, based on Faraday's law of induction, was suggested [16] and experimentally tested [17]. The induction-shimming system consists of a set of overlapping closed high-temperature superconductor (HTS) loops attached to the surface of the superconducting undulators. Each HTS loop covers two adjacent undulators' magnet poles. The undulators' field errors induce currents in the HTS loops and, as a result, the magnetic field generated by these induction currents minimizes the field errors. The compensation effect at a level of 6 mT was measured at a distance of 7.15 mm from the SCU test magnet having a period length of 14 mm. The estimated correction field would be about 17 mT for an undulator with a period length of 15 mm and a pole gap of 5 mm with a peak field of 1.5 T [17].

Superconducting switches are also suggested for use in SCU shimming as described in [18]. This concept utilizes a single current source and a set of superconducting switches to control the current direction in the trim coils.

At the same time, the experience of the APS group demonstrates that magnetic shimming is not required for a relatively short (300-mm-long) undulator magnet. The magnet former was machined with a precision of about 10 μm, and the winding was done accurately on a computer-controlled winding machine. As a result, a phase error below 2° RMS was measured. The required field integrals were also achieved without any magnetic shimming. Such tight mechanical tolerances are practically impossible for longer magnets; therefore, theoretical work was started in order to simulate possible geometrical errors in superconducting magnet windings and calculate their effect on the field quality [19]. It was found that for a given field error range, the phase error scales with the square root of the undulator length. This work needs to be continued to better understand the sources of the field errors in SCU magnets.

SCU COOLING

Heat Loads

Design of an SCU cooling circuit requires reliable prediction of expected heat load in a superconducting undulator. Since an SCU is a superconducting magnet, all the heat loads that are typical for a superconducting magnet system are also present in an SCU. These are conduction heat leaks through current leads and cold mass supports, and radiation heat load from the vacuum vessel at room temperature to a cold mass at liquid helium temperature. Those heat loads could be calculated with good precision.

Another source of heat in the SCU is the electron beam itself. There is a variety of ways for electron beam to generate heat in a beam chamber, but the largest contribution at a level of tens of Watts per a meter of chamber length is due to resistive wall wakefields.

In addition, the SCU could be heated by any uncollimated synchrotron radiation from the upstream bending magnet. This can be mitigated by placing an absorber upfront of the SCU and by making the SCU beam chamber bore wide enough for the bending magnet synchrotron radiation to pass through.

Cooling Schemes

The task of an SCU cooling circuit is to keep the SCU magnet coil cool in the presence of static heat leaks in the cryostat and beam heating.

One possibility is to place the SCU magnet into a liquid helium bath as in superconducting wigglers [20]. The drawback of this approach is that the beam heat goes directly into the coolant and requires substantial cooling power at 4 K. This cooling power could be provided by cryocoolers or by a cryogenic plant. Taking into account that a modern cryocooler delivers only 1.5 W of cooling at 4 K, this approach is limited to a modest heat load at 4 K. The usage of a cryoplant is likely to be cost effective when a long string of superconducting undulators needs to be built, like in free electron lasers. This scheme could be modified by placing a thermal screen, a liner, into a beam chamber bore. This liner could then be cooled by a separate circuit and take most of the heat from the electron beam.

It should be noted that the electron beam heats the SCU magnet when the beam chamber is in thermal contact with the SCU coils. This situation could be avoided by thermally insulating the SCU magnet from the beam chamber. A vacuum gap can simply be used as a thermal insulator. Such an approach is adopted in the SCU for the APS [21]. In this undulator the SCU coils are indirectly cooled by LHe passing through the channels in the magnet cores. The LHe is kept in a tank inside the cryostat and, together with the magnet and piping, makes a closed system. The He vapor in this system is re-liquefied by a recondenser that is located inside the tank and cooled by a cryocooler. An electrical heater is used to trigger a thermosyphon effect for circulating LHe through the magnet cores.

A group in the UK is going to employ a similar cooling scheme for their SCU but will decrease the operating temperature to 1.8 K to gain a safety margin and to achieve the required critical current [9]. A Joule-Thomson expansion valve will be added to a cryogenic circuit, and a pressure of 16 mbar will be required on the effluent side of the helium expansion. A special scroll pump will be used for circulating He through the undulator magnet.

Cryogen-free systems are also possible. The SCU coils are conduction cooled by cryocoolers as in the SCU that is currently being built by the ANKA group and Babcock Noell GmbH [22].

MAGNETIC MEASUREMENTS

Measurement of magnetic performance of an SCU is another challenging task as it requires building a dedicated magnetic measurement facility. The measurement techniques employed for conventional undulators could not be directly applied for SCUs as in these devices the magnetic structure is located inside a cryostat and operated at cryogenic temperature.

It is a common practice that undulator coils are tested in a vertical liquid helium cryostat. Such a system usually contains a single or several Hall sensors mounted on a vertical stage. An example of such a system is CASPER-I (Characterization Setup for Phase Error Reduction) developed at ANKA [23]. Similar systems were built at Brookhaven National Laboratory [24] and the APS.

Recently a more advanced measurement facility called CASPER-II has been built by the ANKA group [25]. This system is targeted at characterization of conduction cooled SCU magnets. It is based on a horizontal, cryogen-free cryostat with easy access to a test coil. The system is equipped with a Hall probe for local field measurements and a stretched wire for measuring the field integrals.

The APS group in collaboration with a team from Budker Institute, Novosibirsk, Russia, has designed and built a horizontal measurement system [26]. This system utilizes a warm guiding tube approach. In this scheme, a Hall probe is guided through a thin-wall warm tube that is stretched inside the cold bore of the SCU beam chamber. The bore of the guiding tube is open at the ends thus giving easy access to the Hall probes and measurement coils. The system has been successfully operated for parameterization of the first superconducting undulator at the APS [27].

The superconducting undulators for free electron lasers are likely to have a smaller pole gap than the SCUs for synchrotron light sources. A technique for magnetic measurements of small-gap SCUs needs to be developed. One promising approach is a pulsed wire technique that can be used for direct measurements of the first and second field integrals. The possibility of using this method for accurate trajectory and phase error measurements is demonstrated in [28].

EXPERIENCE WITH SCU OPERATION

A number of SCU prototypes have been built in various institutions around the world, but a quantity of completed devices is substantially smaller. Therefore any experience of operating a superconducting undulator on a light source is extremely valuable.

Superconducting undulator SCU14 was in operation at ANKA light source for several years after installation in 2005 [29]. This was a 100-period device with a period length of 14 mm and variable gap of 8-25 mm built by ACCEL Instruments GmbH. The magnet was conduction cooled by three cryocoolers. The measured photon spectra of SCU14 agreed very well with the calculations. Initial studies of the SCU heating by the electron beam concluded that the dominant heat source was the synchrotron radiation produced in the upstream bending magnets: 1 W per 100 mA stored current at a beam energy of 2.5 GeV and an undulator gap of 8 mm [30]. The heat load produced by the image current was found to be negligible. In the following years a nonlinear beam chamber vacuum pressure rise with the electron beam current was observed. The large variation of the beam heat load was also measured for different gaps—between 1.6 and 3 Watts for an 8-mm gap with 120-mA average beam current [31]. This was attributed to electron multipacting as the main beam heat source at ANKA for normal user operation [32].

Copyright © 2013 CC-BY-3.0 and by the respective authors

The first superconducting test undulator, SCU0, was built and installed on the APS storage ring in December 2012. After commissioning in January 2013, the undulator is in user operation [33]. The SCU0 contains a relatively short magnet (330-mm length) in a 2-m-long cryostat [8]. The SCU0 magnet has a period length of 16 mm and a pole gap of 9.5 mm. It was designed to operate at a current of 500 A, but it routinely operates at a current of 650 A, delivering a magnetic field of about 0.8 T. The measured heat load on the SCU0 beam chamber is 16 W, which agrees very well with a calculated value of 14 W. For the eight-month period since commissioning, the device has demonstrated a LHe loss-free behavior. It is also observed that an SCU0 quench does not trigger an electron beam dump since the electron trajectory is deviated by only about 50 μm. On the contrary, an unintentional beam dump causes undulator quench. It takes about 20 minutes for the temperatures in the SCU0 to stabilize after quench. The device was characterized in terms of photon flux. As measured, the SCU0 produces about 40% higher photon flux at the photon energy of 85 keV as compared to a 2.4-m-long Undulator A, the most common hybrid undulator at the APS.

RECENT DEVELOPMENTS IN SCUs

A list of SCUs that have recently been built or are in the development stages (to the best of the author's knowledge) is given in Table 2. In this table SC stands for superconductor.

Table 2: SCUs Recently Built or Under Development

Light Source/ Institution	Period (mm)	Pole gap (mm)	K	No. of periods	SC	Status
NSRRC	15	5.6	1.96	≈132	NbTi	Proto-type
SSRF	16	9.5	0.9	10	NbTi	Proto-type
ANKA	15	5-16	2.1 max	100.5	NbTi	Being built
DLS	15.5	7.4	1.83	≈129	NbTi	Proto-type
NGLS/ LBNL	~20	TBD	TBD	~3000	Nb_3Sn	Proto-type
APS	16	9.5	1.2	20.5	NbTi	Built
	18	9.5	1.64	59.5	NbTi	Being built

CONCLUSION AND DISCLAIMER

Superconducting undulators continue to attract the interest of the light source community due to its promise of delivering high magnetic fields and therefore higher photon fluxes, especially at high photon energies.

In recent years a number of SCU prototypes have been manufactured and tested, and more undulators are currently being built. Various solutions are being suggested and implemented to overcome SCU challenges.

Experience gained in operating superconducting undulators confirms that such devices could successfully be operated in synchrotron light sources.

It is inevitable with an overview like this that some excellent work that has made valuable contributions to the development of superconducting undulators has been overlooked, but it was not intentional.

DEVELOPMENT AND OPERATION OF THE SNS FAST CHOPPER SYSTEMS*

R. Saethre, D. Anderson, C. Deibele, V. Peplov, M. Stockli
ORNL, Oak Ridge, TN 37831, USA

Abstract

The Spallation Neutron Source (SNS) at Oak Ridge National Laboratory requires fast chopper systems to create a series of mini-pulses of H^- ions in the Linear Accelerator (LINAC) for injection into the accumulation ring. The fast chopper systems are in the front end of the accelerator with one chopper in the Low Energy Beam Transport (LEBT), immediately upstream of the Radio Frequency Quadrupole (RFQ), and another chopper in the Medium Energy Beam Transport (MEBT), downstream of the RFQ, where the beam energy is approximately 2.5 MeV. Clean bunching requires fast rise and fall time and low jitter to minimize the amount of charge in the ring extraction gap. The chopper systems operate at a burst frequency of 1 MHz and a burst width of greater than 1 ms and burst frequency of 60 Hz. The choppers have had historical reliability issues, especially in the LEBT system. This paper describes the development of reliable LEBT and MEBT choppers and the operational performance since SNS commissioning in 2006.

INTRODUCTION

A layout of the Spallation Neutron Source (SNS) at Oak Ridge National Laboratory is shown in Figure 1. The SNS consists of a Linear Accelerator (LINAC) which injects H^- beam pulses into a proton accumulation ring where they are extracted and transported to a liquid mercury target to generate neutrons for studying neutron sciences. The ion source in the front end system [1] produces an H^- beam that is chopped into mini-pulses for injection into the LINAC. The beam is accelerated through the LINAC and transported through the high energy beam transport (HEBT) section where it is injected into the accumulation ring. More than 1000 turns can be accumulated before the beam is extracted from the ring for transport to the mercury target. Four bipolar high voltage pulse generators in the Low Energy Beam Transport (LEBT) [2-4] section and two unipolar high voltage pulse generators in the Medium Energy Beam Transport (MEBT) [5-8] section create the beam mini-pulses.

The pulse generators and the structures they drive have had many reliability issues which have required extensive research and development to rectify. This paper summarizes the LEBT and MEBT chopper systems function, failure history, and development of reliable modules. It is focused on the reliability of the LEBT high voltage pulse generators used to apply pulses to the lens segments. Detailed descriptions of the LEBT and MEBT structure improvements can be found in the references.

*Work performed at Oak Ridge National Laboratory, which is managed by UT-Battelle, LLC, under contract DE-AC05-00OR22725 for the U.S. Department of Energy.

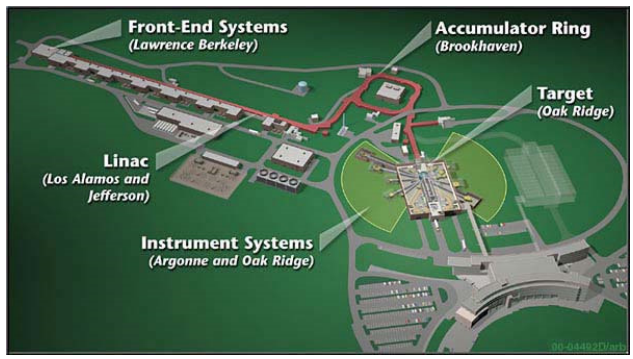

Figure 1: Layout of the Spallation Neutron Source in Oak Ridge, TN.

CHOPPER TIMING REQUIREMENTS FOR BEAM EXTRACTION

The choppers operate by generating fast rise/fall time high voltage pulses interspersed with periods of no high voltage, effectively deflecting the beam from the beamline to a target to generate gaps in the beam. The extraction kicker rise time sets the minimum gap required for the high voltage pulse generators used for chopping in the LEBT and MEBT. The beam gap in the accumulation ring must be clean and wide enough for the extraction kickers to fully turn on. If the head and tail of the beam in the ring are not sharp or the gap is not free of protons, the extraction kickers will partially deflect the beam during kicker turn on, causing activation of the extraction septum magnet.

The extraction kicker system consists of fourteen pulse forming networks (PFNs) located in the Ring Service Building, driving fourteen kicker magnets in the Ring Tunnel. Due to the design of the PFN, the rise time is fixed at approximately 200 ns. Figure 2 is a graph of the rise time of the extraction kicker magnet current.

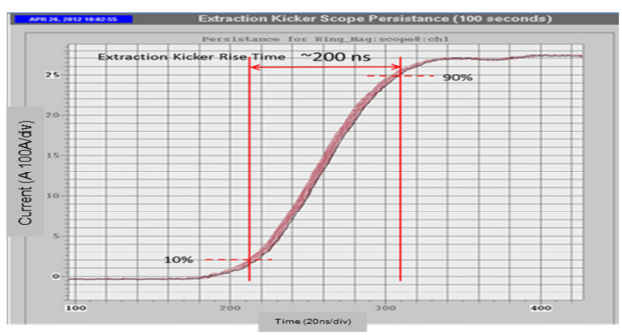

Figure 2: Extraction kicker rise time.

The LEBT chopper structure is an electrostatic einzel lens split into four quadrants to deflect the beam to a diagnostic plate for a minimum of 200 ns to a maximum of 1000 ns, depending on the percentage of ring fill desired. [3] The chopping pattern rotates the beam around the diagnostic plate to limit heating. Figure 3 shows the timing sequence used to move the beam from one segment to another during either beam on or off time.

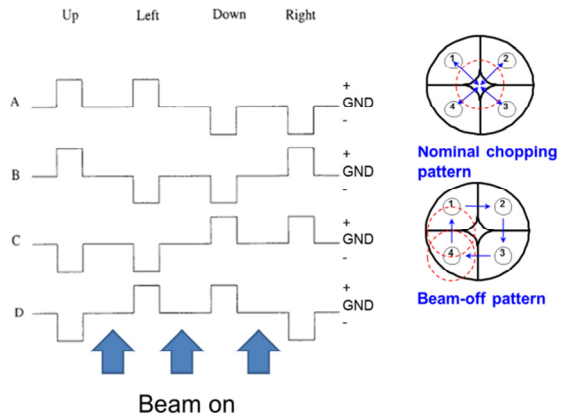

Figure 3: Four phase timing of LEBT chopper.

The LEBT chopper specifications require +/- 3 kV pulses with rise and fall times of < 50 ns and pulse widths varying from 200 ns to 1000 ns. The variable pulse widths provide for the ability to change the beam fill in the ring, beam ramping at the beginning of the macro-pulse and permits accelerator physics studies. See reference [4] for a discussion of the timing limitations of the LEBT high voltage pulse generators.

The MEBT chopper system consists of two high voltage pulse generators of opposite polarities to deflect the beam vertically. MEBT rise and fall times are specified to be less than 10 ns. The MEBT high voltage pulse generators [7-10] are used for sharpening the edges of the pulse and to clean the gap to minimize losses during extraction.

LEBT CHOPPER

The LEBT chopper system consists of four high voltage pulse generators each driving a segment of the einzel lens to deflect the beam. The lens is biased at near -50k Vdc for focusing and each segment is independently offset by another fraction of a 3 kVdc supply for steering. Figure 4 is a simplified block diagram showing the connections within the LEBT chopper system. Capacitive coupling is used to isolate the ground referenced pulse generators from the bias and steering voltage. A 20k Ohm resistor and the inductance of the cabling are used to isolate the bias and steering power supplies from the pulsed high voltage. A relay is used to disconnect the high voltage pulse generator from the structure.

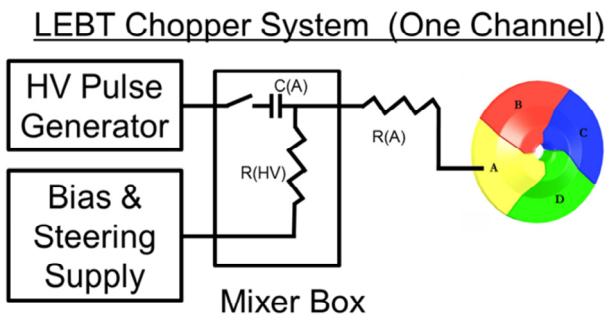

Figure 4: Block diagram of one channel of the LEBT chopper system

LEBT Structure

After very high arc rates in early 2007, the lens was redesigned with glue-free joints and 32 intersegment spark gaps to limit intersegment voltages to about 10 kV and to divert the energy away from the intersegment insulators [11]. In addition, the operational arc rate was reduced with high voltage conditioning and the addition of an automatic disconnect when more than 5 arc events occur in a 6 minute period.

LEBT High Voltage Pulse Generators

The LEBT high voltage pulse generators are a ¾-H bridge design where the capacitive load of the LEBT lens segment is either switched to the positive 3 kV rail, ground, or the negative 3 kV rail. The design uses eight high voltage metal oxide semiconductor field effect transistors (MOSFETs) stacked in series to create a single high voltage switch with enough voltage hold off to permit reliable operation during normal switching operation.

LEBT High Voltage Pulse Generator Failure Analysis

The high voltage pulse generators have experienced high failure rates since commissioning in 2006 with over 180 failures after 30,000 arc events since recording started in 2007.

Normally, a segment of the second lens arcs to ground, which is followed by intersegment arcs. Improvements to the LEBT structure reduced the number of arc events from approximately 8000 to 1000 per ~20 week long accelerator run cycle. The initial high voltage pulse generator failure count was 80 failures per run cycle. Failures of pulse generators only occurred when accompanied by an arc. Figure 5 is a chart of the LEBT high voltage pulse generator failures and arc event counts per run cycle. The rise in 2009 was likely caused by the aggressive increase in duty factor and beam current.

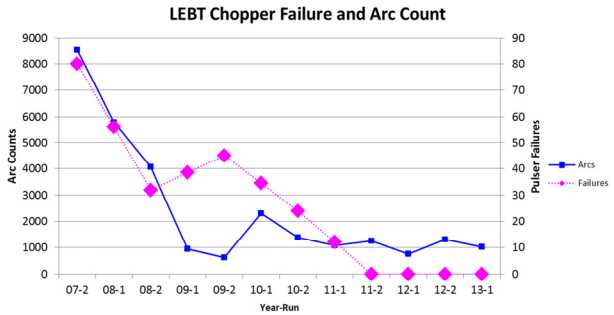

Figure 5: LEBT high voltage pulse generator MOSFET failures and arc events verses run cycle.

SNS has only six of these custom pulse generators in stock and four are used during operations. The two spares were enough to keep SNS running but repeated repairs of the MOSFETS and supporting components has irreparably damaged the printed circuit boards. The replacement time for a failed pulse generator is, at best, 1 hour when the failure occurs during normal business hours and up to 4 hours if it occurs when personnel are not already on-site.

LEBT Chopper Improvements

Multiple improvements to the high voltage pulse generators were tried up to 2011: the existing MOSFET snubber circuits were improved, transorbs on the output node and MOVs in the mixer box were added, and the series resistance was increased to limit the current. All of these resulted in limited improvements as seen in the failure rate in Figure 5.

Changes made during the summer shutdown of 2011 essentially eliminated failures. There have been three failures since 2011. None of these were for high voltage MOSFET failures: a diode isolation board had underrated parts installed, a timing logic board had a bad 1/4W resistor and a control voltage power supply failed after a lightning strike near the facility.

Failure Mode Analysis

MOSFETs can fail by two principle methods: over voltage or over current (thermal overheating). Our HV MOSFETs usually failed as a short. This implies that over voltage or punch through of the wafer was occurring. If the device failed from over current, it would fail as an open circuit when the wire bonds from the leads of the drain or source or the bulk semiconductor fuse open. Over voltage can be caused by the amplitude of the coupled arc voltage exceeding the individual MOSFET's high voltage hold-off rating.

An oscilloscope was added to capture and store every arc event. After more than 300 arc events a pulse generator failed. The oscilloscope traces in Figure a are examples where all high voltage pulse generators survived and Figure b where one did not. There is no significant difference between an event that caused a failure and one that did not. The amplitude, frequency, and shape of the arc voltage appearing at the pulse generator were similar.

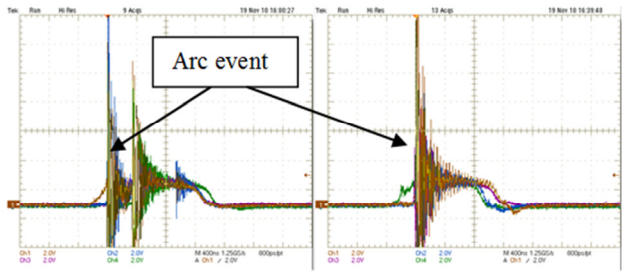

Figure 6: Examples of an arc event which did not result in a failure (Figure 6a) and one that did (Figure 6b).

The output voltage traces for all four pulse generators are shown overlaid to demonstrate the similar amplitude, duration and shape of an arc event. A detailed analysis of the energy transfer during an arc event is given in [5] and summarized here. Figure is a simplified schematic for analysis of the arc event equivalent circuit.

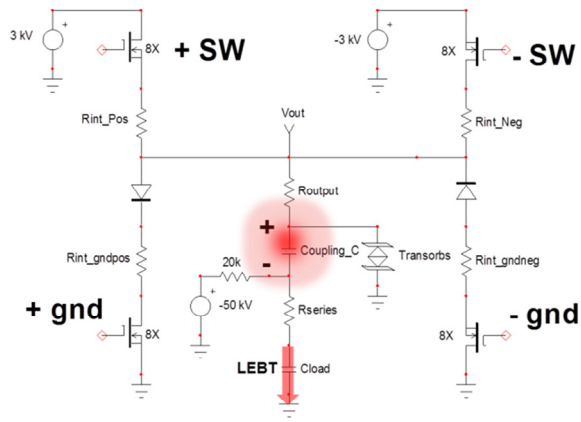

Figure 7: Simplified Schematic demonstrating an arc in the LEBT Structure and voltage reversal on the Coupling Capacitor.

The high voltage pulse generator 3kV power supplies do not supply enough voltage to exceed the 8kV rating of the stack and are therefore not a source of overvoltage failure. The 50 kV bias supply, however, could.

The coupling capacitor (Coupling_C) in the Mixer Box is charged to the dc bias voltage through the impedance of the pulse generator's high voltage circuit. LEBT structure arcing causes the load capacitance (Cload) to short, pulling the series resistor (Rseries) to ground. This causes the coupling capacitor's voltage to appear at the output of the pulser. The Transorbs and MOVs were sufficient to limit the voltage seen by the MOSFETs. Arc event simulations with a spark gap used in place of the LEBT structure showed that the voltage across the stack did not exceed the rating.

Gate Drive Latching

Another discovery was the realization that the fault could be in the gate drive circuit. The gate is turned on with a pulse through an isolation transformer and held on with a diode (D1) as shown in the schematic in Figure .

Copyright © 2013 CC-BY-3.0 and by the respective authors

This circuit is identical for all MOSFETs in each of the four legs of the ¾-H bridge. Another short pulse of negative polarity is sent to turn OFF the gate. The diode does not latch OFF the gate so the voltage decays back to zero after a few microseconds due the RC time constant of the gate capacitance and the series resistance.

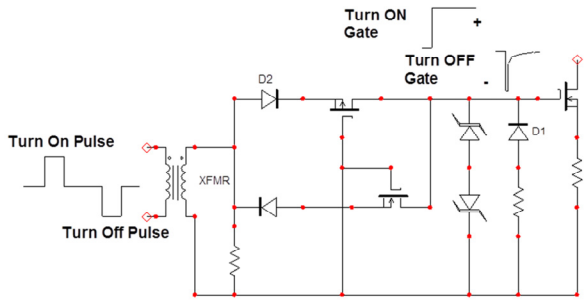

Figure 8: Gate drive schematic.

An arc event can cause a noise pulse in the low level drivers which results in a ringing pulse on the gate of each MOSFET. This places the switches in the high voltage legs at risk. One possibility is that a noise pulse turns ON all eight MOSFETs creating a shoot through condition where both the positive and negative MOSFETs are turned ON, resulting in high currents. This is not suspected as the cause of the failures because analysis of the failed devices determined the root cause to be due to over voltage not over current.

Another possibility is that the noise spike could latch ON only a few of the MOSFETs in a leg and leave OFF the others. This would force the remaining MOSFETs in the stack to hold off a higher voltage. During the normal operation each 1000 V rated MOSFET sees less than 750 V when the power supplies are charged to 3 kV. If two or more gates are latched ON the rest will have to hold off greater than the MOSFET's rating and fail. Transorbs were installed across the drain and source of the MOSFETs in the original design but the parasitic inductance of these devices likely made them ineffective snubbers for these fast transient events.

To simulate an arc event, a spark gap was used in place of the LEBT structure and triggered on command for multiple measurements. Measurements of the gate drive voltages during a simulated arc event showed many oscillations of the gate drive signal.

The oscillations could turn ON and OFF the device until they decayed lower than the gate threshold. If the last oscillation was above threshold for turn ON but lower than the turn OFF threshold the device would stay ON. In the summer of 2011 the diode was reversed in only the high voltage legs of the ¾-H bridge to latch OFF instead of ON. The decay rate was limited so as to exceed the maximum pulse width required for normal operation.

Rise/Fall Time Improvement

When the series resistance was increased during attempts to reduce failures, the rise and fall times on the LEBT structure increased to >100 ns, more than double the initial specification. By implementing the previously stated improvements, the series resistance of the circuit could be reduced, thereby decreasing the RC time constant. [6] The measured rise and fall times were reduced to less than 50 ns when measured on a simulated LEBT structure load as shown in Figure .

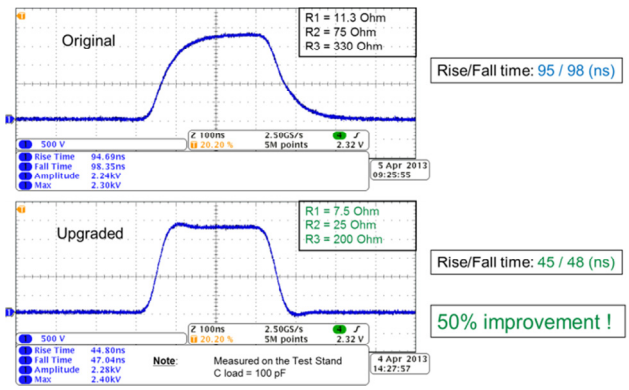

Figure 9: LEBT high voltage pulse generator rise/ fall time improvement chart.

The system with the reduced series resistance was installed during the summer 2013 maintenance period.

MEBT CHOPPER

The MEBT chopper system shown in Figure consists of two high voltage pulse generators of opposite polarities driving a transmission line structure into a 50 ohm load. The MEBT high voltage pulse generators were intended [7-10] to be used for both sharpening the edges of the pulse and to reduce the beam in the gap to minimize losses during extraction. The LEBT choppers were found to be more effective than anticipated so the MEBT choppers are primarily used for cleaning the gap.

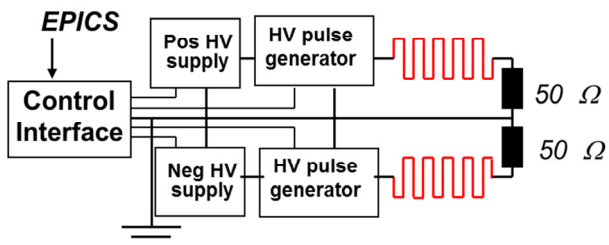

Figure 10: Block diagram of MEBT chopper system.

MEBT Structure

The MEBT rise and fall times were specified to be 10 ns. The pulse generators did achieve these from the start but the system was not impedance matched. The mechanical design of the structure [8] suffered failures due to water leaks, insufficient high voltage clearances and thermal performance issues.

In 2007 the structure was redesigned to eliminate these issues. [11] The new structure changed from the meander line design to a parallel plate transmission line type shown in Figure . The structure and HV pulse generators were impedance matched to reduce reflections of the fast HV edges from the pulse generators.

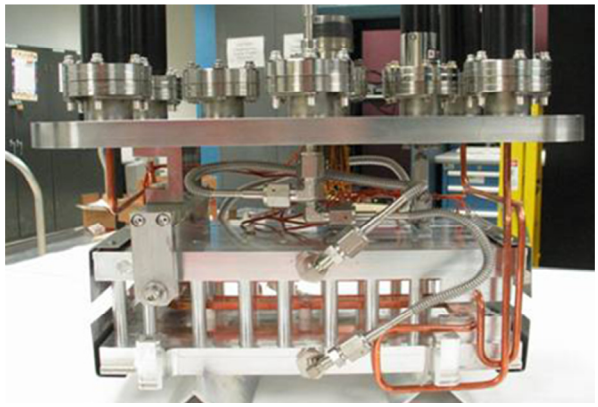

Figure 11: New MEBT structure design.

MEBT High Voltage Pulse Generators

The MEBT high voltage pulse generators are a two MOSFET series-switch design where the output resistive (50 ohm) load is either pulled to the high voltage rail or to ground. There is a positive pulse generator and a negative pulse generator that operate synchronously to assist the LEBT pulse generators in extraction gap formation.

Each high voltage pulse generator design uses five high-speed 1kV rated MOSFETs stacked in series for each leg to provide voltage hold off during normal operation. Improvements to the MEBT HV pulse generators include: matching the output impedance to 50 ohms by a custom cut copper bus (shown in Figure 12) upgrading the water cooled heat sinks and applying the LEBT gate drive latch technique described above.

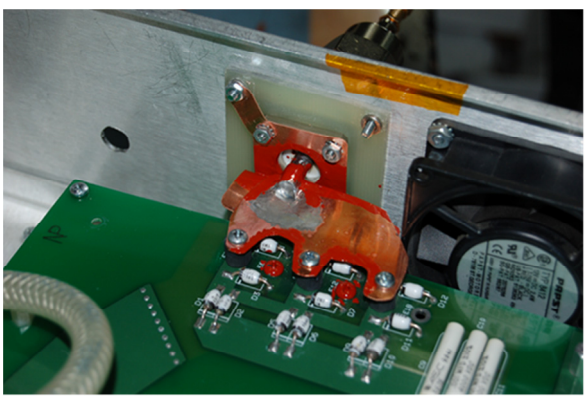

Figure 12: Matching 50 Ohm output impedance.

The pulse timing was changed so that the pulse generators were not ON during the pre-beam and beam OFF times to limit power dissipation in the MOSFETs.

SUMMARY

Continued development of and modifications made to the LEBT and MEBT fast chopper systems have greatly improved their reliability and therefore the availability of the SNS. The LEBT structure modifications and administrative controls to reduce arcing along with MOSFET triggering modifications have virtually eliminated high voltage pulse generator failures. This has permitted reducing the LEBT series resistance to values that meet the original rise and fall time specifications.

The improvements in the MEBT structure and impedance matching improved reliability of the structure. Additional development of the high voltage pulse generator cooling is still required.

ACKNOWLEDGMENT

The authors acknowledge the efforts of Sasha Aleksandrov, Doug Curry, Jeff Patterson and Charles Peters in the development and operation of the SNS fast choppers. In addition, we would like to thank the technicians Joshua Singleton and Jim Hicks for having the patience and skill to consistently repair and keep the choppers operational for years.
