We choose the population size of 120 in each generation for reasonably big sample size and relatively short time for generating the whole population during the experiment. As a result, it takes less than 3 minutes to generate one generation.

Figure 2 shows the results with 211 generations of GA optimization. To reduce the effect of stored beam current decay, we refilled SPEAR3 twice during this experiment

Copyright © 2013 CC-BY-3.0 and by the respective authors

as shown by the normalized stored beam current (scaled stored current shown as red curve). The optimization was paused during the refill and restarted by loading the dumped data after the fill. Overall, the algorithm behaved well. The normalized beam loss rates grow steadily for the first 150 generations, and then start to converge. In Figure 3, we compare the skew quadrupoles currents of the GA solution and the LOCO solution. The beam loss rates for the best solution found using GA are compared with the solution found using LOCO in Table 1. Average vertical beam size and emittance ratio of the ring with these two solutions are also calculated from the fitted model using LOCO.

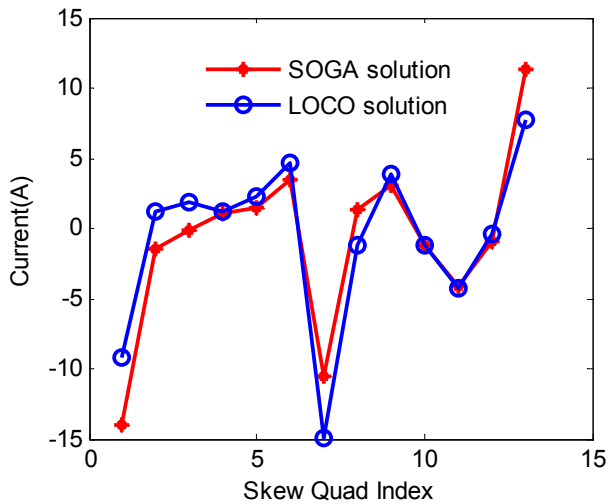

Figure 3: Comparison of the GA solutions and LOCO solution.

The normalized beam loss rate measured with the GA solution is increased by 17.9% from that with the LOCO solution. According to the scaling law in Eq. (1), this is translated to the reduction of vertical beam size by 15.18%. The calculated values using LOCO fitting show a 10.99% reduction of vertical beam size for the GA solution. The discrepancy comes from the accuracy of the fitting in LOCO, loss rates measurement, and the assumption of solely Touschek effect when deriving the scaling law in Eq. (1).

Table 1: Comparison of Solutions

	LOCO	GA
$\bar{\sigma}_y$ (μm)	7.9617	7.087
Emittance Ratio	0.0605%	0.0461%
Normalized Beam Loss rate	2.07	2.44

SUMMARY

Genetic algorithms are believed to be especially suitable for problems with high complexity where traditional gradient-based search methods normally fail to optimize. As the storage ring lattice is well designed, the coupling optimization of the ring tends to be a well behaved problem. This is evident from the final solution: out of 13 skew quadrupoles, only 3 are required to be set above 5A, while most of others are near zero. This fact weakens the advantage of using GA based optimization. Nevertheless, with machine based GA, we are able to find good solution regardless the time spent. Also, we have more confidence in its global validation. In addition, one should note that machine based GA may show advantage in speed over the traditional gradient based techniques when optimizing problems involved with more decision variables. As long as the corresponding hardware can be set roughly simultaneously, the time cost by machine based GA is independent of the number of decision variables. However, most traditional algorithms are scaled with the number of decision variables in high order. Thus, machine based GA can be more valuable for large machines.

The GA techniques we used are far from being refined. In future study, we will focus on improving speed and robustness. One possible approach is to create a hybrid algorithm that combines both GA and one of the traditional techniques for fast local search. When blending the two algorithms, it is challenging to maintain their original advantage, which requires thorough study.

ACKNOWLEDGMENT

We wish to acknowledge X. Huang and J. Corbett for valuable discussions and SPEAR3 operators for assisting in the experiment.

Abstract

The Advanced Light Source (ALS) at Berkeley Lab is one of the brightest sources for soft x-rays worldwide. A multiyear upgrade of the ALS is underway, which includes new and replacement x-ray beamlines, a replacement of many of the original insertion devices and many upgrades to the accelerator. The accelerator upgrade that affects the ALS performance most directly is the brightness upgrade, which reduced the horizontal emittance from 6.3 nm to 2.0 nm (2.5 nm effective), resulting in one of the lowest horizontal emittances of operating light sources. Magnets for this upgrade were installed in late 2012 and early 2013 followed by successful commissioning and user operation with 2.0 nm horizontal emittance.

INTRODUCTION

Over the years, the brightness of the ALS has been steadily improved, keeping the ALS the brightest third generation light source in the energy range below 1 keV (see Fig. 1). The upgrades included improvements in beam parameters (current and emittance), addition of new radiation producing devices (Superbends and advanced insertion devices) as well as stability improvements going hand-in-hand with the brightness improvements.

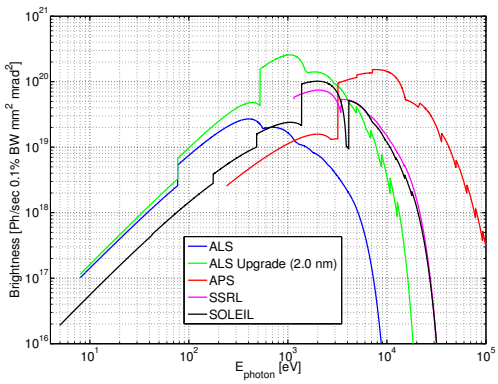

Figure 1: Comparison of the ALS brightness before and a after the low emittance upgrade with several other existing light sources.

The recent low emittance upgrade increased the brightness of the ALS by about a factor three in the bending magnet beamlines, and by about a factor two in the existing insertion device beamlines. The upgrade also opens the door to a potential further increase of the brightness by potentially implementing reduced horizontal beta functions in some straights.

BRIGHTNESS UPGRADE LATTICE

The ALS lattice has a triple bend achromat structure, with a fixed, large defocusing gradient in the bending magnets. Originally, there were only 2 families of sextupoles, with 4 sextupoles in each arc. An attractive set of possible upgrade lattices was found with higher straight section dispersion and an integer tune two units higher than the old lattice [1]. Those lattices have natural emittances of about 2 nm, compared to the more than 6 nm of the old lattice and horizontal beta functions of about 20 m in the straights.

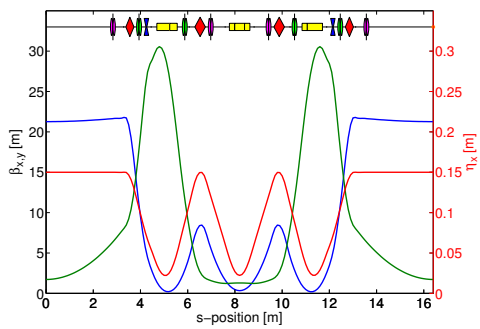

Figure 2: ALS upgrade lattice with 2.0 nm natural emittance at 1.9 GeV.

Later on, more systematic techniques [2, 3, 4] were used to find the global optimal lattices in terms of emittance or brightness. In those studies an additional family of low emittance lattices was found with very small horizontal beta function (order of 0.5 m) in the straights at much higher phase advance, which increase the brightness by better matching to the photon diffraction ellipse. Such low beta straights are still under investigation as an insertion for selected straights.

The high-beta lattices are within the range of the existing quadrupole magnets. However, the original sextupoles would not have been strong enough and the dynamic aperture would have been very poor. Both challenges were overcome with the addition of sextupoles in the straight sections.

MAGNET DESIGN AND PRODUCTION

The design [5] of the new sextupoles was performed in a collaboration by LBNL and SINAP and was finished in 2011. Because of space constraints, 3 different magnet designs are used. One of the families is optimized for small hysteresis and fast time response and has a closed yoke. It is used as the primary correctors in the fast orbit feedback. All new sextupoles also contain skew quadrupole coils (half of them have been initially connected to power supplies). This allows to improve the vertical beamsize stability in the ALS by providing aa local correction of the small skew quadrupole errors of the planar insertion devices. Some of the skew quadrupoles in three of the ALS arcs are also necessary to provide the vertical dispersion bump for the fs-slicing facility in the upgrade lattice.

Magnet production, carried out at SINAP, started with prototype magnets just after the design reviews in early 2011. The pole shapes were manufactured by wire edm on fully assembled magnet cores to achieve excellent field quality. Manufacturing was completed in summer 2012, on time to achieve the project installation milestones. During construction there was a detailed quality assurance program and all magnets were fully qualified by electrical, mechanical, and magnetic measurements. Precise fiducialization was carried out both mechanically and with the help of magnetic measurements. All magnets exceeded all important field quality requirements.

Installation

Thirteen of the new sextupoles were installed ahead of the main upgrade shutdown. This allowed to fully test their corrector functionality (time response, hysteresis) and to incorporate them into the slow and fast orbit feedback. The tests confirmed the excellent performance as corrector magnets and subsequently the remainder of the 48 magnets was installed during the 2013 spring shutdown (see Fig. 3). At the same time, all new power supplies and equipment protection systems were installed. Finally, the top-off interlock ranges were enlarged based on a complete new set of top-off safety calculations, and the interlocks were retested.

Figure 3: SHD magnet installed between the QF and QD quadrupoles.

Other Project Activities

In order to create sufficient space in all locations where new magnets were going to be installed, several modifications of vacuum chambers and stands were completed in 2012. Several candidate power supplies for the new magnets were tested and the control system interfaces for the selected power supplies were completed. Because of the new magnets and new strengths of existing interlocked magnets, parts of the safety analysis for top-off operation needed to be redone. The analysis was completed in time for the installation shutdown and no hardware changes were necessary. The new analysis allowed widening the interlock ranges on many of the top-off interlocked magnets allowing wide flexibility with the new lattices.

For the fs-slicing facility, the ALS has a complex lattice insertion that manipulates the local coupling and vertical dispersion to spatially separate the sliced beam. The new lattices required a completely new solution making use of the additional skew quadrupoles added to the new SHF magnets just adjacent to the insertion devices. The solution was found using genetic algorithms [6] and its lattice functions are shown in Fig. 4.

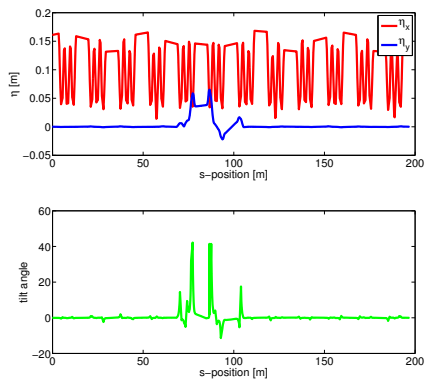

Figure 4: New fs-slicing optics that provides the spatial separation of the energy sliced beam in the new upgrade lattices.

Beyond the baseline of the project, which is aimed at delivering higher brightness, work is also going on to study low alpha modes of operation, which are enabled by the fact that the new sextupoles allow control of the second order momentum compaction factor.

COMMISSIONING

Simulations beforehand had predicted excellent dynamic and momentum aperture as well as lifetime for the optimized upgrade lattices [4, 7]. Fig. 5 shows an measurement of the momentum aperture of the upgrade lattice by recording the Touschek lifetime as a function of the RF acceptance. The measurement confirms that the upgrade lattice has a larger dynamic momentum aperture than the lattice used before the upgrade. In fact, during user operations the

Copyright © 2013 CC-BY-3.0 and by the respective authors

overall lifetime now is as high as before the upgrade, despite the large reduction in horizontal emittance which allowed to further reduce the vertical emittance as well (from almost 50 pm to below 30 pm).

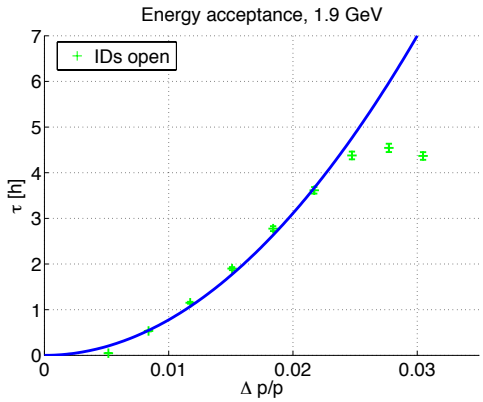

Figure 5: Lifetime versus RF amplitude scan confirming improved dynamic momentum aperture compared to the operation before the upgrade.

Migration to the new lattices was quick (few hours), after verifying all magnet polarities and magnet transfer functions in a beam based way in the old lattice. Further commissioning included optimizing the harmonic sextupole settings, updating the ID feed-forward (tune, beta beating, coupling) for the new lattice, implementing the new dispersion bump for fs-slicing facility and retesting the top-off interlocks with new ranges. The dispersion bump was refined after final lattice optimizations. The dynamic aperture and momentum aperture including the fs-slicing lattice insertion are similar to the bare lattice results and commissioning of the new solution went quickly. The new lattices also provide a larger, intrinsic horizontal separation of the sliced electron beam. We are currently in the process of evaluating how to make best use of this and expect that it will eventually allow a much better signal to noise ratio for the slicing facility.

Optimizing photon beamlines with new beam spots progressed quickly and user beamlines were able to resolve the brightness increase (see Fig. 6). The dynamic aperture and momentum aperture for the upgrade lattice were confirmed to be very close to the expected ones and the Touschek beam lifetime after the upgrade, despite the smaller horizontal and slightly smaller vertical emittance, as predicted is larger than before the upgrade, due to the larger dynamic momentum aperture.

SUMMARY

An upgrade project has been completed improving the brightness of the ALS by reducing the horizontal emittance from 6.3 to 2.0 nm. This resulted in a brightness increase by a factor of three for bend magnet beamlines and at least a factor of two for insertion device beamlines. The ALS now has one of the smallest horizontal emittance of all operating 3rd generation light sources. Initial user operations has been very successful. Most beamlines have been able to benefit significantly from the upgrade. No interruptions during the first 5 months of user operations have been related to the upgrade.

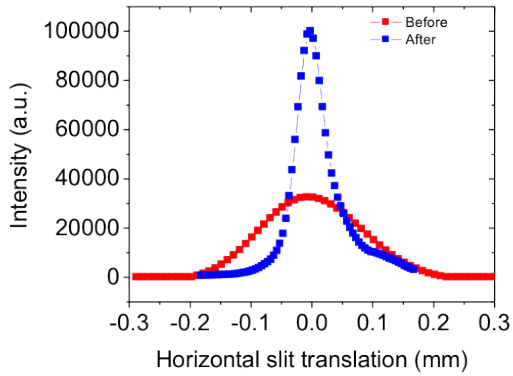

Figure 6: Comparison of the horizontal beam profile before and after the upgrade measured at one user beamline showing the factor of three improvement in brightness.

Building on the success of this upgrade, development work has now started towards a proposal for a more substantial upgrade of the ALS, that could provide diffraction limited performance for soft x-rays in the future. Such a ring, based on nine bend achromats appears feasible and could replace the current ring in the ALS tunnel [8].

ACKNOWLEDGEMENTS

The authors want to thank the ALS management, as well as the ALS user community for encouragement to keep developing the ALS further, as well as their support in securing funding for this upgrade project. We also would like to acknowledge our collaborators at SINAP, where the magnets were build. We are very grateful to D. Blough who helped us with Quality Assurance. We thank M. Kunz and N. Tamura at beamline 12.3.2 for the beam profile measurement.

STUDIES OF THE LOW ENERGY PROTON BEAM HALO EXPERIMENT

Hongping Jiang#,Shinian Fu, Jun Peng, Tao Huang, Fang Li, Peng Li, Huachang Liu, Cai Meng, Ming Meng, Zhencheng Mu, Huafu Ouyang, Peng Chen, Linyan Rong, Biao Sun, jianmin Tian, Biao Wang, Shengchang Wang, Wenqu Xin, Taoguang Xu, Lei Zeng, Fuxiang Zhao

Abstract

We report measurements of transverse beam phase-space properties and transverse beam halo in mismatched proton beams in 28-quadrupole FODO transport channel following the 3.5-MeV IHEP RFQ. Beam profiles in both transverse planes are measured using beam-profile diagnostic. The gradients of the first four quadrupoles can be independently adjusted to match and mismatch the RFQ output beam into beam-transport channel. We also compare the measured beam profile with the 3-D nonlinear macro-particle code IMPACT simulations in the beam halo experiment. Quadrupole scans were used to determinate the transverse properties of the RFQ output beam. The Gaussian distribution was chosen as the initial particle distribution, which is well fit with the measured beam-core profile. We match the beam using the least-squares fitting procedure that adjusted the first four matching quadrupoles to produce equal rms beam size in the last six wire scanners. Simulations had been fairly successful in reproducing the core of the measured matched beam profiles, but there are some differences in the mismatched beam profiles.

INTRODUCTION

The interest in understanding the formation of a halo distribution around an intense proton beam has increased in recent years with the development of new applications requiring such beam, because the beam halo is a major source of beam loss and radioactivation in high-power and high-current proton linacs. Beam mismatch have been identified as the major source of the halo formation [1], space-charge forces in mismatched beam are the main source of beam halo in high current proton beams. Having well matched beam conditions is a fundamental requirement for the operation of proton linacs. And the macroparticle simulation method is widely used in modern accelerator design and beam dynamics studies [2].

In this paper, we present measurements of transverse beam phase-space properties and comparisons of simulation results using the code IMPACT [3] with experimental measurements of the beam profiles in a high-current matched and mismatched proton beam. The beam profiles were measured by the wire-scanners. The transport line was installed after the radio frequency quadrupole (RFQ) accelerator designated for ADS study at the Institute of High Energy Physics (IHEP).

Jianghp@ihep.ac.cn

THE BEAM-CORE MATCHING EXPERIMENT TRANSPORT LINE

The 28-quadrupole beam transport line is installed at the end of the IHEP RFQ, which accelerates the proton beam to 3.54MeV and operates at the frequency of 352MHz. The purpose of this transport line is the experimental study of the beam halo formation and the comparison of the experimental data with the simulations. The block diagram of this transport lattice is shown in Fig. 1. In this line, the first four quadrupoles are independently adjustable to match the beam or to produce mismatches; the last 24 quadrupoles form an FODO lattice.

The transverse beam profiles are measured using beam profile scanners, which consist of wire scanners for measurement of the dense beam core and halo scrapers for measurement of the outer halo regions [4]. In the beam halo experiment, we use the wire scanner to measure the beam profiles, and the wire scanner can provide intensity measurement over a dynamic range of about 10^3. The philosophy of the scanner placement is the following: the first group of two scanners is placed after quadrupole 5 and 6, they separately measure the beam vertical and horizontal profiles which are used to characterize the proton beam output from the RFQ. To observe beam profiles of matched or mismatched case, another two groups of scanners with 6 scanners for each group are placed after quadrupole 17 to 28, covering about two mismatch oscillations.

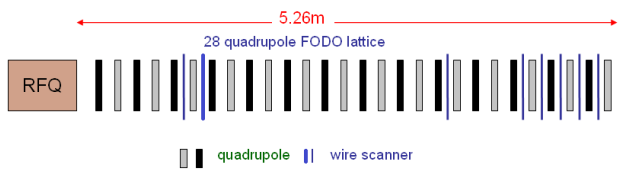

Figure 1: Block diagram of beam-core matching experiment transport line.

CHARACTERIZING THE PROTON BEAM OUTPUT FROM THE RFQ

In order to know the details of the beam, quadrupole scans and multi-wire scanner were used to characterize the transverse beam output from the IHEP RFQ [5]. In the scanning process, we kept the other three quadrupoles the same gradient 25.40T/m and obtained the Gaussian-like beam distributions with different rms radius compared with simulations shown in the Table 1 and Figure 2, the

Copyright © 2013 CC-BY-3.0 and by the respective authors

same with horizontal. Due to the lack of longitudinal measurements, the beam longitudinal Courant-Snyder parameters from the RFQ were predicted by the PARMTEQM [6] RFQ simulation code. Table 2 shows the results: the beam Courant-Snyder parameters and emittances. And the multi-wire scanner results will be show in the future, we can find the difference of parameters between the quadrupole-scan and the multi-wire scanners is about eight percent, which is acceptable in our experiments.

Table 1: The rms Vertical Radius Compared with Simulations under Different Focusing Strength

Q 1 (T/m)	Measurements	Simulation
-21.04	2.96±0.06 mm	2.94 mm
-23.57	2.46±0.05 mm	2.50 mm
-25.19	2.20±0.08 mm	2.27 mm
-26.90	2.10±0.06 mm	2.10 mm
-29.34	1.96±0.06 mm	1.98 mm

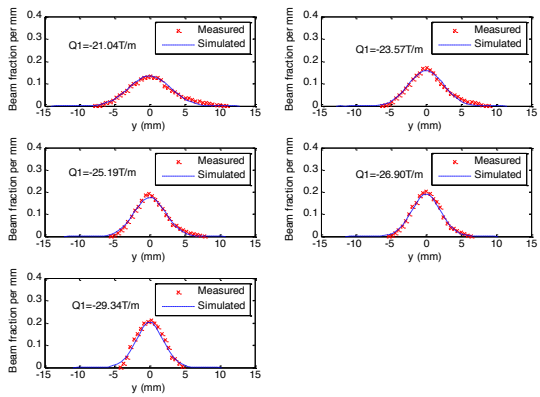

Figure 2: The beam measured vertical profiles compared with simulations under different focusing strength.

Table 2: Unnormalized Emittances and Initial Courant-Snyder Parameters from Quad Scan Analysis

	α	β (mm/mrad)	Emittance rms Unnormalized
Horizontal	3.443	0.42	3.66 mm-mrad
Vertical	-0.165	0.10	5.45 mm-mrad
Longitudinal	-1.564	3.16	0.32mm-mrad (normalized)

THE MATCHED BEAM

A least-squares-fitting procedure was used based on measurements of derivatives of rms sizes with respect to matching quadrupole gradients. Because the lack of vertical wire scanners at the end of transport line, beam was matched by adjusting the first four quadrupoles to produce equal rms sizes in horizontal position at the last 6 wire scanners. The measured results with different location equilibrium horizontal beam-core profiles were shown in Figure 3. As shown in the figure, the beam profiles with different locations have the similar distributions with an rms radius about 1.1mm.

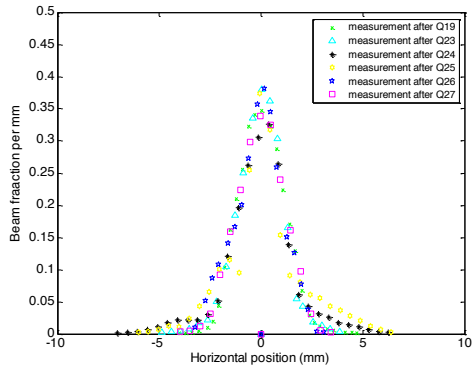

Figure 3: The equilibrium horizontal profiles measured at different locations.

Using the Gaussian distribution with a 24.7-mA beam current as the input distribution, we simulated the beam transported through the beam-core matching experiment. We have used 2×10^8 macroparticles per bunch with a computation grid of 64×64×128. The rms beam size and emittances at the centre of each drift space as a function of distance is given in Figure 4 compared with experimental data. From the figure we can see the rms radius predict an oscillation following the FODO periodic focusing channel and the wire scanner rms radius is perfectly fitting with the simulation, and the emittances are nearly constant. Besides the rms sizes, we also measured the projected density distribution, i.e., beam profiles in horizontal projections at seven locations along the transport channel. Figure 5 compares the simulations with the measured beam horizontal profiles. Simulations are fairly successful in reproducing the core of the measured matched-beam profiles (about 3 rms radius), but there are some discrepancies in the scope larger than 3-rms radius in some locations.

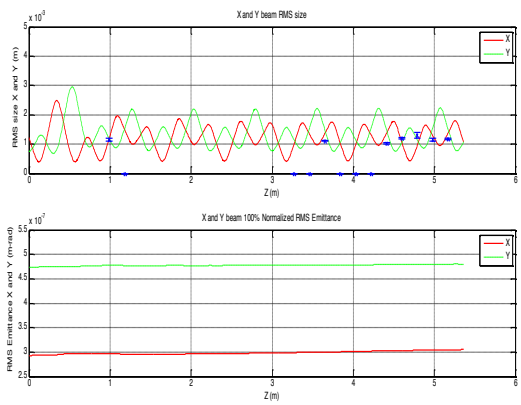

Figure 4: Results of beam rms radius and emittances as a function of distance for a matched beam.

Copyright © 2013 CC-BY-3.0 and by the respective authors

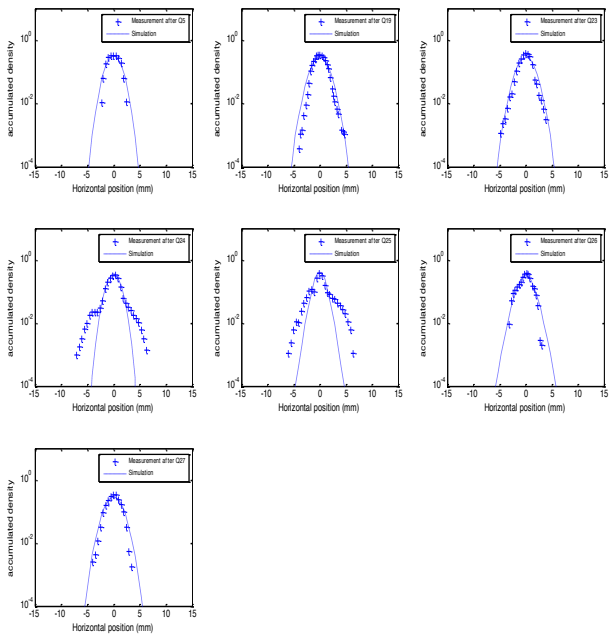

Figure 5: The horizontal profiles from measurements and simulations after Q5 Q19 Q23 Q24 Q25 Q26 Q27 for a 24.7 mA matched beam.

THE MISMATCHED BEAM

After we found the matched case, we adjusted the matching quadrupoles to obtain the mismatched beam. We measured the beam profiles and compared with simulations. The results were shown in Figure 6.

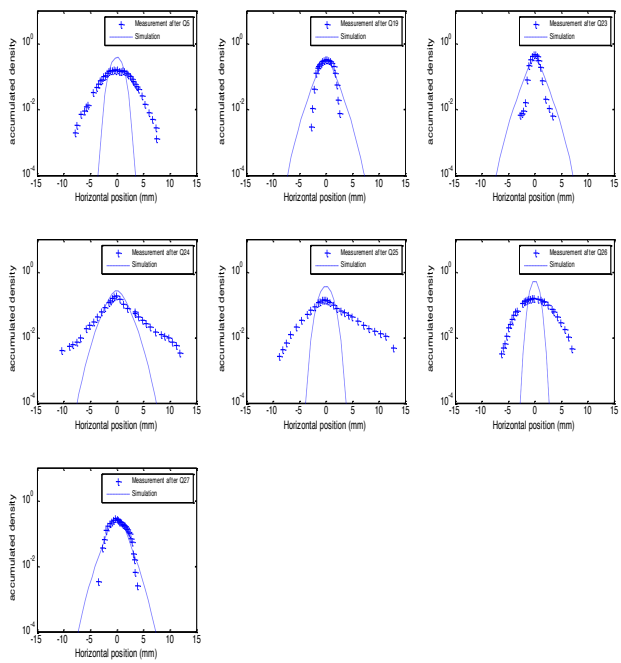

Figure 6: The horizontal profiles from measurements and simulations after Q5 Q19 Q23 Q24 Q25 Q26 Q27 for a 24.7 mA mismatched beam.

From the Figure 6 we can find only three locations beam profiles agree well with the simulations, the others have big differences. The simulation shows that the beam distribution is also a Gaussian distribution, but the measured beam profiles show the beam halo has formated. We need do further study to understand these questions.

CONCLUSIONS

We have used quadrupole scans and multi-wire scanner to determine the RFQ output beam Courant-Snyder parameters and emittances. In the simulation, we choose the Gaussian distribution with the obtained Courant-Snyder parameters as the initial beam-core distribution. We have compared the macroparticle simulations with the measurement data in a matched beam at 24.7mA. Simulations are fairly successful in reproducing the rms properties of the measured matched-beam, and the beam profiles in horizontal projections at the six locations shows that the beam is well matched, but for the mismatched case there are some discrepancies in the beam profiles in some locations. For explaining this phenomenon, we think there are more simulations with errors about the mismatched beam and beam offset to be analysed.

ACKNOWLEDGMENT

We thank Mr Ji Qiang for providing the IMPACT code and for help associated with its use.

LONGITUDINAL BEAM DYNAMICS AND LLRF REQUIREMENTS FOR THE PROJECT X PULSED LINAC*

A. Vivoli†, G. I. Cancelo, B. Chase, N. Solyak, P. Varghese, FNAL, Batavia, IL 60510, USA

Abstract

Project X is a high intensity proton facility being developed to support the intensity frontier physics program over the next two decades at Fermilab. The Reference Design [1] is based on a continuous wave (CW) superconducting (SC) 3 GeV linac providing up to 1 and 3 MW of beam power at 1 and 3 GeV respectively, while a superconducting pulsed linac provides acceleration of roughly 4.3% of the beam delivered from the CW linac to the 8 GeV injection energy of the existing Recycler/Main Injector complex. In this paper we present the results of simulations of longitudinal beam dynamics and Low Level RF (LLRF) control system in the pulsed linac, operated for long pulses in presence of errors and cavity detuning for different RF configurations and settings, and set the requirements for the LLRF necessary to fulfill the specifications of the design.

INTRODUCTION

The pulsed linac is the main part of the third stage of Project X and will accelerate pulses of 4.3 ms duration and 1 mA average current of the H^- beam coming from the 3 GeV linac (and downstream transport beamlines) up to 8 GeV at a repetition rate of 10 Hz. The constraints on the output beam parameters come from the acceptance of the downstream 8 GeV transport line and efficient injection in the Recycler/Main Injector ring. The lattice of the pulsed linac is studied with computer codes for accelerator optics and particle tracking simulating a single bunch. Once a configuration and set of parameters that provide acceptable output are found, multi-bunch simulations are performed to study the behavior of the system (accelerator and beam) during the length of the pulse and in multi-pulse mode. The focus of this study is on the RF system and longitudinal beam dynamics, neglecting beam optics and effects from elements of the beamline except for the accelerating cavities.

SINGLE BUNCH SIMULATIONS

Single bunch simulations are performed with the computer code TraceWin [2]. The current lattice of the pulsed linac and simulation results for the bunch envelopes are showed in Fig. 1. The linac is composed of 3 cryo strings of, respectively, 10, 9 and 9 ILC Type-IV cyomodules [3]. Each cryomodule contains 8 ILC 9-cell cavities and a SC quadrupole at the center.

Each cryo string is preceded and followed by a 2.5 m service box and between service boxes of adjacent cryo strings

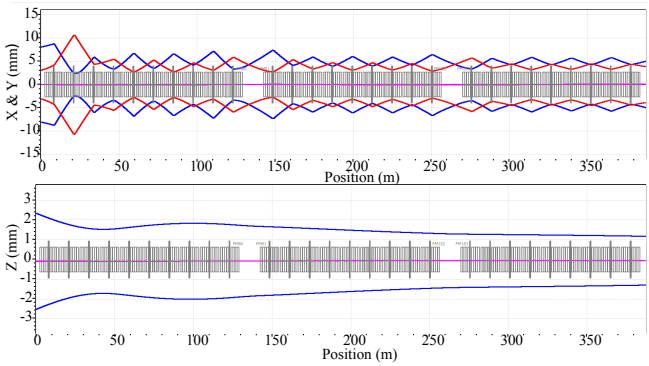

Figure 1: Beam envelopes (3 rms sigmas) in transverse (top) and longitudinal (bottom) coordinate spaces.

7.652 m room temperature areas are placed for beam collimation, diagnostics and maintenance operations. Table 1 shows relevant linac parameters and constraints to be fulfilled.

Table 1: Relevant Linac Parameters and Constraints

Beam Parameter	Initial value	Final value	Requirement
Kinetic Energy (MeV)	3000	8000	8000
Norm. hor. rms emit. (mm mrad)	0.516	0.516	≤ 0.6
Norm. vert. rms emit. (mm mrad)	0.281	0.311	≤ 0.6
Rms bunch length (ps)	2	1.3	≤ 100
Rms energy spread (MeV)	0.9	1.6	≤ 4

MULTI-BUNCH SIMULATIONS

Multi-bunch simulations are carried out employing a MATLAB based code written by the authors. The motivations for running multi-bunch simulations are various:

- To check that the configuration under study can fulfill consistently the specifications of the design during operation in presence of cavity detuning and errors in beam and RF components.
- To set the requirements for parameters of LLRF components to achieve an acceptable performance of the accelerator.

* Work supported by Fermi Research Alliance, LLC under Contract No. De-AC02-07CH11359 with the United States Department of Energy.
† vivoli@fnal.gov

- To study the impact of gradient spread of the cavities fed by a singe RF station.
- To evaluate the reach capabilities of different configurations of the RF power system, like the number of cryomodules fed by each RF station.

The necessity to run the linac with different gradients for cavities fed by the same RF station comes from the fact that not all the cavities may be able to reach their design gradient. In this case, if the difference in voltage between the cavities is not too big, it is possible to adjust the ratios of the power couplers to set the loaded Q_L of each cavity such that they all have the same filling time. If the spectrum of the Q_Ls employed is in the range $7x10^6$–$1.2x10^7$ then operation is possible in presence of different detuning levels. The 2 configurations of the RF power system we want to study are with one power station feeding 8 cavities (1 cryomodule) or one station for 16 cavities (2 cryomodules).

Detuning Model

Most of the cavities in the pulsed linac are supposed to work at 25 MV voltage and around 5° phase. For these values for matched cavities (no reflection) the power needed to drive them is around 25 kW. To take into account power distribution losses, residual detuning after compensation and control overhead a value of 50 kW per cavity has been decided as a requirement for the linac power consumption. Lorentz Force Detuning (LFD) and microphonics cause voltage amplitude and phase of a cavity to change during the pulse and requires more power to drive the cavity at the design values. Methods to compensate them have been developed, resulting in a reduction of LFD at the level of 30 Hz or less for the cavity parameters given above, while microphonics level is around 3 Hz rms [4, 5]. In our simulations we assume LFD compensation is applied and we only use a model for the residual detuning. Analyses at Fermilab led to determine the lowest mechanical resonant frequencies of the cavities to be around 150, 250 and 390 Hz. In our model we assign to each cavity i mechanical frequencies $\omega_{1,i}, \omega_{2,i}, \omega_{3,i}$ around the above values, allowing a 5% of difference from cavity to cavity. Then we assign them three phases $\phi_{1,i}, \phi_{2,i}, \phi_{3,i}$ and 3 amplitudes $\alpha_{1,i}, \alpha_{2,i}, \alpha_{3,i}$ such that $\alpha_{1,i} + \alpha_{2,i} + \alpha_{3,i}$ equals the maximum measured LFD level. We also assign a value $\alpha_{0,i}$ for microphonics compatible with measures. We can write the detuning for each cavity as:

$$\begin{aligned}\Delta f_i = \alpha_{0,i} &+ \alpha_{1,i}\sin(\omega_{1,i}t + \phi_{1,i}) \\ &+ \alpha_{2,i}\sin(\omega_{2,i}t + \phi_{2,i}) \\ &+ \alpha_{3,i}\sin(\omega_{3,i}t + \phi_{3,i})\end{aligned} \quad (1)$$

In our simulations we used 2 types of detuning model: in the first one, uncorrelated, the phases and amplitudes of each cavity are independent. In the second type, correlated, the cavities inside a cryomodule share the same phases and amplitudes. For this second model the peak power delivered by the RF station must be bigger, since all the cavities reach the maximum detuning at the same time, requiring more power from the station at about the same instant. Results of measurements conducted, show some degree of correlation between the detuning of the cavities.

LLRF Control

In order to keep the voltage of the cavities at the design values, continuous correction of the power delivered by the RF station is necessary. Furthermore, different cavities require different corrections, but we can only control their common power source, thus the control can only be applied to the vector sum of the voltages of the cavities. This operation is executed automatically by the LLRF system. A schematic layout of the LLRF of the pulsed linac is showed in Fig. 2.

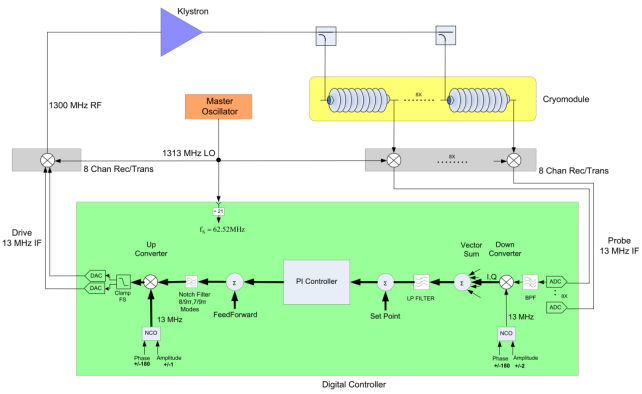

Figure 2: Schematic layout of the LLRF control of the pulsed linac.

More details of the system are available [6]. In our simulations it would be too time consuming to simulate the behavior of each element of the LLRF system, thus we simplify a little the scheme. Our simulated feedback works at a frequency of 1 MHz instead of 62.52 MHz. At each time step, the static and dynamic receiver errors are added to the voltages of the cavities (complex vector variables) and their vector sum is compared to the set point value. For the moment our system only has a proportional gain (no integral gain), so the difference just calculated is multiplied by the proportional gain and the result is summed to the feedforward value. We only simulate the fundamental mode of the cavity. The calculated power and phase are directly sent to the station (Klystron) with a delay of 1 time step (1 μs). The RF station delivers the power and phase requested with RF station errors added to them. Table 2 shows the LLRF parameters used in the simulations.

In addition to the above errors we also added beam intensity errors: 1 ps bunch time jitter (rms), 0.25 MeV bunch energy jitter (rms), 3% bunch-to-bunch intensity jitter (total) and 3% pulse-to-pulse intensity jitter (rms).

RESULTS

We considered two RF configurations with 8 or 16 cavities for RF station. In both cases we studied the dependence

Table 2: LLRF Parameters Used in the Simulations

LLRF Parameter	Value
Cavity detuning level (peak)	30 Hz
Receiver amplitude rms error (static/dynamic)	0.667% / 0.009%
Receiver phase rms error (static/dynamic)	0.667° / 0.005°
Klystron gain	1
Proportional gain	250
Loop delay	1 μs
Klystron amplitude rms error (static)	0.2%
Klystron phase rms error (static)	1°

of the results on the cavity gradient spread. In particular we calculated the rms energy spread of the particles at the end of the linac and the peak power per cavity required during the simulation. As stated above the requirements are $\leq$ 4 MeV rms energy spread and $\leq$ 50 kW per cavity peak power. The other constraints resulted largely fulfilled by any scenario. First we compared the two models of detuning we used (correlated and uncorrelated) and found that in any case the correlated one required more power from the stations than the uncorrelated one (up to 50% more at 70 Hz detuning level) and resulted in larger energy spread (up to 50% at 45 Hz detuning level). Keeping all the other parameters at their nominal values, the difference in the results for a gradient spread varying from 0 to 10% resulted negligible for both the configurations. Since we first want to give conservative constraints we are giving results for simulations with correlated detuning, which are more pessimistic. The configuration with 8 cavities per station required 32 kW per cavity peak power at 0 detuning, resulting in final 1.86 MeV beam rms energy spread. The power needed grew up to 50 kW and more when exceeding 70 Hz of peak detuning. The energy spread grew up to 2 MeV at this detuning. At the nominal 30 Hz the power consumption was about 35 kW. For the 16 cavities configuration, the power consumption was few percent less than the other configuration, reaching the 50 kW limit at around 72 Hz. The energy spread is a more stringent constraint, since it grew from 1.87 MeV at 0 detuning up to around 3 MeV at 45 Hz and exceeding 5 MeV at 50 Hz. The power consumption dependence from the detuning is reported in Fig. 3.

A set of simulations where carried out to study the impact of the LLRF parameters (Table 2). We varied one parameter up to 10 times the nominal value, leaving the others constant, to evaluate the effect. For the moment we only applied this analysis to the receiver and generator errors. Varying the receiver amplitude error up to 0.09% produced a growth of 4% in the peak power, while the energy spread remained unchanged. Receiver phase error produced a 14%

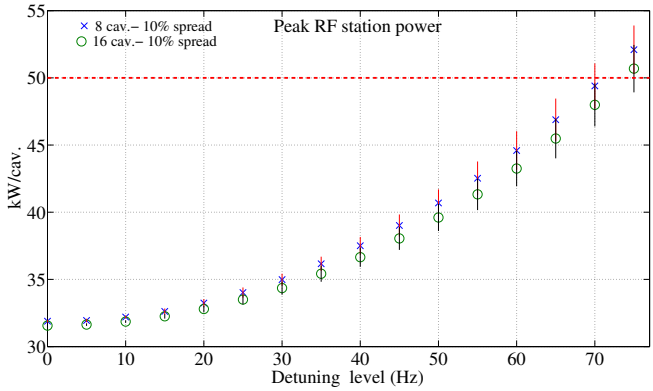

Figure 3: Peak power per cavity dependence on detuning for the 2 configurations studied.

increase in power and negligible in energy spread varying up to 0.5°. Generator amplitude error showed no impact up to 2% and its phase error produced 15% increase in energy spread and 2% peak power when increased to 10°.

CONCLUSION

In this paper we presented the ongoing study on Project X pulsed linac, showing some preliminary results of the multi-bunch simulations performed. Configurations with 8 and 16 cavities per station have been compared in presence of gradient spread and different level of detuning, showing similar performance with nominal parameters but more critical dependence of the 16 cavities configuration on the detuning level, concerning the final energy spread of the beam. Impact of some LLRF parameters have been preliminary studied showing particular importance of the phase errors. A more accurate and wider study of the parameters space is needed. Improvement of the code speed is desirable, giving the opportunity of more accurate simulations of the LLRF system.

MULTI-TURN INJECTION OF 50 MEV PROTONS INTO THE CERN PROTON SYNCHROTRON BOOSTER

V. Raginel, E. Benedetto, C. Carli, B. Mikulec, CERN, Geneva, Switzerland

Abstract

Since 1978, Linac2 produces beams of 50 MeV protons with a current around 160 mA, which are injected into the CERN Proton Synchrotron Booster (PSB) with conventional multi-turn injection using a horizontal septum. It is planned to replace Linac2 during a future long stop with a new H^- linac, Linac4, injecting at higher energy (160 MeV) and making use of the modern charge-exchange injection principle. Due to the age of Linac2 and to a delicate vacuum situation the risk of a serious Linac2 breakdown has to be considered. Therefore it is necessary to study if the PSB could produce beams useful for the LHC and other experiments injecting a Linac4 proton beam at 50 MeV with much lower average current compared to Linac2 and without the need for a long installation of the 160 MeV H^- injection hardware. Benchmarking of the PSB injection model with the existing injection system with Linac2 using the ORBIT code has been done for a LHC-type beam and then the injection model was used to estimate the brightness for LHC-type beams that could potentially be reached in one PSB ring with the injection of a Linac4 proton beam at 50 MeV.

INTRODUCTION

The Proton Synchrotron Booster located at CERN, Geneva, Switzerland, is currently boosting protons injected by Linac2 from 50 MeV to 1.4 GeV. It is the second accelerator of the LHC injector chain and consists of four superposed rings. Linac4 is a 160 MeV linac under construction aiming at boosting the performance of the CERN PSB with higher injection energy and replacing the present conventional multi-turn injection of 50 MeV protons with a septum by H^- charge exchange injection. General planning of the CERN complex foresees the connection Linac4 – PSB not before the end of the second LHC long run. In case of a serious breakdown of the presently used Linac2, which is ageing and showing weaknesses in terms of vacuum tightness, it is envisaged to inject 50 MeV proton beams with lower beam current and emittance from Linac4 as emergency scenario.

This work indicates the brightness that can be expected for a LHC beam (LHC-25ns) in the PSB after a multi-turn injection of 50 MeV protons from Linac4. The results are derived from simulations done with ORBIT. The reference parameters of the PSB injection with Linac2 are first used to test the model and then parameters of Linac4 are used as input of the simulation. An optimization of the injection process can be done to obtain an estimate of the highest reachable brightness for the LHC beam.

PSB MULTI-TURN INJECTION

During injection into the PSB, the beam is stacked in horizontal betatron phase-space using a closed orbit bump generated by four slow kickers to bring the stacked beam very close to the injection septum to minimize the transverse emittance of the resulting beam in the PSB. The incoming beam is deflected by the injection septum, which results in an injection with small position and angle errors. Subsequently the bump decreases and the beam moves to the reference closed orbit (see Fig. 1). The injection septum blade has a thickness of 1 mm and is 40 mm away from the closed central orbit.

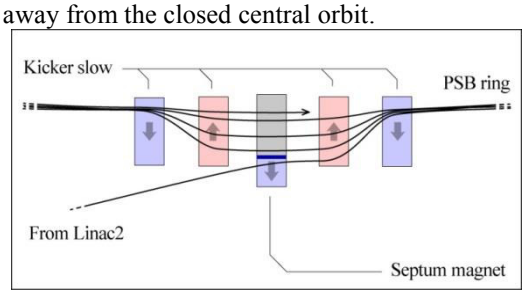

Figure 1: Multi-turn injection principle (after 4 turns).

During operation in order to produce all the required beam types, the following injection parameters can be optimized: the working point at injection, the injection timing and the horizontal and vertical positions and angles of the injected beam.

ORBIT CODE AND PSB MODEL

The ORBIT code (Objective Ring Beam Injection and Tracking) [1] was designed to track macro-particle coordinates through a set of accelerator elements and calculate space charge and other collective effects.

The model of the PSB lattice is composed of bending and quadrupole magnets imported with a special routine from MAD-8 [2] to ORBIT. The horizontal and vertical tune values are fixed in the MAD-8 model. The injection slow kickers are modelled in ORBIT with the ideal bump routine (linear decay of the bump). As ORBIT does not contain a septum module, a foil of thickness null as first element of the lattice and an aperture as last element of the lattice are used to simulate as realistically as possible the injection septum BI.SMH of the PSB [3]. The foil at the beginning of the lattice simulates the septum blade seen by the injected particles and the aperture at the end the septum blade seen by the circulating particles. The transverse space charge is modelled with the 2.5D FFT-PIC (Particle-In-Cell) modules without boundary condition(s). The FFT-PIC is a fast method to calculate transverse space charge, first by binning the

Copyright © 2013 CC-BY-3.0 and by the respective authors

macroparticles to a grid, then calculating the force distribution on the grid using a FFT method, and finally interpolating the force from the grid back to each macro-particle. Transverse space charge nodes are inserted after each transfer matrix included in the lattice file. The longitudinal space charge is modelled with one FFT node.

The 50 MeV proton beams from Linac2 and Linac4 are assumed to have a Gaussian distribution in transverse phase-space and a uniform distribution in longitudinal phase-space. At the injection point for Linac2 and Linac4, the horizontal beam size of the incoming beam is set to half of the PSB β_h [4], while the vertical beam size is matched to the PSB β_v and the waist positions $\beta'_h = \beta'_v$ are set to zero [5]. These parameters were optimized with simulations described in [4] and [5].

LINAC2 SIMULATIONS

The model has to be able to reproduce a LHC-25 beam with similar emittance and injection efficiency to that provided by the actual ring 3 of the PSB. The reference parameters of the PSB injection and of the Linac2 proton beam are listed in Table 1. The injection timing and the horizontal and vertical positions and angles of the injected beam are optimized to reach maximum intensity within the required emittance. The injection timing is defined by the delay between the moment when the injection kicker pulses at its maximum and the moment when the beam is injected.

Table 1: Reference Parameters of the Linac2 Beam and of the PSB Injection

Parameter	Symbol	Value
Linac2 normalized rms beam emittance	$\varepsilon^*_h = \varepsilon^*_v$	1.2 π mm mrad
Linac2 beam current		155 mA
Bump Collapse Time	TIKS	50 μs

In the real case for a LHC-25 beam, 2 turns are injected and the injection working point is Q_h=4.42 and Q_v=4.49. The normalized transverse rms emittances are $\varepsilon^*_h \approx 1.90$ π mm mrad and $\varepsilon^*_v \approx 1.75$ π mm mrad, respectively, and the injection efficiency is around 57% with an intensity of 1.85×10^{12} right after injection before small losses occur due to the capture process.

The simulations are carried out over 100 turns after the start of injection ending before the capture. The bump decay is completed after around 20 turns, with 100000 macroparticles injected per turn. The most optimized simulation shows an injection efficiency of 61%, with an intensity of 1.98×10^{12} protons and $\varepsilon^*_h \approx 1.88$ π mm mrad and $\varepsilon^*_v \approx 1.70$ π mm mrad. The simulations indicate an rms emittance blow-up of less than 4% during the first 10000 turns (~ 16 ms).

These results deduced from the PSB model match well the reality for the LHC-25 beam; however it has to be mentioned that there are still open questions for other beam types.

LINAC4 SIMULATIONS

The PSB model is then used to run simulations injecting a Linac4 50 MeV proton beam. The Linac4 50 MeV proton beam is expected to have a horizontal and vertical normalized rms emittance of 0.4 π mm mrad with a nominal current of 40 mA and a maximal average current of 50 mA. The current limit in Linac4 comes from the power available to compensate beam loading in the first tank of the DTL. The simulations are run for the nominal and for the maximal current and are optimized to produce a beam with the highest achievable intensity within the emittance of the LHC-25 beam currently produced by the PSB. The injection bump collapse time, the injection timing, the number of injected turns and the horizontal and vertical positions and angles of the injected beam are the parameters to tune. The injection working point is the same as for the Linac2 case. The simulations are carried out over 100 turns after injection with 50000 macroparticles injected per turn.

For both Linac4 currents, the simulations show optimum results with an injection of 9 turns and a bump collapse time of 90 μs (see Table 2). The injection efficiency is in the order of 45%, compared to 61% for Linac2.

Table 2: Optimum Results for the Simulation of a 50 MeV Proton Beam Injected from Linac4 into the PSB After 100 Turns

Injection Parameters and Resulting beam	L4 current 40 mA	L4 current 50 mA
Injection Timing [μs]	38.5	40
Initial horizontal offset [mm]	-43	-43
Initial vertical offset [mm]	1	1
Beam Intensity	1.68×10^{12}	2.19×10^{12}
Normalized rms emittance horizontal [π mm mrad]	1.87	1.81
Normalized rms emittance vertical [π mm mrad]	1.78	1.91

Simulations for the optimum cases indicate an emittance blow-up of around 2% for the 40 mA and of around 4% for the 50 mA cases during the first 10000 turns.

RESULTS

We introduce the brightness scaling as the ratio of the brightness obtained for the optimized case with Linac4 to the brightness obtained for the optimized case with Linac2.

Our simulations show that it is possible to reach 83% of today's LHC-25 beam brightness injecting a 40 mA Linac4 proton beam, while injecting a 50 mA Linac4 proton beam, 106% of today's LHC-25 beam brightness could be achieved. These results are slightly beyond expectation [6].

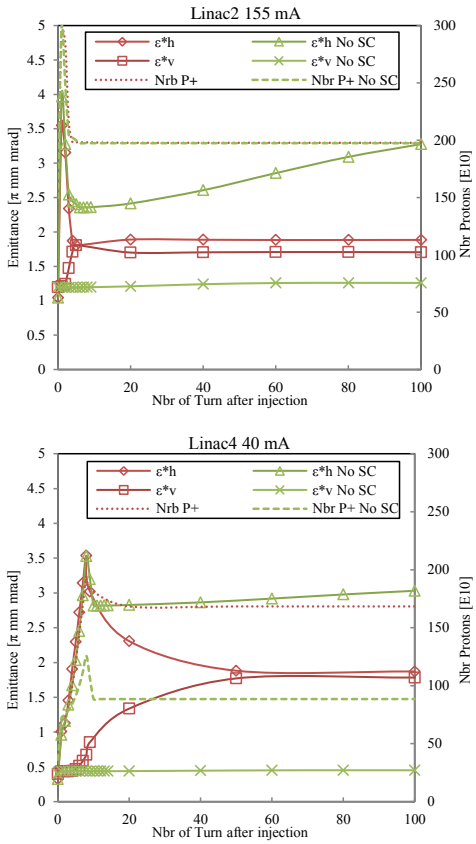

Figure 2: Horizontal and vertical normalized rms emittance (ε^*_h, ε^*_v) and number of protons as a function of number of turns after injection for optimized LHC-25 simulations with and without space charge with a Linac2 (top) and Linac4 40 mA beam(bottom).

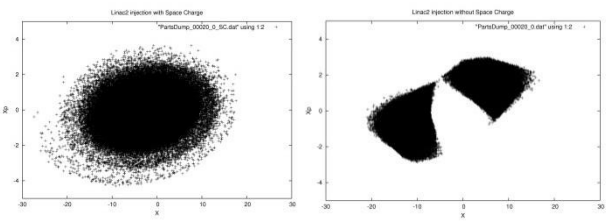

Figure 3: Horizontal phase-space profile of the resulting beam 20 turns after injection for 2 turns injected (Linac2) with space charge (left) and without space charge (right).

Figure 2 shows the results of the optimized simulations for Linac2 and Linac4 injection with and without space charge. In all the cases beam intensity and horizontal emittance increase during subsequent injection turn, i.e. 2 turns for Linac2 and 9 turns for Linac4. Once the injection is finished, beam intensity and horizontal emittance decrease due to horizontal losses at the septum blade. As the horizontal tune is 4.42, each beamlet interacts again with the blade ~2 turns after its injection inducing large horizontal losses. As the injection bump decays, the particles move away from the septum blade and the beam intensity stabilizes.

Space charge introduces a defocusing effect, which is dependent on the particle position inside the bunch and on the bunch distribution itself. It can be seen as an extra rotation in phase-space around the bunch centre and in the opposite direction than the betatron motion. If space charge is present, particles in the injected beamlets will have different tunes depending on their position inside the bunch. This mechanism explains for Linac2 and Linac4 cases with space charge the decrease of the horizontal emittance over few tens of turns after the end of injection, as the mixing of the beamlets and smoothing of the distribution is made possible by space charge. For the cases without space charge, the beamlets do not mix (see Fig. 3 right) and the horizontal emittance increases due to filamentation after injection until it reaches equilibrium (after a few 100 turns). For the Linac4 case the highest resulting beam intensity is reached for the space charge case. As explained before, with space charge the rotation of the particles with the strongest detuning close to the centre of the bunch will be slowed down and eventually they will not interact with the septum because, when they would be in the critical position, the painting bump would have already fallen enough to carry them away from the septum blade. The space charge mechanism is therefore helping in reducing the amount of losses with Linac4 and in producing beam with smaller horizontal emittance in case of Linac2.

CONCLUSION

The model of the PSB gives coherent results for the production of a LHC-25 beam with the present multi-turn injection of a Linac2 50 MeV proton beam. Comparing simulation results of the multi-turn injection with a Linac2 beam and with a Linac4 50 MeV proton beam with nominal average current, i.e. 40 mA, indicates that only 83% of today's brightness of the LHC-25 beams could be reached in the PSB. However assuming 50 mA for the average current of the Linac4 proton beam, i.e. its maximum deliverable current due to klystron power limitations, today's brightness for the LHC-25 type beams could be reached in the PSB. In conclusion Linac4 with a 50 MeV proton beam with 50 mA beam current could be used as backup solution in case of major failure of Linac2, at least to provide usable production beams for the LHC.

nuSTORM: NEUTRINOS FROM STORED MUONS *

Alan D. Bross, Fermi National Accelerator Laboratory, Batavia, IL 60510, USA
for the nuSTORM Collaboration

Abstract

Neutrino beams produced from the decay of muons in a racetrack-like decay ring provide a powerful way to study short-baseline neutrino oscillation and neutrino interaction physics. In this paper, I describe the facility, nuSTORM, and show how the unique neutrino beam at the facility will enable experiments of unprecedented precision to be carried out. I will present sensitivity plots that indicated that this approach can provide 10 σ confirmation or rejection of the LSND/MinBooNE results and can be used to perform neutrino interaction measurements of unprecedented precision. The unique ν beam available at the nuSTORM facility has the potential to be transformational in our approach to ν interaction physics, offering a "ν light source" to physicists from a number of disciplines.

INTRODUCTION

The nuSTORM facility has been designed to deliver beams of $\overset{(-)}{\nu}_e$ and $\overset{(-)}{\nu}_\mu$ from the decay of a stored $\mu^{\pm}$ beam with a central momentum of 3.8 GeV/c and a momentum acceptance of 10% [1]. The facility is unique in that it will:

- Allow searches for sterile neutrinos of exquisite sensitivity to be carried out; and
- Serve future long- and short-baseline neutrino-oscillation programs by providing definitive measurements of $\overset{(-)}{\nu}_e N$ and $\overset{(-)}{\nu}_\mu N$ scattering cross sections with percent-level precision;
- Constitute the crucial first step in the development of muon accelerators as a powerful new technique for particle physics.

The nuSTORM facility represents the simplest implementation of the Neutrino Factory concept [2]. In our case, 120 GeV/c protons are used to produce pions off a conventional solid target. The pions are collected with a magnetic horn and quadrupole magnets and are then transported to, and injected into, a storage ring. The pions that decay in the first straight of the ring can yield muons that are captured in the ring. The circulating muons then subsequently decay into electrons and neutrinos. We are using a storage ring design that is optimized for 3.8 GeV/c muon central momentum. This momentum was selected to maximize the physics reach for both ν oscillation and the cross section physics. See Figure 1 for a schematic of the facility.

Muon decay yields a neutrino beam of precisely known flavor content and energy. In addition, if the circulating muon flux in the ring is measured accurately (with beam-current transformers, for example), then the neutrino beam flux is also accurately known. Near and far detectors are placed along the line of one of the straight sections of the racetrack decay ring. Purpose-specific near detectors can be located in the near hall and will measure neutrino-nucleon cross sections and can provide the first precision measurements of ν_e and $\bar{\nu}_e$ cross sections. A far detector at $\simeq$ 2000 m would study neutrino oscillation physics and would be capable of performing searches in both appearance and disappearance channels. The experiment will take advantage of the "golden channel" of oscillation appearance $\nu_e \rightarrow \nu_\mu$ (μ^+ stored in the ring), where the resulting final state has a muon of the wrong-sign from interactions of the $\bar{\nu}_\mu$ in the beam. This detector would need to be magnetized for the wrong-sign muon appearance channel, as is the case for the current baseline Neutrino Factory detector [3]. A number of possibilities for the far detector exist. However, a magnetized iron detector similar to that used in MINOS is seen to be the most straight forward and cost effective approach.

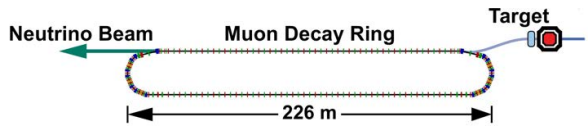

Figure 1: Schematic of the facility.

NUSTORM FACILITY OVERVIEW

The components of nuSTORM are anticipated to consist of six (6) functional areas consisting of the Primary Beamline, Target Station, Transport Line, Muon Decay Ring, Near and Far Detector Halls [4].

These areas will be located south of the existing Main Injector accelerator and west of Kautz Road on the Fermilab site. In general terms, a proton beam will be extracted from the Main Injector at the existing MI-40 absorber, directed east towards a new below grade target station, pion transport line and muon decay ring. The neutrino beam will be directed towards a Near Detector Hall located 20 m East of the muon decay ring and towards the Far Detector located approximately 1900 m away in the existing D0 Assembly Building (DAB). Figure 2 shows the nuSTORM facility components as they will be sited near the Fermilab Main Injector. The nuSTORM facility will follow, wherever possible (primary proton beam line, target, horn, etc.), NuMI [5] designs. Our plan is to extract one "booster batch" at

* Work supported by DOE under contract DE-AC02-07CH11359

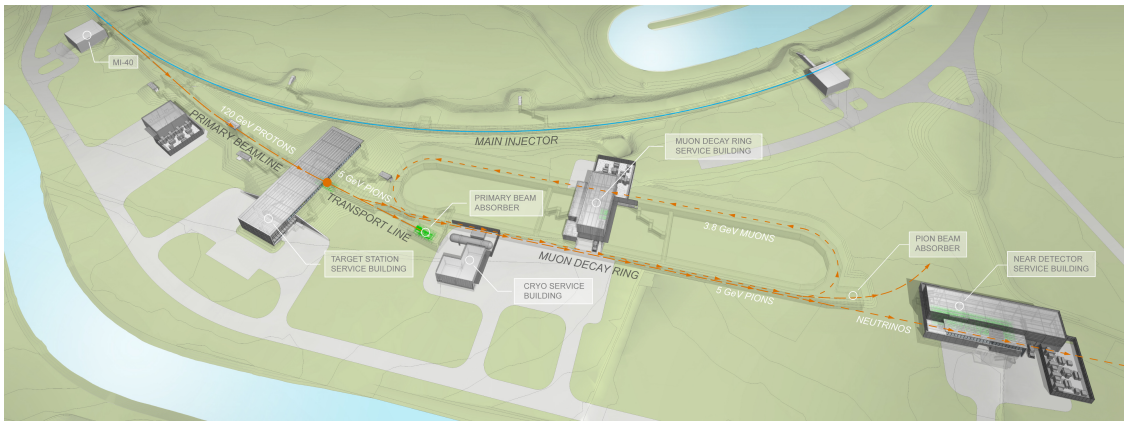

Figure 2: nuSTORM facility components.

120 GeV from the Main Injector ($\simeq 8 \times 10^{12}$ protons) and place this beam on a carbon target. Forward pions are focused by a horn into a capture and transport channel. Pions are then "stochastically" injected into the Decay Ring (see [6]). Pion decays within the first straight of the Decay Ring can yield a muon that is stored in the ring. Muon decay within the straight sections will produce ν beams of known flux and flavor via: $\mu^+ \rightarrow e^+ + \bar{\nu}_\mu + \nu_e$ or $\mu^- \rightarrow e^- + \nu_\mu + \bar{\nu}_e$. For the implementation which is described here, we chose a 3.8 GeV/c storage ring to obtain the desired spectrum of $\simeq 2$ GeV neutrinos. This means that we capture pions at a momentum of approximately 5 GeV/c.

FACILITY DETAILS

As mentioned above, the primary proton beam line and target station (and its components, i.e., target and horn) for nuSTORM follow the NuMI designs. From the downstream end of the horn, however, the nuSTORM beam system is longer similar to a conventional neutrino beam. From the downstream end of the horn, we continue the pion transport with several radiation-hard (MgO insulated) quadrupoles. Although conventional from a magnetic field point of view, the first two to four quads need special and careful treatment in their design in order to maximize their lifetime in this high-radiation environment. The pion beam is brought out of the Target Station and transported to the injection point of the Decay Ring, which we have called the "Beam Combination Section" or BCS. Figure 3 shows the pion transport line and the beginning of the Decay Ring FODO straight section. The Decay Ring straight-section FODO cells were designed to have betatron functions β_x, β_y (the Twiss parameters) optimized for beam acceptance and neutrino beam production (small divergence relative to the muon opening angle $(1/\gamma)$ from $\pi \rightarrow \mu$ decay. Large betatron functions increase the beam size leading to aperture losses, while smaller betatron functions increase the divergence of the muon beam. Balancing these criteria, we have chosen FODO cells with $\beta_{\max} \sim 30.2$ m, and $\beta_{\min} \sim 23.3$ m for the 3.8 GeV/c muons, which for the 5.0 GeV/c pions, implies ~ 38.5 m and ~ 31.6 m for the pion's $\beta_{\max}$ and $\beta_{\min}$, respectively.

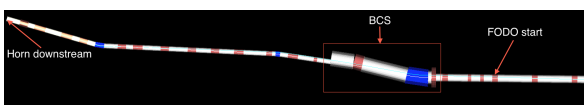

Figure 3: The G4beamline drawing from horn downstream to the FODO cells. Red: quadrupole, Blue: dipole, White: drift.

A large dispersion, D_x, is required at the injection point, in order to achieve π and μ beam separation. The BCS readily reaches this goal. A schematic drawing of the injection scenario is shown in Figure 4. The pure sector

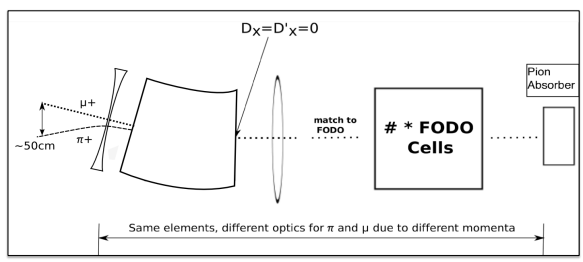

Figure 4: The schematic drawing of the injection scenario.

dipole for muons in the BCS has an exit angle for pions that is non-perpendicular to the edge, and the pure defocusing quadrupole in the BCS for muons is a combined-function dipole for the pions, with both entrance and exit angles non-perpendicular to the edges. The BCS will be followed by a short matching section to the decay FODO cells (see Figure 3). The performance of the injection scenario can be gauged by determining the number of muons at the end of the decay straight using a G4beamline simulation. In this simulation, we were able to obtain 0.012 muons per POT (see Figure 5). These muons have a wide momentum range (beyond that which the ring can accept, 3.8 GeV/c $\pm$ 10%) and thus will only be partly accepted by the ring. The green region in Figure 5 shows the 3.8$\pm$10% GeV/c acceptance of the ring, and the red region shows

Copyright © 2013 CC-BY-3.0 and by the respective authors

the high momentum muons which will be extracted by the mirror BCS at the end of the injection straight (see below). Within the acceptance of the decay ring, we obtain approximately 0.008 muons per POT.

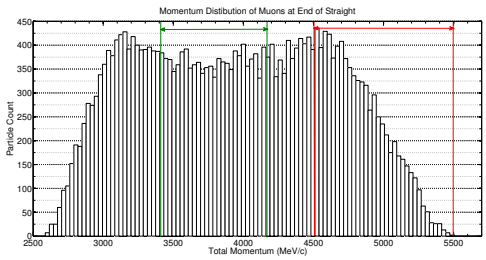

Figure 5: The muon momentum distribution at the end of decay straight.

Decay ring

We propose a compact racetrack ring design (480 m in circumference) based on large aperture, separate function magnets (dipoles and quadrupoles). The ring is configured with FODO cells combined with DBA (Double Bend Achromat) optics. The ring layout, including pion injection/extraction points, is illustrated in Figure 6 and the current ring design parameters are given in Table 1. With the 185 m length for the injection straight, $\sim 48\%$ of the pions decay before reaching the arc. Since the arcs are set for the central muon momentum of 3.8 GeV/c, the pions remaining at the end of the straight will not be transported by the arc, making it necessary to guide the remaining pion beam into an appropriate absorber. Another BCS, which is just a mirror reflection of the injection BCS, is placed at the end of the decay straight. It extracts the residual pions and muons which are in the 5±0.5 GeV/c momentum range. These extracted muons will enter the absorber along with pions in this same momentum band and can be used to produce an intense low-energy muon beam.

Figure 6: Racetrack ring layout. Pions are injected into the ring at the Beam Combination Section (BCS). Similarly, extraction of pions and muons at the end of the production straight is done using a mirror image of the BCS.

PERFORMANCE

With an exposure of 10^{21} 120 GeV protons on target, we obtain approximately 1.9 $\times 10^{18}$ useful μ decays. The appearance of ν_μ, via the channel $\nu_e \rightarrow \nu_\mu$, gives nuSTORM broad sensitivity to sterile neutrinos and directly tests the LSND/MiniBooNE anomaly [7]. A contour plot showing the sensitivity of the ν_μ appearance experiment to sterile neutrinos, utilizing a boosted-decision-tree (BDT) multivariate analysis, appears in Figure 7 for the exposure given above.

Table 1: Decay Ring Specifications

Parameter	Specification	Unit
Central momentum P_μ	3.8	GeV/c
Momentum acceptance	$\pm$ 10%	
Circumference	480	m
Straight length	185	m
Arc length	50	m
Arc cell	DBA	
Ring Tunes (ν_x, ν_y)	9.72, 7.87	
Number of dipoles	16	
Number of quadrupoles	128	
Number of sextupoles	12

KINETIC THEORY OF HALO FORMATION IN CHARGED PARTICLE BEAMS*

Wilson Simeoni Jr.† and Felipe B. Rizzato
IF-UFRGS, 91501-970, Porto Alegre, RS Brasil

Abstract

The proceeding proposes a derivation of the Vlasov-Poisson equation where the distribution function is splitted in a main part standing for the core and a fluctuating part standing for the halo, with which the kinetic theory of halo formations and core-halo dynamics are analysed.

INTRODUCTION

High-power hadron beams are more and more requested in multiple research fields like fusion material studies, neutrino physics, nuclear transmutation, accelerator-driven systems. Among the most recent projects, the IFMIF accelerators [1] break the record of high intensity, leading to a multi-MW beam power at relatively low energy. The concern for such accelerated beams is the predominance of the self-field energy upon the beam energy. In these conditions, the space charge effect is at its maximum, which triggers different non-linear mechanisms implying emittance growth, halo formation and sudden particle lost. The challenge is then to be able to control the total beam size, to maintain it well inside the beam pipe, and to avoid particle losses on its wall at the level of 10^{-6} in order to preserve hands-on maintenance. Careful studies of the dynamics of high intensity charged particles are thus mandatory to better understand and characterise the beam non-linear behaviour.

In the space-charge dominated regime, the space-charge effects result in emittance growth and halo formation, which contribute to beam losses. A change of focusing lattice or inadequate knowledge of proper injection conditions can cause a mismatch between the beam and the transport system. This mismatch may result in an oscillation of the beam envelope and generally excite a superposition of the envelope eigenmodes. These envelope modes possess additional free energy compared with the stationary distribution. Particles with appropriate oscillation frequencies can resonate with these envelope modes through the so called parametric $2:1$ resonance and attain large amplitude to form a halo [2]. These halo particles extract the energy from the envelope modes and convert free energy from mismatch into thermal energy, which causes beam emittance growth. The goal of this proceeding is proposes a derivation of the Vlasov-Poisson equation where the distribution function is splitted in a main part standing for the core and a fluctuating part standing for the halo, with which core-halo interactions will be analysed.

CORE-HALO EQUATIONS

The beam is assumed to propagate with a constant axial velocity $v_z\hat{\mathbf{e}}_z$, so that the axial coordinate $s = z = v_z t$ play the role of time. The external focusing field is given by $\mathbf{B} = B_0\hat{\mathbf{e}}_z$ and is used to compensate the repulsive Coulomb force between the beam particles. It is convenient to work in the Larmor frame [3] which rotates with respect to the laboratory frame with angular velocity $\Omega_L = qB_0/2\gamma_b mc$, where c is the speed of light in vacuo, and q, m, and $\gamma_b = 1/\sqrt{1-\beta_b^2}$ are the charge, mass and relativistic factor of the beam particles respectively.

A collisionless charged particle beam is usually described in a self-consistent mean-field approximation by the Vlasov-Poisson system :

$$\frac{df_b}{dt} = \frac{\partial f_b}{\partial t} + \mathbf{v}\cdot\frac{\partial f_b}{\partial \mathbf{r}} + \mathbf{F}\cdot\frac{\partial f_b}{\partial \mathbf{v}} = 0, \quad (1a)$$

$$\mathbf{F} = -\kappa_z\mathbf{r} - \nabla\phi, \quad (1b)$$

$$\nabla^2\phi = -4\pi q n_b(\mathbf{r}, s). \quad (1c)$$

where N_b is the number of particles per unit axial length, $\mathbf{r}$ is the position vector in the tranverse plane, $\mathbf{v} = \frac{d\mathbf{r}}{ds}$ is the transverse velocity, $n_b(\mathbf{r}, s) = q_b\int d\mathbf{v}^2 f_b(\mathbf{r}, \mathbf{v}, s)$ is the transverse beam density, $\kappa_{z_0} = qB_0/2\gamma_b\beta_b mc^2$ is the focusing field, and $K = 2q^2B_0^2/\gamma_b^3 v_z^2 m^2 c^2$ is the perveance, which is a measure of the beam space charge. In Eq. (1), ϕ is a scalar potential that incorporates both self-electric and self-magnetic fields, $\mathbf{E}^s$ and $\mathbf{B}^s$. We shall take zero of the scalar potential to be at r_w, the position of the conducting channel wall. The distribution function is normalized so that $\int d\mathbf{v}^2 d\mathbf{r}^2 f_b = 1$. In the Larmor frame, the system corresponds to a two dimensional non-neutral plasma of pseudo particles of mass $m = 1$ and charge $q = \sqrt{K/N_b}$ interacting by a repulsive logarithmic potential $\phi(\mathbf{r}) = -q^2\ln(r/r_w)$ confined in a parabolic potential well of $U(\mathbf{r}) = \kappa_z r^2/2$.

The Vlasov equation (1) express the conservation of the distribution function in phase space. We assume that the initial condition in phase space consists of a patch of uniform distribution function ($f_0 = \eta_0$) surrounded by vacuum ($f_0 = 0$). After some evolution, the patch mixes with vacuum and the coarse-grained (i.e. locally averaged) distribution function $\bar{f}$ takes values between 0 and η_0. The fact that the coarse-grained distribution function cannot exceed the maximum value η_0 of the initial condition is responsible for an effective "exclusion principle "leading to degeneracy effects. This degeneracy, resulting from the incompressibility of the Vlasov equation in phase space , was first recognized by Lynden-Bell [4] is his study of equilibrium.

Suppose that the *coarse-grained* [5] distribution function is the distribution f_c for *core* of the beam and the fluctua-

Copyright © 2013 CC-BY-3.0 and by the respective authors

tions of the distribution function is the distribution f_h for the beam *halo* [6, 7].

We introduce the decomposition $f_b = \bar{f}_b + \tilde{f}_b$ $[f_b = f_{b_c} + f_{b_h}]$ where $\bar{f}_b$ $[f_{b_c}]$ is the *coarse-grained* distribution function and $\tilde{f}_b$ $[f_{b_h}]$ is the fluctuations. We assume that $\bar{f}_b$ $[f_{b_c}]$ results from the statistical average so that $\overline{\bar{f}_b} = \bar{f}_b$. Taking the local average of the Vlasov equation we obtain a convection-diffusion equation:

$$\frac{\partial f_{b_c}}{\partial t} + \mathbf{v}\cdot\frac{\partial f_{b_c}}{\partial \mathbf{r}} + \mathbf{F_c}\cdot\frac{\partial f_{b_c}}{\partial \mathbf{v}} = -\frac{\partial \mathbf{J}}{\partial \mathbf{v}}, \quad (2a)$$

$$\mathbf{J} = \overline{\mathbf{F_h} f_{b_h}}, \quad (2b)$$

for the *core* distribution function, with a diffusion current $\mathbf{J} = \overline{\mathbf{F_h} f_{b_h}}$ related to the correlations of the fine-grained fluctuations [8] (to describe the perturbations inside the *core* and to describe the retroaction of the *halo* on the *core* [7]). Note that the diffusion occurs only in velocity space. There is no diffusion in position space since the velocity $\mathbf{v}$ is a pure coordinate and therefore does not fluctuate. The problem in hand consists in determining the diffusion current $\mathbf{J}$. Since the diffusion current $\mathbf{J} = \overline{\mathbf{F_h} f_{b_h}}$ is related to the fine-grained fluctuations of the distribution function, any systematic calculation starting from the Vlasov equation must necessarily in corporate the evolution equation of f_{b_h}. This equation is simply obtained by substracting equation (1a) from (2a) :

$$\frac{\partial f_{b_h}}{\partial t} + \mathbf{v}\cdot\frac{\partial f_{b_h}}{\partial \mathbf{r}} + \mathbf{F_c}\cdot\frac{\partial f_{b_h}}{\partial \mathbf{v}} = -\mathbf{F_h}\cdot\frac{\partial f_{b_c}}{\partial \mathbf{v}} - \mathbf{F_h}\cdot\frac{\partial f_{b_h}}{\partial \mathbf{v}} + \frac{\partial \overline{\mathbf{F_h} f_{b_h}}}{\partial \mathbf{v}} \quad (3a)$$

The essence of the quasi-linear theory is to assume that the fluctuations are weak [9] and neglect the non-linear terms in (3) altogether. In that case (2a) and (3) reduce to the coupled system:

$$\frac{\partial f_{b_c}}{\partial t} + \mathbf{v}\cdot\frac{\partial f_{b_c}}{\partial \mathbf{r}} + \mathbf{F_c}\cdot\frac{\partial f_{b_c}}{\partial \mathbf{v}} = -\frac{\partial \overline{\mathbf{F_h} f_{b_h}}}{\partial \mathbf{v}}, \quad (4a)$$

$$\frac{\partial f_{b_h}}{\partial t} + \mathbf{v}\cdot\frac{\partial f_{b_h}}{\partial \mathbf{r}} + \mathbf{F_c}\cdot\frac{\partial f_{b_h}}{\partial \mathbf{v}} = -\mathbf{F_h}\cdot\frac{\partial f_{b_c}}{\partial \mathbf{v}} \quad (4b)$$

Physically, these equations describe the coupling between the *core* (*coarse-grained* distribution f_{b_c}) and the *halo* (the small-scale fluctuations f_{b_h}).

To resolve the equations (4a) and (4b) we assume during beam evolution, the system tends to maximize its rate of entropy production while satisfying all the constraints imposed by the dynamics.

Relaxation Process of the Beam Core and Halo Formation

The evolution of the system equations (4a) e (4b) is extremely complicated. Although the dynamics is collisionless, the fluctuations of the electromagnetic potential are able to redistribute energy between beam particles and provide an effective relaxation mechanism on a very short timescale (violent relaxation [4]).

The system develops an intricate filamentation in phase space (*phase mixing*). In physical space, this *mixing* process is associated with the heavily damped oscillations of beam away from mechanical equilibrium. In a strict sense, the distribution function $f_b = f_{b_c} + f_{b_h}$ does not reach an equilibrium distribution but develops smaller and smaller filaments. However if we introduce a coarse-graining procedure and locally average over the filaments, the coarse-grained distribution function $\bar{f}_b$ is expected to reach a stationary state on a short timescale. It is usually advocated that this metaequilibrium state is a particular stationary solution of the Vlasov equation [10]. A statistical theory appropriate for this process of violent relaxation has been developed by Lynden-Bell [4]. Unfortunately, the statistical prediction of Lynden-Bell is limited by the problem of incomplete relaxation [11]. Beams tend towards the equilibrium state during violent relaxation but cannot attain it: the fluctuations of the potential die away before the relaxation process is complete [12].

Equation (4b) is first solved formally with the help of Green functions [13]. This gives rise to an iterative process. This iterative process is truncated to quadratic order and the result is substituted back into (4a). The diffusion current $\mathbf{J}$ does not have yet a closed form as it involves the equal-time correlation function. To close the system, we assume that the fluctuations of the distribution function in two different macrocells are decorrelated. The resulting equation is now self-consistent [5].

Our working hypothesis is that during the stage of violent relaxation, the particles of beam extract their energy from the rapid fluctuations of the eletromagnetic field. By this process, some particles may acquire very high energies and escape from the beam forming the *halo*.

Process of the Core-Halo Interactions

With the halo formation, the relaxation of system from equilibrium becomes incomplete [14]. It starts a process of interaction *core-halo* where the terms on the right side of the equations (4a) and (4b) dominate the dynamic. The field energy generated by the core interact with the halo and the fluctuations tend to become weaker. The core reaches a stationary state [15].

Relaxation processes of Beam Halo via thermal bath

As the core is quasi-equilibrium state and the fluctuations are weakening, the core will serve as a thermal bath to the halo. This allows us to we find a quasi-equilibrium solution for the system core-halo in a relaxed state [16, 17, 18].

CONCLUSIONS

The maximum transportable current density of an ion beam with high space-charge intensity propagating in a periodic focusing lattice is a problem of practical importance.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Accelerator applications such as Heavy Ion Fusion (*HIF*), High Energy Density Physics (*HEDP*), and transmutation of nuclear waste demand a large flux of particles on target. A limit to the maximum current density can result from a variety of factors: instability of low-order moments of the beam describing the centroid and envelope, instability of higher order collective modes internal to the beam, growth in statistical phase-space area (rms emittance growth) and excessive halo generation.

The most important examples of a nonstationary beam are a beam with an rms mismatch, a nonstationary distribution function (the distribution function is not a solution of the stationary Vlasov equation), and a misaligned beam. If the beam is initially nonstationary, it has a higher average energy per particle than the stationary beam. The energy difference represents the free energy that can be thermalized by nonlinear space charge forces, collisions, or instabilities. As a result of such a process, the emittance increases as the beam relaxes toward its final quasistationary state.

The deviation of beam distribution from the stationary state may be understood as the main cause of halo formation. Whenever a beam is not in its own stationary state, it naturally tries to approach closer to there, minimizing the nonlinear field energy. During this process, plasma oscillations are excited in the beam core, driving a portion of it into a halo. Inversely speaking, if a beam injected into a uniform channel is fine grainedly matched to it, there is no reason to expect the development of a halo unless the distribution itself is intrinsically unstable against perturbation. While several different factors have been considered as the possible sources of halo formation, it seems, after all, that the important point is how much a beam is deviated from the stationary state

In Linac the effective phase space volume occupied by a beam can grow rapidly if the beam intensity is sufficiently close to the space charge limit and if a source of instability is available. In principle there are three sources of instability: in a continuously focused beam it can be a nonmonotonic distribution function, like the K-V distribution; in two or three dimensional beams it can be an anisotropic distribution with different emittance and/or energy in two phase planes; in addition, periodic focusing can act as a source if an eigenoscillation is in resonance with the period of focusing.

In this proceeding a derivation of the Vlasov-Poisson equation where the distribution function is splitted in a main part standing for the core and a fluctuating part standing for the halo, with which the kinetic theory of halo formations and core-halo dynamics are analysed.

BEAM DYNAMICS STUDIES OF A 30 MeV STANDING WAVE ELECTRON LINAC *

R. Dash#, HBNI, Mumbai 400094, India
J. Mondal, Archana Sharma, K.C. Mittal, BARC, Mumbai 400085, India

Abstract

For a high quality beam delivery to the users in application areas like material science and neutron spectroscopy, it is very important for the linac to keep the growth of transverse emittance and self field effects a minimum in order to limit the radioactivity and the cost of the linac itself and increase the transmission efficiency. This paper presents the results of electron beam tracking for a 30 MeV standing wave electron linac. This is a general purpose facility for neutron generation and will produce 10^{12}-10^{13} n/sec for measurement of neutron cross-section of (n, gamma), (n, xn) and (n, f) reactions. The effects of input beam size, divergence, field gradient and space charge effect on the beam quality have been studied with ASTRA beam dynamics code. This beam dynamics study explores the optimized beam parameters and beam quality for the linac operation.

INTRODUCTION

In this paper we have studied the beam dynamics of a 30 MeV, 6 kW bi-periodic coupled cavity standing wave electron linac under development at Electron Beam Centre (EBC) Kharghar, Navi Mumbai, India. In order to predict the quality of electron beam [1], [2], [3] the electron-tracking algorithm ASTRA [4] has been used. Although there are a few self-consistent space-charge codes that can be used to study the emittance evolution, we choose the ASTRA model in order to provide a fast parametric study.

The accelerating module (Fig. 1) contain a 85 keV thermionic electron gun, an injector section and two accelerating sections of 22 cell and 23 cell respectively operating in π/2 mode at a frequency of 2856 MHz. The injection section consists of three bunching cells and a power feed cell. The length of each accelerating cell is 52 mm, whereas the buncher cells are 45, 48 and 50 mm respectively. The bore radius is 5mm for all the buncher cells and accelerating cell. The effective shunt impedance for the buncher cells is ~ 80 MΩ/m, while for the accelerating cells, it is ~ 90 MΩ /m.

MULTIPARTICLE SIMULATION WITH SPACE CHARGE

For the present work the longitudinal electric field components on the symmetry axis of the injector and accelerating sections have been computed using CST MWS [5]. The tracking code ASTRA does not need a geometrical description of the structures. For ASTRA code, the space-charge fields are calculated in the beam rest frame via Poisson's equation in free space and Lorentz's transformed back into the laboratory frame. ASTRA is based on Runge-Kutta integration of 4th order with fixed time step through the user defined external electric and magnetic fields, taking into account the space charge field of the particle cloud. A cylindrical grid, consisting of rings and slices, is set up over the bunch extension for the space charge calculations. The code automatically updates the mesh size as the simulation progresses. For all the simulations presented in the following, we have used 2.5 x 10^4 macro particles in uniform distribution. The initial energy of the particles injected in the guide is 85 keV. The particles are distributed quasi-randomly following the Hammersley sequence in such a way that statistical fluctuations are reduced and artificial correlations are avoided.

Effect of Space Charge on Beam Dynamics

Figure 2 gives the evolution of rms beam size for the nominal energy of 30 MeV. We have used a uniform distribution of particles having energy 85 ± 2 keV for the longitudinal direction with rms bunch length of 15.61 mm and bunch charge of 0.175 nC and Gaussian distribution in all transverse dimensions with rms beam sizes of 0.8 mm each. The results show that space charge gives rise to a transverse spread of the beam in the injection section and 1st cavity at low energies.

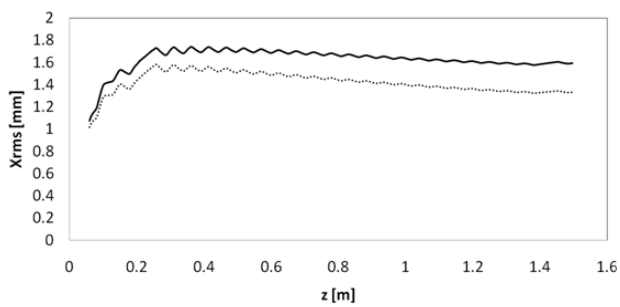

Figure 2: rms beam size without space charge (Dotted line) and with space charge (solid line).

PARAMETRIC STUDY OF INPUT BEAM

Emittance of a beam is a suitable parameter to define the qualities of a beam in terms of size and divergence of the beam. Beam emittance is given approximately by the product of spot size and divergence, and is proportional to the volume of the bounding region that each bunch occupies in its region of six-dimensional phase space. The normalized RMS emittance is defined by [6]

$$\epsilon_{n,rms} = \beta\gamma\sqrt{\langle u^2\rangle\langle (u')^2\rangle - \langle uu'\rangle^2} \quad (1)$$

All the simulations data presented in this section have been noted at z = 2.64 m, that is at the end of the linac.

Evolution of Emittance with Space Charge

The general increasing nature of transverse emittance in Fig. 3 shows what we would expect: the beam has more of a tendency to diverge due to higher magnitude of self fields and leads to overall transmission loss. This curve changes significantly as we vary other parameters such as initial spot size, field strengths, cavity phases, etc.

For example, if we decrease the input rms beam size from 0.8 mm to 0.1 mm, the space charge effects becomes quite prominent and leads to growth of curve at a faster rate as shown in Fig. 3.

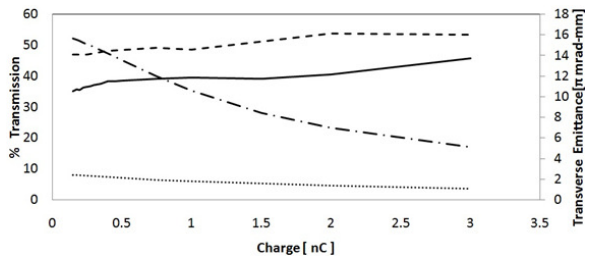

Figure 3: Effect of space charge on transverse emittance (solid line) and % transmission (Dash-dot-Dash) for rms beam size of 0.8mm .Transverse emittance (Dashed line) and % transmission (Dotted line) for rms beam size of 0.1 mm.

Evolution of Emittance with Beam Size

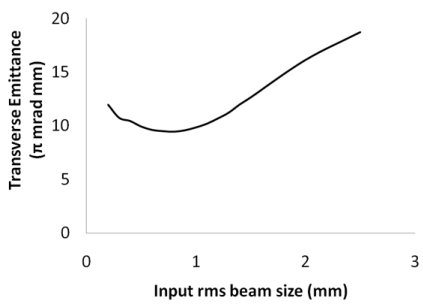

Figure 4: Evolution of transverse emittance with input beam size.

In rf cavities the radial component of the electric field grows quadratically with radius up to half of maximum radius of the rf cavity, whereas the longitudinal electric field increases linearly toward higher radii. As a result, the variation of the beam size (due to RF focussing) depends nonlinearly on the value of the beam size itself, therefore an increase of the emittance, proportional to the fourth power of the beam radius, is to be expected when a beam crosses a rf cavity .In order to numerically test this effect, we have tracked beams of charge 0.175 nC and of different transverse sizes through the rf cavity. Figure 4 describes the transverse emittance as a function of input rms beam size.

Evolution of Emittance with Divergence

In rf cavities the beam divergence strongly affects the beam behaviour. In order to study the emittance growth due to beam divergence we have taken an input beam of rms size 0.8 mm and varied the beam divergence as given in Table 1. We find that the transverse emittance shows a linear growth with increase in beam divergence, which leads to loss of electrons through the beam tube.

Table 1: Effect of Input Beam Divergence on Emittance

Input divergence	Transverse Emittance	Percentage transmission
2.1	7.71	55
6.2	8.53	54
9.4	9.67	53
12.5	10.65	52
15.6	11.48	50
18.7	12.52	47

Evolution of Emittance with Beam Aspect Ratio

We have studied the effect of the aspect ratio of the rms beam sizes in transverse direction and their effects on emittance growth. The summary of the results are given in Table 2. We observe that for any beam, the emittance growth in one transverse plane of the beam as compared to the other plane is within space-charge statistical error.

Table 2: Effect of Beam Aspect Ratio on Emittance

Beam Size x_{rms} (mm)	Beam Size y_{rms} (mm)	Emittance, ϵ_x (π mrad-mm)	Emittance, ϵ_y (π mrad-mm)
↑	1.5	11.25	12.67
0.82	2.0	9.24	17.83
↓	3.0	8.69	23.56
1.5	↑	13.65	10.33
2.0	0.82	18.18	8.91
3.0	↓	23.58	8.35

Copyright © 2013 CC-BY-3.0 and by the respective authors

Thus we treat each plane irrespective of the other plane, i.e. the two transverse planes behave independently of each other.

Effect of Variation of Field Gradient

We have studied the evolution of the beam subject to variation in field gradient. The results are given in Table 3 and from this we can estimate the changes in the output due to errors in the field gradient. An error of ± 4% in the field gradient changes the output energy gain ≈ ± 4% and error in gradient of ± 8% changes the output energy gain ≈ ± 8%.

Table 3: Effect of Field Gradient on Output Beam

Field Gradient (MV/m)	Output Energy (MeV)	Energy Spread (keV)	Transverse Emittance (π mrad-mm)
22	27.5	1230	11.78
23	28.8	908	11.21
24	30.0	720	10.65
25	31.2	648	10.03
26	32.4	678	9.58

Effect of Solenoid Focusing on Beam Quality

We have studied the quality of beam subjected to solenoid focusing. An air core solenoid of length 15 cm and 15000 ampere-turns is applied over the injection section as shown in the Fig. 1.The solenoid field reduce the beam diameter from ~ 8 mm to ~ 4.5 mm and improve the overall transmission ≈ 9%. Figure 5 describes the computed beam envelope over the entire length of the linac without solenoid and with solenoid.

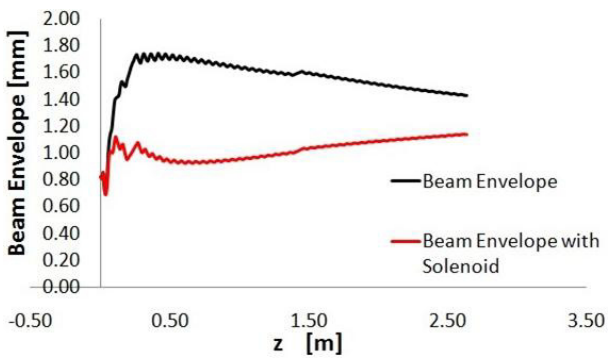

Figure 5: Computed beam envelope over the entire length of linac.

Transverse phase space of the electron beam at the end of the linac are shown in the Fig. 6 for without space charge effect and with space charge effect along with the focusing effect of the solenoid.

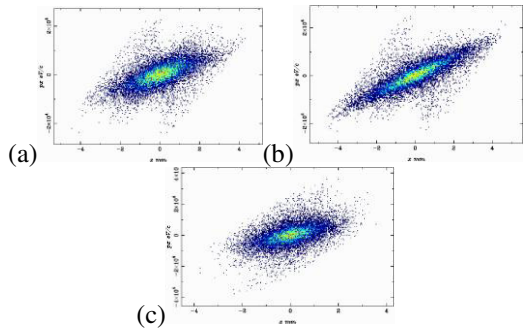

Figure 6: Transverse phase space of the electron beam at the end of the linac (a)without space charge, (b)with space charge, (c)with space charge and solenoid focusing.

CONCLUSION

We have investigated the effect of horizontal plane and vertical plane on beam dynamics and found that both the planes can be treated separately excluding space charge effect. A bunch charge of 0.175 nC is used to obtain a low emittance beam along the transverse and longitudinal direction with a reduced space charge effects. Also we have determined that a field gradient of 24 MV/m is to be maintained in order to have nominal energy gain of 30 MeV with minimum energy spread of 720 keV. We conclude from these beam dynamics studies that space charge effect plays a pivotal role in the injector section and 1st cavity of the 30 MeV linac. We have applied a solenoid of length 15 cm and 15000 ampere turns over the injector section to compensate the space charge effect. An energy spread of ~ 2.5% improves the quality of the output beam. With a beam size of ~ 4.5 mm in the bore of aperture diameter 10 mm, the beam loss on the cavity wall is minimized and the heavy irradiation of accelerator components is prevented.

PRE-SEPARATOR DESIGN OF THE IN-FLIGHT FRAGMENT SEPARATOR USING HIGH-POWER BEAM*

J.Y. Kim, C.C. Yun, D.G. Kim, E.H. Kim, M.J. Kim, M. Kim, J.W. Kim#,
Institute for Basic Science, Daejeon, Korea

Abstract

In-flight fragment separator of the rare isotope science project (RISP) is a main device to produce isotope beams for nuclear science research and applications. The separator is divided into pre and main stages. The pre-separator contains a thin target to produce the isotope beam and beam dump to remove unreacted primary beam. The maximum primary beam power is 400 kW. As a result, radiation level is very high in the target area and some of the magnets will utilize high-Tc superconductor coils operating at 20-50 K to efficiently remove the radiation heat deposited on the coil. A major function of the pre-separator is to remove the primary beam, which is complicated by different charge states produced when the primary beam passes through the target and wedge-shaped energy degrader. Some detailed calculations in beam optics and on the layout of the major separator components have been performed using GICOSY and LISE++ considering contaminant isotope beams due to nuclear reactions.

INTRODUCTION

In-flight fragment separator using the high power primary beam with large acceptance will allow researches for rare isotopes near the boundary of the nuclear chart. The next-generation in-flight separator is characterised by two major features: large acceptances of wanted isotope beam and two-stage scheme [1]. In-flight fragmentation and in-flight fission by using U beam are two major reactions to produce RI beam with an in-flight fragmentation method. It is expected new understanding on the nuclear physics can be obtained with this new device.

Currently, rare isotope science project (RISP) to construct a next-generation radio-active isotope (RI) beam facility is underway in Korea. Both Isotope separation on-line (ISOL) and the in-flight fragment separation methods will be utilized [2]. A super-conducting linear accelerator is the main driver that can accelerate a uranium beam to 200 MeV/u at a maximum beam power of 400 kW. The optical design of the in-flight separator has been performed by using GICOSY [3].

Figure 1 shows a schematic layout of the two-stage separator, in which superconducting magnets with large aperture are used to achieve large acceptance. The first stage serves to produce an RI beam of interest and to remove the unreacted primary and unwanted RI beams. The second stage aims to purify and to identify the isotope beam of interest. Major technical challenges are associated to the design and construction of the pre-separator, where the target and beam dump are located. The area including the target and beam dump is under the influence of high radiation.

In this paper, in-flight fragment separator of RISP is briefly introduced. Then optical properties and performance of the pre-separator are mainly discussed.

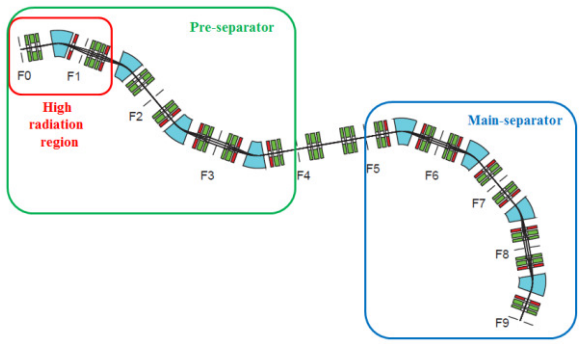

Figure 1: Schematic layout of the fragment separator.

DESIGN OF AN IN-FLIGHT SEPARATOR

The separator consists of pre and main separator, and a matching section in between is placed. The pre-separator from the production target to the F4 focus is composed of a four-bend achromatic spectrometer, consisting of four super-conducting dipole magnets with bending angle of 30 degree and seven superconducting quadrupole triplets.

As mentioned above, radiation level is very high in the target and beam dump area, so that radiation heating in superconducting coils is concerned. To remove the heat efficiently, one dipole and two quadrupole magnet triplets in the front end of the pre-separator will use high-Tc superconducting (HTS) coils. The rest of magnets in the pre-separator will use low-Tc superconducting (LTS) coils.

The main separator from the F5 focus to the F9 focus consists of eight superconducting quadrupole triplets and four dipole magnets. The F1, F3, F6 and F8 are momentum-dispersive focal planes, and the rest are achromatic planes. A wedge-shaped degrader can be used at each momentum dispersive focus to separate isotopes with the same q/A ratio by Z-dependent energy loss.

The goals of momentum acceptance and angular acceptance of the IF separator are ±5 % and ±50 mrad, respectively.

OPTICS OF THE PRE-SEPARATOR

The pre-separator contains four dipoles and seven quadrupole triplets, and its maximum magnetic rigidity is chosen to be 10 Tm considering the accelerator energy upgrade to 400 MeV/u for uranium beam in the future. The first-order optics of pre-separator is shown in Fig. 2. The production of RI beam using high power primary beam demands substantial radiation shielding compared to the facilities utilizing the maximum beam power of a few tens of kW. Radiation damage and shielding structure are main consideration in the design of pre-separator.

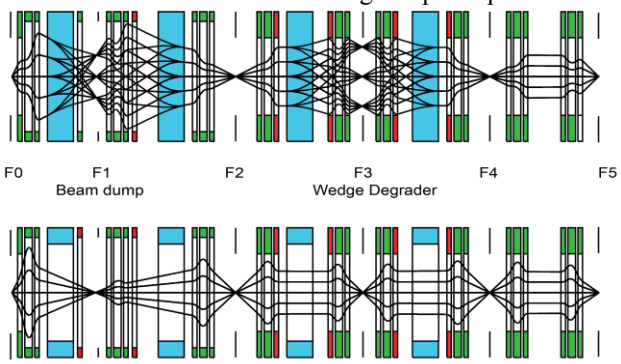

Figure 2: The first-order optics of pre-separator under consideration: The upper envelopes are in the horizontal plane, while the lower ones in the vertical plane.

To reduce radiation damage on magnetic components behind production target, the optics of pre-separator has a dispersive focus directly after the first dipole, where the dump is located. A merit of this solution is to limit an area of high level activation thereby minimizing the number of radiation resistant magnets.

For the space of the shielding walls, we leave long drift spaces of 2.6 m after second quadrupole triplets and 5.2 m between third and fourth triplets. A drift space of 1.95 m after the first dipole is to be occupied by the beam dump. Some parameters of the pre-separator are listed in table 1.

Table 1: Some Parameters of the Pre-Separator

Configuration	Four bends
Maximum magnetic rigidity	10 T/m
Momentum acceptance	±4.3%
Angular acceptance	±40 mrad (h)
	±50 mrad (v)
Momentum dispersion	+2.3 cm/% at F1
	-3.05 cm/% at F3

The large acceptance is needed to collect RI beam produced via ^{238}U fission. The angular and momentum spreads of RI beam produced by in-flight fission of uranium beam at 200 MeV/u can be over 100 mrad and 10%, respectively, when symmetric fission is assumed. The superconducting quadrupole triplets need to have large apertures and the dipole a large gap. The total length of pre-separator is currently about 57 m.

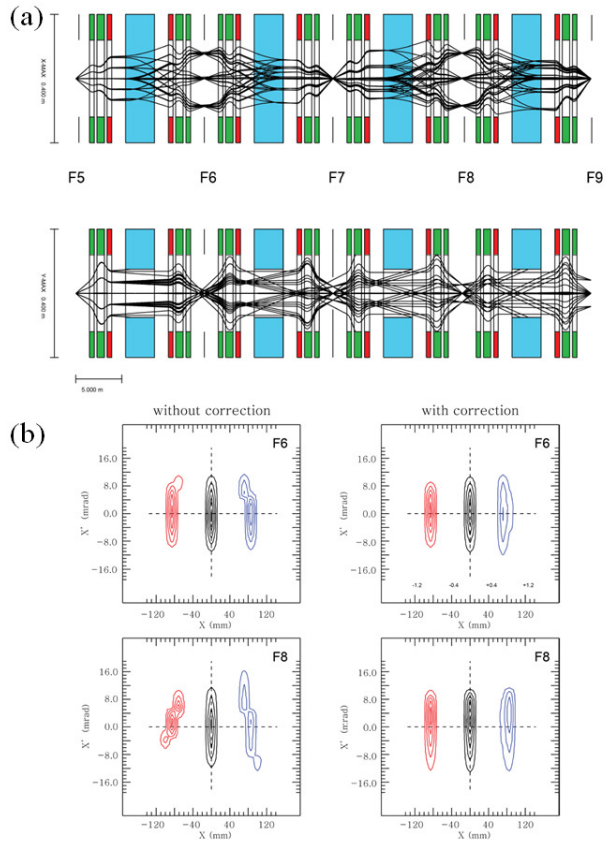

Figure 3: Correction of phase space distortion in the second order optics of pre-separator at F1 and F3.

Figure 3 is the result of 2nd order correction with hexapole magnet (red color). The beam phase spaces at F1 and F3 are compared before and after 2nd correction in Fig. 3 (b), which shows significant improvement.

PRE-SEPARATOR PERFORMANCE

Parameters of the pre-separator and the purity of ^{132}Sn at the exit of pre-separator were evaluated by simulations with the LISE++ code [4]. ^{132}Sn ion, which is double magic nucleus, is a main isotope beam of interest used for the separator design. A 200 MeV/u $^{238}U^{79+}$ primary beam was used with a graphite target of 303 mg/cm^2 thick to produce ^{132}Sn in the simulation. The momentum acceptance of ±3% was assumed using a wedge shaped degrader in F3 focus. The material of degrader is aluminium with central (on-rigidity) thickness of 1.57 mm corresponding to approximately 30% of ^{132}Sn beam range.

As can be seen in Fig. 4, the transmission of ^{132}Sn in 1st order simulation was calculated to be about 25.3%, when the selection slits in the pre-separator were completely open. Large losses of ^{132}Sn occur at the F1 focus, where the beam dump is located. Fission fragments are produced from the target with large spreads in both angle and

Copyright © 2013 CC-BY-3.0 and by the respective authors

momentum. Magnetic rigidities that are larger by 3% than the selected value are removed at the beam dumps, as shown in Fig. 5.

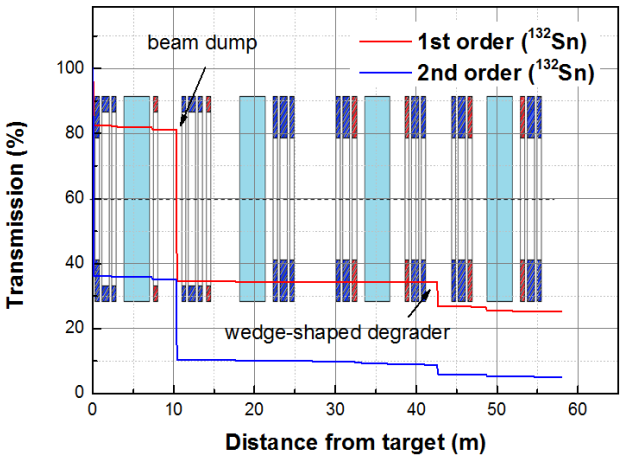

Figure 4: Comparison of transmission efficiency of ^{132}Sn produced via in-flight fission simulated in 1st and 2nd order optics on the pre-separator.

A less significant loss occurs due to multi charge states of ^{132}Sn ions generated by the electronic interactions in the wedge. The loss in transmission for ^{132}Sn derived from 2nd order aberrations is due to the increase in the size of the beam envelope compared to the first order beam envelope. The transmission of ^{132}Sn in 2nd order simulation is about 5.1%. Further optimization on high order aberration correction scheme is necessary to improve the 2nd order or higher order transmission efficiency.

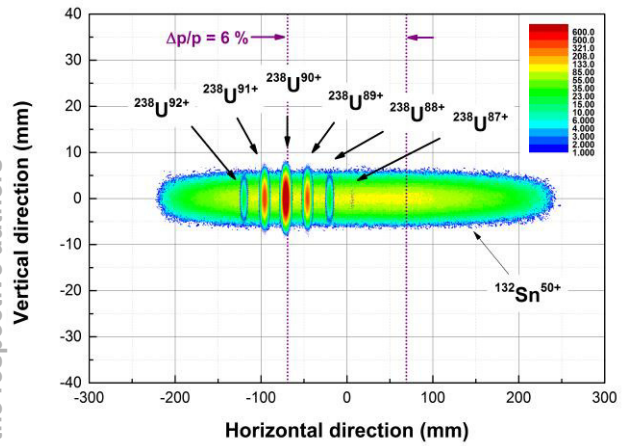

Figure 5: The primary beam and ^{132}Sn beam profiles at the F1 focus, where the beam dump are located.

Figure 6 is a part of the chart of nuclides indicating the yield rate of ^{132}Sn and un-wanted fragments at the end of the pre-separator. The production rate of ^{132}Sn is about 1.34×10^{7} pps with the purity of about 0.03%. The most intense contaminants are nuclei which are located closer to the valley of stability. The purity of ^{132}Sn can be improved by isotopic selection of the main separator.

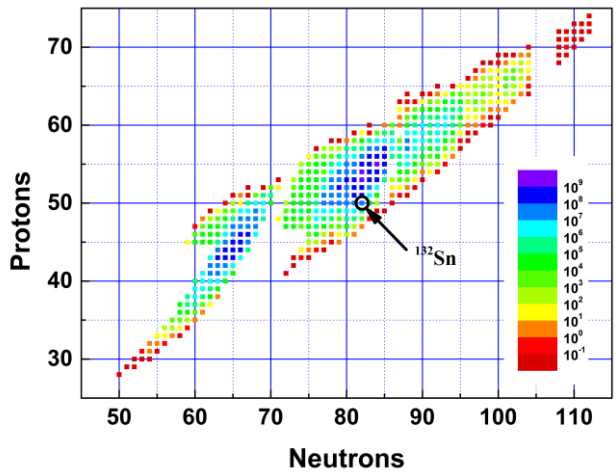

Figure 6: The rate of ^{132}Sn and un-wanted fragments transmitted to the end of pre-separator.

CONCLUSIONS

The design of in-flight separator using high-power primary beam has been carried out for the RISP in Korea. Main considerations on optical design of pre-separator are associated with shielding high-level radiation and removing the primary beam almost completely. The optimization process has been underway to deal with main considerations, and to improve the purity and the transmission of fragments. To evaluate the performance of current pre-separator, transmission efficiency and rate of ^{132}Sn were calculated by using LISE++ to be achieved 25.3 %, 1.34×10^{7} pps, respectively.

HORIZONTAL DISPERSION STUDIES FOR THE CERN PROTON SYNCHROTRON BOOSTER RINGS

V. Raginel, B. Mikulec, S. Gilardoni, CERN, Geneva, Switzerland

Abstract

In order to confirm the value of horizontal dispersion of the CERN Proton Synchrotron Booster (PSB) given by the MADX model, the horizontal dispersion has been measured using pick-ups and wire scanners on its four rings. The dispersion value of the PSB rings is of interest for example as input for the emittance measurements critical for high-brightness beam production for the LHC, for future optics studies related to the planned upgrades of the PSB or for optics studies of the ejection lines. In this study, the dispersion measurement protocol and the analysis of the measurements are presented. The measurement results point out differences with respect to the MADX model and also differences between the four rings. It was then investigated using horizontal orbit measurement and MADX matching routines whether misalignments of quadrupole magnets could explain these differences.

INTRODUCTION

The knowledge of the dispersion of the Proton Synchrotron Booster (PSB) rings is of interest for cross check the optics of the ring currently in use, but also as input for the emittance measurements [1] or for the optics matching studies of the injection/ejection lines. While the dispersion in the PSB is estimated by a MADX model [2], measurements of dispersion are necessary to validate the simulated optics. The horizontal dispersion $D_x(s)$ can be defined by:

$$\Delta x(s) = D_x(s) \cdot \delta$$

where $\Delta x(s)$ is the horizontal beam centroid displacement at the location s and $\delta=\Delta p/p_0$ is the relative momentum offset with respect to the nominal momemtum p_0. The dispersion can be measured by changing the beam momentum via the RF system, observing the beam displacement at the location of the beam position monitors and the variation of the revolution frequency. The momentum deviation is evaluated via the momentum compaction factor and the measured frequency change. The measurements were done for all four rings of the PSB. The dispersion was obtained off-line using a fitting routine on the beam position monitors data and then compared to the MADX model.

DISPERSION MEASUREMENTS

The dispersion was measured using a LHC 50 ns beam (the luminosity production beam for the LHC 2012 run) for each ring using the programmable RF radial position function which converts a given change in the average orbit into energy offset. The radial position function was modified 760 ms after the start of the cycle, just before the extraction flat top of the magnetic cycle when the beam momentum is 2126 MeV/c. The horizontal beam displacement and the revolution frequency were acquired for various values of the radial position function averaging over three measurements. The horizontal beam displacement was observed by the sixteen pick-ups of each ring (BRi.UES1L3, BRi.UES2L3 ..., and BRi.UES16L3, with i=1, 2, 3, 4 indicating the fours PSB rings), one pick-up per section, and by one wire scanner in the section 2 of each ring (BRi.BWS.2L1). The pick-ups of the PSB rings are installed in-between the first focusing quadrupole (QF) and the defocussing quadrupole (QD) with the basic optics cell of the PSB being bending1-QF1-QD-QF2-bending2. The readout chain per section of the pick-ups is the same for each ring (multiplexing) [3].

A too large horizontal beam displacement can cause beam losses when the aperture limit is reached. The maximum variations of the radial position function with no beam losses were determined for both positive and negative displacement. The measurements were done between these maximum variations.

DISPERSION ANALYSIS AND RESULTS

Determination of the Dispersion in Each Ring

The measurements yield the displacement of the center of the beam and the corresponding revolution frequency. The relative momentum deviation was derived from the relative variation of the revolution frequency thanks to the following relation:

$$\Delta f / f_0 = -\eta \cdot \delta$$

where $\eta = \eta_0 + \eta_1 \delta + O(\delta^2)$ is the phase slip factor [4]. The frequency f_0 corresponds to the naturally centered orbit by introducing no offset in the radial loop function. A first assumption is to simplify the phase slip factor to the first order. The analysis was done using the relation

$$\Delta f / f_0 = -\eta_0 \cdot \delta$$

where $\eta_0 = \alpha_0 - 1/\gamma^2$ with α_0 being the first order momentum compaction factor, which is equal to 0.0609 in the PSB, and γ being the relativistic gamma of the proton beam. Δx vs. δ is then plotted for each pick-up and the wire scanner, examples of a plot of Δx vs. δ is shown in Figure 1 (black dashed line). The data fits show that the data is not linear, but rather parabolic.

Copyright © 2013 CC-BY-3.0 and by the respective authors

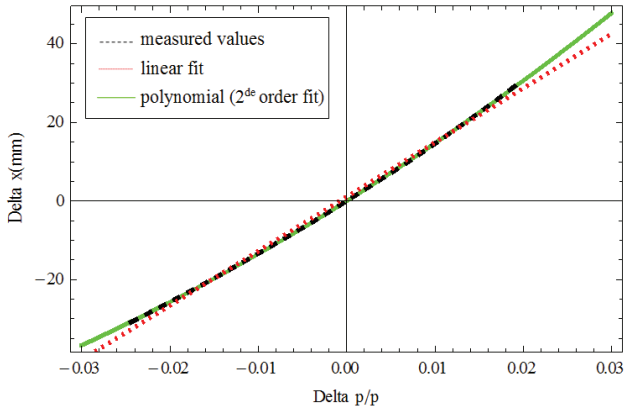

Figure 1: Plots of Δx vs. δ resulting from measurements done on the pick-up BR1.UES5L3 using the simplified relation $\Delta f/f_0 = -\eta_0 \cdot \delta$.

A second analysis was subsequently done using the relation

$$\Delta f / f_0 = -(\eta_0 + \eta_1 \cdot \delta) \cdot \delta$$

where $\eta_1 = \alpha_0 \cdot \alpha_1 + 3\beta^2 / 2\gamma^2 - \eta_0 / \gamma^2$ [5]

with α_0 being the first order momentum compaction factor and α_1 being the second order momentum compaction factor. The second order momentum compaction factor was determined for the PSB in the same way already used before in the PS [6]. The second order momentum compaction factor α_1 is related to the total momentum compaction factor α_p given by the MADX model of the PSB:

$$\alpha_p = \alpha_0 (1 + 2\alpha_1 \delta) + O(\delta^2) \text{ [4]}$$

The total momentum compaction factor α_p was simulated for nine momentum offsets Δp = ±40, ±30, ±20, ±10 and 0 MeV. α_1 was then derived from the slope of α_p vs. δ, and yields α_1 = 2.237. The resulting horizontal beam displacement as a function of the relative momentum spread becomes then a linear function. The relative position error of the pick-ups is considered to be within ±0.1 mm, except for the pick-ups 2L3 and 10L3 (±0.2 mm and ±0.3 mm, correspondingly) [7]. The calibration of the wire scanners indicates that the response of the wire scanners is linear in the range ±10 cm and that the relative horizontal position error is negligible. The data of the pick-ups BR2.UES6L3 and BR2.UES10L3 show some incoherency with the others pick-ups probably due to malfunctioning of the system and thus are excluded from the analysis. The slope of the linear fit gives the dispersion at each measurement point in the four rings. A comparison of the measured horizontal dispersion of all four rings and the horizontal dispersion D_x predicted by the PSB MADX model is shown in Figure 2. One can see in Figure 3 that the maximal relative differences of D_x predicted by the PSB MADX model and obtained by measurements on the 4 rings is ~10%. The dispersion values of MADX agree rather well with the measured values; however the dispersion of the MADX model shows an offset of ~0.05 m compared to the dispersion measured in the 4 rings, which is not well understood yet. The measurements show that dispersion is different from ring to ring, in the next section it is investigated whether misalignments of the defocusing quadrupoles explain these differences.

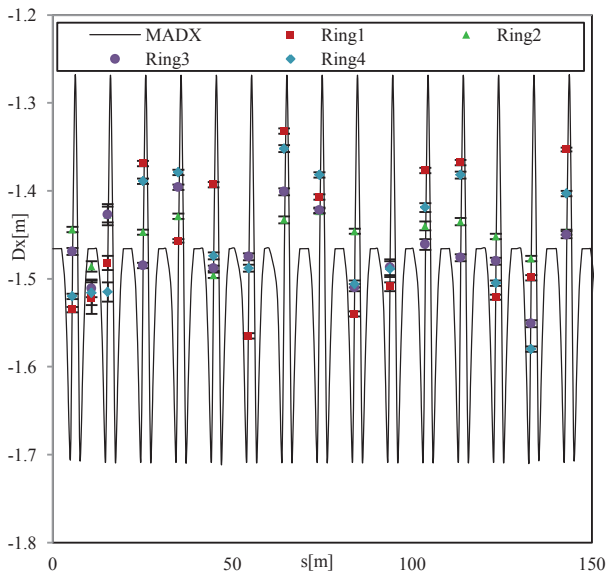

Figure 2: MADX simulation of the horizontal dispersion along the PSB ring (solid line) with the measurement points for the horizontal dispersion D_x for the 4 rings.

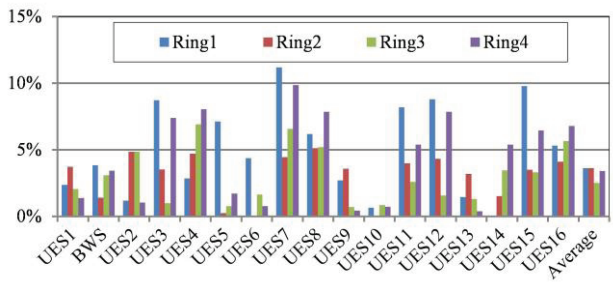

Figure 3: Relative differences of D_x given by the MADX model and obtained by measurements for the 4 rings. The pick-ups UES6 and UES10 of Ring2 are excluded from the analysis.

Analysis of the Differences Between the PSB Rings

It is investigated if the differences in dispersion between the four rings could be explained by the horizontal misalignments of the defocusing quadrupoles (QD). It has to be noted that a tilt of each QD affects differently the four superposed rings of the PSB because the alignment of the rings for the tilt is done by rotating the magnet stack around the centre of ring 3, which is at the same vertical level than the injection/extraction line. The method used was to estimate the horizontal misalignments of the QDs from closed orbit measurements for each of the four rings and then to

Copyright © 2013 CC-BY-3.0 and by the respective authors

compute the horizontal dispersion ring by ring inserting the estimated misalignments into the MADX model.

As the closed orbits in the PSB are dominated by misalignment effects [8], the horizontal misalignments of the defocusing quadrupoles can be estimated as follows. First the horizontal closed orbits were measured 760 ms after the start of the cycle for all the four rings averaging over three measurements, including the transversal misalignments of the pick-ups. Second in the MADX model, virtual horizontal kickers were inserted in the centre of each QD to represent the misalignments of the QDs. Their strength was then determined by reproducing the closed orbit via the MADX model. The kicks were then translated into misalignments using the relation $\Delta x_{QD} = \theta/(L \cdot k)$ with Δx_{QD} being the horizontal misalignment of the defocusing quadrupole, θ being the kick found by matching, L being the magnetic length of the quadrupole and k being the normalized gradient of the quadrupole. The estimation of the horizontal misalignment of the QDs was done independently ring by ring. Finally the estimated horizontal misalignments of the QDs were introduced into the original MADX model and the closed orbit and dispersion were computed. The dispersion function at the pick-ups is not strongly dependant on the number of misaligned QDs, when using two or more misaligned QDs.

From Figure 4, one can note that the offset between the measured dispersion and the one given by the MADX model is ~0.06 m. The misalignments of the QDs in the MADX model induce an oscillation of the dispersion around its average value. These oscillations agree rather well with the oscillations observed in the measured dispersion as shown in Figure 4 for rings 1, 3 and 4. For ring 2 it is difficult to conclude, as the dispersion measurement does not have a clear dispersion pattern due to the exclusion from the analysis of the pick-ups UES6 and UES10. It has to be noted that the absolute error of the pick-up orbit measurement is estimated to be ~1 mm [9], which leads to uncertainties on the estimated misalignments of the QDs and subsequently on the estimated dispersion with these misalignments.

However there are good indications that the misalignments of the QDs in the PSB explain the oscillations of the dispersion around its average value and thus explain partially the differences of the measured horizontal dispersion between the four rings.

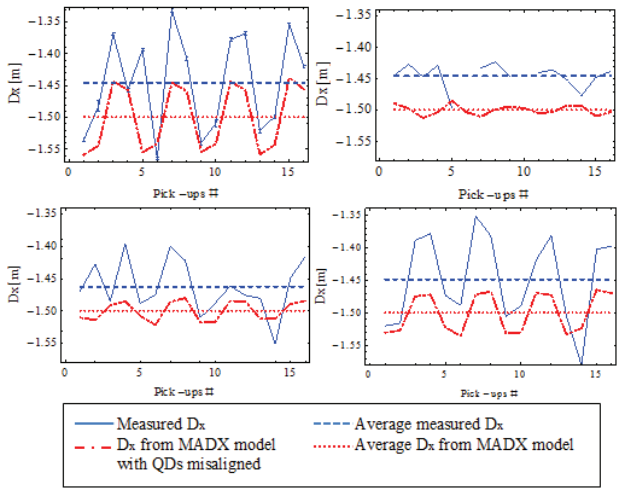

Figure 4: Comparison of the measured horizontal dispersion at the 16 pick-ups with the dispersions given by the PSB MADX model with misalignments of the QDs for ring 1 (top left), ring 2 (top right), ring 3 (bottom left) and ring 4 (bottom right).

CONCLUSION

The horizontal dispersion was measured using 16 ring pick-ups (1 per section) and a wire scanner (1 per ring) for the 4 rings of the PSB. The measured horizontal dispersion is consistent with the values of MADX within maximum 10% relative error and amounts to -1.45 m in average at the pick-ups. However slight differences between the four rings were observed. Using orbit measurements to estimate the misalignments of the QDs in each of the four rings it was shown that the difference in horizontal dispersion between the four rings could be partially explained by misalignments of the QDs. During the long shutdown 2013-2014 the PSB rings have been realigned; according to this study it can be expected to obtain a more uniform horizontal dispersion between the four rings after the 2014 restart.

BEAM DYNAMICS AND WAKEFIELD SUPPRESION IN INTERLEAVED DAMPED AND DETUNED STRUCTURES FOR CLIC*

Abstract

Acceleration of multiple bunches of charged particles in the main linacs of the Compact Linear Collider (CLIC) with high accelerating fields provides two major challenges: firstly, to ensure the surface electromagnetic fields do not cause electrical breakdown and subsequent surface damage, and secondly, to ensure the beam-excited wakefields are sufficiently suppressed to avoid appreciable emittance dilution. In the baseline design for CLIC, heavy wakefield suppression is used (Q ~ 10) [1] and this ensures the beam quality is well-preserved [2]. Here we discuss an alternative means to suppress the wakefield which relies on strong detuning of the cell dipole frequencies, together with moderate damping, effected by manifolds which are slot-coupled to each accelerating cell. This damped and detuned wakefield suppression scheme is based on the methodology developed for the Japanese Linear Collider/Next Linear Collider (JLC/NLC) [3]. Here we track the multi-bunch beam down the complete collider, under the influence of transverse wakefields and record the final emittance dilution at the end of the linac. We utilize the code PLACET [4] for all tracking simulations and include systematic and random fabrication errors; the latter are particularly beneficial in reducing the impact of the wakefield on the beam quality. Results of some initial alignment studies are also provided.

INTRODUCTION

The CLIC scheme entails two beams, one of which is the high-current drive beam (~ 100 A), and the other is a low-current accelerated beam. The drive beam is decelerated and provides an electromagnetic field which is coupled to the main accelerating linac. These main linacs are required to accelerate electron-positron beams to a final collision centre of mass energy of 3 TeV. Recent studies anticipate a staging to a reduced centre of mass energy of 375 GeV, as a prelude to the full collision energy. Here we focus on the 3 TeV design, which requires more than 71,000 accelerating structures. In this baseline design, each structure accelerates 312 bunches, each of which consists of ~ 4 x10^9 particles per bunch. The corresponding beam current of ~ 1 A removes energy from the accelerating electric field, and loads it down. The beam-loaded accelerating field is designed, on average, to be 100 MV/m. The electric field is a little more than a factor of two larger on the walls and the magnetic field is constrained to provide a pulse temperature rise on the copper walls of no more than 56 K [5]. A relatively compact accelerating structure is obtained by adopting an X-band accelerating frequency of 11.994 GHz. The iris radius of each accelerating cell largely determines the shunt impedance, which ideally should be maximized, but since shrinking it down also enhances the transverse dipole fields, a compromise must be achieved. In our design we focus on an average iris radius to free space wavelength: $\langle a \rangle/\lambda \sim 0.13$. The average iris radius determines the short-range wakefield, or the field experienced along the bunch itself. The transverse wakefield experienced by succeeding bunches in the multi-bunch train is influenced by several factors. In principle it can be suppressed by heavy damping, and this is indeed the method adopted in the baseline design for CLIC in which field is coupled out from each cell and immediately dissipated in attached ceramics. This ensures the wakefield on the first trailing bunch is constrained to less than 6.7 V/pC/mm/mm [5] and all subsequent bunches experience an even lower wakefield. Recent high power tests have indicated this structure is able to sustain the requisite surface electromagnetic fields at the design gradient [6].

However, here we discuss a method which entails changing the dipole frequency of each of the cells within a given structure and hence ensuring the eigenmodes, corresponding to these fields, add up in a deconstructive manner [3]. In our alternative design the iris is tapered down in an erf function manner, and this ensures the wakefield decays with a Gaussian envelope. However, the finite number of cells within each structure corresponds to a sampling of the field. This will ultimately lead to a point at which the eigenmodes add together coherently and hence will force the wakefield to rise above the constrained value. We provide four waveguide-like manifolds, slot-coupled to each cell in the structure, to ensure this recoherence in the wakefield is sufficiently suppressed. We have constrained our design to utilize the same number of cells as the baseline design, namely 24. This short structure is of course insufficient to provide adequate sampling, and hence we interleave the frequencies of several neighbouring structures in order to obtained the requisite wakefield suppression -12 and 16 fold interleaving is focused on in this article (corresponding to an equivalent structure of 288 and 384 cells, respectively).

This paper is organized such that the next section provides a description of the wakefield suppression used, followed by a section entailing tracking the beam throughout the complete linac under the influence of expected fabrication errors, and finally by a penultimate

* This research has received funding from European Commission under the FP7 Research Infrastructure grant no. 227579

section concerned with an initial investigation of the implication of structure misalignment on emittance dilution. A final set of concluding remarks is also given.

DDS INTERLEAVED DESIGN

The accelerating structures investigated here are based on those optimised in [7], and a single one of these structures is referred to as CLIC_DDS_A. This optimisation was focussed on adhering to the semi-empirical design constraints specified for CLIC –and entails, *inter alia*, ensuring the surface electromagnetic fields are within given bounds [5], and the overall efficiency of the collider is maximised. The inter-bunch spacing was changed from the baseline value of 6 rf cycles to 8, in order to relax the required suppression on the first trailing bunch –which is governed by the frequency spread of the dipole modes. This allowed a bandwidth of 11.8 % (~ 2 GHz) with a span of 3.48σ to be assigned to the first dipole band. Higher order bands provide appreciably smaller transverse momentum kicks [8] to the beam and hence we focus on the first dipole band in this work.

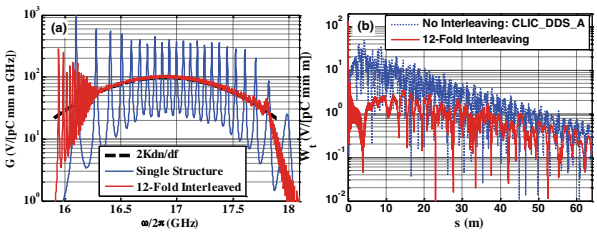

Figure 1: Spectral function (a) for a single structure (in blue) and a 12-fold interleaved series (in red), together with the Fourier transforms thereof, the corresponding wakefunctions W_t (b). Also shown is twice the kick factor weighted frequency density distribution (2Kdn/df).

Before discussing the wakefields, and beam dynamics of the multi-structure configurations relevant to CLIC, we note that a single structure, CLIC_DDS_A, has been fabricated and is being scheduled to be high power tested at CERN. All cells of this 24-cell structure have been precisely made by milling with a carbide tool on the outer area of each cell, followed by diamond-point turning in the beam-hole area and finally, chemically rinsed and diffusion bonded together. It remains to complete the process by attaching couplers and tuning stubs.

The transverse, long-range wakefield in these multi-cell structures is assessed using a spectral function method [9,10]. This method was developed to take into account the strong coupling of modes. The Fourier transform of the spectral function provides the wakefield experienced by the beam. A single structure consists of no more than 24 cells and hence will be woefully inadequate in suppressing the wakefield. However, provided the dipole modes are interleaved between successive structures, the wakefield will be well-suppressed. We have found 12-fold interleaving of modes to be sufficient (equivalent to a single structure consisting of 288 cells). The spectral function, and corresponding wakefunction, for a single structure and a 12-fold interleaved series of structures is shown in Fig 1. Also indicated is 2Kdn/df, the original uncoupled design. The short-range wakefield (the first 2 m or so), corresponding to the Fourier transform of the uncoupled design and coupled spectral functions, should be virtually identical and we have verified this during our calculations. It is interesting to note that the minimum spacing and indeed maximum spacing of the modes (corresponding to the spacing in the peaks in Fig. 1 (a) for example) provides an indication as to where the modes will recohere. The minimum and maximum separation of peaks in Fig. 1 (a) for a single structure is 61 MHz and 342 MHz, and for 12-fold interleaving of structure frequencies it is 5 MHz and 19 MHz. These separations correspond to recoherance positions of 5 m and 1 m for a single structure, and 60 m and 16 m for the interleaved structures. Inspection of the wakefields in Fig. 1 (b) confirms this behaviour. Clearly the interleaving enhances the overall sampling, and hence provides a better representation of the Gaussian distribution, and also pushes the recoherence position further down the bunch train.

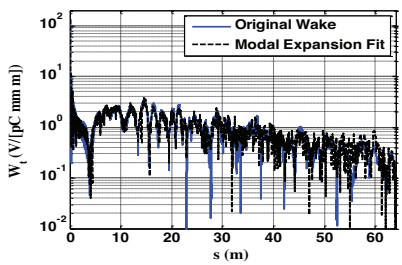

Figure 2: Envelope of fitted transverse wakefunction of (dashed and in black) together with that of the Fourier transform of the spectral function (solid blue) for a 12-fold interleaved structure.

The wakefield presented in Fig. 1 (b) is not that experienced by the beam, as the envelope, or worst case wakefield is illustrated. The tracking code we utilise, PLACET, requires the mode frequencies, Q's, and corresponding kick factors [4,11] as input parameters to assess the impact of these wakefields. We utilize the peaks in the spectral function and assign these to the modal frequencies, the remaining parameters are obtained by taking the usual modal expansion [12] and performing a non-linear least-square error fit. To provide some confidence in the fitting method, we compare the original Fourier transform of the spectral function to the fitted modal sum, and this is displayed in Fig. 2. We analyse the impact of these transverse long-range wakefields on the beam dynamics in the next section

BEAM DYNAMICS STUDIES

Here we assess the implications of these wakefields for two particular situations. In case I we investigate a 12-fold interleaved version of the original design, in which

Copyright © 2013 CC-BY-3.0 and by the respective authors

bunches were spaced from their neighbours by 8 rf cycles. In case II, we maintain the original distribution, but modify the bunch spacing to 6 rf cycles, and in this case we discover further interleaving, to the extent of 16-fold, is needed to contain the emittance dilution to acceptable limits. This of course has implications on the fabrication tolerances, as the minimum frequency spacing for the latter structure is 3.4 MHz**.** However, these tolerances are still compatible with those assigned to the accelerating mode –which is < 1 MHz. We performed beam tracking simulations down the complete linac, for a bunch train initially offset by σ_y (0.5 μm), and observed an emittance dilution in case I and II to be 4.4 % and 3.6 %, respectively.

However, these simulations neglected anticipated sources of experimental errors. To provide a more realistic assessment of the beam dynamics we conducted further simulations for both cases, in which systematic and random frequency errors were included. These beam dynamics simulations are time consuming, and in order to provide a rapid initial assessment of the effect of the wakefields on the beam dynamics, we also calculate S_{RMS} (the RMS of the sum wakefield [13]).

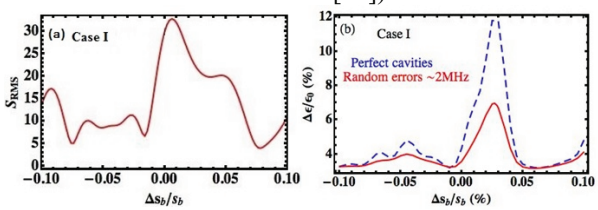

Figure 3: S_{RMS} (a) together with the vertical emittance dilution at the exit to the linac (b), as function of the fractional deviation in the bunch spacing from the nominal case for case I. A linac fabricated with no random errors, is simulated (shown dashed in blue), together with a linac incorporating random errors (the solid red curve).

The results of these beam dynamics simulations, alongside S_{RMS}, for both cases, are displayed in Figs 3 and 4. We note that the random errors adding in both cases had a Gaussian distribution and were restricted to 2 MHz RMS spread. Inspection of Fig. 3 reveals the maximum emittance dilution is 12 % for case I with no random errors. This is reduced to 7 % once random errors are added. Similarly, for case II, random errors bring the maximum emittance dilution down from 9 % to 6 %. We also note that S_{RMS} provides a qualitative guide as to the expected worst-case region for emittance dilution.

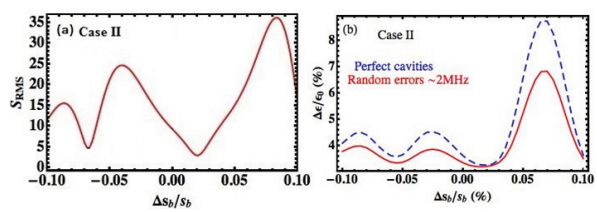

Figure 4: S_{RMS} (a) together with the vertical emittance dilution at the exit to the linac (b) for similar parameters as in Fig. 3, but for case II.

MISALIGNMENT STUDIES

The pre-alignment tolerance on the transverse positions of the components (accelerator structures, BPM, girders) of the CLIC linacs is 10 μm rms over distances of 200 m [14]. Beam-based alignment and emittance tuning bumps [15] are used to ensure the emittance dilution associated with this alignment is kept to acceptable limits.

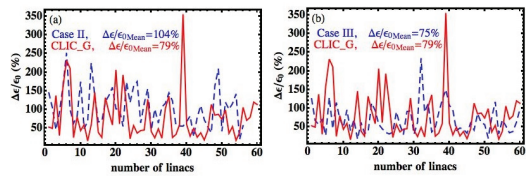

Figure 5: Emittance dilution for misaligned structures for CLIC_G (shown in red), together with case II (a) and III (b) -both shown dashed and in blue.

We investigated a case of which consisted of perfect linacs in which we added vertical random offsets of 10 μm rms to all the structures and this is compared to the baseline design, CLIC_G. We performed simulations for case II (Fig. 5 (a)), and also for case III (Fig. 5 (b)) which consists of 16-fold interleaving of mode frequencies and bunches spaced 8 rf cycles from their neighbours. However, the implications of not being able to accommodate 16 structures on a girder are not taken into account, as it is a considerable task to redesign the associated beam optics, and hence it remains a subject for a future publication.

FINAL REMARKS

A damped and detuned structure, with appropriately interleaved dipole mode frequencies, has been shown to be suitable for the CLIC main linacs. Two cases have been investigated, based on a bunch spacing of 6 and 8 rf cycles. The S_{RMS} parameter provides a qualitative indication as to the location of the worst-case emittance dilution. Preliminary studies on the dilution due to structure misalignments, based on case II and III indicate similar values to the baseline design.

BEAM-BASED ALIGNMENT OF SEXTUPOLES AT THE APS *

A. Xiao †, V. Sajaev, ANL, Argonne, IL 60439, USA

Abstract

Sextupole magnet offsets play a large role in modern storage ring coupling control. Due to the non-linear field of sextupoles, their beam-based alignment becomes more difficult and often requires a sophisticated post-data process. A simple method had been developed at the APS that measures the vertical orbit variation (orbit change at BPMs with sextupole strength) versus beam trajectory through a sextupole in one plane while keeping the trajectory in the other plane fixed. This method converts the non-linear problem into a linear one, and experiment results show very good reproducibility and accuracy.

INTRODUCTION

Given the strong sextupoles used in modern storage rings, such as light sources with emittance for producing x-rays near the diffraction limits and/or colliders (B-Factory or damping ring) with very low vertical emittance, misaligned sextupoles tend to be the main sources of large coupling and optics perturbation. It affects the ability to model the machine, and correct orbit, tune and coupling, often resulting in a reduced dynamic aperture and beam lifetime.

For a sextupole installed next to a quadruple, the alignment is as simple as aligning its magnet center to the next quadrupole, and then performing a commonly used beam-based alignment (BBA) technique on the quadrupole. At the APS, however, the majority of sextupoles (four of seven per cell) are on "dipole" girders that do not have quadrupoles, thus we cannot rely on BBA of quadrupoles. Other means of measuring the sextupole magnet offsets need to be developed.

In a previous paper [1], we presented a matrix fitting method to fit all sextupole offset errors together with other machine errors, so that the fitted model agrees with the response matrix measurement. The advantage of this method is that one can quickly get results. The disadvantage is that results are obtained in an "indirect" way and could be mixed up with other effects.

Similar to the beam-based quadrupole offset measurement method, a "direct" beam-based sextupole offset measurement method has been developed since then. This method measures the vertical orbit variation (orbit change at BPM with variation of sextupole strength) versus beam trajectory through a sextupole in one plane while keeping the trajectory in the other plane fixed. The small change of data acquisition and manipulation converts the non-linear problem into a linear one, and experiment results show very good reproducibility and accuracy. Details of the method, simulation, and experiment results are discussed in this paper.

PRINCIPLE

The closed orbit displacement (COD) at position s, rising from a kick error θ at position s_0, is given by

$$u(s) = \frac{\sqrt{\beta_{u,s_0}\beta_{u,s}}}{2\sin\pi\nu_u}\theta\cos[\pi\nu_u - (\phi_{u,s} - \phi_{u,s_0})] = A\cdot\theta, \tag{1}$$

where $u(s)$ represents x or y; β and ϕ are the β-function and the betatron phase; and ν is the betatron tune. For a sextupole with misalignment of x and y, the kick angle is given by

$$\begin{aligned}\theta_x &= \frac{1}{2}\cdot K2L\cdot(x^2 - y^2),\\ \theta_y &= K2L\cdot x\cdot y,\end{aligned} \tag{2}$$

where $K2L = \frac{e}{cp}\partial^2 By/\partial x^2\cdot L$ is the integrated sextupole strength. The corresponding kick angle from a misaligned quadrupole is given by

$$\theta_x = K1L\cdot x \qquad \theta_y = K1L\cdot y. \tag{3}$$

Equations (2) and (3) have different character, one is linear and the other is non-linear. However, if we keep either x or y unchanged during the measurement, i.e., $\theta_y = (K2L\cdot x)\cdot y$ or $\theta_y = (K2L\cdot y)\cdot x$, Eq. (2) becomes as linear as Eq. (3). In other words, by fixing x while varying y and the sextupole strength, we are doing the vertical offset measurement of a quadrupole with strength $K1L = K2L\cdot x$. Similarly, by fixing y while varying x and the sextupole strength, we are doing the horizontal offset measurement of a quadrupole with strength $K1L = K2L\cdot y$. The only difference in this case is that we measure the vertical orbit variation instead of the horizontal orbit variation for a real quadrupole offset measurement.

SIMULATION STUDY

The principle of the method is simple and straightforward. However, other effects, such as coupling from misaligned sextupole etc., need to be considered, too. We studied different misalignment scenarios through simulations before testing with beam. The calibrated lattice model obtained from LOCO fit [2] (includes normal- and skew-quad errors) is used for simulation. One sextupole (S17B:S3) is misaligned intentionally in three different sets: $DX = 2$ mm, $DY = 1$ mm; $DX = 1$ mm, $DY = 1$ mm; and $DX = 0$ mm, $DY = 0$ mm. Sextupoles within the measurement bump are kept on or turned off.

Similar to the BBA of quadrupoles, the simulation (and, later, measurement) is done in the following steps:

- Generate a local orbit bump at the BPM next to the sextupole, and scan the bump amplitude with $u_A = \pm 2$ mm in 1-mm steps (total $5 \times 5 = 25$ orbit sets).
- At each orbit bump, vary sextupole settings I between 0 and its maximum value in 4 steps. Record vertical orbit y at all BPMs.
- Calculate dy/dI (the slope of vertical orbit variation vs sextupole settings) at each BPM over the ring (Fig. 1).
- For the same x orbit, plot dy/dI over y; the crossing point is the sextupole's vertical offset (Fig. 2).
- For the same y orbit, plot dy/dI over x; the crossing point is the sextupole's horizontal offset (Fig. 3).

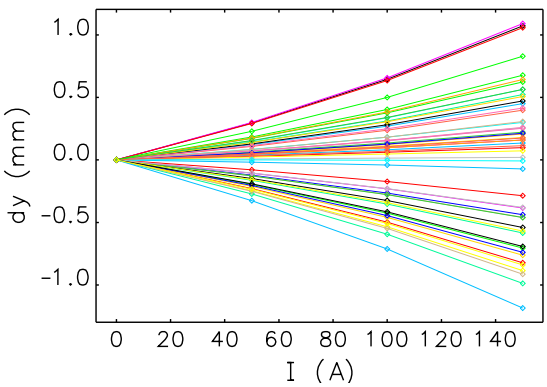

Figure 1: Vertical orbit variation dy vs. sextupole current change (symbols). Case for $DX = 2$ mm and $DY = 1$ mm. Data from the same BPM are connected; likewise for following figures.

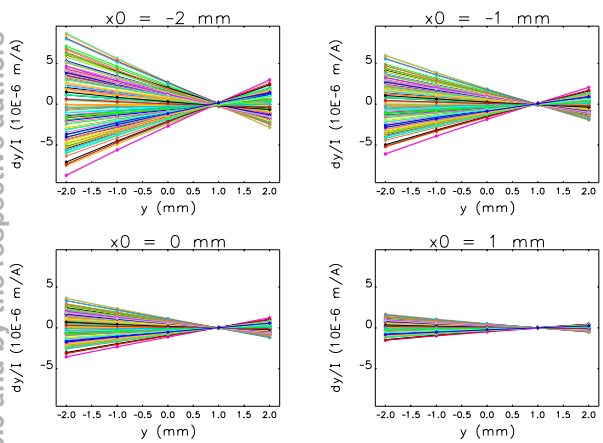

Figure 2: Calculated dy/dI vs. vertical beam orbit y (symbols). Results for different horizontal beam offsets (shown on top). Lines crossing at $y = 1.0$ mm indicate that the vertical sextupole offset is $y = 1$ mm.

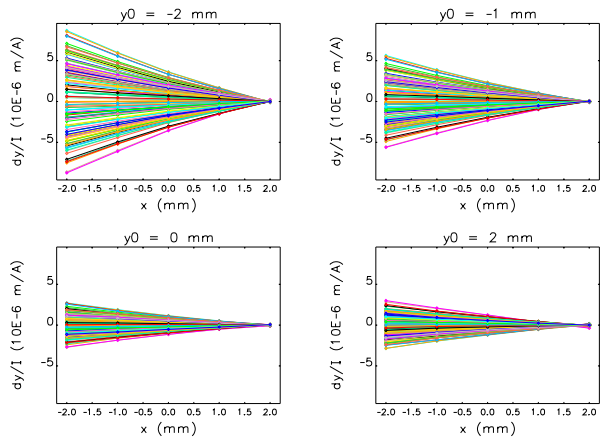
Sextupole offset is determined where $dy/dI = 0$. The histogram distribution of $dy/dI = 0$ from all BPMs is shown in Figure 4. The average derived x and y offsets using this method are 1.83 mm and 0.98 mm, respectively. Compared with our initial assumption in simulation (2 mm in x and 1 mm in y), the agreement on vertical offset measurement is very good (better than 50 μ m), while the horizontal result seems to have a significant systematic error. Further simulations with different sextupole offsets or in cases when other sextupoles are turned off inside the bump all give similar results, i.e., good agreement on vertical offset prediction but large systematic errors for horizontal results.



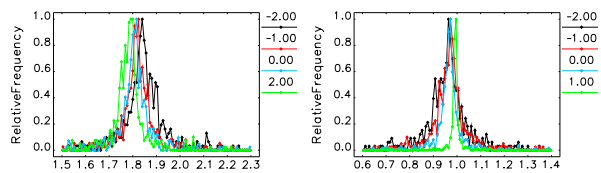


Figure 3: Calculated dy/dI vs. horizontal beam orbit x (dots). Results are grouped with the same vertical beam offsets (shown on top). Lines crossing at $x = 2.0$ indicate the horizontal sextupole offset is $x = 2$ mm.

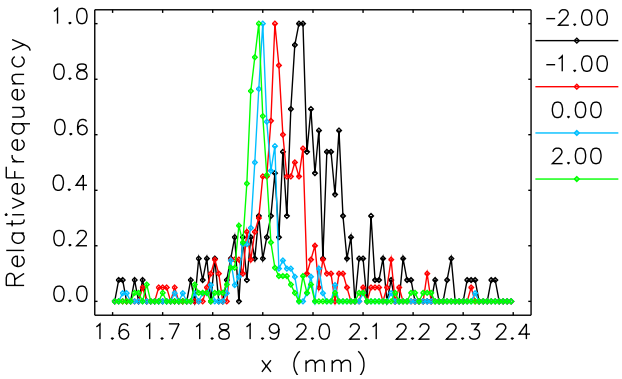
(a) (b)

Figure 4: Histogram distribution of $dy/dI = 0$ vs. x (a) and vs y (b). Legend shows beam orbit in the other plane.

Further investigation of the method reveals that the linear dependence on x requires a fixed vertical orbit y inside the sextupole, while the strength change of the sextupole also causes y variation and leads to an additional vertical kick. This second-order effect has been ignored up to now. To include this effect we fit dy/I vs. $x(y)$ to the second order, and calculate the value to give $dy/I = 0$. Results including this second-order correction from the same data set are shown in Figure 5. The offset determined this way is closer to the input sextupole offset ($DX = 2$ mm).

The sensitivity of measurement depends on the product of beam offset "xy". As shown in Figure 5, a larger beam offset $y = -2$ mm gives more precise results. If either x or y are actually close to the sextupole offset (beam going through the sextupole center), the results become noisy, as

Copyright © 2013 CC-BY-3.0 and by the respective authors



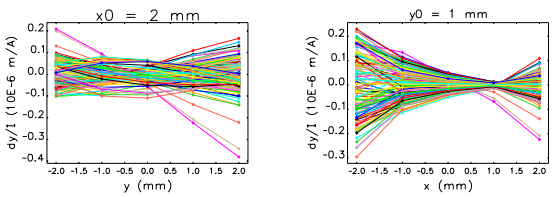


Figure 5: Histogram distribution of $dy/dI = 0$ vs x using second-order correction. Legend shows the beam orbit in y-plane.

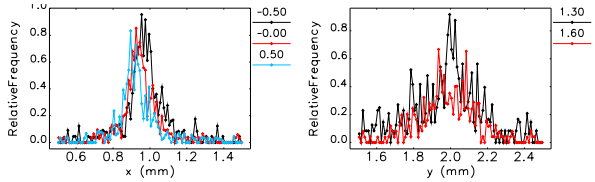
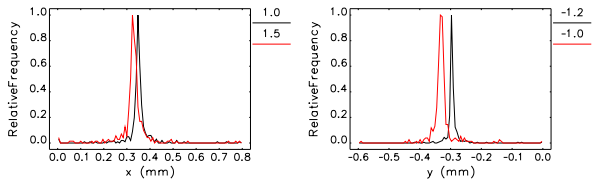
can be seen in Figure 6. To have meaningful measurement results, two sextupole settings (to obtain dy/I) at each $3 \times 3 = 9$ orbit offset are needed.



(a) (b)

Figure 6: Noisy results when beam is going through the sextupole center: $x0 = DX$ (a), and $y0 = DY$ (b).



EXPERIMENT RESULTS

The method has been tested at the APS storage ring with beam. In preparing for the superconducting undulator (SCU) commissioning [3], we measured the sextupole offsets next to the 6BM (S6B:S2 and S6B:S3). Three x orbit offsets with $x = 1.0$, 1.3, and 1.6 mm and three y orbit offsets with $y = -0.5$, 0, and 0.5 mm were used in the measurement. Histogram distributions of $dy/dI = 0$ vs. beam orbit are shown in Figure 7. The predicted sextupole offsets are $DX = 0.95$ mm and $DY = 2$ mm. For DX measurement, all y orbits are moved away from the predicted sextupole center DY, so all measurement results are valid. We learned from simulation that the systematic error does exist and is reduced as y moves away from DY, as can be seen from both Figures 5 and 7. In this case, results from $y = -0.5$ mm should be taken as DX; the measurement error is believed to be within 50 μm. For DY measurement, the measurement made at $x = 1.0$ mm is too close to the sextupole center and gives noisy data similar to an example shown in Figure 6, and was discarded from the plot. Two other measurements predict the same DY results, agreeing with simulation. The accuracy of DY measurement is better than 50 μm. Similar results have been found with another sextupole (S18B:S3). Results are shown in Figure 8.

(a) (b)

Figure 7: S6B:S2 offset measurement results. Legend shows beam orbit in the other plane.

(a) (b)

Figure 8: S18B:S3 offset measurement results. Legend shows beam orbit in the other plane.

CONCLUSIONS

A direct beam-based sextupole offset measurement method has been developed at APS. This method converts the sextupole field from nonlinear to linear by keeping the beam orbit in the X plane unchanged while measuring the vertical beam orbit variation as a function of sextupole strength. The validity of the method had been tested through simulation and beam experiment. The second-order effect from orbit variation in the unmeasured plane was noticed and fixed through a second-order polynomial fit. The accuracy of this method is of the order of 50 μm.

The direct sextupole offset measurement takes more time compared with the "LOCO" fit method we originally reported in a previous paper [1]. Nevertheless, this is a suitable method if a direct measurement is required.

ENERGY CALIBRATION IN THE AGS USING DEPOLARIZATION THROUGH VERTICAL INTRINSIC SPIN RESONANCES*

Y. Dutheil, L. Ahrens, H. Huang, F. Méot, V. Schoefer
BNL, Upton, Long Island, New York

Abstract

The AGS tune jump system consists of two fast pulsed quadrupoles used to accelerate the crossing of 82 horizontal intrinsic resonances. Timing of the tune jumps requires accurate tune and energy measurements. Although cross calibration using measurements of the beam revolution frequency shows good accuracy for most of the AGS energy range it is not adequately sensitive as the beam becomes highly relativistic. This drives a strong interest for a new independent energy measurement method.

Reduction in the vertical tune across vertical intrinsic spin resonances can induce significant depolarization of the beam. Therefore it was proposed to use the negative vertical tune shift created by this tune jump system to calibrate the energy measurement at few locations along the AGS acceleration cycle. The fast tune jump, of $\Delta Q \approx -0.02$ within $100\,\mu$s in the vertical plane, allows to accurately locate the spin resonant condition, independently from orbit or field conditions. Simulations using the AGS Zgoubi online model facilitate the interpretation of the experimental results. This paper introduces the experimental procedure and shows some of the latest results.

INTRODUCTION

The partial snakes configuration of the AGS creates horizontal intrinsic spin resonances by tilting the stable spin direction away from the vertical direction [1]. The resonant condition $Q_s \pm Q_x = n$ is satisfied twice per unit of $G\gamma$ during the ramp, inducing every time a small depolarization of the beam. The polarization losses are reduced by quickly changing the horizontal tune Q_x, increasing the crossing rate of the resonance [2].

The system is composed of two fast quadrupoles allowing a change in the horizontal tune of $\Delta Q_x = +0.04$ in $100\,\mu$s. One of the main challenge is the accurate timing required for each jump, such that the tune jump is centered around the resonance.

Tune Jump Timing

While the spin tune Q_s is a function of the energy, tune and energy measurements along the ramp allow precise timing of each jump. During the polarized protons operations these measurements are regularly used to generate new timings for the tune jumps. This is supposed to compensate for any drift in the location of the resonant condition, for instance due to a drift of the tune over time. During the AGS Polarized Proton Run 13, these measurements were regularly conducted to provide the highest polarization to the RHIC.

Table 1: Polarization Measurements During Run 13

Measurement date	Timings	Polarization
May 5th	from April 6th	$66.0 \pm 0.9\,\%$
May 5th	from April 29th	$59.7 \pm 1.1\,\%$
May 5th	from May 5th	$62.8 \pm 1.1\,\%$
June 6th	Uncalibrated	$64.4 \pm 3.9\,\%$
June 6th	Calibrated	$70.9 \pm 1.6\,\%$

In late April 2013, after a few weeks of running with the same tune jumps timings, new timings were generated but the polarization decreased. Table 1 shows that on May 5th the measured polarization was higher for the older timings. The two sets of timings more recently generated led to a consistently lower polarization.

To explain this deterioration the entire process from the computation of the jumps timing to the trigger of the pulsed power supply was verified, without finding any error. We decided to investigate on the measurements used to compute the jump timings : tune and energy measurements.

The tune measurement is based on the free oscillation of the beam, it is therefore an absolute measurement and is unlikely a source of significant error. The energy measurement is more complex and needs to be calibrated, making a possible suspect for our problems.

ENERGY MEASUREMENT IN THE AGS

The AGS uses a dedicated device called the *GgammaMeter* to measure the energy along the ramp. The energy is determined using the measured RF frequency f and average radius of the beam dR (Eq. 1) or the measured field $(B_{\text{inj}} + B_{\text{clock}}/C_{\text{scal}})$ and the average radius (Eq. 2) :

$$G\gamma = G\frac{1}{\sqrt{1-\frac{1}{c^2}\left(\frac{f}{h}\right)^2(2\pi)^2(R_0+dR)^2}} \quad (1)$$

$$G\gamma = G\sqrt{\left[\frac{(1+\gamma_{tr}^2 dR/R_0)\rho_0 c(B_{\text{inj}}+B_{\text{clock}}/C_{\text{scal}})}{M_0}\right]^2+1} \quad (2)$$

With γ_{tr} the transition energy, R_0 the radius and ρ_0 the radius of curvature of the AGS. The parameters in red (f, dR and B_{clock}) are measured quantities while the blue ones are machine parameters(R_0, γ_{tr}^2, ρ_0, B_{inj} and C_{scal}) that can be adjusted and the black are fixed physical constants.

The *GgammaMeter* is cross calibrated : at low energy the machine parameters in equations 2 and 1 are adjusted manually until the two methods report the same energy along

* Work supported by Brookhaven Science Associates, LLC under Contract No. DE-AC02-98CH10886 with the U.S. Department of Energy.

Copyright © 2013 CC-BY-3.0 and by the respective authors

the ramp. But at high energy the measurement based on the RF frequency (Eq. 1) is too sensitive, due to the highly relativistic beam.

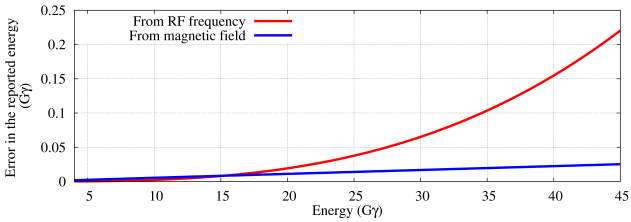

Figure 1: Error on the reported energy caused by an error of 1 mm in the measured average beam radius.

Figure 1 shows the derivative of equations 2 and 1 with respect to the measured average radius : $\partial G\gamma/\partial(dR)$. As the energy increases, we can see that the sensitivity of the energy measurement based on the revolution frequency becomes very large. While we consider that the measured average radius is known within a fraction of millimeter we also need an accuracy of around $0.01\,G\gamma$. It becomes apparent that the actual method of cross calibration is very hard at high energy.

This drives a strong interest to develop an independent method on energy measurement, possibly to calibrate the *GgammaMeter*.

Since the AGS accelerates polarized protons, methods based on the depolarization of the beam can be explored. A promising method using the current hardware of the AGS uses the tune jump system to accurately locate a strong vertical intrinsic resonance.

Tune Jump and Depolarization

While the tune jump system is used for its effect on the horizontal tune, it also induces a tune shift of $\Delta Q_y \sim -0.02$ in the vertical plane, within $100\,\mu$s. In addition, the partial snake configuration of the AGS modifies the spin tune, opening a forbidden band or "spin gap" in which the vertical tune is placed to avoid the vertical intrinsic resonances $Q_s \pm Q_y = n$. It is then possible to use a single tune jump to lower the vertical tune below the maximum value of the spin tune $Q_s^{\max}$, leading to a depolarization of the beam.

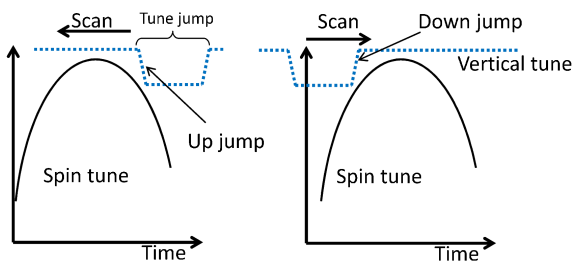

Figure 2: Illustration of the method used to locate the vertical intrinsic resonance.

Figure 2 shows the principle of the measurement. First the vertical tune is lowered to just above $Q_s^{\max}$, such that the tune jump is able to lower the vertical tune out of the spin gap. Then the timing of the tune jump is scanned across the spin resonance and the polarization at the end of the ramp is measured for each timing of the tune jump. If the spin tune crosses the vertical tune, a lower polarization is measured due to the depolarization across the resonance. The up-jump determines the location of the right side of the resonance and the down-jump allows to locate the left side.

The single crossing of the resonance, at the regular acceleration rate, has to strongly depolarize the beam in order for the difference in polarization to be clearly measured. Therefore the measurement is only carried at the two very strong vertical intrinsic resonances : $0+$ and $36+$.

While the method shown in figure 2 is very simple, several factors complicate the expected behavior :

- The vertical and spin tunes possess some spread due to energy spread of the beam and chromaticity of the machine, potentially blurring the transition between no depolarization and depolarization.
- The two resonances in each sides of $Q_s^{\max}$ can have different strengths, depending on the distance between them.

The experimental results are expected to be complex and no simple theoretical model can predict the observed polarization, the only solution to take everything into account would be to completely simulate the experiment. Thankfully the Zgoubi code[3] and the AGS Zgoubi online model[4] provide the perfect tools to simulate this experiment.

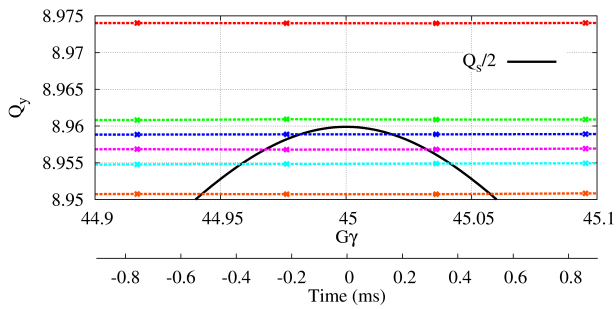

Figure 3: Vertical tune for the 5 different simulations and resonant condition for the second order snake resonance ($Q_s/2$) as a function of the energy or the time from $G\gamma = 45$.

Simulation at 36+

At $G\gamma = 45$, where the resonance $Q_y + 36 = Q_s$ is located, strong enough that the crossing of the second order snake resonance ($Q_s + 2Q_y = n$) induces a significant depolarization of the beam.

Multiparticle trackings using the Zgoubi code were done for a short simulation from $G\gamma = 44.5$ to $G\gamma = 45.5$. Realistic lattice conditions and acceleration rate were set up using the AGS Online model[4]. Each simulation consists

Copyright © 2013 CC-BY-3.0 and by the respective authors

in a tracking of 408 particles picked in a realistic 6-D Gaussian distribution for 3800 turns. The simulations total up around 20 000 CPU·hours[1].

Figure 3 shows the vertical tune without tune jump at $Q_y \sim 8.975$, lower than the operational tune across this resonance in order to cross the spin resonance when the jump quads are fired. Below, the different tunes on the jump were chosen across a wide range to determine the best configuration for the measurement.

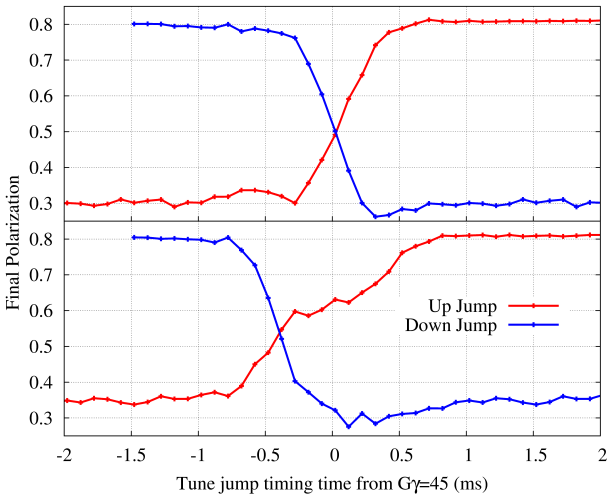

Figure 4: Final polarization for the up and down jump locations as a function of the time from $G\gamma = 45$ for the vertical tune on the jump just below the resonant condition (top plot) and for $Q_y = 8.951$ (bottom plot).

Figure 4 shows the experiment simulated for 2 different vertical tune on the jump. On the top plot the vertical tune on the jump is very close to the maximum value of the spin tune and the two vertical intrinsic resonances on either side of $G\gamma = 45$ are so close that they have the same effect on the beam and the figure is very symmetric, centered around $G\gamma = 45$. For a lower vertical tune the result is distorted due to the two resonances having different strengths when the distance separating them increases. These simulations show that the vertical tune on the jump should be positioned as close as possible from the maximum value of the spin tune.

Experiment at 36+

To correctly place the vertical tune we determined the maximum value reached by the spin tune across the resonance. By measuring the final polarization as a function of the vertical tune across $G\gamma = 45$ we determined that $Q_s^{\max}/2 = 0.956$. The vertical tune on the jump was placed at $Q_y = 8.954$ just below the resonant condition.

The polarization on the flat-top was measured as a function of the up and down jumps locations, by step of 200 μs. Figure 5 shows the measured data along with the simulation closest to the experimental conditions. The simulation results were numerically matched : vertically to account for the polarization lost outside the simulated range and horizontally shifted.

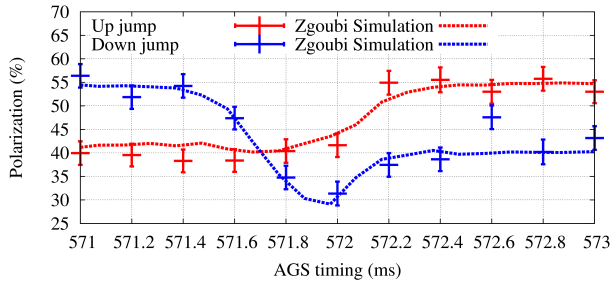

Figure 5: Final polarization for the up and down jump locations as a function of the time AGS time.

The matched horizontal shift of the simulation allows to determine that $G\gamma = 45$ is crossed at $T = 571.85$ ms. From the *GgammaMeter* data, we expected to see $G\gamma = 45$ at T = 572.7 ms. This difference is equivalent to $\sim 0.1\, G\gamma$.

RESULTS

The energy measurement at 36+ led to surprising results but the magnitude would suffice to explain an important loss of efficiency for the tune jumps. The same method was applied at $G\gamma = 9$ where a strong vertical intrinsic resonance is located, reporting a smaller disagreement with the energy measured by the *GgammaMeter* of $\Delta T = 0.1$ ms. Therefore it would appear that the energy reported by the *GgammaMeter* drifts along the ramp.

These results were used to recalibrate the the *GgammaMeter* and generate new tune jumps timings. Higher polarization was measured with the new timings on June 6th(Table 1), giving strong confidence into the energy measurement.

CONCLUSION

The energy measurement based on depolarization provided interesting results but the procedure is complex and the data taking is very long. But a faster method based on a continuous polarization measurement along the ramp is being developed and could be used for operation while the method described in this paper would be an important tool for experts to cross-check the results.

HALO CONTROL AND GENERATION IN RHIC *

C. Montag, K. A. Drees, BNL, Upton, NY 11973, USA

Abstract

In the next 5-10 years, RHIC will be colliding gold ions in the center-of-mass energy range of 5 to 20 GeV, which is below the regular injection energy. Though the machine has already successfully provided collisions at CM-energies of 7.7 and 11.5 GeV, a significantly higher luminosity than so far achieved is required for a meaningful physics program. While an electron cooler is presently being designed to provide the desired luminosity gain, this is a long-term project that is expected to be completed in 2018. As a short-term alternative the STAR collaboration has proposed installation of an internal halo target in the STAR detector beam pipe. To study the generation and control of the beam halo, we have performed dedicated beam experiments aimed at the bunch-by-bunch uniformity, and long as well as short-term stability of collimator loss rates.

INTRODUCTION

The Relativistic Heavy Ion Collider (RHIC) consists of two superconducting storage rings with a circumference of 3.8 km. In heavy ion collider mode, beams are injected at a rigidity of $B\rho = 81\,\mathrm{Tm}$ and accelerated to $B\rho = 833\,\mathrm{Tm}$ before they are brought into collision in the two detectors STAR and PHENIX. In the case of fully stripped gold ions, these beam rigidities correspond to an injection energy of 9.8 GeV/nucleon and a storage energy of 100 GeV/nucleon.

In recent years, nuclear physicists have become increasingly interested in searching for the critical point in the phase diagram of nuclear matter, which is expected to occur in the center-of-mass energy range between $\sqrt{s_{\mathrm{NN}}} = 5$ and 30 GeV, see Figure 1. To provide collisions in the desired energy range in collider mode, gold beams therefore have to be stored and collided at energies as low as a quarter of the nominal RHIC injection energy, which is extremely challenging due to large multipole errors in the superconducting magnets at these energies, as well as space charge and intrabeam scattering effects.

In 2010, RHIC has been successfully operated at center-of-mass energies of 7.7 and 11.5 GeV per nucleon pair [1]. However, to reach the desired integrated luminosities for the beam energy scan, RHIC would have to operate for a total of 70 weeks at these energies. Furthermore, performance at $\sqrt{s_{\mathrm{NN}}} = 5\,\mathrm{GeV}$ has not yet reached any level sufficient for meaningful physics operations, though beams have already been stored successfully at this energy [2], albeit at tiny intensities, and studies are underway to improve the performance [3].

* Work supported by Brookhaven Science Associates, LLC under Contract No. DE-AC02-98CH10886 with the U.S. Department of Energy.

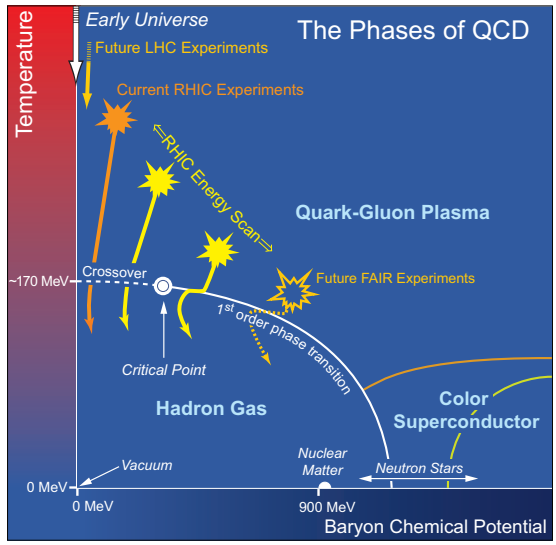

Figure 1: The QCD phase diagram, with the critical point expected in the center-of-mass energy range between $\sqrt{s_{\mathrm{NN}}} = 5$ and 30 GeV.

To improve the luminosity at low energies, an electron cooling system is currently being designed [4]. However, since this new device is scheduled to become operational in 2018, and because the lowest desired beam energy of 2.5 GeV per nucleon may turn out to be outside the useful reach of RHIC, the STAR collaboration has proposed the installation of a thin gold target in their detector area to study low energy gold-gold collisions in fix target mode rather than in collider mode [5].

The proposed internal target consists of a 30 mil (750 μm) thick gold foil that is installed in the RHIC beam pipe 2 m away from the STAR interaction point such that it intercepts the halo of the circulating Yellow beam upstream of the STAR detector, see Figure 2. To avoid potential damage to the target in case of an abort kicker pre-fire, which deflects the beam horizontally, the proposed target geometry is chosen such that it intercepts the beam halo only in the vertical plane. Furthermore, only the lower part of the beam pipe is equipped with the target foil, so in case the foil comes lose it does not drop into the beam path where it could block the aperture.

The aperture of the gold foil target needs to be chosen smaller than the 40 mm inner diameter detector beam pipe to make the target the local aperture limitation. On the

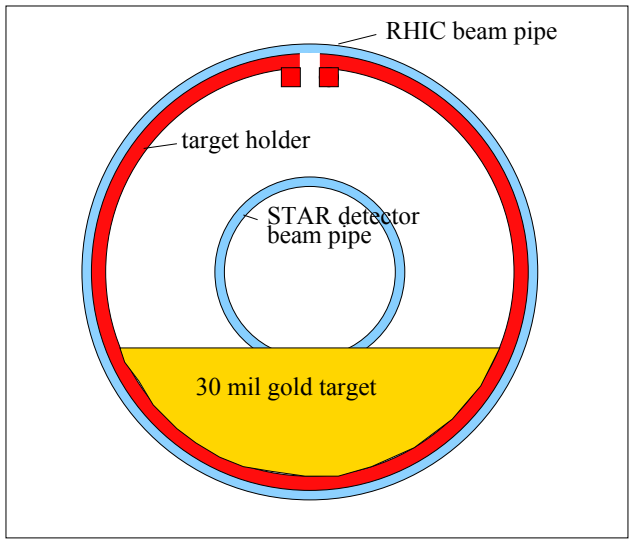

Figure 2: Schematic drawing of the proposed STAR internal target (Not to scale). The target will be installed at a distance of 2 m from the interaction point in the 3 inch inner diameter beam pipe. The aperture of the target is chosen slightly smaller than the 40 mm ID detector beam pipe.

other hand, the target must not interfere with regular collider operation. This can be accomplished by selecting a 16 mm half aperture for the target. This provides sufficient aperture at store as well as at injection, even when taking into account the $\pm 5\,\mathrm{mm}$ separation bumps around the interaction point. In dedicated target mode the target can deliberately be made the limiting aperture by increasing the separation bumps and blowing up the beam emittance.

Operating an internal halo target in a storage ring is challenging for various reasons, as the experience with the HERA-B target has shown [6, 7]. For instance, target interaction rates can vary greatly if the beam position is not stable enough due to mechanical vibrations of accelerator magnets, and/or the diffusion is not sufficient to replenish the transverse tails of the distribution. These large variations in the interaction rates tend to overwhelm the detectors with bursts of interactions, followed by periods without any rates at all, which makes data taking very difficult.

If transverse beam emittances vary greatly bunch-by-bunch, only the few bunches that have the largest emittances contribute to the interaction rates, resulting in similar detrimental effects as orbit jitter, albeit on a much faster time scale.

Finally, since the proposed STAR internal target is not moveable, interaction rate control has to be accomplished by manipulating the beam instead of adjusting the target position. While the target can be made the limiting aperture by applying a larger amplitude separation bump and increasing the emittance, sufficient diffusion has to be created to stabilize the interaction rates. Since the target will only be operated in a dedicated mode no special care has to be taken to preserve the emittance of the beam core for collider operation.

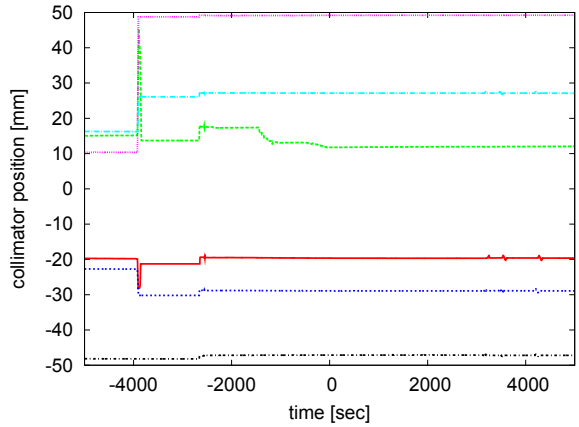

Figure 3: Recorded RHIC collimator positions during the beam experiment. The vertical collimator (green line) reached its final position at 11.5 mm. The horizontal axis is consistent with the one used in Figure 4.

To study the controlability and bunch-by-bunch uniformity of the target interaction rates as well as their stability at typical vibration frequencies up to hundreds of Hertz, beam experiments were performed during the FY 2013 polarized proton run.

EXPERIMENTS

Using the stored polarized proton beam at injection energy, a vertical collimator jaw was inserted into the beam halo until a loss rate of about 100 Hz per bunch was recorded by the local PIN diodes, which corresponds to a total rate of roughly 10 kHz from the 109 stored bunches. The resulting collimator position was measured by the BPMs and the collimator mechanics to be 11.5 mm from the beam center, as shown in Figure 3. With the tunes initially set to $(Q_x/Q_y) = (28.696/29.691)$, collimator loss rate control was attempted by moving the working point closer to the nonlinear resonances at $2/3$ and $7/10$, as shown in Figure 4.

In the first step, the horizontal tune was raised to $Q_x = 28.698$, which had little effect on the collimator loss rate, as can be expected since the collimator intercepts the halo vertically. Next, the vertical tune was raised towards $7/10$ as well, which also moves the working point closer to the coupling resonance. This resulted in the loss rates increasing from 100 to 200 Hz per bunch. However, when the tunes were kept constant at these new values the interaction rate dropped to its initial value within two to three minutes.

Finally, the vertical tune was slowly lowered towards the third order resonance at $2/3$, resulting in a rapid increase of the collimator loss rates as soon as it reached 28.683. Lowering it further to 28.678 raised the loss rates to 400 Hz per bunch. After about two minutes with stable tunes, the loss rate had dropped to 200 Hz per bunch, and remained

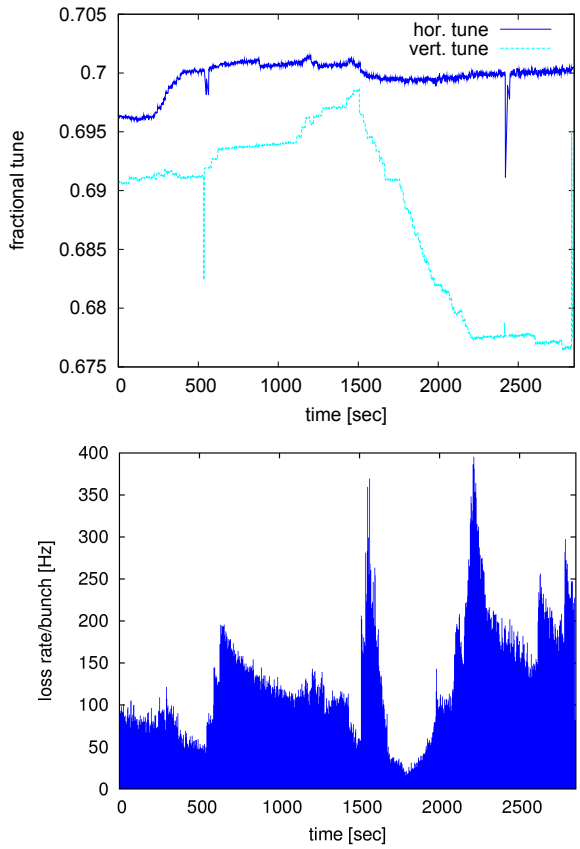

Figure 4: Loss rates during the tune scan. The horizontal scale is consistent with the one used in Figure 3, i.e. the tune scan starts after the collimators have reached their final position.

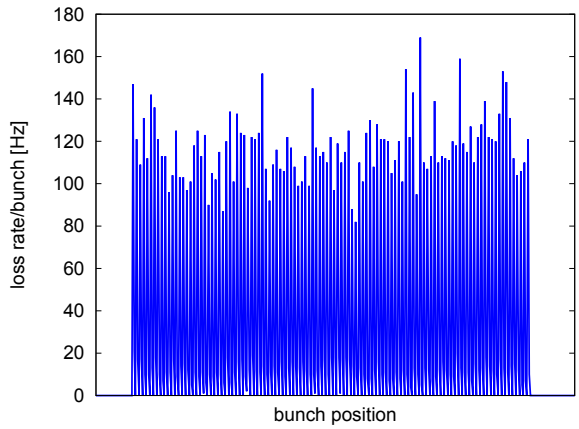

Figure 5: Bunch-by-bunch loss rates at a fixed point in time during the tune scan.

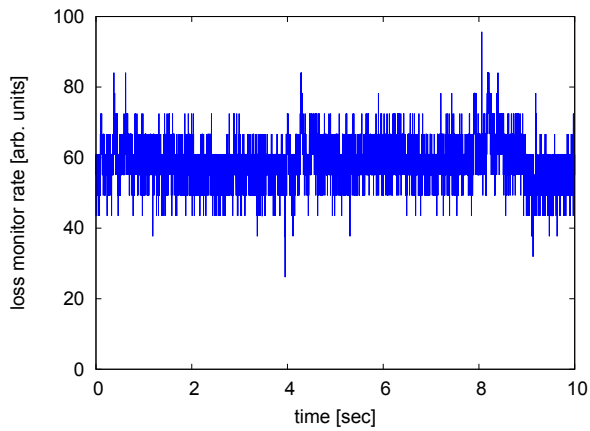

Figure 6: Loss monitor rates in the vicinity of the vertical collimator, sampled at 720 Hz.

reasonably constant there with a slow decrease from 200 to 120 Hz during the next five minutes.

Zooming in on the data during this stable period reveals the bunch-by-bunch structure of the collimator loss rates, Figure 5. As this plot shows, the bunch-by-bunch loss rate is very uniform along the entire train of 109 bunches.

Finally, the short-term stability of the target interaction rate can be studied using RHIC loss monitors in the collimator vicinity sampled at a high frequency of 720 Hz. As Figure 6 shows, the loss rates fluctuate very little over a time scale of 10 sec, indicating that high frequency rate variations due to effects like beam orbit jitter are practically non-existent.

SUMMARY

As these experiments have demonstrated, the interaction rate at the proposed internal target at STAR can be controlled by proper choice of a working point near a low-order resonance, in this case 2/3. While these experiments were carried out with a stored proton beam, the actual physics run will use gold ions. The higher IBS rates of such a gold beam compared to the proton beam used in this test are expected to improve the performance even further, making it possibly unnecessary to continuously move the tune towards a resonance to keep the interaction rate constant.

A GRAPHIC INTERFACE FOR FULL CONTROL OF THE RHIC OPTICS*

G. Robert-Demolaize, M. Bai, Brookhaven National Laboratory, Upton, NY, USA
Xiaozhe Shen, Indiana University, Bloomington, IN, USA

Abstract

A high level application has been developed for the RHIC collider to provide a complete package for optics control. Optics can be measured using three different algorithms to process turn-by-turn (TBT) beam position monitor (BPM) data from either free (tune meter) or driven (AC dipole) betatron oscillations, and corrected via SVD on a response matrix built around specific sets of quadrupoles. The following reviews the details of those methods, and includes the first results of the operational commissioning of the application.

INTRODUCTION

One of the methods to measure the linear RHIC optics for any of its high energy heavy ions or polarized protons runs relies on AC dipoles (ACD's). In a particle accelerator, ACD's are designed to adiabatically drive coherent betatron beam oscillations with a frequency close to the beam tune. For RHIC, a GUI application called *loptics* was built to control the amplitude and frequency of the dipole field of a given ACD when measuring the optics of the corresponding beamline. Once the ACD is triggered, all BPM's around the considered ring record the beam oscillations over 1024 turns; linear optics are then derived using fitting algorithms on each BPM dataset [1]. With the recent successful developments of β_z-beating correction methods at RHIC in Run12 and Run13 [2], a major upgrade of *loptics* was to turn the application into a complete tool for measurement, correction as well as control of linear optic functions.

LINEAR OPTICS MEASUREMENTS

Fitting Driven and Free Oscillations

For coherent oscillations driven by an ACD at a tune $\nu_{\mathtt{AC}}$, the beam actually "sees" both $\nu_{\mathtt{AC}}$ and $1-\nu_{\mathtt{AC}}$ driving tunes according to the Nyquist sampling theorem. The transverse beam position $z_i^s(N)$ (for either plane) measured at the ith BPM and Nth turn at the longitudinal coordinate s in RHIC can then be derived as:

$$\begin{aligned} z_i^s(N) &= A_m \cos\left(2\pi\nu_{\mathtt{AC}}N + \psi_m(s)\right) \\ &- A_p \cos\left(2\pi\nu_{\mathtt{AC}}N - 2\pi\nu_{\mathtt{AC}} + 2\chi_{\mathtt{AC}} - \psi_m(s)\right), \end{aligned} \quad (1)$$

with $\psi_m(s) = -\pi\left(\nu_{\mathtt{AC}} - \nu_z\right) + \chi_{\mathtt{AC}} - \psi_z(s)$ and:

$$A_m = \frac{B_m L}{4\sin\left(\pi\left(\nu_{\mathtt{AC}} - \nu_z\right)\right) B\rho}\sqrt{\beta_z(s)\beta_z^0},$$

$$A_p = \frac{B_m L}{4\sin\left(\pi\left(\nu_{\mathtt{AC}} + \nu_z\right)\right) B\rho}\sqrt{\beta_z(s)\beta_z^0}.$$

where $B_m L$ is the integrated strength of the ACD field, $B\rho$ the magnetic rigidity, $\beta_z(s)$ and $\psi_z(s)$ the betatron function and phase advance at the ith BPM, β_z^0 the betatron function at the ACD, and $\chi_{\mathtt{AC}}$ the ACD initial phase. Eq. (1) can be written in both a compact form [3] (Eq. (2)) and a tune-phase dissociated form [4] (Eq. (3)):

$$z_i^s(N) = A_d\sqrt{\beta_d(s)}\cos\left(2\pi\nu_{\mathtt{AC}}N + \left[\psi_z(s) + \chi_{\mathtt{AC}}\right]\right), \quad (2)$$

$$z_i^s(N) = A_m\left[\cos(\psi_m(s))F_N - \sin(\psi_m(s))G_N\right]; \quad (3)$$

with $r = \sin\left(\pi\left(\nu_{\mathtt{AC}} + \nu_z\right)\right) / \sin\left(\pi\left(\nu_{\mathtt{AC}} - \nu_z\right)\right)$ one gets:

$$F_N = \cos\left(2\pi\nu_{\mathtt{AC}}N\right) - r\cos\left(2\pi\nu_{\mathtt{AC}}(N-1) + 2\chi_{\mathtt{AC}}\right),$$

$$G_N = \sin\left(2\pi\nu_{\mathtt{AC}}N\right) + r\sin\left(2\pi\nu_{\mathtt{AC}}(N-1) + 2\chi_{\mathtt{AC}}\right).$$

The compact form from Eq. (2) is then solved using the nonlinear Levenberg-Marquardt [5] fitting method on the three variables $A_{tot}(s) = A_d\sqrt{\beta_d(s)}$, $\nu_{\mathtt{AC}}$ and $\psi_{tot}(s) = \psi_z(s) + \chi_{\mathtt{AC}}$. The dissociated form in Eq. (3) can be solved with a linear fitting algorithm for the variables $A_m\cos(\psi_m(s))$ and $A_m\sin(\psi_m(s))$ once the driving tune $\nu_{\mathtt{AC}}$ is found using a fast Fourier transform (FFT) on the TBT data at the considered BPM. The ratio of amplitudes A_{tot} or A_m between two BPM's are then directly proportional to the ratio of the $\beta_z(s)$ functions at the BPM's locations. The phase advance $\psi_z(s)$ can only be calculated from $\psi_{tot}(s)$ or $\psi_m(s)$ with a precise knowledge of the initial ACD phase $\chi_{\mathtt{AC}}$; instead, *loptics* provides the phase difference $\Delta\psi_z(s)$ between two consecutive BPM's, which is independent of $\chi_{\mathtt{AC}}$.

The $\beta_z(s)$ and $\Delta\psi_z(s)$ derived from fitting Eq. (2) are actually the "driven" amplitude and phase of the beam oscillation. Results from the nonlinear fitting will therefore carry some artificial β_z-beating with an amplitude [6]:

$$\frac{\beta_d(s) - \beta_z(s)}{\beta_z(s)} \approx \frac{2\pi\left(\nu_{\mathtt{AC}} - \nu_z\right)}{\sin\left(2\pi\nu_z\right)}\cos\left(2\psi_z(s) - 2\pi\nu_z\right). \quad (4)$$

For typical ACD operations at RHIC, this amplitude is estimated at about 7% for $\nu_{\mathtt{AC}}$-ν_z=±0.01. For a linear machine, the artificial β_z-beat can be reduced experimentally to about 0.3% by driving the beam oscillations with $\nu_{\mathtt{AC}} > \nu_z$ in one measurement and $\nu_{\mathtt{AC}} < \nu_z$ in another, and averaging the fitted optics.

Free oscillations can be generated from beam injection oscillations or a coherent excitation by a single turn kicker magnet (e.g. for tune measurements), with $z_i^s(N)$ defined as:

* Work supported by Brookhaven Science Associates, LLC under Contract No. DE-AC02-98CH10886 with the U.S. Department of Energy.

Copyright © 2013 CC-BY-3.0 and by the respective authors

$$z_i^s(N) = A^s_{calc}\cos\left(2\pi\nu_{calc}N + A^s_3\right),$$
$$\text{with: } A^s_{calc} = A^s_1 \exp\left(-2.0\left(\frac{\pi N}{A^s_2}\right)^2\right). \quad (5)$$

The three variables $A^s_{1,2,3}$ are fitted similarly to driven oscillations using Levenberg-Marquardt. This allows the application to analyze any TBT oscillations dataset acquired during RHIC operations and derive the linear optics. Like in the nonlinear case, ν_{calc} is calculated for each BPM dataset via FFT and should be close to the machine tune ν_z. $\beta_z(s)$ and $\Delta\psi_z(s)$ are then determined from the fitted values A^s_1 and A^s_3 at each BPM.

Data Analysis in loptics

Figure 1 shows the graphical interface (GUI) of *loptics* with the ACD control options on the right hand side. Users can provide initial guesses for all parameters to be fitted in the bottom right side. The measured $\beta_z(s)$ and $\Delta\psi_z(s)$ are plotted against their respective design values as calculated by the RHIC online model. The corresponding β_z-beat and phase-beat plots are displayed in a separate tab and saved for further use with the optics correction algorithms. β^*_z and s^* at all IP's are also interpolated and displayed in a dedicated table. One of the upgrades to *loptics* is the calculation of horizontal and vertical phase advances between each IP, providing valuable information when commissioning the new RHIC lattices with e-lens compensation schemes [7].

More than one dataset can be analyzed at a time, with error bars calculated accordingly. Another recent upgrade to the application allows users to analyze datasets acquired with different $\nu_{\mathtt{AC}}$ in order to get rid of the artificial β_z-beat when using the linear fitting method. Each driving tune setpoint makes for an independent measurement, and all related datasets are grouped in the same data analysis process; all calculated average values and error bars are then recombined using the rules of propagation of uncertainty.

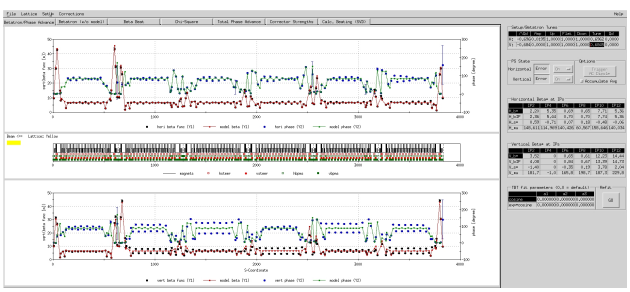

Figure 1: *loptics* graphic interface showing the results of data analysis of AC dipole driven Yellow polarized protons beam oscillations for 255 GeV optic functions (black dots) and phase advance (blue dots) measurements, compared to expected values from the RHIC online model (red and green traces respectively). Both horizontal (top) and vertical (bottom) planes were measured.

CORRECTION ALGORITHMS

In addition to new fitting methods, *loptics* now features a correction algorithms package for the RHIC linear optic functions. The first method is based on a singular value decomposition (SVD) of a response matrix R built around the machine settings as defined in the RHIC online model. Based on the wiring scheme of the RHIC insertions [8], one can find a group of n quadrupoles with individual power supplies to operate as a β_z knob for optics corrections. For all m BPM's in a given beamline, the online model can calculate $(\Delta\beta_z/\beta_z)_p, p = 1\ldots m$ at the pth BPM resulting from a small gradient error $\Delta k_j, j = 1\ldots n$ at the jth selected quadrupole. The matrix $R_{m,n}$ is then built as:

$$\begin{pmatrix}(\Delta\beta_z/\beta_z)_1\\ \vdots \\ (\Delta\beta_z/\beta_z)_m\end{pmatrix} = R_{m,n}\cdot\begin{pmatrix}\Delta k_1\\ \vdots\\ \Delta k_n\end{pmatrix}. \quad (6)$$

Following the data analysis and optics calculations previously described, *loptics* can solve Eq. (6) for $\Delta k^{err}_j, j = 1\ldots n$ by inverting $R_{m,n}$ with SVD:

$$\begin{pmatrix}\Delta k^{err}_1\\ \vdots\\ \Delta k^{err}_n\end{pmatrix} = -\left(R^{-1}_{m,n}\right)\cdot\begin{pmatrix}(\Delta\beta_z/\beta_z)_1\\ \vdots\\ (\Delta\beta_z/\beta_z)_m\end{pmatrix}_{meas} \quad (7)$$

The correction strengths derived from Eq. (7) can be tested in the online model before being applied to the machine, in full or in incremental steps. Figure 2 shows the calculated gradient errors and the corresponding predicted β_z-beat derived from a measurement of the RHIC Yellow lattice optic functions during a beam experiment with polarized protons at 255 GeV. One can notice that all quadrupole magnets selected for the optics corrections are located in all six RHIC interaction regions (IR's) to allow for the maximum number of power supplies to be used, therefore increasing the efficiency of the SVD package. Figure 3 presents the corrected β_z-beat from the optics shown in Figure 1 once 100% of the calculated correction strengths are applied to the Yellow lattice. There is a significant improvement especially in the vertical plane, where the peak-to-peak amplitude of the beating is reduced to about $\pm$ 20%. One should note that in *loptics* the size of $R_{m,n}$ takes into account the status bit of each BPM prior to SVD: any status other than "good" and the entire corresponding row in the response matrix is discarded. Another filter could be implemented that would discard BPM data (and matching $R_{m,n}$ row) if the measured β_z-beat appears to be too unrealistic (e.g. very large reported amplitude compared to other BPM's).

A segment-by-segment method (SBST) [2] is also currently being added to *loptics*. SBST can be used to determine significant gradient errors in individual IR magnets and would allow correcting optics locally, reducing the global β_z-beat to be corrected via SVD. Experiments with beam to test this two-pronged method are being discussed for the coming Run14 of RHIC.

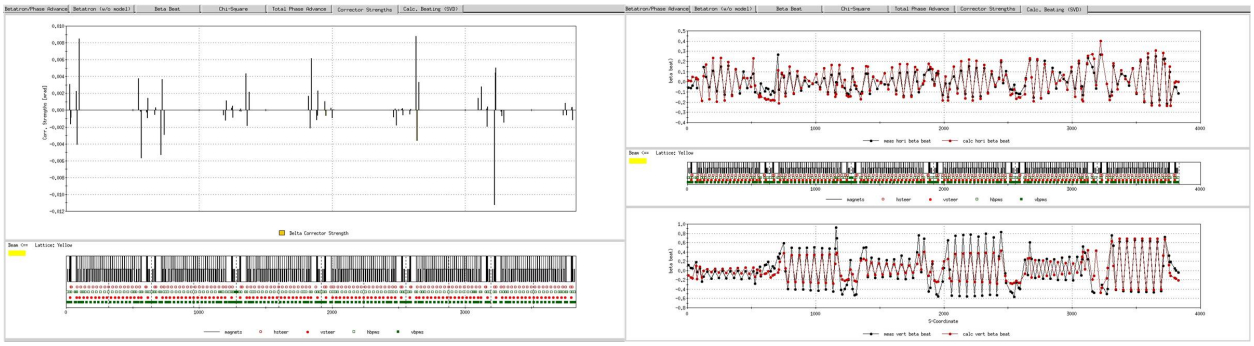

Figure 2: Strength of the gradient errors Δk_j^{err}, $j = 1 \ldots n$ (left) calculated using the global SVD correction scheme newly implemeted in *loptics* for the optics shown in Figure 1 and the selected quadrupole knob. The β_z-beat from these Δk_j^{err} as predicted by the RHIC online model (right, red trace) is compared to the measured one (right, black trace) to determine the quality of the determined solution.

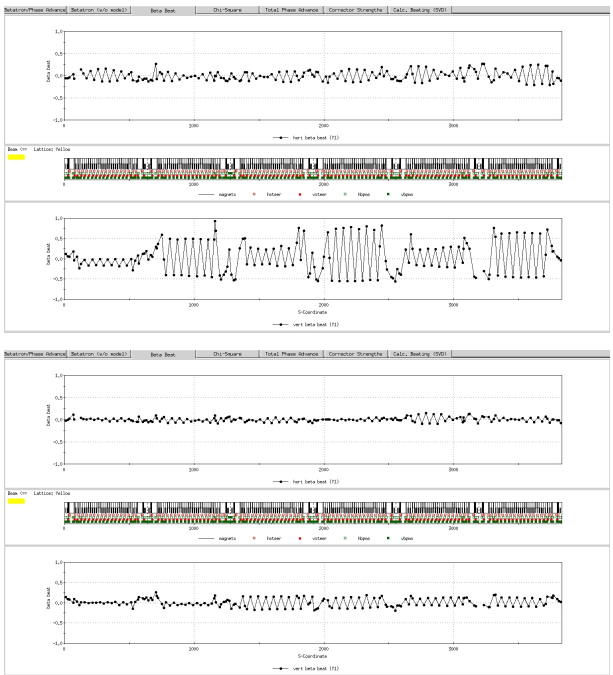

Figure 3: Measured (top) and corrected (bottom) Yellow 255 GeV polarized protons beam optics using the global SVD correction algorithm described in Figure 2.

CONCLUSION

loptics has been upgraded to allow for linear optics measurement using either free or driven turn-by-turn oscillations, with a graphic interface displaying all relevant parameters. Additionally, a correction algorithm based on SVD calculations on a response matrix built with the RHIC online model is now part of the application after being tested with beam as a standalone procedure. Its use in *loptics* allows predicting the accuracy of the correction before sending the knob values to the machine.

Further improvements include the combination of SBST and SVD correction methods, as well as adding an Independent Component Analysis (ICA) model for optics calculations [9]. ICA allows splitting the beam oscillations measured at each BPM into their betatron and synchrotron motions components, as well as filter out any background noise inherent to the electronics involved, leading to a more precise determination of β_z and $\Delta\psi_z(s)$ before corrections.

AKNOWLEDGEMENTS

The authors would like to thank Al Marusic and Simon White for their contribution in developing the new tools and their participation in the optics measurement experiments.

TRAJECTORIES OF LOW ENERGY ELECTRONS IN PARTICLE ACCELERATOR MAGNETIC STRUCTURES*

E.E. Cowan, Dept of Physics, Syracuse University, NY, USA
Kiran G. Sonnad†, CLASSE, Cornell University, NY, USA
Seth Veitzer, TechX Corp. Boulder, CO, USA

Abstract

It has been observed recently that low energy electrons, or electron clouds formed within quadrupoles can remain trapped for time periods beyond a beam revolution period at Cesr [1]. This paper provides some results obtained from analysis and numerical tracking of low energy electrons in quadrupoles under conditions similar to those when the above mentioned data was collected.

MOTION OF PARTICLES IN A NONUNIFORM MAGNETIC FIELD

Electron clouds generated in positively charged beams are known to negatively interfere with the beam. Most of the simulations done for various accelerators for estimating the cloud buildup have been for the duration of the passage of a single train of bunches. However if an electron remains trapped for long enough in a magnetic structure such as a quadrupole after the passage of a train, this trapped electron will encounter the next passage of a bunch train. The electron may then impinge upon the walls and potentially produce secondary electrons. Such a mechanism could lead to a progressive enhancement in cloud densities with repeated train passages and can have adverse consequences on the properties of the beam.

Trapping of electrons has been observed in the PSR [2]. In this experiment the proton beam was allowed to circulate and produce electrons and the beam was then deflected out of the storage ring, while the electron cloud was allowed to evolve. It was observed that electrons in quadrupoles persisted for a time period exceeding 50-100μs. More recently, experiments performed at Cesr observed electron trapping in quadrupoles in the presence of a beam [1]. The revolution period of the beam in Cesr is about 2.5 μs.

In this paper, we report results obtained from single particle tracking and compare them with theoretical expectations. The parameters of our computations were similar to those of the operating conditions when the data reported in Ref. [1] was taken. A similar study was performed earlier for the KEKB [3]. This study clearly showed that trapping of electron in quadrupoles can be important and requires a careful study.

Adiabatic Invariants

In dynamical systems exhibiting periodic motion, the quantity $\oint p \cdot dq$, which is the phase space area encompassed by the trajectory, also known as the Poincare invariant is a conserved quantity [4]. If a system undergoes a very gradual change, this quantity remains conserved so long as the relative value of this change over a full period of motion is very small, (see for example Ref. [4]). A classic example is a simple pendulum where the length of the string is gradually altered at a rate such that over the course of the oscillation period, $\delta l/l << 1$. Then the quantity E/ω remains constant and is the adiabatic invariant. The same principal of adiabatic invariance can be applied to a particle executing cyclotron motion in a magnetic field (see for example Ref. [5]). For a particle in this situation, the magnetic moment

$$\mu = IA = \frac{mv_\perp^2}{2B} \tag{1}$$

is conserved as long as $dB/B << 1$ over the cyclotron period T_c. This is equivalent to the following condition,

$$\frac{|\nabla B|}{B} r_c << 1, \tag{2}$$

where r_c is the cyclotron radius. On the other hand, energy which is given by

$$\mathcal{E} = \frac{1}{2} m(v_\perp^2 + v_\parallel^2) \tag{3}$$

being an absolute invariant always remains conserved. In the above equation, $v_\perp$ and $v_\parallel$ are velocities perpendicular and parallel with to the magnetic field, respectively.

Magnetic Mirroring

If energy and the magnetic moment are conserved, one can obtain a formula for magnetic mirroring. As B increases, $v_\perp$ increases and $v_\parallel$ decreases. If $v_\parallel$ decreases to zero, the trajectory turns around. This phenomenon is referred to magnetic mirroring. Since $v_\perp$ is rotating around the field line, one can associate this condition with a cone in velocity space. A particle would lie within the "loss" cone if

$$v_\parallel / v_\perp > 1 - (B_{bd}/B_{in})^{1/2}. \tag{4}$$

Here B_{in} is the magnetic field value at the initial point, and B_{bd} is the magnetic field on the same field line at the boundary of the vacuum chamber. A particle lying outside this cone in velocity space at the given point will remain trapped.

Motion Transverse to Magnetic Field

Magnetic mirroring is a consequence of the effect of the particle motion along the magnetic field lines. Additionally, in the presence of a nonuniform field, the particle undergoes a "grad B" and a "curvature drift", which are perpendicular to the field lines. In the absence of any current sources, where $\nabla \times \mathbf{B} = \mathbf{0}$, the curvature of the field can be related to its gradient, and the expressions of the two drifts may be combined in the following form,

$$v_{curv} + v_{\nabla B} = \frac{m}{q} \frac{\mathbf{B} \times \nabla B}{|B|^3} (v_{\parallel}^2 + \frac{1}{2} v_{\perp}^2) \qquad (5)$$

The values of the magnetic field here correspond to points along the motion of the guiding center. While it is clear that a particle can never be trapped indefinitely because of this drift, what matters in our study is if the particle is trapped for the period of one beam revolution. Fringe field effects have been disregarded throughout this study, which would become important for electrons that are either formed in this region or drift into this region due to the effect described above. Nevertheless, we show that for electrons to undergo a prominent longitudinal drift, they have to acquire energies close to 1 KeV, which are typically high for electrons formed from multipacting.

RESULTS FROM TRACKING STUDIES IN QUADRUPOLE FIELDS

In order to test the validity of the loss cone and Eq. 4, five different initial positions were chosen. These points lay on a horizontal line parallel to the cross-section of the beam pipe and passing through the center of the cross-section. In order to determine the loss cone angle for these points, one needs to determine the field value at the given point as well as the "escape" point. The latter was determined with the help of a program we developed that traced the path along the field line. The point beyond which the particle was considered lost was located on this field line, very close to the boundary of the chamber. The chamber shape consists of two circular arcs (radius 0.075m) on the top and bottom, connected with flat side planes. It is about 0.090m from side to side and 0.050m between the apices of the arcs. The magnetic field is given by $B_x = ky$ and $B_y = kx$ with $k = 7.4T/m$, which is close to the value set during the operation of Cesr at 5.3 GeV.

Table 1: Cases Studied to Confirm Trapping

x(m)	B_{in} (T)	B_{bd}	θ_m (deg)	$\angle$ 1, $\angle$ 2
0.0005	0.0365	0.2261	66.2989	65, 67
0.015	0.1095	0.2386	47.3414	45, 48
0.025	0.1825	0.2626	33.507	32, 34
0.035	0.2555	0.2972	21.9773	20, 23
0.04	0.2920	0.3184	16.7044	15, 17

Table 1 shows all the initial positions from where electrons were tracked. The critical angle θ_m is equal to $90deg-$ (loss-cone-angle). Since the points lay on the horizontal axis, the magnetic field direction for all of them was vertical. Thus, if the particle launch angle with respect to the horizontal axis was less than θ_m one would expect it to be trapped. The tracking was performed using the plasma simulation program Vorpal [6]. The particles were launched at angles (with respect to the horizontal axis) just above and below the critical angle, indicated as $\angle 1$ and $\angle 2$ respectively. For each case, the energies used were 1eV, 10eV, 100eV and 1 KeV. In most cases, particles that started at $\angle 2$ remained confined while those with $\angle 1$ were lost. The only exceptions were when the particles were at $x = 0.05cm$ with energies 1Kev and 100eV, when particles at both the starting angles were lost. It was also confirmed that when particles were incrementally close to the center, they were lost within $2.5\mu s$ even at an energy of 1eV regardless of the initial direction of motion.

For a quadrupole magnetic field, one can easily verify that the condition of adiabatic invariance, given by Eq. (2) becomes weaker as one approaches the center. Depending on the particle energy, it becomes invalid at a certain point close enough to the origin. This explains the poor confinement for particles that cross points close enough to the center.

Overall, one could divide the trajectories into three classes, (1) Those that escape because their parallel and perpendicular velocities are distributed such that they lie within the loss cone. (2) Particles that remain trapped because they lie outside the loss cone, and the condition for adiabatic invariance remains satisfied. (3) Particles that cross points sufficiently close to the center that that the motion becomes non-adiabatic in the vicinity od the center. As these particles move away from the center due to inertia, they begin to move into an area of higher magnetic field, where the motion may become adiabatic. If they are within the loss cone, they escape. If they are outside the loss cone, they get reflected back toward the center. Depending upon the phase of the cyclotron motion they acquire near the center, they may stray away from the center in an entirely different direction. This process repeats itself until it enters the loss cone and impinges against the wall.

Figure 1 is an example of a particle that escapes because it is within the loss cone. Figure 2 is an example of particle that remained trapped for the period of $2.5\mu s$ because it was located outside the loss cone. Figure 3 was a particle very close to the center that exhibited non-adiabatic motion. The energy in all these cases was 1 KeV.

Figure 4 shows the three dimensional motion of a trapped particle at 1 KeV, clearly indicating the drift along the longitudinal direction. Figure 5 is a plot of the same z motion as a function of time. This plot compares the motion of the full trajectory, as computed by the tracking, the guiding center motion obtained from the tracking by numerically averaging over the cyclotron periods, and the motion as predicted by Eq. 5. We see that the analytic results agrees well with the numerically computed guiding center motion. The longitudinal distance covered by the

Copyright © 2013 CC-BY-3.0 and by the respective authors

particle in 2.5μs was found to be about 0.34m, while the length of the quadrupole is about 0.6m. Additionally, it is known from build up simulations that the fractional population of particles with energies of 1 KeV are not more than a few percent. Based on Eq. 5, one can state that the distance covered by the particles is roughly proportional to the energy (disregarding the details of the parallel vs perpendicular distribution of the velocities). Typical energies of the electrons is of the order of 100eV. One can thus argue that the longitudinal drift of trapped electrons does not contribute significantly to their escape before the arrival of a subsequent bunch train.

A LINEAR ENVELOPE MODEL FOR MULTI-CHARGE STATE LINAC*

Z. He#, FRIB, Michigan State University, USA; Tsinghua University, China
J. Wei, Y. Zhang, Z. Liu, FRIB, Michigan State University, USA
R. M. Talman, Cornell University, USA

Abstract

The traditional linear envelope tracking model is widely used in linac design and on-line tuning. However, for multi-charge state acceleration, where the transfer matrix acts differently on different charge-states, the linear envelope tracking model cannot be utilized. A direct way to handle multi-charge state acceleration is using multi-particle tracking, which is usually high in precision, but lacking in efficiency, therefore is not suitable for linac on-line beam tuning. In this paper, a new approach of adapting linear envelope tracking model to multi-charge state acceleration is proposed. The lattice of FRIB is used to test this technique in both linac segment and folding segment. The result is then benchmarked with a multi-particle tracking program IMPACT to ensure its precision with enhancement in efficiency.

INTRODUCTION

The traditional linear envelope tracking model is widely used. Instead of tracking every particle, the method is capable of keeping track of beam envelopes by knowing an initial theta matrix and the transfer matrix between the initial point and the objective point, which is shown below.

$$x_i^{(1)} = R_{ij} x_j^{(0)}$$

$$\sigma_{ij}^{(0)} = \frac{\sum_n \left(x_{ni}^{(0)} x_{nj}^{(0)} \right)}{N}$$

$$\sigma_{ij}^{(1)} = \frac{\sum_n \left(R_{ik} x_{nk}^{(0)} R_{jm} x_{nj}^{(0)} \right)}{N} = R_{ik} \sigma_{km}^{(0)} R_{jm}$$

Numbers of linac code are based on or contains this scheme, such as Trace 3D. The advantage of envelope tracking model is obvious: fast in calculation speed, simple and clear in physics, therefore, remains to be a preferable way in computational intensive applications like case-by-case based linac lattice global optimization, and time restricted applications like linac on-line beam tuning.

For traditional accelerators like electron or proton machines, only one charge state is presented and the traditional linear envelope tracking model can be directly adopted. However, Facility for Rare Isotope Beams (FRIB) is accelerating multiple charge states in order to enhance the beam current. For this kind of accelerators, the traditional linear envelope tracking model can no longer be adopted directly, extensions onto multi-charge states acceleration problems are needed.

HOW TO DEAL WITH MULTI-CHARGE STATE ACCELERATION

There are three different schemes to handle multi-charge state acceleration problem. The most simple and straight forward one is multi-particle tracking. The advantage is we can expect minimum change of existing tracking code, attain high precision and detailed information. Particle tracking code like IMPACT, is utilizing this scheme. However, the shortcoming is high computational intensity and slow speed. And computer takes over all the calculation would result physics to be unclear.

The second way is to treat charge state deviation as momentum deviation for magnetic field. This method can give exact result on transverse coordinates and can reuse most part of existing code. But the problem the method can only handle all-magnetic field lattice. The imaginary extra momentum deviation can cause imaginary change in time-of-flight for non-relativistic cases. This method is sometimes quite useful when calculating multi-charge beam behaviour in a bending magnet.

THREE-STEP SCHEME

The third way is to treat different charge states separately using envelope tracking scheme. This method can be divided into three steps:

Step 1: Use an ideal particle with centre charge state to initiate the machine parameters, such as RF phases, bending magnet strength. Keep record of the particle and make it the reference of the whole beam.

Step 2: Choose the particle located at beam centre of each charge state as a reference particle and do single particle tracking according to the initialized lattice parameter. Keep record of each particle and make it the reference for each charge state beam.

Step 3: Do envelope tracking for each charge state beam. The transfer matrix should be adjusted according to its own charge state and reference orbit.

This method of handling multi-charge state is a combination of precision of particle tracking method and efficiency of envelope tracking. The calculation efficiency is quite high. Details can vary while the three step scheme concept is universal. For next part, the FRIB lattice would be analysed as an example using this method.

APPLICATION TO FRIB LATTICE

The FRIB project, built at the Michigan State University in corporation with the US Department of

Copyright © 2013 CC-BY-3.0 and by the respective authors

Energy (DOE), will deliver all stable ion beams with energy more than 200MeV/u and target beam power more than 400kW. In order to meet this goal, multi-charge state acceleration is needed, especially for heavy ions, to increase the beam current and beam power. For the Uranium case, the 33+, 34+ charge states are accelerated in linac segment 1, and after a charge stripped and charge selector, the 76+, 77+, 78+, 79+, 80+ charge states are selected and accelerated all the way to the target. Fig. 1 shows detailed layout of FRIB lattice.

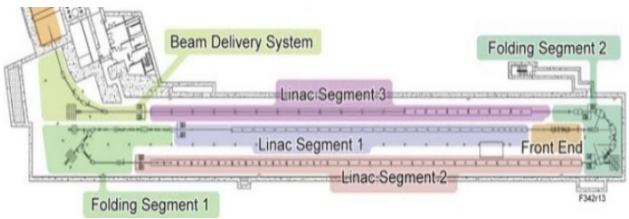

Figure 1: Layout of FRIB lattice.

Linac Segment

The linac segment is where heavy ions gain most part of its kinetic energy. For linac segment 1, superconducting quarter-wave resonators (QWRs), are used for accelerating ion beams while for linac segment 2, superconducting half-wave resonators (HWRs) are used. For both linac segment 1 and linac segment 2, superconducting solenoids are the main component used for focusing ion beams.

Linear Matrix Models: To track the energy and phase advance for synchronous particle in an RF cavity, the Drift-Kick-Drift thin lens model is utilized:

$$\begin{cases} W_f = W_i + qV_0T(k)\cos\varphi_i - qV_0S(k)\sin\varphi_i \\ \varphi_f = \varphi_i + \dfrac{qV_0}{2W_i}k[T'(k)\sin\varphi_i + S'(k)\cos\varphi_i] \end{cases}$$

T, T', S, S' are Transit Time factors. Two gap accelerating model is utilized to decrease the error caused by constant velocity assumption [1].

The longitudinal phase space transfer matrix comes from differentiation of the longitudinal Drift-Kick-Drift thin lens model and keeping the linear term of energy and phase deviation. The transverse phase space transfer matrix also comes from a Drift-Kick-Drift thin lens model. For each acceleration gap, the total transfer matrix can be decomposed into drift spaces between two focusing/ defocusing gaps and an acceleration.

A soft edge solenoid model is used in our model:

$$M_{soft\,sol} = M_{edge}M_{sol}M_{edge}$$

$$M_{edge} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ -\Phi & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & -\Phi & 1 \end{bmatrix}$$

M_{sol} is the traditional hard edge solenoid transfer matrix M_{edge} describes the edge effect. $\Phi = -\frac{g^2a}{2}$, $= \frac{Bqc}{2\beta E_{tot}}$, and a is the solenoid radius [2].

These models have been verified by envelope tracking of single charge state after benchmark with a multi-particle tracking code IMPACT [3]. Then we can use the three step scheme to extend the model to handle multi-charge state acceleration.

Linac Segment 1: First step is to initialize the lattice parameters using a centre charge state. For linac segment 1 case where the two charge states are 33+ and 34+, either one can be used as reference charge state. Here we choose 33+ as the reference charge state and the lattice is initialized using an ideal 33+ particle. After initializing the lattice parameters, the centre particle for 33+ and 34+ charge states are tracked and results are recorded as reference orbit for each charge state. Then we can use envelope tracking scheme to track the envelope of 33+ and 34+ beam bunch separately. Transfer matrix can be influenced not only by charge states but also by reference orbit. Beam centre and RMS envelope evolution results can be seen in Fig. 2.

We can see from the figure that the 33+ charge state particle tends to have larger phase, because the 33+ charge state would always be dragged off and fall behind due to lack of acceleration efficiency compared to 34+. For transverse direction, the centre of beam for both charge states is coincident with the beam axis. Due to the different focusing strength for the different charge states, the focusing lattice cannot match both charge states at the same time, so we can see oscillation comes from mismatch for both charge states.

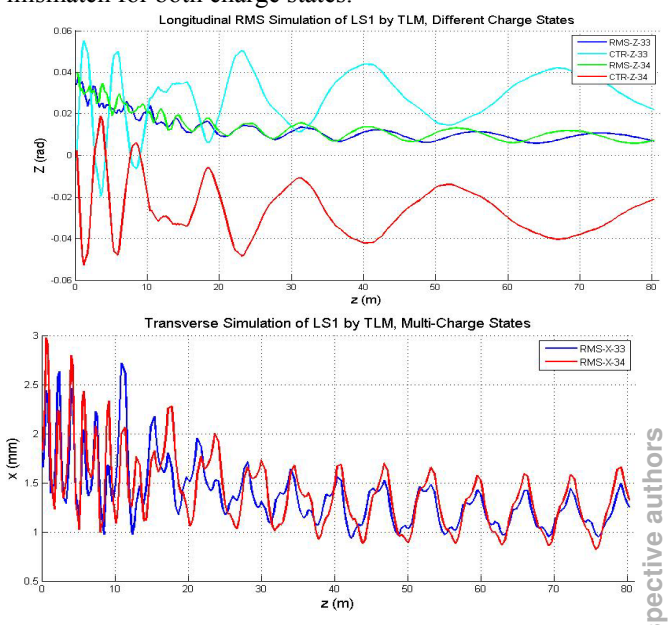

Figure 2: Upper: Linac segment 1 longitudinal phase centre deviation for the 33+ and 34+ two charge states and the phase spread RMS envelope in the centre of mass frame Lower: transverse beam RMS envelope for the 33+ and 34+ two charge states.

RMS Envelope Re-combine: For real experiment, we usually measure the whole bunch beam size. So, we need to calculate the total RMS beam size. In the centre of mass frame, $\bar{x}$ is centre of beam for each charge state, σ is the RMS size, N is particle number, foot note i represents different charge state, than the whole bunch RMS beam size equals:

Copyright © 2013 CC-BY-3.0 and by the respective authors

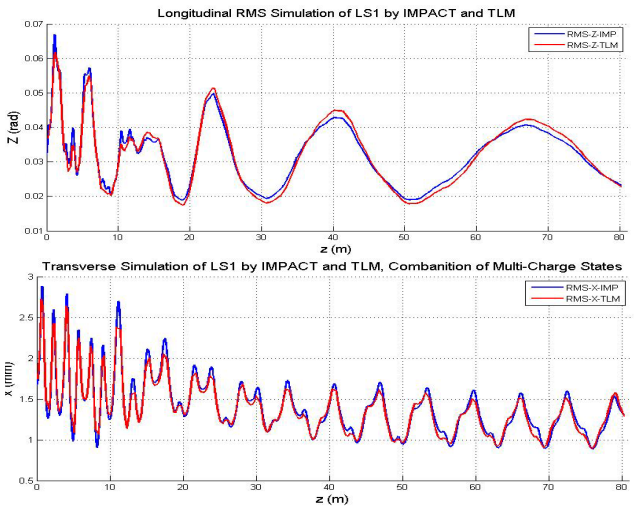

Figure 3: Re-combine of RMS envelope and benchmark with IMPACT. Upper figure, Re-combine of RMS envelope for the longitudinal direction, Lower figure, Re-combine of RMS envelope for the transverse direction.

$$\sigma = \sqrt{\frac{\sum_i N_i(\sigma_i^2 + \bar{x}_i^2)}{N}}$$

Using this scheme to recombine the beam size and benchmark with IMPACT, we can get the result shown as Fig. 3. We can see that the simple envelope model for handling multi-charge state benchmarks well with IMPACT simulation.

Folding Segment

There are two 180 degree benders linking three linac segments. For charge state far away from centre whose equivalent dispersion is quite high, higher order term may appear. In order to suppress the potential influence from higher order term, a new scheme has been proposed.

First, use a centre charge state to initialize lattice parameter, for uranium beam in bending segment 1 case where the charge states are 76+, 77+, 78+, 79+ 80+, the charge state 78+ is chosen to initialize the lattice. Then, for the centre particles of the remaining charge states, their own reference orbits are set up. Note that in order to suppress the possible higher order term coming from bending magnet, the exact transfer map is used to track the reference particles [4].

After setting up reference orbits, we can use envelope model to do envelope tracking. For this time, the traditional bending magnet transfer matrix for non-relativistic ion beams can be used.

By using the scheme, we can also obtain the beam centre and beam RMS size of each charge state in folding segment 1, the result is shown as Fig. 4. After recombination and benchmark with IMPACT, we arrive in the final result benchmark with IMPACT shown as Fig. 5. The thin lens model agrees well IMPACT result.

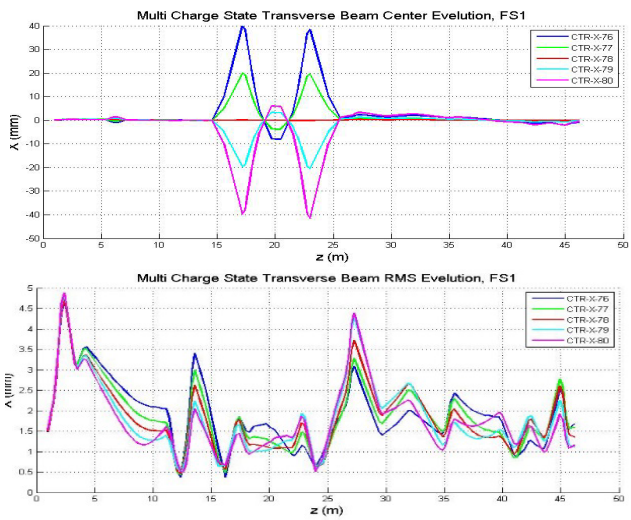

Figure 4: Transverse beam centre (upper) and beam RMS envelope (lower) evolution of five different charge states in folding segment 1.

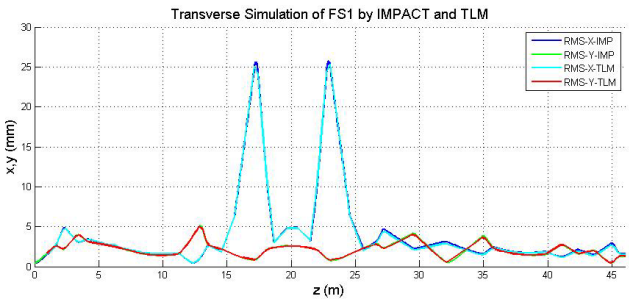

Figure 5: Re-combine of transverse RMS envelope of five different charge states in folding segment 1 and benchmark with IMPACT.

CONCLUSION

The multi-charge state envelope tracking model has proved to be precise and efficient. The result agrees well with multi-particle tracking. Very minor modification of currently available model is needed. The computational efficiency also turns out to be high. A beginning to end of FRIB lattice parallel computation of multi-particle tracking by IMPACT would take several minutes, while multi-charge state envelope tracking method would take only several seconds. The increment in efficiency makes the model promising in further development of on-line applications like fast beam tuning and lattice optimization for multi-charge state acceleration machine as FRIB.

CALCULATION OF THE KICK MAPS GENERATED BY A HOLLOW ELECTRON LENS FOR STUDIES OF HIGH-ENERGY HADRON BEAM COLLIMATION*

G. Stancari†, M. Chung, A. Valishev, Fermilab, Batavia, IL 60510, USA
V. Moens, EPFL, Lausanne, Switzerland, H. J. Lee, Pusan National University, Korea

Abstract

Collimation with hollow electron beams is a technique for halo removal in high-power hadron beams. It was experimentally studied at the Fermilab Tevatron collider using electron lenses and it is being considered as an option to complement the collimation system for the LHC upgrades. In the ideal case, the magnetically confined electron beam has a hollow, axially symmetric current-density distribution, whose fields affect the beam halo, leaving the core of the circulating beam unperturbed. We address the effects of imperfections in the current density based upon profiles measured in the Fermilab electron lens test stand. We also study the effect of the bends used to inject and to extract the electron beam from the overlap region. The calculated field distributions will serve as inputs for tracking simulations, which are needed to estimate the effects of the electron lens imperfections on beam core dynamics, such as nonlinearities and emittance growth.

INTRODUCTION

Hollow electron beam collimation is a new technique for collimation and halo scraping of intense hadron beams in storage rings and colliders [1]. In a hollow electron beam collimator, a magnetically confined, pulsed, low-energy electron beam with a hollow current-density profile overlaps with the circulating beam over a short section of the ring. Figure 1 shows the layout of one of the Tevatron electron lenses. The beam is formed in the electron gun inside a conventional solenoid and guided by strong axial magnetic fields. Inside the superconducting main solenoid, the circulating beam interacts with the electromagnetic fields generated by the charge distribution of electrons. The electron beam is then extracted and deposited in the collector. The halo of the circulating beam can be smoothly scraped. The core is unaffected if the distribution of the electron charge is axially symmetric. One cause of asymmetry is the space-charge evolution of the electron beam as it propagates through the electron lens. Another source of asymmetry are the bends that are usually used to inject and extract the electron beam from the interaction region. Although small, these asymmetries may have detectable effects on core lifetimes and emittances because of their nonlinear nature, especially when the current of the electron pulse is changed turn by turn to enhance the halo removal effect by resonant excitation of selected particles.

In this paper, we discuss the effects of these asymmetries from experimental data and from calculations. In particular, the asymmetries in the charge distribution are translated into transverse kick maps for the circulating beam. These kick maps are provided as inputs for numerical tracking simulations of the Fermilab Tevatron collider and of the Large Hadron Collider at CERN with the Lifetrac or SixTrack codes. This work is in support of a conceptual design for a proposed hollow electron beam collimator for the LHC upgrade [2]. The same techniques can be applied to different current-density profiles (Gaussian, flat, etc.) to study perturbations in nonlinear integrable optics with electron lenses for the IOTA ring at the Fermilab ASTA facility [3].

AZIMUTHAL ASYMMETRIES

Two-dimensional azimuthal asymmetries of the electron current density in the overlap region inside the main solenoid (neglecting the injection and extraction regions) may be caused by the space-charge evolution of the hollow electron beam as it propagates through the electron lens (diocotron instability), or by imperfections in the electron gun geometry, magnetic field lines, etc.

Electron guns are characterized at the Fermilab electron-lens test stand. Current-density profiles are measured as a function of beam current and axial magnetic field. Space-charge evolution of the electron beam profiles is mitigated by increasing the guiding magnetic fields. The measured profiles are used to calculate the corresponding transverse electric fields inside the beam pipe using the Poisson

solvers of the Warp plasma particle-in-cell code [4]. A few examples of these calculations can be found in Ref. [5]. Inside the hole of the electron beam, where no charge is present, the potential satisfies Laplace's equation and the effect of the asymmetries can be characterized as a superposition of multipoles. Elsewhere, a more general parameterization is necessary. This approach was used to compare calculated and measured halo removal rates in the Tevatron [6]. For the Tevatron lattice and tune working point, the only azimuthal asymmetry seen to cause extra losses in the core was the quadrupole component in a particular resonant mode (pulsing the electron beam every 6th turn). Calculations for the LHC are under way and will be presented in the conceptual design report.

EFFECT OF BENDS

In an electron lens, toroidal bends are used for injecting and extracting the electron beam (Figure 1). To study whether the curved charge distribution of electrons has a significant effect on the dynamics of the circulating beam, we rely on the Tevatron experiments and on calculated kick maps.

Most of the Tevatron experiments on hollow electron beam collimation were done in continuous mode: the electron current was kept constant turn by turn. Under these conditions, no deteriorations of core lifetimes or luminosities were observed. For the LHC, to extend the range of achievable halo removal rates, resonant operation is also being considered: in this mode, the voltage in the electron gun is changed turn by turn according to a sinusoidal function, in resonance with betatron oscillations, or with the same amplitude, skipping a given number of turns [7]. Resonant operation was used for abort-gap cleaning in the Tevatron [8], but no systematic experimental studies were done on the effects of time-varying pulse amplitudes on the beam core. For this reason, numerical tracking studies are planned, and here we describe the calculation of the kick maps to be used as inputs.

The parameters of the proton beam are used to calculate beam sizes in the interaction region. We assume a round proton beam with a typical rms beam size $\sigma_p = 0.317$ mm. The hollow electron beam is represented by a cylindrical bent pipe with a curvature radius $R = 0.7$ m, inner radius $r_i = 1.27$ mm $= 4\sigma_p$, and outer radius $r_o = 2.39$ mm $= 7.5\sigma_p$. The ratio between the outer and the inner radius is chosen to reproduce the dimensions of the cathode in the existing 1-inch hollow electron gun [5, 9]: (12.7 mm)/(6.75 mm). The bent tube of electrons spans a bend angle of $\theta = 30$ deg. A total of $N_e = 1048576 = 2^{20}$ electron macroparticles is used to reproduce the static charge density distribution of a 1-A, 5-keV electron beam. The z-axis is chosen along the direction of the circulating proton beam. The x-axis points horizontally outward. The upward direction is represented by the y-axis. The origin of the coordinate system coincides with the point where the axis of the bent electron beam intersects the axis of the circulating beam (Figure 2).

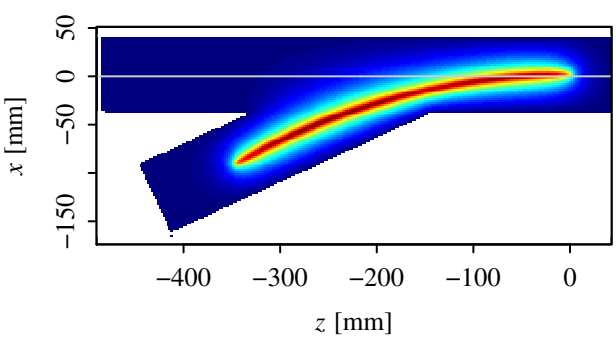

Figure 2: Conductor geometry and calculated electrostatic potential on the plane of the bent electron distribution. Dark red corresponds to −1.2 kV, dark blue represents 0 V. The horizontal gray line is the axis of the proton beam.

A multigrid Poisson solver within the Warp particle-in-cell code is used to calculate the electrostatic fields. The boundary conditions are defined by a long cylindrical main beam pipe and by a cylindrical injection beam pipe stub, joining the main pipe at an angle (Figure 2). This arrangement is a simplified version of the injection scheme in the Tevatron electron lenses (Figure 1). Both pipes have an inner radius $r_{\text{pipe}} = 40$ mm.

Space is subdivided into 2 discrete grids, a coarse one (2-mm spacing) covering the whole space, and a fine one (0.1 mm) around the central trajectory of protons. The transverse coverage of the fine mesh, $-10\sigma_p \le x, y \le 10\sigma_p$, is designed to obtain kick maps for both the core and the halo of the proton beam.

Figure 2 shows the electrostatic potential $V(x,y,z)$ on the xz-plane of the bend. The electrostatic fields E_x and E_y are integrated over straight paths to calculate the transverse momentum kicks $\Delta p_{x,y}$ experienced by the circulating proton beam:

$$k_{x,y}(x,y) \equiv \int_{z_1}^{z_2} E_{x,y}(x,y,z)\,dz, \qquad (1)$$

$$\Delta p_{x,y} = \int_{t_1}^{t_2} F_{x,y}\,dt = \frac{q}{v_z}\int_{z_1}^{z_2} E_{x,y}\,dz = \frac{q}{v_z}k_{x,y}, \qquad (2)$$

where q, v, and p are the charge, velocity, and momentum of the circulating beam, F is the electrostatic force, t is time, and the integrated fields k_x and k_y are later loosely referred to as 'kicks.' Only transverse kicks are considered, as the longitudinal kicks of two symmetric bends cancel out. The transverse kicks due to two bends, on the other hand, have the same sign and will add up. The typical angles of the proton trajectories are of the order of $\sigma_p' = 1.6\ \mu$rad, so the resulting position variations over the length of the bend can be neglected. For 7-TeV protons, an integrated field of 10 kV generates an angular deviation of 1.4 nrad. The kick maps on the fine mesh are represented as contour plots in Figure 3. Protons on axis experience a negative horizontal integrated field of −9.1 kV, whereas

Copyright © 2013 CC-BY-3.0 and by the respective authors

the vertical kick vanishes. The vertical kick on the plane of the bend is zero.

For tracking simulations, one can interpolate the given kick maps in 2 dimensions for each particle. Alternatively, to speed up calculations, one can use an analytical formulation of the functions $k_x(x,y)$ and $k_y(x,y)$. We use a parameterization in terms of the outer product of 1-dimensional Chebyshev polynomials in x and y up to a given order N. Because of the symmetry of the charge distribution, the horizontal kicks are even functions of y and only contain even powers of the vertical coordinate, whereas the vertical kicks are odd functions of y. At order $N = 7$, for instance, the standard deviation of the residuals of this interpolating model is about 150 V.

To study the sensitivity of the results to the geometry of the system, cases with different beam pipe radii and injection angles are simulated. The chosen beam pipe radii were 35 mm, 40 mm (reference case), and 45 mm. The chosen bend angles were 25 deg, 30 deg (reference case), and 35 deg. The changes in geometry considered in this study amount to a change in the kicks of less than 300 V.

Further details on the calculation of these kick maps can be found in Ref. [10].

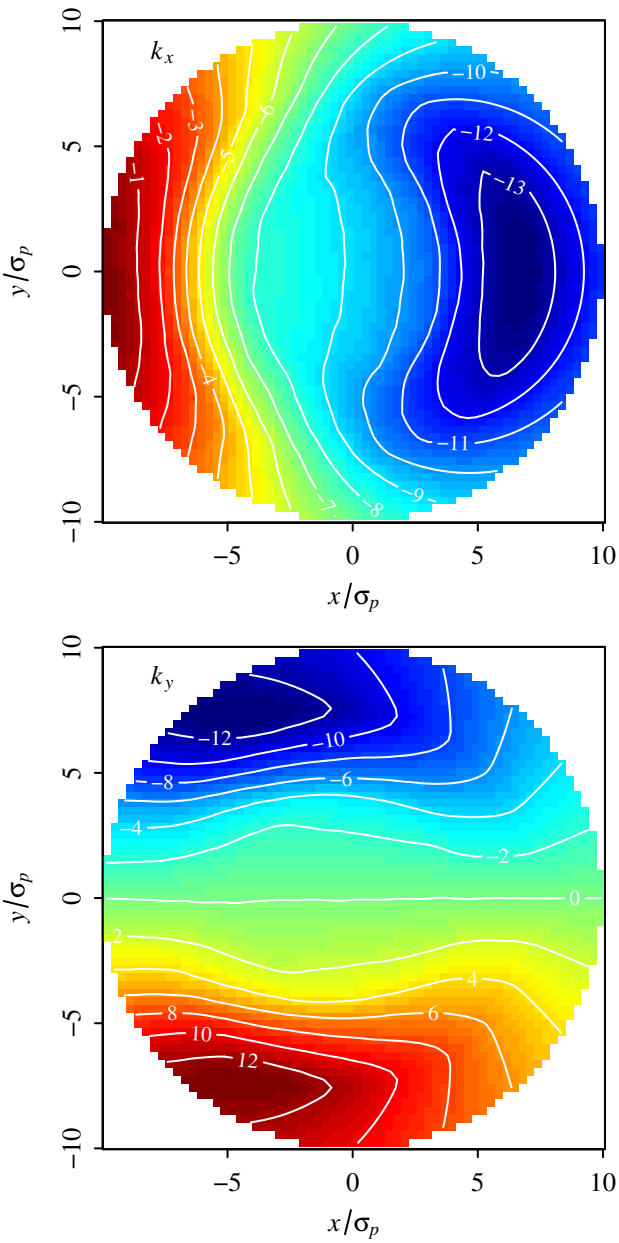

Figure 3: Contour plots of the integrated fields k_x (top) and k_y (bottom) as a function of scaled transverse coordinate. The contour lines are labeled with the value of the integrated field in kilovolts.

CONCLUSIONS

We studied some of the effects of electron-lens asymmetries on the circulating beam for hollow electron beam scraping. Two-dimensional current-density distributions are measured in the Fermilab electron-lens test stand and are used to calculate the transverse electric field distributions for tracking simulations. The electrostatic fields generated by the injection and extraction bends in an electron lens were also estimated. A bent, 1-A, 5-keV electron beam creates nonlinear transverse integrated electric fields of the order of 10 kV. Kick maps are provided on a fine grid for 2-dimensional interpolation and as coefficients of truncated power series of orthogonal polynomials for evaluation with analytical formulas in numerical tracking codes.

LIMITATIONS OF INCREASING THE INTENSITY OF A RELATIVISTIC ELECTRON BEAM*

J.E. Coleman#, D.C. Moir, C.A. Ekdahl, B.T. McCuistian, J.B. Johnson, G.A. Sullivan, and M.T. Crawford, LANL, Los Alamos, NM 87545, USA

Abstract

A 7 cm cathode has been deployed for use on a 3.8 MV, 80 ns (FWHM) Blumlein, to increase the extracted beam current from the nominal 1.7 kA to 2.9 kA. The intense relativistic electron bunch is accelerated and transported through a nested solenoid and ferrite induction core lattice consisting of 64 elements, exiting the accelerator with a nominal energy of 19.8 MeV. The principal objective of these experiments is to quantify the space charge limitations on the beam quality, in addition to its coupling with the corkscrew and the beam breakup (BBU) instabilities. Time resolved centroid measurements indicate a reduction in BBU >5x with simply a 20% increase in the average B-field used to transport the beam though the accelerator. A qualitative comparison of experimental and calculated results are presented, which include axial BBU amplitude with different accelerator lattice tunes.

INTRODUCTION

Relativistic electron beams used to study fundamental nuclear physics or provide intense sources of photons are challenged with instabilities to overcome when increasing the intensity of the beam. One of particular interest is the beam breakup (BBU) instability which manifests itself as a transverse magnet coupling to destroy the beam quality. BBU was first observed in the 1960s [1] and reported in detail by Stanford Linear Accelerator Center scientists in 1968 [2]. Shortly after its discovery, BBU was studied for the first time in detail on the Advanced Test Accelerator, a linear induction accelerator [3].

The first axis of the Dual-Axis Radiography for Hydrodynamic Testing (DARHT) facility is exploring the limitations of increasing the intensity of the electron beam for future radiographic capabilities. DARHT Axis-1 is unique for these studies because it is relatively simple to change the cathode emission size to increase or reduce the total current and therefore change the space charge of the beam while holding everything else constant. In order to effectively increase the intensity of the beam, the BBU instability must be quantitatively understood and effectively reduced. Beam Position Monitors (BPMs) provided time resolved centroid and BBU measurements.

EXPERIMENTAL SETUP

The experimental configuration used to study the BBU instability was the DARHT Axis-1 linear induction accelerator (Fig. 1). The accelerator is composed of a 4 MV Blumlein injector [4] and 32 Blumleins [5] used to drive at total of 64 induction cells (2 cells per Blumlein). The linear induction accelerator is broken up into 8 cell blocks consisting of 8 ferrite induction cores in each cell block for a total of 64 induction cells and 65 anode-cathode gaps. Each induction cell has the ability to impart 250 keV of energy into the beam for a total of 16 MeV in addition to the 3.8 MeV acquired in the diode.

Beam Position Monitors

The transported beam current and centroid is monitored by BPMs at the end of each cell block and internal to each cell block, so there is a BPM every 4 cells with axial spacing between 185-224 cm. The BPMs consist of 8 B-dots, or inductive monitors, oriented azimuthally every 45°. There are 4 position B-dots, 1 top and bottom for ±y measurements and 1 left and right for ±x measurements.

The ±x and ±y B-dots in each BPM were used to measure the BBU amplitude throughout the accelerator. This was done by measuring the unintegrated Δx and Δy which was sampled up to 8 GHz. A fast Fourier transform was applied to the signal over ± 50 ns in addition to the

pulse length of the beam. The frequency spectrum was then integrated from 600-900 MHz to determine the BBU intensity

BEAM BREAKUP INSTABILITY

The BBU growth along the accelerator is characterized by the equation [6]:

$$\frac{\xi}{\xi_o} = \left(\frac{\gamma_o}{\gamma}\right)^{1/2} \exp\Gamma_m, \qquad (1)$$

where ξ is the measured BBU amplitude and ξ_o is the measured at the entrance of the accelerator. The amplitude decreases with acceleration to ½ power and increases exponentially with the growth factor, Γ_m

$$\Gamma_m = \frac{1}{c} I_b N_g Z_\perp \left\langle \frac{1}{B} \right\rangle, \qquad (2)$$

where c is the speed of light, I_b is the beam current, N_g is the number of gaps, $Z\perp$ is the transverse impedance, and $<1/B>$ is the average of the inverse magnetic field strength.

TRANSPORT AND BBU MEASUREMENTS

We began tuning the 2.9 kA beam envelope using the nominal tune for the 1.7 kA beam and the initial conditions measured from a sweep of the first transport magnet (Fig. 2). These measurements were also compared with calculations made with the TRAK code [7] and provided the initial conditions at z = 167 cm of a = 35 mm and a' = -17.5 mrad. Initially it was assumed because of the high space charge (K = 6 x 10^{-4}) of the beam coming out of the gun we could not converge the beam envelope too steeply because it would overfocus in the low or field-free regions between cell blocks. This first attempt is shown in Fig. 2 for Tune 4 where a gradual increase of the magnetic field from 360 G at the beginning of the first cell block to > 800 G at the end of the second cell block we were able to gradually converge the beam envelope down to ~13 mm. Evidence of the space-charge force quickly increasing the 2.9 kA beam radius between the cells is shown at z = 650 cm in Fig. 2(a). Initially only three magnets were changed in cells 8,9, and 10 to tune the envelope of the 2.9 kA beam from the nominal 1.7 kA tune, this is evident for the <B> calculated in Fig. 2(b) where there is only a slight difference after cells 5-8 (z = 572 cm) and cells 9-12 (z = 796 cm).

After initially attempting Tune 4 and examining Eqs. 1&2 it was expected that the BBU should increase by exp(2.9/1.7) ~ 5.5. However, after quickly investigating the signals on the downstream BPMs it was apparent that there was a substantial amount of BBU, which manifests itself as RF superimposed on the beam envelope. The top row of Fig. 3 shows the BBU on the raw signal of the 2.9 kA beam is ~20x higher than the 1.7 kA beam. After performing a fast Fourier transform over the 200 ns window of interest the frequency spectrum indicates nearly a ~40x increase in BBU. Both data sets indicate the BBU spectrum ranges from 700-850 MHz. Each of the cases shown here are a single shot representation of the average BBU amplitude for 5 shots.

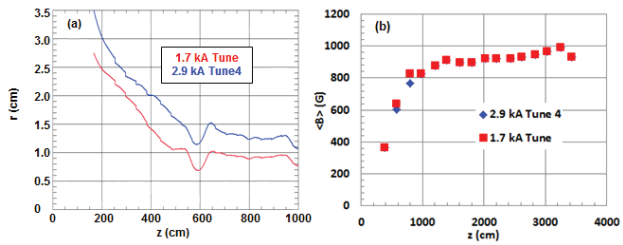

Figure 2: (a) Envelope comparison between the nominal 1.7 kA beam (red) and the first attempt at transporting the 2.9 kA beam (blue) in the first two cell blocks and; (b) <B> for 4 cells in each cell block for both tunes.

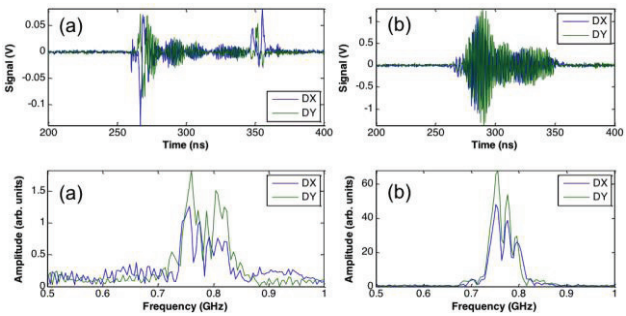

Figure 3: Top row: unintegrated Δx and Δy signals measured at BPM 20 (z = 36.1 m). Bottom row: fast Fourier transform of the signal above to indicate the amplitude and frequency of the BBU on the beam for: (a) the 1.7 kA beam; and (b) Tune 4 for the 2.9 kA beam.

A more detailed analysis made it apparent that the average BBU growth for the 2.9 kA tune was >10x higher than measured with the 1.7 kA beam (Fig. 4(a)). BBU is negligible for the nominal 1.7 kA tune until BPM07 (z = 980 cm) and the average measured value for 5 shots is $<\xi>$ = 0.044 ± 0.032. The BBU amplitude for Tune 4 matches the 1.7 kA tune at BPM07 (CB 2) and then increases ~11x the amplitude of the 1.7 kA beam at BPM09, through the 3rd cell block. The error bars in Fig. 4(a) indicate the shot to shot variation of the BBU amplitude which ranges from 10-60% depending on the amplitude and location. Over the length of the accelerator BBU increases 500x for the 1.7 kA beam and >10^3x for Tune 4, leading to factor of ~28x higher BBU for the 2.9 kA beam at BPM 20 (z = 3.6 m) (Fig. 4(b)). Direct comparison of the BBU measurements for the 1.7 kA beam with the 2.9 kA beam clearly shows $\xi_{2.9}/\xi_{1.7}$ >> exp(2.9/1.7) ~ 5.5. Applying a least squares fit to both data sets in Fig. 4(b) we are able to back out the slope of the exponential BBU growth and determine a

Copyright © 2013 CC-BY-3.0 and by the respective authors

measurement of the transverse impedance of the accelerator cells. The slopes are slightly different; the 1.7 kA data set yields 887 Ω/m and the 2.9 kA data set yields 1121 Ω/m. Each are within the measured and calculated cavity values of 400-1200 Ω/m over frequency ranges of 300-900 MHz.

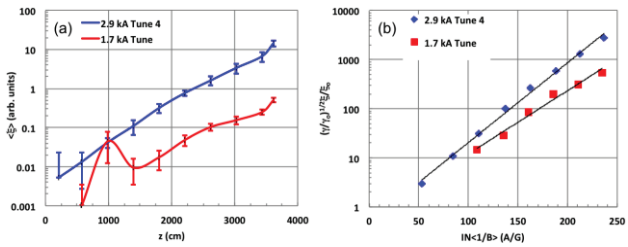

Figure 4: (a) Increase of the average BBU amplitude <ξ> over 5 shots due to the increased beam current from 1.7 (red) to 2.9 kA (blue); and (b) comparison of BBU growth along the accelerator. Each tune indicates a constant transverse impedance.

With this substantial growth in the BBU amplitude it was necessary to develop a tune with increased <B> along the length of the accelerator. The <B> in 4 cells of each cell block for each of the successive tunes and their corresponding envelopes are shown in Fig. 5. Each tune iteration brought the beam envelope down more steeply by increasing the <B> at the end of the accelerator, where the BBU amplitude was most apparent. Eventually we had to work our way upstream and begin tuning from the 1st cell block, in Tune 6, because of the lack of suppression.

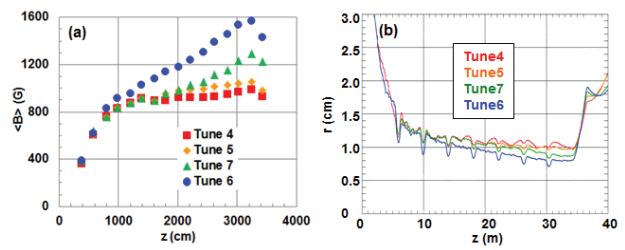

Figure 5: (a) <B> for 4 cells in each cell block used reduce BBU; and (b) the reduced 2.9 kA beam envelope for Tunes 4-7.

BBU at the upstream end of the accelerator is negligible for Tunes 5-7; it did not begin to become apparent until BPM 07 (z = 980 cm) as shown in Fig. 6(a). A reduction in <ξ> of ~5x is evident at BPMs 17-20 (z > 30 m) in Fig. 6(a) over tunes iterations from 4-6. The BBU growth along the accelerator for each successive tune is shown in Fig. 6(b). The initial BBU amplitude, ξ_o, is different for each tune contributing to the staggering of each curve. In addition the final product of growth factor, IN<1/B>, decreases for each successive tune as expected, from 237 A/G for Tune 4 to 194 A/G for Tune 6; an increase in <B> of 20%. Tune 7, which has a slightly reduced <B> compared to Tune 6, is shifted down on the BBU growth curve because its initial amplitude at BPM 7, 0.0275 >> <ξ> at BPM 7 for Tune 6. Each tune has nearly the same slope on the BBU growth curve (Fig. 6(b)) indicating the consistency in the transverse impedance of the induction cells in the accelerator lattice. The average transverse impedance for these four tunes is 1086 ± 26 Ω/m.

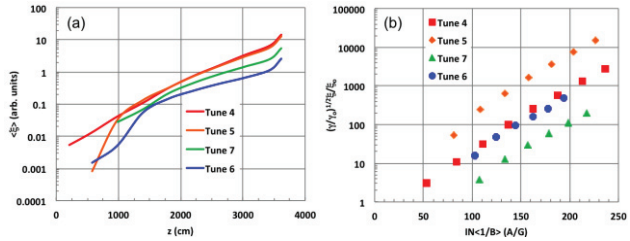

Figure 6: (a) Reduction in the average BBU amplitude, <ξ>, over 5 shots at each z-location due to the increased <B> with each successive tune; and (b) comparison of BBU growth along the accelerator for each successive tune. Each tune indicates a constant transverse impedance.

CONCLUSION

An increase in the intensity of the DARHT Axis-1 beam by 70%, with nearly the same transport lattice, lead to a ~28x increase in the final BBU amplitude. After several tune iterations, we successfully reduced the BBU amplitude 5x by simply increasing the <B> in the accelerator 20%. A more detailed explanation of these results and a further reduction in the BBU amplitude will be published elsewhere.

ACKNOWLEDGEMENT

I would like to take the opportunity to thank the DARHT Axis-1 operators and technicians James Carothers, Sam Snider, Melissa Reed, Jules Carson, Tim McCurdy, Rudy Valdez, and Edward Jacquez for their continued support.

SYNCHROTRON RADIATION NEAR FIELD IN 3D*

C.-K. Huang#, B. E. Carlsten, and T. J. T. Kwan, Los Alamos National Laboratory,
Los Alamos, NM 87545, USA

Abstract

The Coherent Synchrotron Radiation (CSR) effect plays an important role in particle accelerators where high current electron beams are required, e.g., in X-ray Free Electron Laser. These electron beams are typically compressed to kA current in magnetic bends therefore they are subject to CSR effect. The widely used 1D CSR model relies on particle's radiation field along the circular trajectory near its present position, i.e., Green's function in 1D. We augment our previous 2D numerical CSR model by extending the synchrotron radiation near field calculation in the vertical direction. Our 3D calculation includes the dependence of the field on the relativistic beam energy through the scaled spatial variables and can be used to construct an efficient 3D CSR model due to the self-similarity of the field pattern in these variables.

INTRODUCTION

Coherent synchrotron radiation occurs in accelerators when high current beam bunches move along a circular beam path. It is a collective effect due to the coherence of the synchrotron radiation emitted by individual charge particle in the beam. As the radiation field on a particle is enhanced by the number of nearby particles if they emit coherently, the beam can undergo emittance growth or microbunching instabilities from interacting with its own coherent radiation. CSR is a major adverse effect on the performance of the FEL and has been investigated extensively in 1D and 2D [1-8]. As accurate understanding of the CSR effect requires modeling that accounts for the realistic beam shape and parameters, a 3D model will be essential and valuable. Although various CSR models have been developed so far, the most efficient and widely used models are based on a convolution approach using the time-independent longitudinal synchrotron radiation near-field, i.e., the "Green's function", of a single particle. We note that this near-field Green's function is relative to the present position of the radiating particle and in fact consists of both the near field and far field contributions from the particle at various retarded positions. Extending such CSR model into 3D requires an accurate description of the said Green's function in 3D, which is described in detail in the next two sections.

APPROXIMATE GREEN'S FUNCTION FOR RADIATION FIELD IN 2D

In this section we first review the 2D CSR model developed in Ref. [9]. This will serves as the premise of the 3D model discussed in the next section.

A diagram of the geometry is shown in Fig. 1. It is assumed that an electron is moving along a prescribed circular trajectory of radius R at constant angular velocity in the bending plane perpendicular to the magnetic field. The present and retarded positions of the particle are denoted as P and P', the corresponding velocities denoted as $\vec{\beta}$ and $\vec{\beta}'$, respectively. The field point A is represented by its coordinates (x, α) in this 2D geometry where x is the radial displacement of A relative to P and α is the angular difference between these two points.

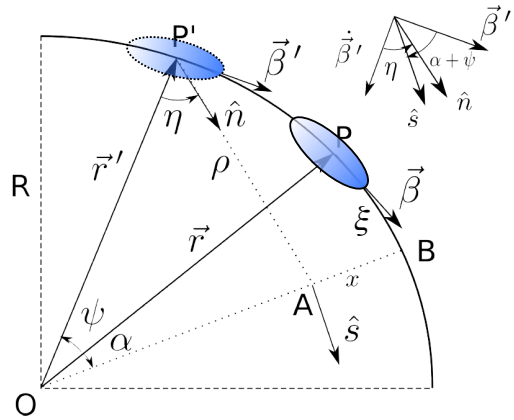

Figure 1: Geometry of the 2D model for calculating the longitudinal electric field from the synchrotron radiation of a particle in uniform circular motion. P and P' are the present and retarded positions of the particle, respectively.

The geometric relations that relate the present and retarded position of the particle are,

$$1+(1+x)^2-2(1+x)\cos(\alpha+\psi)=\psi^2/\beta^2 \qquad (1)$$

$$1+\psi^2/\beta^2-2(\psi/\beta)\cos\eta=(1+x)^2 \qquad (2)$$

where x has been normalized to R.

Using the Padé approximation

$$\cos(\zeta)\approx(1-5\zeta^2/12)/(1+\zeta^2/12)$$

and $|x|<<1$, $|\alpha|<<1$, $\psi^2<<12$, the transcendental equation Eq. (1) can be approximated as,

$$x^2+\alpha^2+2\alpha\psi+(x-\gamma^{-2}\beta^{-2})\psi^2-\psi^4/12\beta^2=0 \qquad (3)$$

After adopting the scaled variables $\tilde{x}=x\gamma^2$, $\tilde{\alpha}=\alpha\gamma^3$ and $\tilde{\psi}=\psi\gamma$, dropping the second term α^2 on the left hand side of Eq. (3) which is only important at the opposition

*Work supported by the LDRD program at LANL.
#huangck@lanl.gov

Copyright © 2013 CC-BY-3.0 and by the respective authors

direction of the forward radiation cone and β^2, this equation can be written in general form,

$$\tilde{x}^2 + 2\tilde{\alpha}\tilde{\psi} + (\tilde{x}-1)\tilde{\psi}^2 - \tilde{\psi}^4/12 = 0 \qquad (4)$$

Similarly, the longitudinal electric field from the particle's synchrotron radiation $E_s = -\partial(\phi - \beta A_s)/\partial\xi$, can be written into these scaled variables.

Since

$$(\phi - \beta A_s) = \frac{e\beta[1-\beta^2\cos(\alpha+\psi)]}{R\psi(1-\beta\sin\eta)} \qquad (5)$$

one can obtain,

$$(\phi - \beta A_s) \approx \frac{e\gamma(1+\beta\sin\eta)}{R\tilde{\psi}[1+(\tilde{\psi}/2-\tilde{x}/\tilde{\psi})^2]} \qquad (6)$$

It can be shown that $(1+\beta\sin\eta)$ weakly depends on γ in most regions at the $(\tilde{x},\ \tilde{\alpha})$ plane except for the vicinity of the negative $\tilde{\alpha}$ axis where radiation is negligible. Therefore,

$$E_s \approx \gamma^4 F(\tilde{x},\ \tilde{\alpha},\ \tilde{\psi})\ . \qquad (7)$$

Here $F(\tilde{x},\ \tilde{\alpha},\ \tilde{\psi})$ is the functional form of the longitudinal electric field that only depends on $\tilde{x}$, $\tilde{\alpha}$ and $\tilde{\psi}$. We can then introduce the normalization of the electric field $\tilde{E}_s = E_s/(e\gamma^4/R^2)$ which reveals its amplitude scaling with the particle's energy.

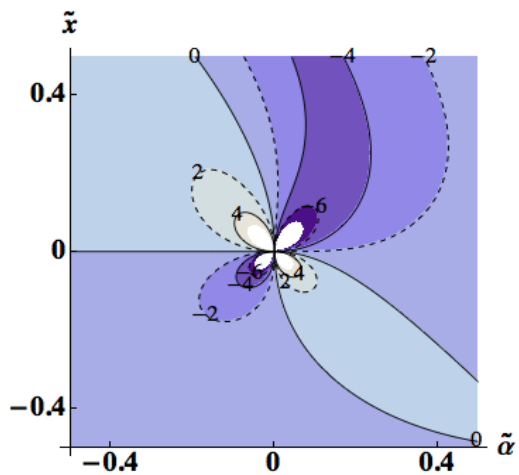

Figure 2: The general near field pattern of the longitudinal synchrotron radiation electric field in 2D for a particle in uniform circular motion.

Since $\tilde{\psi}$ implicitly depends on $\tilde{x}$, $\tilde{\alpha}$ from Eq. (4), Eq. (7) indicate that the longitudinal synchrotron radiation near field can be obtained, to a good approximation, from the invariant (with respect to γ) function $F(\tilde{x},\ \tilde{\alpha},\ \tilde{\psi}(\tilde{x},\ \tilde{\alpha}))$ with the proper scaling of the spatial variables and amplitude with the particle's energy.

Figure 2 shows the longitudinal electric field $\tilde{E}_s = E_s/(e\gamma^4/R^2)$ as a function of $\tilde{x}$, $\tilde{\alpha}$. The field's amplitude is large along the four diagonal directions, forming a cloverleaf like pattern. While the fields quickly decreases along the other three diagonal directions, it extends to far greater distance in the top-right corner as shown in Fig. 2.

APPROXIMATE GREEN'S FUNCTION FOR RADIATION FIELD IN 3D

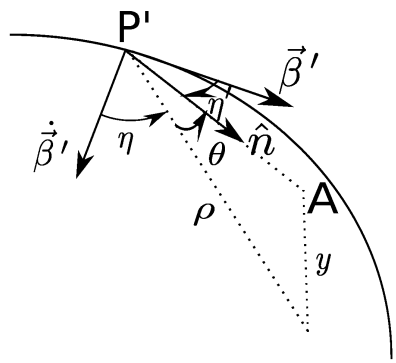

Figure 3: Schematic for the calculation in 3D.

We are now ready to extend the above result to 3D. In 3D, the position of field point A is denoted by its coordinates in the bending plane (x, α) and its vertical displacement y from this plane. Figure 3 shows the position of A and the angles it forms with respect to P'.

It is straightforward to show that in 3D Eq. (1) and (2) become,

$$1 + (1+x)^2 - 2(1+x)\cos(\alpha+\psi) = \psi^2/\beta^2 - y^2, \qquad (8)$$

$$1 + (\psi^2/\beta^2 - y^2) - 2\sqrt{\psi^2/\beta^2 - y^2}\cos\eta = (1+x)^2, \qquad (9)$$

where y is also normalized to R.

Since x^2 and y^2 appear together in Eq. (8) and (9), one can treat x and y similarly and define scaled variable $\tilde{y} = y\gamma^2$. With this scaled variable, Eq. (4) becomes,

$$\tilde{x}^2 + \tilde{y}^2 + 2\tilde{\alpha}\tilde{\psi} + (\tilde{x}-1)\tilde{\psi}^2 - \tilde{\psi}^4/12 = 0\,. \qquad (10)$$

In 3D, the unit vector $\hat{n}$ is not necessarily in the bending plane, thus $\hat{n}\cdot\vec{\beta}' = \beta\cos\eta' = \beta\sin\eta\cos\theta$. Hence,

$$(\phi - \beta A_s) = \frac{e\beta[1-\beta^2\cos(\alpha+\psi)]}{R\psi(1-\beta\sin\eta\cos\theta)}\ . \qquad (11)$$

Next we consider the $[1-\beta^2\cos(\alpha+\psi)]$ term and the $(1-\beta\sin\eta\cos\theta)^{-1}$ term in Eq. (11) separately. It is easy to show,

Copyright © 2013 CC-BY-3.0 and by the respective authors

$$1-\beta^2\cos(\alpha+\psi)=\gamma^{-2}\left[1-\frac{(\tilde{x}^2+\tilde{y}^2)\beta^2\gamma^{-2}-\tilde{\psi}^2}{2(1+\tilde{x}\gamma^{-2})}\right]\approx\gamma^{-2}, \quad (12)$$

and

$$(1-\beta\sin\eta\cos\theta)^{-1}=(1+\beta\sin\eta\cos\theta)(1-\beta^2\sin^2\eta\cos^2\theta)^{-1} \quad (13)$$

The first term on the right hand side of Eq. (13) varies slowly with particle energy and is bounded, $0\le(1+\beta\sin\eta\cos\theta)\le 2$. The second term can be further simplified using the following relation,

$$\gamma\beta\cos\eta\cos\theta=\gamma\psi/2-\gamma\beta^2(2x+x^2+y^2)/2\psi\approx\tilde{\psi}/2-\tilde{x}/\tilde{\psi} \quad (14)$$

leading to,

$$1-\beta^2\sin^2\eta\cos^2\theta\approx\gamma^{-2}\left[1+\tilde{y}^2/\tilde{\psi}^2+(\tilde{\psi}/2-\tilde{x}/\tilde{\psi})^2\right]. \quad (15)$$

With the above simplification, Eq. (11) reduces to a form akin to Eq. (6),

$$(\phi-\beta A_s)\approx\frac{e\gamma(1+\beta\sin\eta\cos\theta)}{R\tilde{\psi}[1+\tilde{y}^2/\tilde{\psi}^2+(\tilde{\psi}/2-\tilde{x}/\tilde{\psi})^2]}. \quad (16)$$

Therefore, in 3D, the functional form of Eq. (7) becomes

$$E_s\approx\gamma^4 G(\tilde{x},\ \tilde{y},\ \tilde{\alpha},\ \tilde{\psi}). \quad (17)$$

From the Liénard-Wiechert formula, the longitudinal radiation field is given by,

$$E_s=\frac{e}{c\rho}\cdot\frac{(\hat{n}\cdot\dot{\vec{\beta}}')(\hat{n}\cdot\hat{s}-\vec{\beta}'\cdot\hat{s})-(\hat{s}\cdot\dot{\vec{\beta}}')(1-\hat{n}\cdot\vec{\beta}')}{(1-\hat{n}\cdot\vec{\beta}')^3}. \quad (18)$$

After the retarded angle $\tilde{\psi}$ is solved from Eq. (10), one can use the following identities,

$$\hat{n}\cdot\vec{\beta}'=\beta\sin\eta\cos\theta,\ \hat{n}\cdot\dot{\vec{\beta}}'=(\beta^2 c\cos\eta\cos\theta)/R,\ \hat{n}\cdot\hat{s}=\sin(\alpha+\psi+\eta)\cos\theta \quad (19)$$

Eq. (18) becomes,

$$\tilde{E}_s=\frac{\beta^3}{\gamma^4\psi(1-\beta\sin\eta\cos\theta)^3}\cdot[(\sin\eta-\beta\cos\theta)\cdot\cos(\alpha+\psi+\eta)-\sin^2\theta\sin(\alpha+\psi+\eta)\cos\eta] \quad (20)$$

Figure 4 shows $\tilde{E}_s$ as a function of $\tilde{y}$ and $\tilde{\alpha}$ for $\tilde{x}=0$. It should be noted that the radiation field is strongest in the forward direction within a ~ 45 degree cone in the scaled variables $\tilde{y}$ and $\tilde{\alpha}$, which is consistent with the well-known $1/\gamma$ radiation cone in the un-scaled spatial variables. This also implies that for a beam that is sufficiently large in the vertical y direction, both the 1D and 2D models in the $(\tilde{x},\tilde{\alpha})$ plane will overestimate the longitudinal CSR force.

Similar to our previous 2D CSR model [9], the calculation presented here can be done once and applied to a range of beam parameters. The key to such flexibility is the recognition of the self-similarity of the radiation field in three spatial dimensions through the scaled variables. This follows the pioneering work in one spatial dimension by several other authors [5,6]. However, due to the complex radiation field pattern in 3D, it is rather difficult to derive an analytic formula for such field in the identified scaled variables. Numerical calculation for the 3D radiation field of a single particle is generally necessary and possible, as demonstrated in this paper, whose result can then be used to construct a 3D CSR model through the convolution with the beam shape.

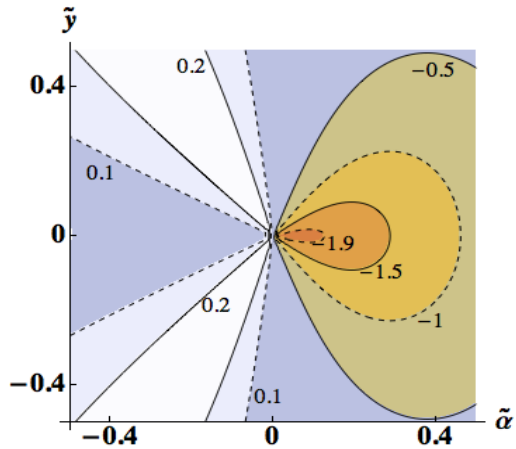

Figure 4: Longitudinal radiation field pattern for a highly relativistic in the vertical $(\tilde{y},\ \tilde{\alpha})$ plane at $\tilde{x}=0$.

EXPERIMENTAL VERIFICATION OF DIPOLE EDGE FOCUSING IN LINEAR MODEL BY OPERATING IN THE WEAK FOCUSING REGIME AT THE LOS ALAMOS PROTON STORAGE RING*

J. Kolski†, D. Barlow, R. Macek, and T. Spickermann, LANL, Los Alamos, NM, 87545, USA

Abstract

Linear optics models are important for the operation of circular accelerators because of their ability to predict the linear lattice functions, primarily betatron amplitude functions and betatron tunes. The accuracy of the liner model's prediction is dependent on how well the real machine's focusing lattice is known and represented. While quadrupoles may be mapped magnetically and their focusing properties well understood, the focusing effect due to dipole edge fields is less certain. For rings with rectangular dipoles like the Proton Storage Ring (PSR) at Los Alamos National Laboratory, the dipole edge focusing can be a significant contributor to the vertical focusing. Most accelerator modeling codes, like MAD and AT (Accelerator Toolbox), use the K. Brown formulation[1], but this approach can lead to errors ∼10% in the models betatron tune prediction[2]. Here we discuss particle tracking through simulated dipole fields, including edge effects, with TOSCA 3D to obtain the focal lengths of the edge focusing. We verify model and focal lengths by operating the PSR in the weak focusing regime (without vertically focusing quadrupoles) and show that the model predicts the betatron amplitude functions and tunes even in this unusual operating condition.

INTRODUCTION

The PSR is a 90 m circumference circular accelerator with broken ten-fold FODO cell symmetry, which occurs in the injection section (top of Fig. 1). While most cells have a 36° dipole magnet (SRBM), the injection section starts with a SRBM-type dipole that is shunted by 100 A (SRBM01) to allow room for RIBM09, which merges H- beam with the circulating H+ beam for charge-exchange injection. The dipole at the beginning of the next cell is replaced with two large gapped C-magnets (SRBM11 and SRBM12) accommodating a dump line. Relevant parameters for the five PSR dipoles types are listed in Tab. 1.

All PSR dipoles are rectangular, so including a good representation of the edge focusing is very important for the PSR linear model. There are three parameters in the edge focusing model: gap width, edge angle, and the fringe field integral (FINT) defined by

$$\kappa = \int_{-\infty}^{\infty} \frac{B_0 B_y(s) - B_y^2(s)}{g B_0^2} ds \qquad (1)$$

simulation to determine the dipole edge focusing. The resulting betatron tunes from the baseline model are compared with measurement in Tab. 2. We note that the vertical tune difference between baseline model and measurement is not good, 0.05. To understand the origin of the vertical tune difference between baseline model and measurement, we plot the difference between measured and baseline model phase advance in Fig. 2. Note the vertical phase demonstrates a systematically increasing phase difference between baseline model and measurement. We conclude that the baseline model systematically over focuses vertically. Since the baseline model horizontal tune result is good, we concentrate our model improvement efforts on the only model element that effects vertical and not horizontal focusing: the rectangular dipole edge focusing.

RAY TRACING THROUGH THE FRINGE FIELDS

Ultimately, the most important part in considering fringe fields from rectangular dipoles is obtaining the edge focusing focal length. To determine the edge focusing focal length, we traced on-momentum parallel rays through 3D magnetic field from TOSCA simulations of the PSR dipoles. The parallel rays were initially positioned on a 4×4 cm transverse grid with a ray every centimeter at

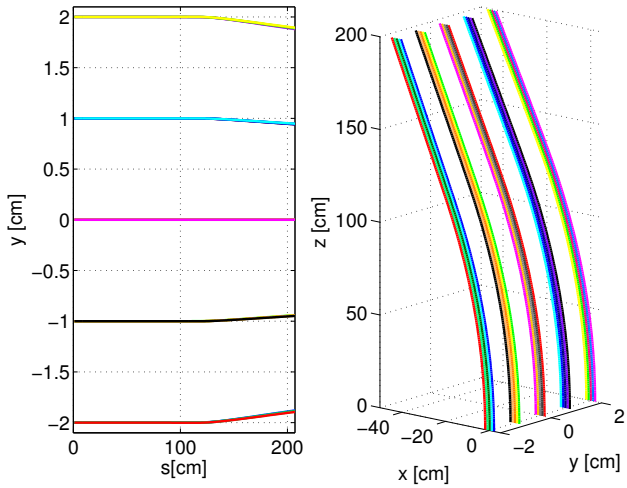

Figure 3: (Color) (Left) Rays' vertical position as a function of longitudinal coordinate, which encounter edge focusing $s \simeq 120$ cm. (Right) Ray position in the magnet-based coordinate system.

the longitudinal center of the dipole and traced through the downstream half of the PSR dipoles, Fig. 3. The fringe field focal length can be calculated from the ray tracing data for each of the PSR rectangular dipole types.

We can reverse engineer the K. Brown model of edge focusing, Eqs. (1) to (3), to produce the focal length calculated from the ray tracing data. We choose to modify the FINT parameter because the gap width and edge angle are physical parameters. In Tab. 3, we compare the edge focusing focal length and FINT from ray tracing, which we will call improved model, explained later, and the baseline model. Note the that the baseline model edge focusing focal lengths are systematically smaller than from ray tracing with the largest fractional difference in the SRBM and SRBM01 type dipoles. This is the cause of the vertical over focusing in the baseline model.

We construct an improved model using the FINT parameter determined by the ray tracing data and compare it with measurement in Tab. 2 and Fig. 2. Note the improved model has a much better prediction of the vertical tune and little systematic phase advance difference.

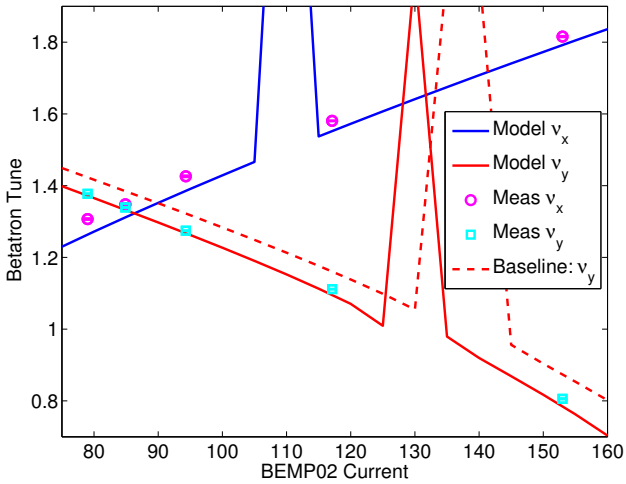

Figure 4: (Color) Model and measured tunes as a function of horizontal focusing quadrupole current: measured tunes (horizontal: magenta circles and vertical: cyan squares), model tunes (horizontal: blue line, and vertical baseline: dashed red line, vertical improved: solid red line).

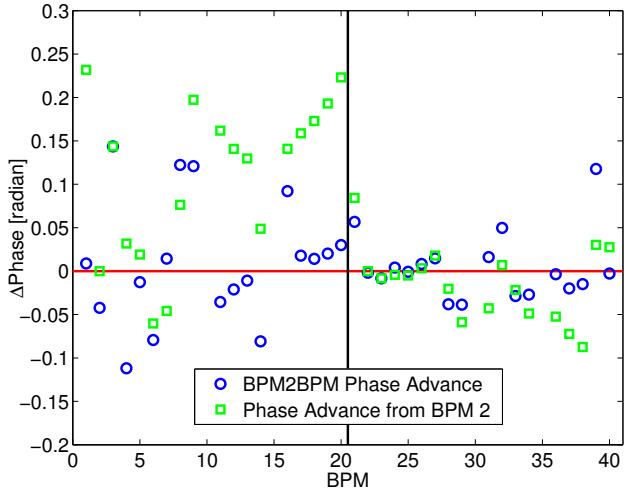

Figure 5: (Color) Difference in phase advance from the first BPM after injection (BPM 2 and 22, green) and the difference in BPM-to-BPM phase advance (blue) between measured and improved model at focusing quadrupole current 89.4 A. ORM BPM indexing convention is used as described in Fig. 2.

OPERATING THE PSR IN THE WEAK FOCUSING REGIME

The improved model uses an engineered FINT to produce the edge focusing focal lengths calculated from the ray tracing data. The edge focal focal length was not actually measured. Can we make a more direct, physical measurement? To isolate the edge focusing in a beam-based measurement, we operate the PSR with the vertically focusing quadrupoles at 0 A. To provide stable beam with this set up, the horizontally focusing quadrupole current (BEMP02) needs to be dramatically reduced so as to not overcome the edge focusing in the vertical. The improved model indicates that there are several regions of transverse stability, Fig. 4.

We measured the betatron tune at several stable points with reduced horizontally focusing quadrupole current and compared them with predictions from the improved model, Fig. 4. Note that even with the vertically focusing quadrupoles turned off, the improved model does a decent job at reproducing the measured vertical tunes, much better than the baseline model. Of course, we would like the model to yield closer results. Also note the greater discrepancy between the measured and model horizontal tune, as much as 0.03. This may be an indication that the current to gradient length conversions used in the model for the horizontally focusing quadrupoles do not work well due to a lack of magnet mapping data for such low currents and that we need to add the residual field effect in the vertically focusing quadrupoles.

Figure 5 compares the measured and model phase for horizontally focusing quadrupole current 89.4 A. Note in the vertical, both the phase advance from the first BPM after injection and the BPM-to-BPM phase advance deviation between the improved model and measurement is much smaller than in the horizontal.

We need to refine the improved model horizontal tune and phase predictions prior to fitting the edge focusing in the vertical. In continuing studies, we intend to fit the horizontally focusing quadrupole strengths to the measured horizontal tunes and then fit the FINT for each of the five PSR rectangular dipole types to match the measured vertical phase advance. Because the improved model performs well for normal operating conditions, we expect only a few percent adjustment to refine the improved model FINT.

CONCLUSIONS

We corrected the PSR linear model by engineering the FINT to yield the same focal length as found by tracing parallel rays through 3D magnetic fields resulting from TOSCA simulations. We compared linear lattice functions predicted by the improved model with measurement, in particular the betatron tune and phase advance. Although the improved model is better than the baseline model, we realize that we did not directly measure the FINT. To isolate the edge focusing in measurement, we operate the PSR without vertically focusing quadrupoles. We compare improved model predictions with measurements of the tune and find the model reproduces the measured vertical tunes well but not the horizontal. We need to correct the horizontal model before we can reliably fit the FINT.

COHERENT SPACE CHARGE TUNE SHIFT MEASUREMENTS IN THE LOS ALAMOS PROTON STORAGE RING*

J. Kolski†, R. Macek, and T. Spickermann, LANL, Los Alamos, NM, 87545, USA

Abstract

The coherent space charge tune shift describes the average frequency shift experienced by particles due to the effects of the beam's image charge and current and is proportional to the instantaneous beam current. For long beam pulses like the 290 ns long accumulated beam bunch in the Los Alamos Proton Storage Ring (PSR), we can observe the change in the coherent space charge tune shift longitudinally along the pulse. We measure an asymmetric betatron tune profile about the bunch center even though the beam current profile is symmetric about the peak intensity. In addition, we observe the coherent space charge tune shift to vary as a function of turn during a store. Quality measurements of the coherent space charge tune shift may provide a unique handle on interesting physics including wake field effects and electron cloud (EC) buildup. We digitize the vertical sum and difference signals from a beam position monitor, stack the digitized vector turn-by-turn, and fit the tune for each slice (0.5 ns digitization bin) along the pulse after a single-turn vertical kick. We compare the difference between the measured/fitted tune and the measured bare tune with the theoretical tune shift and infer a charge neutralization, which we relate to the EC density along the pulse and buildup in turn number.

INTRODUCTION

The coherent space charge tune shift (measured tune − bare tune) is due to image charge and current effects[1, 2],

$$\Delta\nu_y = -\frac{r_p N}{\pi\beta^2\gamma}\left[\frac{\bar{\beta}_y(\text{ring})}{2\gamma^2 B_f h^2}(1-\eta)+\frac{\pi^2\beta^2 C_2\bar{\beta}_y(\text{bend})}{24g^2}\right], \quad (1)$$

where r_p and N are the classical proton radius, number of protons, β and γ are the relativistic Lorentz factors, $\bar{\beta}_y$ is the average beta function either around the ring or in the dipoles, and B_f, h, η, C_2, and g are the bunching factor (average / peak or instantaneous current), beam pipe radius, beam neutralization, fraction of circumference occupied by dipoles, and the dipole half gap respectively. The first term in Eq. (1) describes the dependence of the coherent tune shift on the instantaneous current, while the second term relates the contribution from the average current. For the PSR, the second contributes ∼15% to the tune shift[1].

We construct a simple simulation of the coherent space charge tune shift using the model in Eq. (1) and a measured beam profile, Fig. 1. To match our measurements (described later), we divide the beam longitudinally into 0.5 ns slices. Initially the simulated beam centroid is offset transversely to produce coherent betatron oscillation, then the transverse beam centroid position is tracked for 420 turns. The FFT along turn for each slice's position yields the tune. The simulation results in a symmetric tune distribution along the bunch as expected because the beam

profile is symmetric about the peak. Compare simulation with the measured coherent tune shift along the bunch, Fig. 2. Note that the measured tune distribution has much larger spread for slices on the leading edge than in simulation. This is because the tune for these slices is actually changing over the domain of the FFT.

From the model, we expect a symmetric tune distribution about the center of the bunch because the beam profile is symmetric about the bunch, but the measured tune distribution along the bunch is asymmetric about the bunch center. Note, the greatest discrepancy between model and measurement, particularly the magnitude of the tune FFT, occurs on the trailing edge. The difference could be due to many physical effects not included in the simple coherent space charge tune shift model of Eq. (1): EC multipactoring and neutralization, wake fields, etc. A recent study from Cornell[3] relates the coherent tune shift to beam neutralization due to the EC and changing tune shift along a train of bunches to EC build up. We will concentrate our efforts on determining the EC density.

The PSR is a harmonic one machine with only one beam bunch in the ring. For the purposes of EC buildup, the PSR beam can be thought of as a train of 100s - 1000s of bunches, so we may be able to relate changing coherent tune shift turn-by-turn to EC buildup. The PSR bunch is also a long 290 ns bunch, so we may be able to relate different coherent tune shifts along the bunch to EC density variations and gain insight into pinch dynamics and multipactoring of the EC.

MEASUREMENT AND ANALYSIS

To observe the coherent space charge tune shift, the beam must undergo coherent transverse motion, which we induce using a single-turn kick during a beam store after accumulation. The beam store is typically 200 - 400 μs. We digitize beam position and current signals at 2 GS/s (0.5 ns binning). Each digitization bin is a slice along the bunch. The digitized signal is stacked turn-by-turn such that all data for one slice is in the same row of the data matrix [# of slices, # of turns]. FFTs of data for each slice produced the contour in Fig. 2.

Hundreds of turns are required for precise frequency results from an FFT. The tune changes much faster, so we fit the position to a cosine to obtain the tune,

$$x_n = A\cos\left(2\pi\nu(n-1)+\phi\right)+O, \qquad (2)$$

where A, ν, n, ϕ, O are the amplitude, tune, turn index, phase, and offset respectively. To observe the tune change as a function of turn for each slice, we fit 30 turns. We step the domain of each successive fit by 10 turns to smooth the tune change as a function of turn. The tune fit is very good, typically yielding a fitting uncertainty $\sim 10^{-3}$.

We observe small but measurable changes in the tune as a function of turn number. Figure 3 shows the fitted tune as a function of fit number for slice 300. It is clear that we can measure a changing tune, but we are really interested in observing a change in beam neutralization.

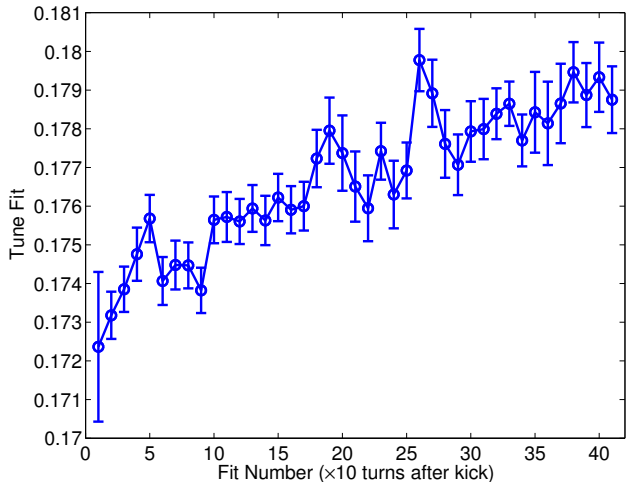

Figure 3: Fitted tune as a function of fit number (10 turn steps) after a single-turn kick for slice 300 (∼25 ns in front of the peak) with one rms fitting uncertainty.

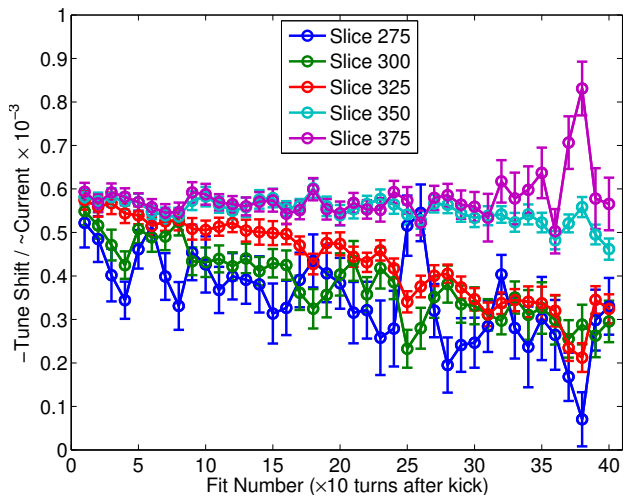

Figure 4: (Color) Normalized tune shift as a function of fit number for several slices along the bunch with one rms uncertainty. Slice 350 is the center of the bunch.

For the preliminary analysis and results reported in this paper, we note that the coherent space charge tune shift for a slice is proportional to the instantaneous current and simply normalize the measured tune shift for a slice to the average current during the fit for the slice to obtain a quantity proportional to the neutralization. If we observe the normalized tune shift measurably vary, we can conclude that the beam neutralization varies as well. We plot the normalized tune shift verses fit number for several slices in Fig. 4. The trend in the normalized tune shift is different for each time slice along the bunch. Note the normalized tune shift for slices 325 and 375, which are symmetric about the peak, has distinctly different slopes. We observe a steeper trend for slices located in front of the peak and observe lit-

Copyright © 2013 CC-BY-3.0 and by the respective authors

tle change in the slices on the trailing edge, which is similar to the measured tune distribution in Fig. 2.

Because the PSR bunch is a long 290 ns, in this measurement, we can also observe the measured normalized tune shift for each slice along the bunch as a function of fit number (turn number), Figs. 5 and 6.

Figure 5 plots the results for a bunched PSR production-like beam. Note the first fit after the single-turn kick yields a consistent normalized tune shift along the bunch. This is as expected if the neutralization along the bunch is constant. The structure along the bunch of the normalized tune shift is much more complicated 400 turns later. Note again the difference between leading and trailing edge. There are low frequency oscillations on the leading edge and high frequency oscillations on the trailing edge. This may be an indication of EC density variation along the long PSR bunch with EC pinch dynamics on the leading edge and multipactoring on the trailing edge.

Figure 6 plots the results for an accumulated bunched coasting beam with RF buncher off. Again, we observe for the first fit after the single-turn kick a constant normalized tune shift. Also notice the structure in the last fit, 800 turns after the single-turn kick. The spikes on the trailing edge start growing about 600 turns after the single-turn kick. Since the RF buncher is off, there is considerable beam in the gap between turns. This provides a very different beam potential that effects both EC pinch dynamics and multipactoring.

CONCLUSIONS

We measured the coherent space charge tune shift in the PSR. We digitized beam position and current signals at 2 GS/s, where each 0.5 ns digitization bin constitutes a slice longitudinally along the beam, stacked the beam signal turn-by-turn, and took an FFT along position for each slice to obtain the tune. We induced coherent transverse motion with a single-turn kick during a beam store after accumulation. We compared model and simulated tune distributions along the pulse and found the measured tune distribution was asymmetric about the peak even though the beam profile was symmetric.

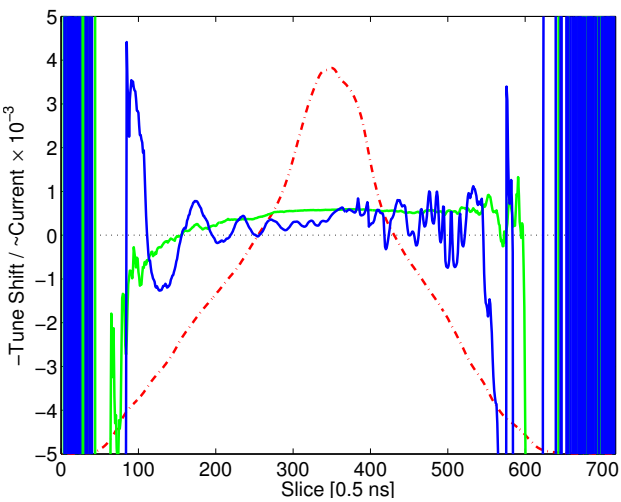

Figure 5: (Color) The measured normalized tune shift immediately after the single-turn kick (green) and 400 turns later (blue) as a function of slice along the bunch for bunched production-like beam with the RF buncher on and the last turn beam profile (red).

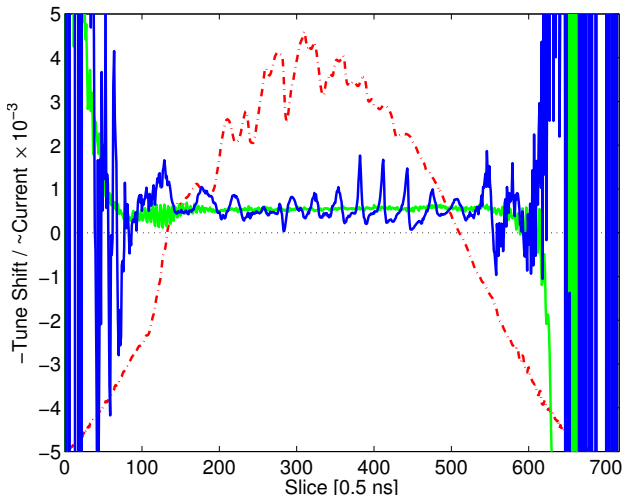

Figure 6: (Color) The measured normalized tune shift immediately after the single-turn kick (green) and 800 turns later (blue) as a function of slice along the bunch for bunched coasting beam with RF buncher off and the last turn beam profile (red).

We show the ability to measure small changes in the tune shift as a function of slices along the bunch and turns by fitting 30 turns of beam position to a cosine. When we take into account the instantaneous current, we observe a quantity proportional to beam neutralization that also varies with turn and slice along the bunch indicating EC density variations.

We have not positively identified the changing tune shift to be neutralization due to the EC. Further work to be done includes acquiring coherent space charge tune shift data at different beam intensities and bunch lengths and using Eq. (1) in the analysis to solve directly for the beam neutralization instead of simply normalizing the tune shift to the instantaneous beam current.

Abstract

Earlier experiments at Fermilab's A0 Photoinjector Laboratory demonstrated successful transverse-to-longitudinal emittance exchange (EEX) using a transverse-deflecting cavity (TDC) located between two identical doglegs. Such a design has the disadvantage of transversely displacing the beam. An alternative is an EEX beamline designed out of a variable R_{56} bunch compressor chicane. In this paper, we present designs and simulation comparisons for several emittance-exchanger beamlines, including the double-dogleg and chicane designs, as well as variations of the chicane design that allow for increasing its dispersion which proportionally decreases the field-strength requirements on the TDC. These comparisons are performed with PIC models of space charge and coherent synchrotron radiation.

INTRODUCTION

Transverse-to-longitudinal "emittance exchangers" (EEXs) allow for the exchange of a particle beam's transverse and longitudinal phase spaces. [1, 2] An early emittance exchanger design consisting of a transverse deflecting cavity (TDC) between two identical doglegs, each comprised of two opposite dipoles and a drift, was demonstrated at Fermilab's A0 Photoinjector Laboratory [3, 4]. A major disadvantage of such a configuration is its resulting offset of the beam's direction, which has significant impact on linac design as an elaborate dispersion correction scheme would be needed to operate the beamline in its non emittance-exchanging configuration.

A modification of the original design, based on a variable-R_{65} chicane, allows for the exiting beam to remain in-line with the incoming beam [5]. Furthermore, this design allows for almost-arbitrary adjustment of the dispersion at the TDC location, which reduces its power requirements. In this paper, we present three phase-space exchanger designs and performance comparisons between them.

We use two sets of beam parameters for these studies. The first is based on a study of partially compressed beams at ASTA [6], while the other is a smaller set of emittances used for comparisons with reduced second-order effects. Both are presented in Table 1.

LPS chirp	$\mathcal{C}_{z,0}$	0.0	0.0	m^{-1}

OVERVIEW OF PHASE SPACE EXCHANGER DESIGNS

In this Section we summarize the properties of the three beamlines considered through out this paper. Each of the designs must generally satisfy three different requirements [7]. For the dispersive section upstream of the TDC, M_-, we must control of the upstream dispersive section's x dispersion, η_-, and its derivative, $\eta_-\prime$. For TDC section, M_{TDC}, we must control the strength of the TDC as $\kappa = -\frac{1}{\eta_-}$, operated at zero-crossing. For the downstream section, M_+, the dispersive section's transfer matrix must be finely controlled such that the properties satisfy

$$\mathbf{D}_+ = \begin{pmatrix} R_{11,+} & R_{12,+} \\ R_{21,+} & R_{22,+} \end{pmatrix} \mathbf{D}_-, \text{and} \quad (1)$$

$$\kappa = -1/\eta_-. \quad (2)$$

where the $+$ and $-$ signs refer to values associated to respectively the downstream and upstream dispersive sections and $\widetilde{\mathbf{D}} \equiv (\eta, \eta' \equiv d\eta/ds)$ is the dispersion vector.

The most basic design is the Double Dogleg EEX (DDEEX), of a design similar to that implemented at A0. The dispersion η of each dogleg is 0.5 m, and the TDC is centered between the upstream and downstream doglegs. An accelerating-mode cavity is placed immediately downstream of the TDC to correct for the R_{65} term [8]. The dipoles are rectangular, and the exact lengths and distances are described in Fig. 1.

A similar design is a the Nominal-Dispersion EEX (NDEEX), in which the bend angles and geometry of each dogleg are the same, except the bend angles of one of them are reversed such that it forms a chicane rather than a pair of symmetric doglegs. Quadrupoles are placed inside the

Copyright © 2013 CC-BY-3.0 and by the respective authors

chicane between each of the existing elements, which allow for specific tailoring of the transfer matrix of the upstream and downstream doglegs. The quadrupole magnets are used to adjust the sign of the dispersion the upstream dogleg, while those of the downstream dogleg are used to meet the new requirements on the transfer matrix. For the simplest case, we choose the new dispersion of the upstream dogleg, M_-, to have the same magnitude as that of the DDEEX, i.e. $\eta_- = -0.5$. Diagrams of the DDEEX and NDEEX designs are presented in Fig. 1.

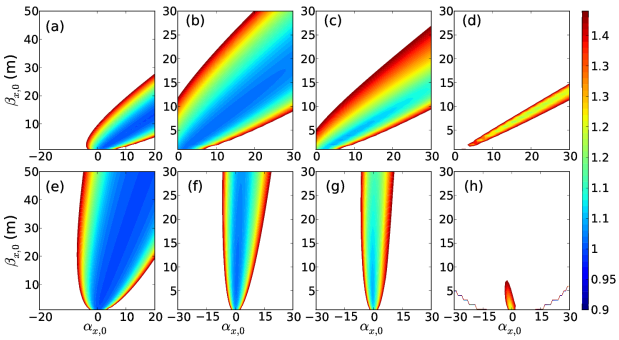

Figure 1: The DDEEX (top) and chicane-like (bottom) emittance-exchanger configurations. The TDC is centered between B2 and B3, and an accelerating mode cavity is placed immediately downstream.

The boosted-dispersion EEX (BDEEX) uses the same components and configuration of the NDEEX chicane. Rather than using the quadrupole magnets in M_- to change only the sign of its dispersion, we increase its magnitude as well, while correspondingly adjusting the downstream transfer matrix.. This has the crucial advantage of decreasing the requirement on the cavity kick-strength, as per Eq. 2. As the dispersion η_- increases, the requirements on η_+ become more difficult to satisfy while keeping the beam envelope well-constrained. We explore boosted values of $2\eta_-$ to $6\eta_-$.

Table 2: Beamline Parameters of the EEX Configurations in Fig. 1

Parameters	Value	Units
Dipole Length	0.30	m
Bend Angle	± 18	degrees
Beam Energy	50	MeV
$\lvert\eta_-\rvert$	[0.5, 1.0, 1.5,2.0,2.5,3.0]	m
$\lvert\eta'_-\rvert$	0.0	m
$\lvert\kappa\rvert$	[2.0,1.1,0.66,0.5,0.4,0.33]	m^{-1}

The exchanger beamlines were optimized in the simulation code ELEGANT [9], and then imported into IMPACT-Z [10], which allows for the implementation of SC effects with a three-dimensional PIC model, and with a one-dimensional model of CSR [11].

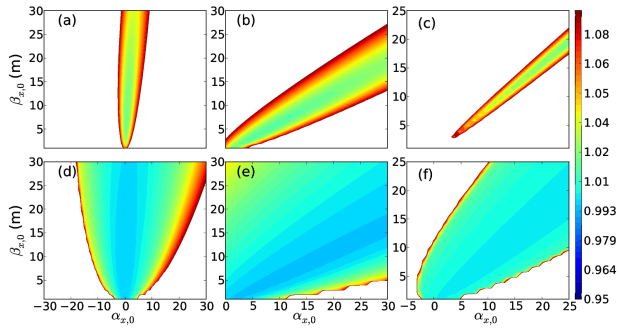

Figure 2: Contour plots comparison of three models (DDEEX (a,d), NDEEX (b,e), and BDEEX(c,f)) with IMPACT-Z for 0 nC for both $\mathcal{F}_{x\to z}$ (a-c) and $\mathcal{F}_{z\to x}$ (d-f), as functions of the C-S parameters at the EEX entrance, $\beta_{x,0}$ and $\alpha_{x,0}$.

BEAMLINE COMPARISONS

As a way to measure the relative performance of the various configurations, we performed scans of the initial Courant-Snyder (C-S) parameters, $\beta_{x,0}$ and $\alpha_{x,0}$ at the entrance of the EEX. This is required to account for varying optics between each of the configurations and the second-order effects of varying strengths that result from the differing optics.

We compare the core emittance exchanger designs for equivalent doglegs with dispersion of $|\eta_x| = 0.5$m, and the BDEEX design for $|\eta_x| = 1.0$m. Units for the color scales are μm when presenting the normalized emittances, mm for RMS bunch sizes, and unit-less when presenting the "exchange quality", $\mathcal{F}_{x\to z} \equiv \frac{\varepsilon_{z,f}}{\varepsilon_{x,0}}$ and $\mathcal{F}_{z\to x} \equiv \frac{\varepsilon_{x,f}}{\varepsilon_{z,0}}$, where perfect emittance exchange occurs at $\mathcal{F} = 1$. We also define the term "acceptance" with regards to the range over which the emittance exchange quality is near unity.

In Fig. 2, the DDEEX, NDEEX, and BDEEX are compared for the case of no collective effects. Boosting the dispersion causes a notable decrease in the acceptance of initial C-S parameters, as the quadrupole settings within the chicane cause the transverse beam sizes to be more erratic along the beamline.

When SC+CSR are introduced for a 1 nC bunch, as shown in Fig. 3, the acceptance is reduced for all three configurations. Comparisons of σ_z to the contour plots for the emittance exchange quality reveal a significant degradation to the emittance exchange quality that occurs when the beam size is at its minimum, i.e. when the final LPS is upright, a vital part of achieving optimal beam shaping. This indicates a significant barrier to achieving optimal shaping while also achieving optimal emittance exchange, and that there is some significant trade-off that must be determined when setting the EEX settings.

DISPERSION BOOSTING

Boosting the dispersion up to 6x of the nominal value (in this case, 3.0 m) introduces significant complications to

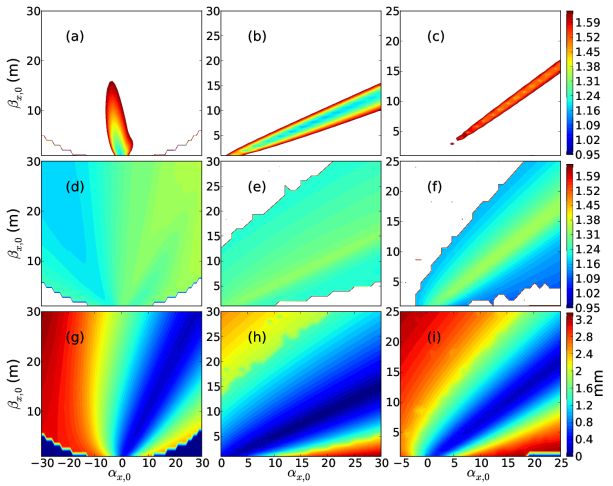

Figure 3: Contour plots comparison of three models (DDEEX, NDEEX, and BDEEX(2×) with IMPACT-Z for 0 nC for both $\mathcal{F}_{x\to z}$ and $\mathcal{F}_{z\to x}$, as functions of the C-S parameters at the EEX entrance, $\beta_{x,0}$ and $\alpha_{x,0}$.

beam control. As the x transfer matrix in the second dog-leg must be controlled to specifically satisfy the basic requirements for perfect emittance exchange, the y dynamics becomes difficult to control. For an example of optimized functions (via the same method of C-S scans presented earlier), see Fig. 4, using both ASTA and A0-style beam emittances.

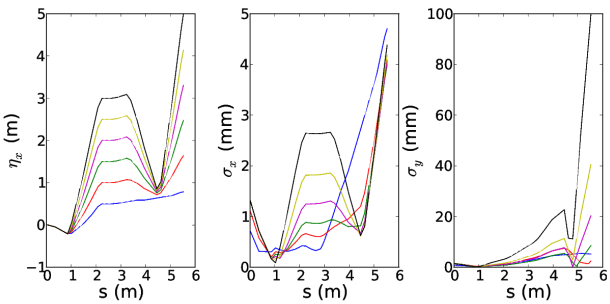

Figure 4: Horizontal dispersion η_x (left), σ_x (middle), and σ_y (right) along the NDEEX and BDEEX designs for $\eta_- =$ 0.5 m (blue), 1.0 m (red), 1.5 m (green), 2.0 m (magenta), 2.5 m (yellow) and 3.0 m (black).

The key difference between these simulations and those of the nominal-dispersion and double-boosted-dispersion is that σ_y is large and divergent, in addition to σ_x, which is large and divergent due to the kick from the TDC. Switching to smaller emittances reduces the beam size and the resultant emittance growth from second-order effects; see Table 3.

The key feature of dispersion boosting is the reduced requirements on the TDC, so while the quadrupole strengths are increased, the transverse beam size is less dominated by the TDC kick. The trade-offs that must be considered

Table 3: Quality of Emittance Exchange for Various Dispersions using the BDEEX Configuration, along with Which Emittances were Used

η_- (m)	Beam Type	$\mathcal{F}_{x\to z}$	$\mathcal{F}_{z\to x}$
0.5	1	1.00	1.00
0.5	2	1.00	1.00
1.0	1	1.04	1.02
1.0	2	1.01	1.00
1.5	1	1.08	1.01
1.5	2	1.01	1.000
2.0	1	2.407	1.05
2.0	2	1.22	1.000
2.5	1	10.42	1.12
2.5	2	3.43	1.01
3.0	1	79.98	1.75
3.0	2	25.35	1.04

are not simple, and depend greatly on both initial bunch length and transverse emittances. Dispersion-boosting up to 3x of the baseline dispersion is possible with ASTA-scale beam parameters, but greater dispersion is feasible for lower emittance regimes.

ION BEAM CHARGE NEUTRALIZATION BY FERROELECTRIC DISCHARGE PLASMA *

A.D. Stepanov, E.P Gilson, L.R. Grisham, R.C. Davidson
Princeton Plasma Physics Laboratory, Princeton, New Jersey, 08543, USA

Abstract

Space-charge forces limit the possible transverse compression of high perveance ion beams that are used in ion-beam-driven high energy density physics applications; the minimum radius to which a beam can be focused is an increasing function of perveance. The limit can be overcome if a plasma is introduced in the beam path between the focusing element and the target in order to neutralize the space charge of the beam. This concept has been implemented on the Neutralized Drift Compression eXperiment (NDCX) at LBNL using Ferroelectric Plasma Sources (FEPS). In experiments at PPPL, a perveance-dominated ion beam was propagated through a FEPS and the transverse beam phase space was measured with a slit-slit emittance scanner to characterize the effect of charge-neutralizing plasma on beam divergence.

INTRODUCTION

To reduce the divergence of high-perveance ion beams due to space charge, electrons can be introduced into the beam volume. In most experimental applications, electrons are produced by ion impact ionization of background gas and from secondary electron emission (SEE) from surfaces impacted by the beam. Electrons become confined the electrostatic potential well of the ions, reducing the magnitude of the potential well, which decreases until equilibrium is established between electron production and loss rates. For charge neutralization by ionization of background neutrals, this process typically takes 50 μs.

For charge neutralization of pulsed ion beams with duration < 100 μs, a volume plasma can be introduced into the beam path to provide electrons. Ferroelectric Plasma Sources (FEPS) can produce volume plasmas with low electron temperatures, and have been used successfully on NDCX-I to neutralize the space charge of a converging high-perveance ion beam pulse. Herein, experiments on charge neutralization of a 32-42 keV Ar+ beam with a plasma produced in a ferroelectric discharge are presented.

FERROELECTRIC PLASMA SOURCES

Ferroelectric materials (FE), such as PZT and ($BaTiO_3$) are characterized by a high relative dielectric constant ($\epsilon_r > 1000$) and the presence of a spontaneous electric polarization. It was found that under the application of a fast-changing electric field, high electron current densities are be emitted from the FE surface [1, 2], and plasma can be produced. Plasma sources based on $BaTiO_3$ have been built for use on NDCX-I/II [3] for ion beam charge neutralization. The basic configuration of a ferroelectric plasma source (FEPS) is a slab of ferroelectric material placed between two flat electrodes, one of which is perforated. When a fast-rising voltage pulse (~ 5 kV) is applied between the electrodes, a plasma is formed at the side of the perforated electrode at points of juncture between metal, ceramic, and vacuum. In addition, gas desorption occurs during FEPS discharge, which most likely plays a role in plasma formation. The precise mechanism of operation of FEPS is still under investigation [4].

EXPERIMENTAL SETUP

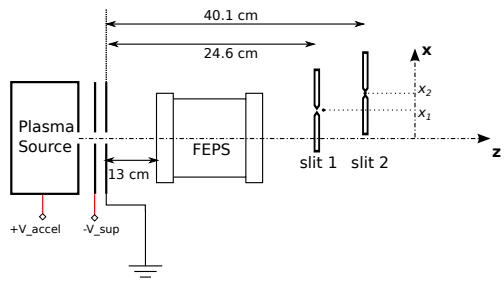

Figure 1: Diagram of the beamline used in the experiment. An Ar^+ beam, extracted from a plasma, propagates through a cylindrical FEPS. Downstream of the FEPS, the beam is intercepted by a two-slit emittance scanner which is used to measure the transverse current distribution of the beam.

The experiments were carried out on the Princeton Advanced Test Stand (PATS) at PPPL. Ar^+ ions are extracted from an RF-driven plasma and formed into a beam with a 3-electrode, accel-decel extraction system with gap length $d = 1.1$ cm and plasma aperture with radius $r_B = 1.5$ mm. The plasma is generated in a multicusp RF source with an internal antenna [5], driven by a pulsed RF power supply. Ion current density up to 28 mA/cm^2 can be extracted. Accelerating potential V_{accel} (30-60 kV) is supplied by an HV pulser [6].

The ion beam exits the accelerator through a grounded aperture at $z = 0$. At $z = 13$ cm, the beam enters a 10.1 cm long FEPS with an inner diameter of 7.62 cm. After the FEPS, the beam is intercepted by a slit-slit emittance scanner. The slits, located at $z_1 = 24.6$ cm and $z_2 = 40.1$ cm, are 2.5" long, 0.1 mm wide, and oriented horizontally. The second slit, referred to as the slit-cup, has a Faraday cup (FC) with SEE suppressor grid mounted directly behind it

for measuring ion current. Both slits are mounted on linear motion feedthroughs and can be moved in the vertical direction. The feedthroughs are driven by stepper motors, which provide positioning accuracy better than 0.1 mil.

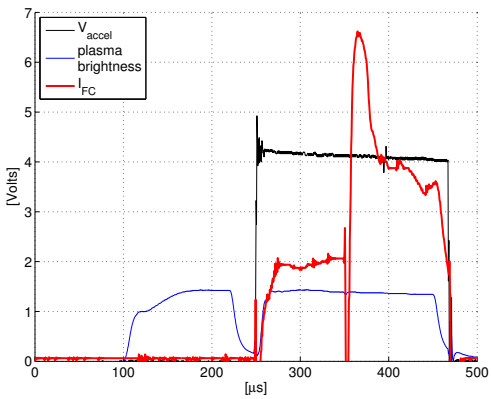

Figure 2: Waveforms of plasma density (blue trace), accelerating potential V_{accel} (black trace, 1 V = 10 kV), and FC current I_{FC} (red trace, 1 V = 1 μA) measured with the slit-cup positioned on beam axis. $V_{accel} = 42$ kV and $I_B = 0.7$ mA. FEPS was triggered at $t = 350$ μs. Plasma density is inferred from plasma light emission intensity.

The emittance scanner diagnostic provides $y-$integrated measurements of the transverse distribution $f(x, v_x, y, v_y)$. The first slit can be moved out of the way, so the beam is intercepted by the slit-cup only. Then, $y-$integrated transverse current density profiles $I_{FC}(x_2) = \int j(x_2, y)dy$ at $z = z_2 = 40.1$ cm can be obtained by recording I_{FC} for a range of slit-cup positions. If the beam is made to pass through both slits, then the current $I_{FC}(x_1, x_2)$ will be due to beam ions with $x = x_1$ and transverse angle $x' = (x_2 - x_1)/D$, where $D = z_2 - z_1 = 15.5$ cm is the $z-$ distance between the slits. In this way, the $y-$ integrated trace-space distribution $f(x, x')$ at $z = z_1 = 24.6$ cm can be measured.

In the experiment, ion beam pulses were generated every 2 seconds, with 200 μs-long RF and V_{accel} pulses applied concurrently. Afterglow plasma from an earlier RF pulse (from $t = -180$ μs to $t = -30$ μ s) was used as source of electrons to improve RF breakdown and plasma density rise-time. The FEPS was triggered 100 μs after the start of beam pulse. Typical waveforms of $I_{FC}(t)$, $V_{accel}(t)$ and plasma density are shown in Fig. 2.

EXPERIMENTAL RESULTS

In general, the beam divergence was greatly reduced when the FEPS was triggered, as can be seen in Fig. 2, showing $I_{FC}(t)$ for the slit-cup positioned on the beam axis. The increase in current after the FEPS is triggered at $t = 350$ μs, corresponds to the narrowing of the beam profile. $I_{FC}(t)$ reaches a maximum 15 μs after the FEPS discharge. Data from slit-cup profile scans and trace-space scans is used to investigate the timing and duration of charge neutralization and the minimum beam divergence that can be attained.

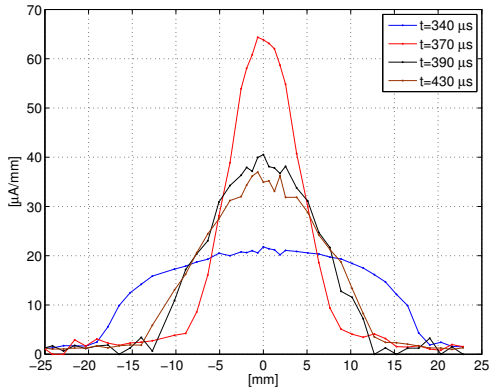

Figure 3: Transverse current density profiles $I_{FC}(x_2)$ taken with the slit cup at different times in the shot.

In the analysis, the effectiveness of neutralization is characterized by a decrease in beam divergence. For an ion beam extracted from a free plasma boundary, experimentally measured divergence is due several factors. The beam will expand due to space charge, characterized by generalized perveance $Q = (1/4\pi\epsilon_0)\sqrt{M/2e}I_B/V_{accel}^{3/2}$, and transverse emittance ϵ, due to finite temperature of plasma ions. These effects are included in the envelope equation for $r(z)$:

$$\frac{dr^2}{dz^2} = \frac{Q}{r} + \frac{\epsilon^2}{r^3} \quad (1)$$

Equation (1) can be solved numerically with initial conditions (r, r') at $z = 0$, which correspond to initial beam radius and divergence at the exit of the accelerator. In a plasma ion source, beam current and accelerating potential can be controlled independently, and the initial divergence of the beam depends on the perveance match. According to [7], the divergence angle $\omega = 0.29S(1 - 2.14Q/Q_0)$, where S is the aspect ration of the extraction gap and Q_0 is the optimal perveance. The optimal divergence that was obtained experimentally in [7] was 1.2°, as measured by $1/e$ Gaussian half-width.

In order to compare experimental results to the envelope model, transverse current density profiles $I(x)$ are measured with the slit-cup for beam energies of 32, 38, and 42 kV, and beam currents from 0.4 to 0.8 mA. Time evolution of total current $I_B(t)$ and HWHM profile width $x_{HWHM}(t)$, calculated from profiles of $I(x)$, is shown in Fig. 4. $I_B(t)$ remains the same before and after the FEPS is triggered, except for the dip in at 350 μs due to electrical noise from the FEPS HV pulse. The curve of $x_{HWHM}(t)$ shows that before neutralization, $x_{HWHM}(t)$ reaches steady state quickly. After the FEPS is triggered, $x_{HWHM}(t)$ decreases to a minimum at $t = 365$ μs, and then increases but remains smaller than before neutralization. Transverse current density profiles at different times are plotted in Fig. 3.

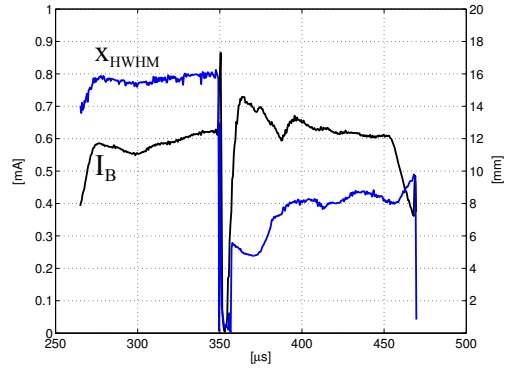

Figure 4: Time evolution of total beam current I_B (black trace) and x_{HWHM} (blue trace) computed from slit-cup profile data for $V_{accel} = 42$ kV, $I_B = 0.7$ mA

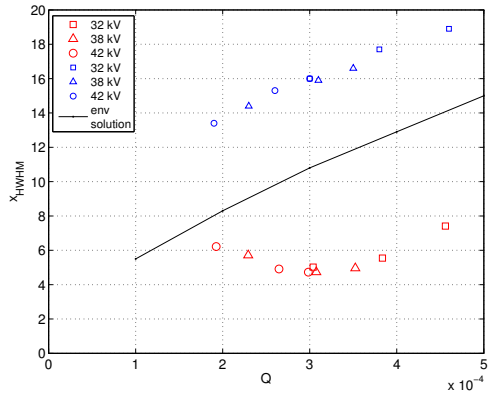

Figure 5: Profile widths characterized by x_{HWHM} versus generalized perveance Q for unneutralized (blue) and neutralized (red) cases at $z = 40.1$ cm. The solution to the envelope equation $r_B(Q)$ (black) is also plotted.

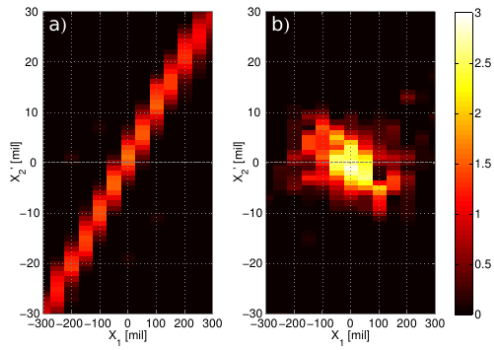

Figure 6: Trace-space data a) before neutralization ($t = 340$ μs) and b) after neutralization ($t = 365$ μs). The horizontal line $x_2' = 0$ corresponds to straight ion trajectories from the extraction aperture of the ion beam to the diagnostic.

Beam divergence, characterized by half-width, half-max of profiles $I(x)$ is plotted as a function of Q in Fig. 5 before neutralization ($t = 340$ μs, blue dots) and at optimal neutralization ($t = 365$ μs, red dots). Beam radius $r_B(Q)$ calculated from the envelope equation with $r(z = 0) = 0.15$ cm and $r'(z = 0) = 0$ is shown for comparison. For the unneutralized case, x_{HWHM} monotonically increases with Q, consistent with space charge expansion. For the neutralized case, x_{HWHM} vs Q has the shape of a perveance curve with a minimum at $Q \simeq 2.9 \times 10^{-4}$, suggesting that beam divergence is due to perveance match in the accelerating gap. At optimum perveance, the 1/e Gaussian half-width divergence angle is equal to 0.87°.

This angular divergence is close to optimal divergence of 1.2° obtained in [7] with a DC ion beam neutralized by ionization of neutral gas. This suggests that observed divergence is due to initial divergence at the exit of the accelerator, and that the beam propagated with $Q_{eff} \simeq 0$ from the source to the diagnostic. This means that that electrons from the FEPS plasma filled the volume of the whole beam and the beam propagated ballistically. This is evident from measurements of the trace-space distribution $f(x, x')$ with the two slit method.

In order to visualise the shape of the beam ellipse in $x - x'$ trace-space, a transformation $x' \rightarrow x_2'$ was applied:

$$x_2' = x_2 - \frac{D_2 + D_1}{D1} x_1 = x_2 - 1.61 x_1 \qquad (2)$$

Here, D_1 and D_2 are distances from the extractor to the first and second slits respectively. With this transformation, the horizontal line $x_2' = 0$ corresponds to the two slits being positioned on line-of-sight to the extractor. In Fig. 6, results of trace-space measurements are shown, comparing an unneutralized beam with the beam during optimal neutralization, which occurs 15 μs after the FEPS is triggered. The unneutralized beam has greater laminar divergence than lines-of-sight to the extractor, with the apparent source point located at $z = 3.6$ cm. This is consistent with space-charge expansion, when divergence angle r' increases with z. In the neutralized case, the beam trajectories are more convergent than lines-of-sight to the extractor, with the apparent source point located at $z < 0$. This indicates that the ion beam was completely charge-neutralized by FEPS plasma.

IDENTIFICATION OF INTRA-BUNCH DYNAMICS USING CERN SPS MACHINE MEASUREMENTS*

Ozhan Turgut†, John Cesaratto, John Dusatko, John D. Fox
Kristin Pollock, Claudio Rivetta, SLAC, Menlo Park 94025, USA

Abstract

Modern control techniques can be used to design feedback systems for stabilizing the intra-bunch dynamics in the presence of electron cloud (ECI) and transverse mode coupling (TMCI) instabilities. These techniques require reduced models of the bunch dynamics. We present a methodology to identify reduced order linear models representing single bunch dynamics using CERN SPS machine measurements. Vertical motion, in response to a wideband excitation signal, is sampled multiple times across the 5 ns bunch. The data and an observable canonical structure [1] are used to identify the dynamics, which is represented as a discrete time multi-input multi-output (MIMO) system. We focus on mode 0 (barycentric) and mode 1 (head-tail) data to identify a reduced order model. Results show that models clearly capture dominant dynamics and replicate machine measurements with corresponding central tune, damping value for each mode and correct separation between the modes.

INTRODUCTION

Electron cloud and machine impedance can cause intra-bunch instabilities [2]. Modern control techniques can be used to mitigate these problems but require reduced order models of intra-bunch dynamics to design optimal and robust controllers for wideband feedback systems [3]. We use system identification techniques to estimate parameters of linear models representing single bunch dynamics. We briefly explain the reduced order model and identification method. Experimental data was collected from a single bunch with 1×10^{11} protons at 26 GeV with low chromaticity configuration at CERN SPS. This paper includes results from mode 0 and mode 1 dynamics analysis but the methods are in principle applicable to N modes.

MODEL AND IDENTIFICATION

The physical system analyzed in this study is a nanosecond scale SPS bunch. The interaction with the bunch is done via control variables (momentum kick / driving signal) and measured variables (vertical displacement). The control variables and measured variables are discretized to represent the physical system in a MIMO form. The number of samples is arbitrary and depends on the sampling rate of the data acquisition system. These studies use 3.2 GS/s sampling rate allowing us to sample 16 different locations across 5 ns RF bucket [3]. The goal is to estimate the intra-bunch dynamics using these input and output signals.

Reduced Order Model

Any linear dynamical system can be represented in state space matrix form. A discrete time system sampled at every revolution period k with p inputs and q outputs is:

$$\begin{aligned} X_{k+1} &= AX_k + BU_k \\ Y_k &= CX_k \end{aligned} \tag{1}$$

where control variable (external excitation) $U \in R^p$, vertical displacement measurement $Y \in R^q$, system matrix $A \in R^{n\times n}$, input matrix $B \in R^{n\times p}$, and output matrix $C \in R^{q\times n}$. For a MIMO system, the model order determines the complexity.

Identification

Identification of a linear dynamical system is done by casting this problem into a linear least squares form. Assuming full observability, we can represent our state space in discrete time observable canonical form. This will enable us to estimate a minimum number of parameters [1]. However, even for linear systems there are two well known limitations for identification. These are the effect of noise and lack of persistent excitation.

Persistent Input

Input signal design and persistent excitation are critical aspects of system identification. Given a quasi-stationary input of u with a dimension nu and with a spectrum $\phi_u(\omega)$, $\phi_u(\omega) > 0$ should hold for at least n distinct frequencies for u to be a persistent excitation [4]. Random noise would be ideal to excite all the modes in the system but requires high excitation power and bandwidth. The hardware used in these measurements puts constraints on both power and bandwidth. The design of an input signal for identification under given constraints becomes an important question for the future studies.

Noise Sensitivity

Noise affects the performance of the identification, and in certain cases can make identification impossible. We can quantify the effect of the noise by adding noise on a known system until the identification can no longer clearly estimate the known dynamics. We drive a synthetic 2×2 coupled MIMO system using a frequency chirp signal with random noise added to the output signals. The effect of noise is tested by running the identification algorithm

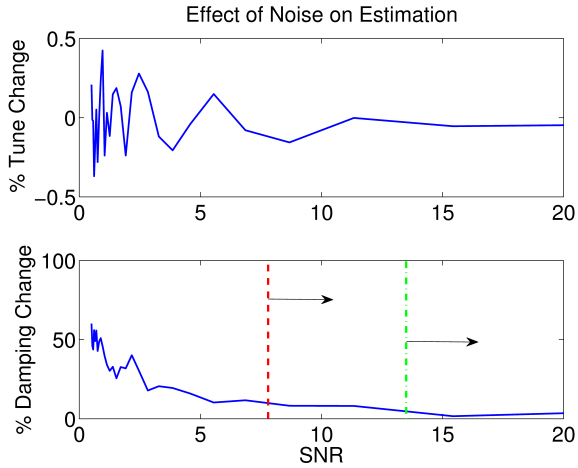

Figure 1: Deviation of estimated natural tune and damping of the 1^{st} mode from the true value for different SNR values. Red line shows min SNR to get errors less than 10%, green line is for errors less than 5%.

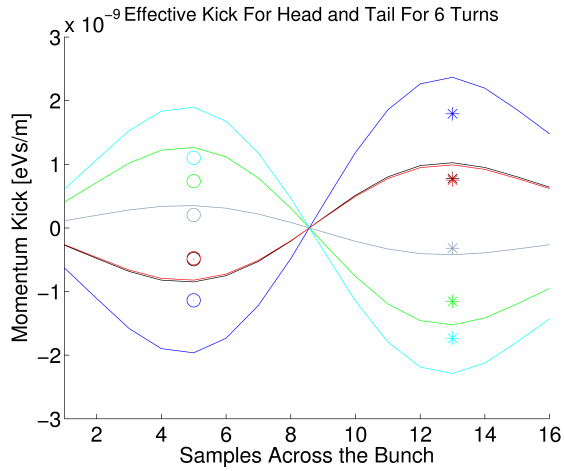

Figure 2: Amplitude modulated momentum signal used to kick particles in vertical plane. Each color represents the kick applied at a single turn. Average kicks, o : head, $*$: tail.

on input - output data as we increase the noise level. Parameters of the model and the corresponding modes of the identified model are estimated for different noise cases. We observe the effect of noise on the mode estimation by looking at the natural frequency and damping values of the first mode for different values of signal to noise ratio (SNR). Figure 1 shows the impact of noise on estimation of system parameters. For identification algorithm to perform well, we need to have SNR $>\sim 8$.

APPLICATION : SPS MEASUREMENTS

In this case the persistent excitation condition is satisfied because we are analyzing the dynamics of mode 0 and mode 1 excited by a chirp excitation, where the frequency changes over 15000 turns.

Our data processing uses a time varying bandpass filter to improve SNR to $\sim$ 20. A window of 500 turns is used to calculate corresponding center frequency of the filter, which follows the chirp excitation.

We focus on mode 0 (barycentric) and mode 1 (head-tail) dynamics. Dynamics, input-output relation of momentum kick and vertical displacement, can be defined by 2 coupled 2^{nd} order differential equations and represented as 2 $\times$ 2 MIMO system with $p = 2$, $q = 2$ and $n = 4$. As mentioned before the number of inputs and outputs depends on the sampling across the bunch. Measurement data should be arranged in such a way that we have 2 $\times$ 2 system. As an initial approach we separate the bunch into two parts. The samples lying in the first part (head) are represented by a macro particle. Its motion is calculated by taking the average motion of the all samples in the head. The same approach is used for the second part (tail) of the bunch. Similarly we calculate an effective kick for the head and the tail by using same technique. At each turn we calculate the effective kick that the head and tail experience by averaging the waveform between samples 1-8 and 9-16. Figure 2 shows 6 sequential traces (each represents a different turn) of the momentum waveform across the bunch and corresponding effective kicks for head and tail.

Results

In driven measurements we use both mode 0 and mode 1 excitations [3]. Excitations and corresponding bunch measurements are used to estimate the parameters of the model. In Fig. 3 the top left plot shows the vertical displacement of the centroid of the head with measurements in blue and the response of the model in red. The bottom left plot shows the same for the tail. Note that our reduced order model is linear time invariant. It cannot capture external perturbations or parameter variations in the bunch. Still the envelope of the amplitude of the centroid motions is captured in the time domain. The figures on the right show measurements and response of model in frequency domain. As an example of external perturbation, we see modulations in FFT data. One of mechanisms for these effects can be tune modulation. From both the time and frequency domains we observe that in this specific measurement, mode 0 is dominantly excited in the tail of the bunch. Although it is a frequency chirp sweeping both mode 0 and mode 1 frequencies, the excitation signal was generated and time aligned to dominantly excite mode 0. Figure 4 shows another data with strong excitation of mode 1. On the left, we see the RMS spectrogram of the driven measurement with clear mode 0 and mode 1 excitation around turns $\sim$ 4000 and $\sim$ 9000. On the right side, we show the RMS spectrogram of bunch's vertical motion predicted by reduced model. The model is able to capture dominant characteristics such as motions at mode 0 and mode 1 tune together with the effect of chirp and mode 0 residual motion.

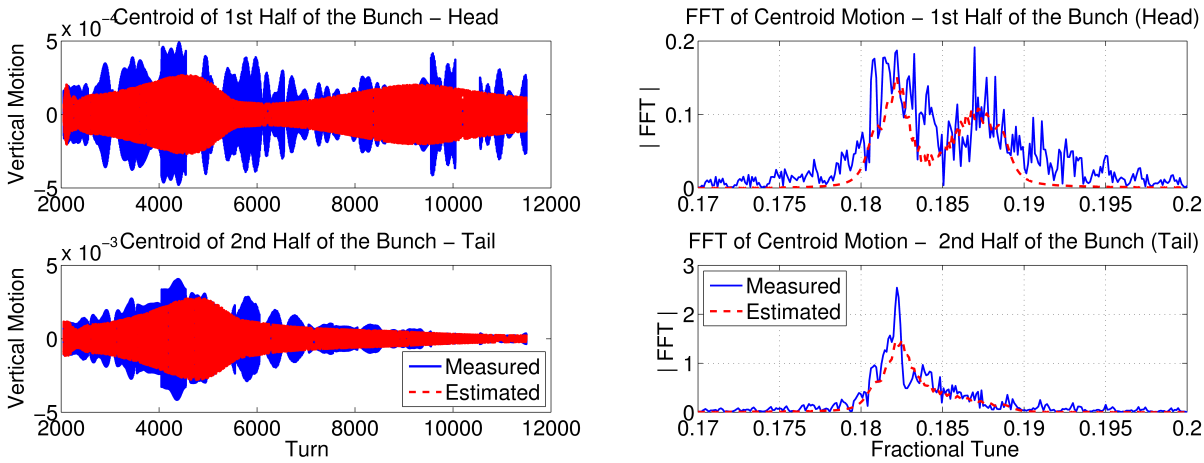

Figure 3: Comparison of the reduced order models response with machine measurements in time and frequency domain.

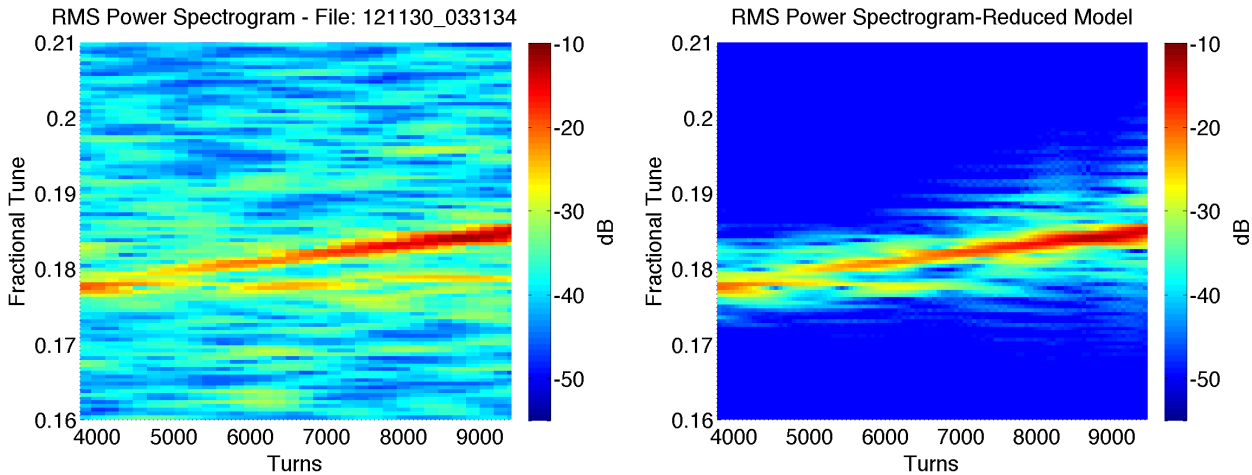

Figure 4: On the left we see the spectrogram of physical measurement showing both chirp excitation where we excite mode 0 and mode 1 around turns ~ 4000 and ~ 9000, respectively. On the right, we see the same excitation and analysis applied to the reduced order model.

CONCLUSION

Control of intra-bunch instabilities via a wideband feedback control system with optimal control algorithms requires a model of the intra-bunch dynamics. We show initial promising system identification results. We identify parameters of a reduced order model that captures mode 0 and mode 1 dynamics from CERN SPS machine measurements. The natural tunes, damping values and the separation of modes associated with the motion seen in measurements are estimated correctly using a linear model. Future work is aimed at estimating more internal modes as the wideband kicker is available late 2014. The techniques used are also applicable to explore optimal and robust control techniques using nonlinear simulation codes [5].

NONLINEAR BEAM DYNAMICS STUDIES OF HIGH-INTENSITY, HIGH-BRIGHTNESS PROTON DRIVERS *

Saeed Assadi#, Karie Melconian, Peter McIntyre, Texas A&M University, College Station, TX

Abstract

Space charge effects, beam losses, wake fields, and orbital control are significant collective effects that affect beam dynamics. The strong-focusing cyclotron incorporates helical orbits with a strong-focusing lattice and high-gradient cavities. It makes it possible to fully separate orbits and suppress interaction between bunches on neighboring orbits. We simulate nonlinear synchro-betratron coupling and explore methods to use the tools of strong-focusing to suppress beam blowup mechanisms.

INTRODUCTION

The Accelerator Resarch Lab at Texas A&M University is developing designs for a strong-focusing cyclotron (SFC) as a high-current (12 mA CW) proton driver for ADS fission [1], production of medical isotopes, and neutron damage studies [2]. The purpose of this paper is to explore how the unique features of the SFC can be used to control nonlinear dynamical effects that limit beam current in accelerators.

Particle motion in the SFC is described in terms of six phase space coordinates (x,x',y,y',ΔE,Δϕ]. The lattice of the Strong Focusing Cyclotron (SFC) requires inclusion of longitudinal or synchrotron motion as one cannot decouple longitudinal and transverse planes past mid-plane analysis. In this case synchrotron motion causes modulations of the parameters or forces and sidebands appear as a result in the tune space. The effects of synchrobetatron couplings and resonance-crossing should become dominant as intensity increases or bunch length elongates.

The SFC lattice combines periodic quad-focusing elements [FD] with common sector magnets and RF cavities, and in this respect it is similar to a combined-function synchrotron. The orbits however are spirals, and dynamics is strongly dependent on initial conditions, and in this respect it is similar to linacs. This results in synchrotron sidebands [1] in the betatron motion with chromaticity as developed by Orlov [2] and synchrobetatron resonances caused by chromaticity as analyzed in a review by Suzuki [3]. The SFC lattice is highly regulated by the arrangement of superconducting beam transport channels (BTCs) [4], Mobius-geometry RF cavities [5], and low-field superconducting sector dipoles [6] to produce matched beta function [β_x, β_y], dispersion [D] and D' to manage emittances. We simulate the SFC as a spiral transmission line, and we include forces from error fields, wake fields, cavity-coupling of bunches, and space charge.

Designs have been developed for a 6-sector 100 MeV SFC (TAMU100, shown in Figure 1) and for a 12-sector 800 MeV SFC (TAMU800) for which TAMU100 would serve as injector. A key element of the SFC is its use of the beam transport channels (BTC), installed along the equilibrium trajectory or each orbit in each sector as shown in Figure 1b. Each BTC contains an FD doublet of Panovsky quadrupoles (up to 6 T/m, used to local tune) and a window-frame dipole (up to .02 T, used to control isochronicity).

Simulation of beam dynamics in both SFCs starts by tracking a 4D map of a bunch propagating through the lattice elements and interacting with EM fields, similarly to the kick codes COSY-INFINITY, Elegant, MADx, and CERN Mathematica. We have started with that framework and added complexity to the simulation as the design progresses. The framework utilizes a combination of mathematical scripts based on COSY-INFINITY fed by Madtomma. Tracking is made using CSRtrack. Figure 2 shows the elements of one cell of an SFC lattice.

We impose a shell on the kick code that operates a simultaneous quadratic optimization, in which we can optimize up to 48 variables that define the isochronous orbits. The framework has evolved to include space charge, chromatic effects, and evolution of bunch-length.

Beam position monitors are provided in a gap at the end of each sector for each orbit. In the planning for commissioning of TAMU100, we plan to inject low-power beam into the first two turns of the lattice with RF off and capture it on a retractable beam dump. That will enable us to verify injection matching and BTC alignment before

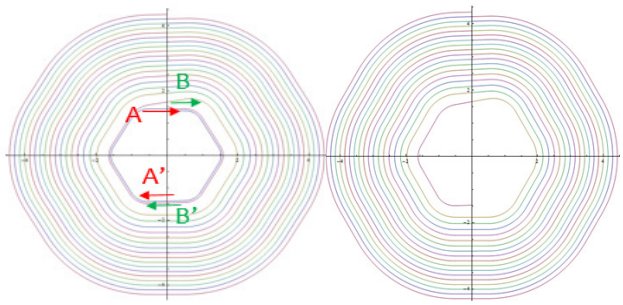

Figure 3, Reference orbits in the 6-sector TAMU100, before and after optimization of the injection orbit.

'threading the needle' of orbits with acceleration. The retractable beam dump can also be traversed to dump the beam after any desired orbit.

Figure 3 shows a first example of how the BTCs convey benefit in optimizing the SFC. Figure 3a shows a reference orbit for TAMU100 in which the orbit was launched from the extraction point and tracked back to injection, optimizing for isochronicity, maintaining stable phase advance in all cells, and holding constant betatron tunes from injection to extraction to a favorable operating point. Figure 3b shows a second optimization in which the optimization of the first two orbits was added to the optimizer criteria.

BEAM DYNAMICS STUDIES

We have studied beam dynamics using the tools described above. We established that the BTC quadrupoles can be grouped into 6 families (3x, 3y) and still provide excellent control with which to set tunes to any desired operating point and hold it there throughout acceleration.

We implemented a similarly grouped set of sextupoles at the exit from each sector to provide control of chromaticity, and a set of beam position monitors that will enable us to develop a correspondence between simulation and actual operation of the accelerator. With those tools, we proceeded to simulate the phase space dynamics of bunches, starting with low current and increasing to our design value.

Figure 4 shows Poincare plots for the 1σ-5σ contours of a bunch in a 3.5 mA 162 MHz SFC, tuned to hold $(\nu_x,\nu_y) = (3.196, 3.241)$. The first three plots show that the phase space has very regular motion throughout acceleration with no particles reaching the BTC apertures.

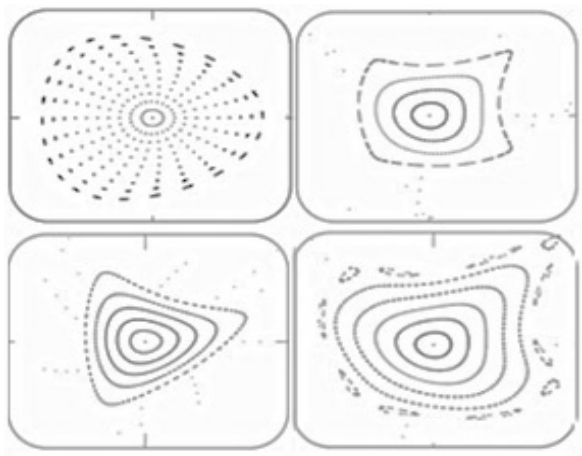

Figure 4. Poincare plots of a 3.5 mA 116 MHz bunch as it is accelerated in an optimized TAMU100 lattice.

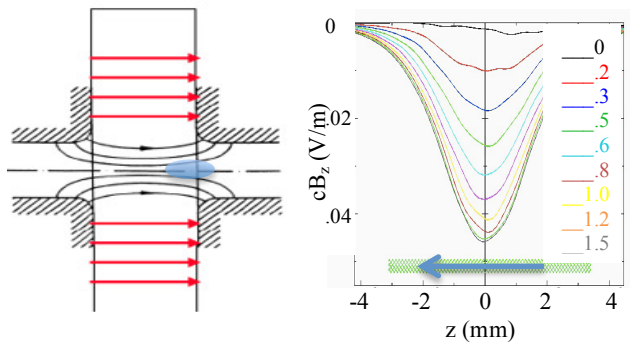

Figure 5. Effect of space charge on longitudinal bunch dynamics: a)bunch passing through cavity; b) longitudinal field inside bunch showing asymmetry from space charge.

For the last plot ν_x was moved near a 7th-order resonance. By the 9th orbit (40 MeV) beam breakup is evident on the 5σ plot. This result gives an example of the simulation at work, and it underscores the importance of controlling tune in a high-current cyclotron.

The nonlinearity and couplings are essentially due to two factors. First, off-momentum particles that go through cavity and then the edge of the sector magnet will go under a different chromatic affect. One aspect of this is shown in Figure 5b, where the space charge of the bunch produces asymmetric fields in the center of the bunch. Such chromatic effects result in synchrobetatron coupling.

We simulated the acceleration of the bunches in a 10 mA CW beam, for a favorable operating point and for tunes near 3rd- and 5th-order resonance. The favorable-tune case produced Poincare plots similar to those of Figure 4a-c; the cases near resonance are shown in Figure 6. When the tune is near a 3rd order resonance, clumping is evident by end of the 2nd orbit and the clumps can be seen driven apart. Similar clumping is evident when the tune is near a 5th order resonance, but clumps remain close. In both cases the beam was lost by 20 MeV. We conjecture that the clumps are driven apart in the 3rd order case by fringe fields of the sector dipoles and by cavity fields, both of which couple to 3rd order in the 6-sector lattice. For a favorable tune, clumping was not observed until near 100 MeV, and the beam profile remained intact.

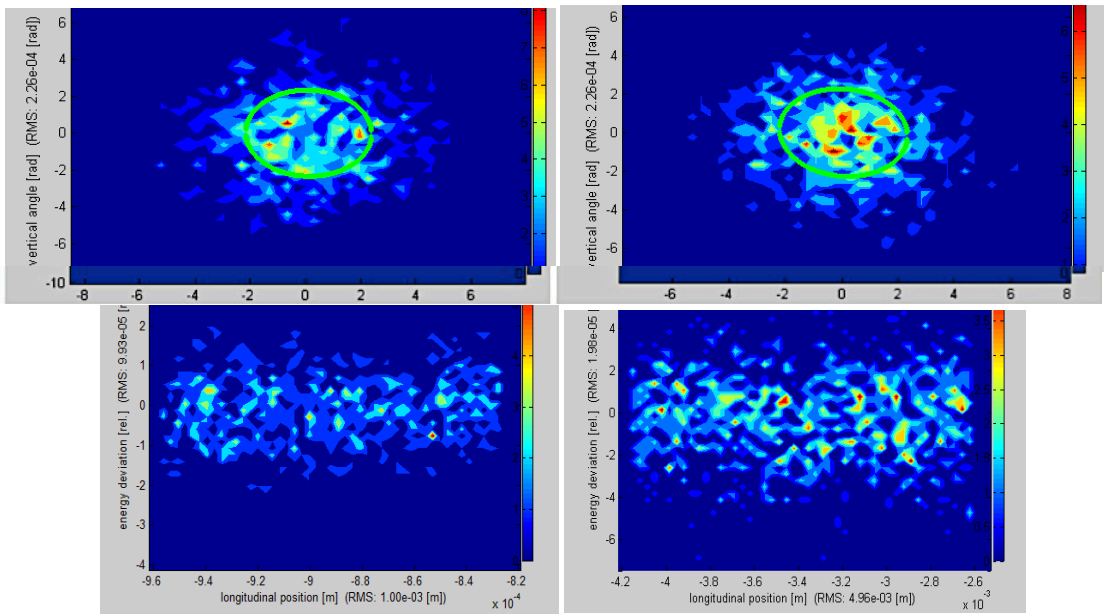

Figure 6. a) Beam breakup in transverse phase space after 2nd orbit when tune is near 3rd order and 5th-order resonances; b) beam breakup in longitudinal phase space when tune is near 5th order resonance.

Figure 7 shows similar dynamics for the longitudinal phase space of bunches in a 10 mA beam with favorable tune. ΔE grew from ±5° at injection to ±6° at extraction; Δϕ increased by 30%; the bunch was accelerated without loss from the 20 MV bucket.

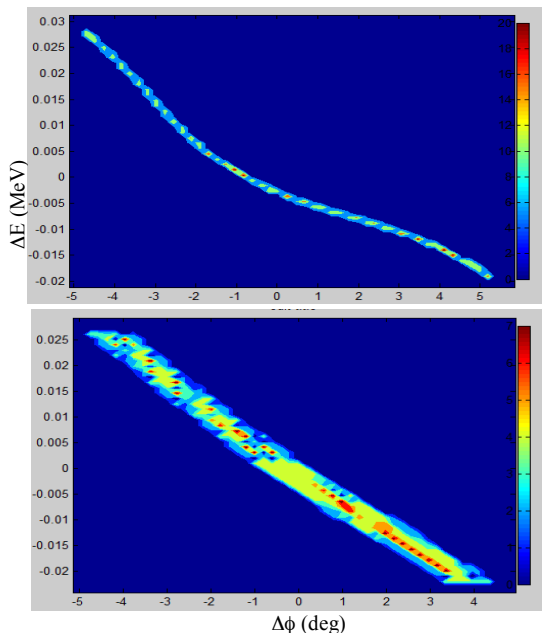

Figure 7. Longitudinal phase space of a bunch in a 10 mA beam: a) after first half-turn; b) 100 MeV.

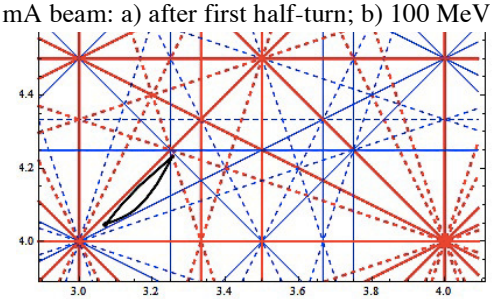

Figure 8. Tune distribution of points on the 5σ trajectory for a favorable tune.

Figure 8 shows a map of the tunes of individual particles on the 5σ contour of a bunch in 10 mA beam, accelerated using a favorable operating point. The tune can be positioned so no resonance crossing occurs, even at 5σ.

CONCLUSIONS

The above results are the beginning stages of a systematic investigation of non-linear dynamics in our strong-focusing cyclotron as it accelerates >10 mA of proton beam to 800 MeV for ADS fission and other applications.

Abstract

The Electron Ion Collider (EIC) will be a next-generation facility for the study of the strong interaction (QCD). JLab's Medium-energy Electron Ion Collider (MEIC) is designed for high luminosities of up to 10^{34} $cm^{-2}s^{-1}$. This is achieved in part due to an aggressively small beta-star, which imposes stringent requirements on the collider rings' dynamical properties. Additionally, one of the unique features of MEIC is a full-acceptance detector with a dedicated, small-angle, high-resolution detection system, capable of covering a wide range of momenta (and charge-to-mass ratios) with respect to the original ion beam to enable access to new physics. The detector design relies on a number of features, such as a 50 mrad beam crossing angle, large-aperture ion and electron final focusing quads and spectrometer dipoles as well as a large machine-element-free detection space downstream of the final focusing quads. We present an interaction region (IR) design developed with close integration of the detection and beam dynamical aspects. The dynamical aspect of the design rests on a symmetry-based concept for compensation of non-linear effects. The optics and geometry have been optimized to accommodate the detection requirements and to ensure the interaction region's modularity for easiness of integration into the collider ring lattices. As a result, the design offers an excellent detector performance combined with the necessary non-linear dynamical properties.

INTRODUCTION

The MEIC accelerator complex at Jefferson Lab is designed to pursue a high luminosity to understand QCD in the nuclear physics programs [1]. As an interface between the beam acceleration/transport system and the detector, the interaction region (IR) is one of the most challenging parts of the MEIC design and largely determines the performance of the detectors and colliders. To achieve the required physics goals, the IR design should go through an optimization process between the physics requirements and accelerator performance. Besides, as part of the optics design of the complete accelerator complex, the IR design should also consider the modularity for its integration into the collider rings. This paper provides an overall consideration from the detection and accelerator performance points of view in the IR design and demonstrates a well-developed multi-function MEIC IR layout.

#fanglei@jlab.org

IR DESIGN REQUIREMENTS AND CONSTRAINTS

Detector Requirements

The primary full-acceptance detector has a sufficiently large magnet-free space near the interaction point (IP) for detection of particles down to about 0.5° in front of the final focus blocks. In addition, to allow detection of particles scattered between 0-0.5°, the hadrons and electrons need to pass through the large-aperture final focusing quadrupoles and are detected by the further downstream (up to 37 m) detector components. To maximize the detector's acceptance to the forwarding-scattered hadrons and electrons, both the ion and electron beams are focused downstream of the forward final focus so that small beam sizes at the focal points allow one to place the detectors closer to the beam centers. In combination with ~1 m dispersion at those points, this allows detection of particles with small momentum offset $\Delta p/p$. This optics was optimized to maximize its angular and momentum acceptance and detector resolution [2].

The considerations of detection performance in the IR design can be comprehensively described as follows,

1. large detector space (-4.4m / +7m) for a full-acceptance detector,
2. detection of forward scattered hadrons down to 0° achieved by
   - large aperture downstream ion final focusing quadrupoles,
   - strong spectrometer dipole,
   - large machine-element-free drift space after the spectrometer dipole,
   - secondary focus after the spectrometer dipole combined with large dispersion for better momentum resolution,
3. detection of low-Q^2 electrons and electron momentum analysis,
4. large 50 mrad crab crossing angle for faster beam separation to
   - reduce parasitic collisions due to high repetition rate,
   - increase space for magnets,
   - obtain better detector resolution,
5. IP locations
   - close to exit from ion arcs to reduce the residual gas scattering background,
   - far from exit from electron arcs to reduce synchrotron radiation background.

Beam Dynamic Requirements

To achieve the required high luminosity, the colliding beams are strongly focused to a small spot at the IP, associated with a large transverse beam expansion before its focusing. This unavoidably induces a large chromatic betatron tune spread and chromatic beam smear at the collision point. The betatron tune spread is limited by the beam resonances and therefore restricts the ring's momentum aperture. The chromatic beam smear increases the beam spot size at the IP, resulting in a luminosity loss. A dedicated compensation approach to the chromatic effects has been reported and studied systematically by using a symmetric Chromaticity Compensation Block (CCB) [3,4,5,6,7]. The symmetries of particle's orbital motions and dispersion in the CCB allow simultaneous compensation of the 1st-order chromaticities and chromatic beam smear at the collision point without inducing significant 2nd-order aberrations and therefore preserving the ring's dynamic aperture.

In addition, the IR design was performed to consider a simultaneous optimization of chromatic compensation and detector requirements. Such an optimized optics is asymmetrically detector-optimized, with the upstream final focusing elements placed much closer to the IP than those on the downstream side, as shown in Figs. 1 and 2 for the MEIC ion and electron collider rings. This will be beneficial in reducing both the maximum betatron functions on the upstream side and the contribution to the chromaticity.

The layout of magnets in this detector-optimized optics is shown in Fig. 3, a complete 3D model of the detector region implemented using G4beamline/GEANT4 [7]. Special attention was paid to sizes and positions of the detector region elements to avoid interference with each other and with the detector functionality. For example, i) two permanent magnetic quadrupoles were used in the electron upstream final focusing block so that they are very close to the IP to maximize the detector acceptance by reducing the solid angle blocked by the final focusing quadrupoles; ii) the upstream ion final focusing block was designed using standard ring elements as much as possible and its layout was adjusted to minimize its interference with the forward electron detection; iii) the apertures and position of the downstream electron final focusing block were optimized to maximize the forward electron acceptance while ensuring proper fit of the electron and ion quads.

Geometric Constraints

The figure-8 MEIC collider rings are designed to have two collider rings' arcs vertically stacked in the same underground tunnel. Each arc bends the beam by 240° in the horizontal plane and two arcs in one ring are connected by straights with 60° crossing angle. With the 50 mrad crab crossing angle between the two collider rings at the IP, the geometry of the IR affects the overall ring geometry. The optics design decouples this dependence of the ring geometry from the IR design by imposing the following constraints to both electron and ion ring.

1. Electron ring
   - IR
     - zero net bend and zero transverse beam shift on each side of the IP,
   - Arcs
     - 240° bending angle including the spin rotators,

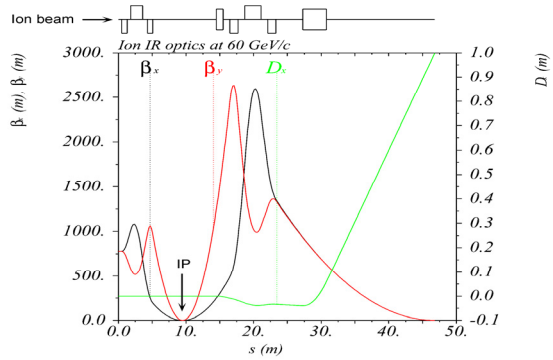

Figure 1: Detector region optics in the MEIC ion collider ring.

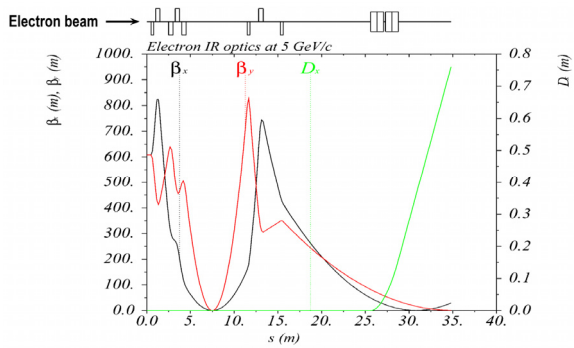

Figure 2: Detector region optics in the MEIC electron collider ring.

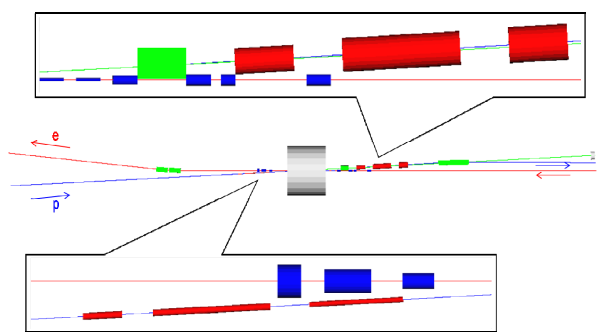

Figure 3: Layout of magnets in the detector region of MEIC collider rings.

2. Ion ring
   - IR
     - 50mrad net bend on each side of the IP to compensate the crossing angle (opposite bends on two sides of the IP),

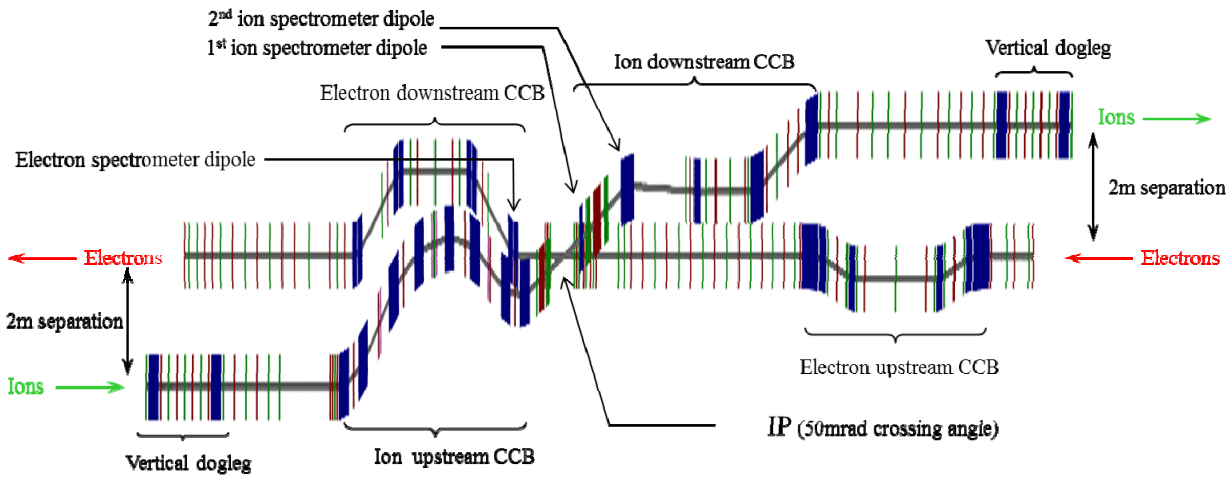

Figure 4: MEIC interaction region components and layout.

- ° 2m transverse beam shift on each side of the IP with respect to the electron ring,
- − Arcs
  - ° 240° arc bend,
  - ° 2m transverse separation from the electron ring at the arc ends.

These geometric constraints to the optics promise that the IR design is modular and any lattice changes in the IR will not interfere with the rest of the collider rings' configuration.

Combining all these considerations of detection, beam dynamics and geometry requirements, the interaction region components and its layout are shown in Fig. 4. Note that the two beam lines are parallel at the entrance and the exit of the interaction region with 2 m separation on each side. In order to compensate the chromatic aberrations at the IP and in the ring, each collider ring has two CCBs located upstream and downstream of the IP. The ion upstream and downstream CCBs produce a 50 mrad net bending angle for the crab crossing. The electron upstream CCB is moved away from the IP to avoid synchrotron radiation background in the detector.

CONCLUSIONS

An asymmetric detector-optimized IR optics design was developed for a full-acceptance detector simultaneously considering the detection requirements, chromatic compensation and rings' geometric constraints. The design provides the necessary properties of both the physics detection and beam dynamical aspects. In addition, such optics and geometry guarantee that the interaction region is modular and can be easily integrated into the collider ring lattices. We next plan to validate the design by tracking simulations.

MODELING SPACE CHARGE EFFECTS IN OPTICAL BUNCHERS*

L.V. Ho, P. Musumeci, J. P. Duris, R. K. Li, UCLA, Los Angeles, CA 90095, USA

Abstract

This paper introduces a 1-D, self-consistent simulation of Inverse Free Electron Laser (IFEL) based optical bunchers. Starting with a review of the conventional (monochromatic) IFEL bunching, we consider slow amplitude variation and multiple harmonics of the fundamental radiation wave. We model two new bunching schemes – the adiabatic and harmonic microbuncher and compare the bunching mechanisms between the optical bunchers as well as space charge effects to the modified IFEL interaction. Here, we present a model approximating the space charge fields and verification of the simulation with the well-known Free Electron Laser (FEL) simulator, Genesis 1.3.

INTRODUCTION

In recent years, the Inverse Free Electron Laser (IFEL) has gained popularity because of its accessibility as table-top accelerator with high energy gradient and most of all– because of its ability to microbunch beams on orders of the radiation scale [1]. Microbunched beams finds various applications throughout accelerator and beam physics including its use as a seed for high-gain harmonic generation (HGHG) FEL, preinjectors for advanced accelerators, and production of high quality, high current beams [2, 3].

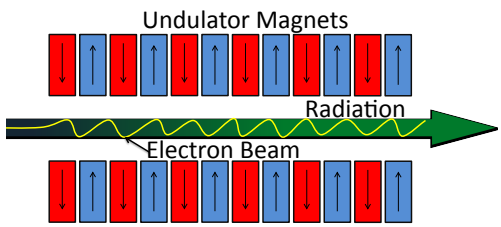

Figure 1: IFEL Interaction - Copropogating electron beam and laser within an undulator.

An IFEL consists of a laser and an electron beam copropogating within an undulator such that the electric field of the radiation is parallel to the wiggling of the electrons induced by the undulator (Figure 1). Efficient energy exchange between the beam and laser occurs when the resonant condition is satisfied – that is, when the electrons have energies such that the oscillation induced by the wiggler in its rest frame is in resonant with the electric field of the laser. This is satisfied when electrons has energy [1]:

$$\gamma_r^2 \simeq \frac{\lambda_\omega}{2\lambda}\left(1+\frac{K^2}{2}\right) \tag{1}$$

where γ_r is the resonant electron energy, λ_ω is the undulator wavelength, λ is the radiation wavelength, and $K = \frac{eB}{mck_\omega}$ is the normalized undulator parameter.

The IFEL was introduced by Palmer in 1972, who proposed the possibility of 10 GeV electron acceleration using the IFEL interaction [4]. In recent years, various experiments have shown the success of IFEL to achieve high-energy gradients with good beam quality [2], with experiments being done in national laboratories such as ATF and Livermore [5, 6]. In addition, the use of the IFEL microbunched beams have been demonstrated to increase radiation gain of over seven orders of magnitude in the HGHG FEL [3].

Here we present a 1-D IFEL simulation with the capability of including slow amplitude variation and multiple harmonics of the fundamental radiation wave. Thus, we can model the three different types of IFEL based optical bunchers: the conventional (monochromatic), harmonic, and the adiabatic microbuncher. With the newly proposed harmonic and adiabatic buncher, the ability to modulate the electron beam density is increased significantly, with bunching factors larger than 90 % [2, 7]. Space charge effects in ultra-relativistic electron beams may no longer be neglected, and considerations of its effects on the resulting beam becomes more important. We first present a review of the IFEL based optical bunchers. Then, we introduce a model approximating the space charge fields and verification of the bunching simulation with Genesis 1.3.

MICROBUNCHING THEORY

Monochromatic Microbuncher

The basic IFEL interaction of microbunching can be described in terms of phase space variables, γ and ψ, as alternative representations of the momentum and position of the electrons. The equations of motion are [1]:

$$\frac{d\gamma_i}{dz} = \frac{1}{2}kK_l\frac{KJJ}{\gamma_i}\sin\psi_i + \frac{e}{m_0c^2}E_i^{sc} \tag{2}$$

$$\frac{d\psi_i}{dz} \simeq k_\omega - k\frac{1+K^2/2}{2\gamma_i^2} \tag{3}$$

where the i denotes the i^{th} electron, $k_\omega = \frac{2\pi}{\lambda}$ is the undulator wavenumber, $k = \frac{2\pi}{\lambda}$ is the radiation wavenumber, $K_l = \frac{eE_0}{m_0c^2k}$ is the normalized radiation potential, and $JJ = J_0(G) - J_1(G)$ is the coupling factor due to the geometry of the undulator, where $G \approx \frac{K^2}{4+2K^2}$.

In the special case where there is no net energy exchange between the radiation and electrons, the resonant energy is constant, $d\gamma/dz = 0$, and modulation of the density of

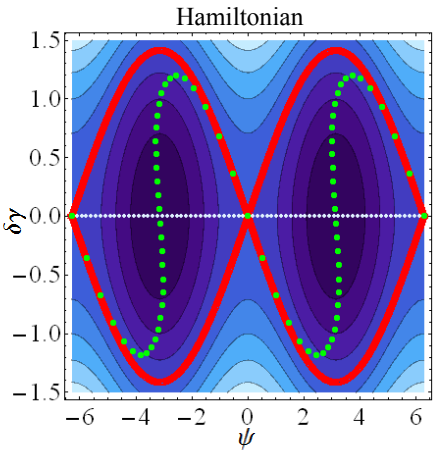

Figure 2: IFEL Hamiltonian for small oscillations and electron trajectories near resonant particle.

the electron beam occurs (microbunching). Figure 2 illustrates a contour of the Hamiltonian as well as the separatrix (bucket), denoted by the solid red line, and its reduction to a cosine-like potential for small oscillations about the resonant particle. In addition, Figure 2 shows the phase space evolution of electrons with energies close to the resonant energy (within the separatrix) reveal rotation within phase space, indicating the modulation of electron densities.

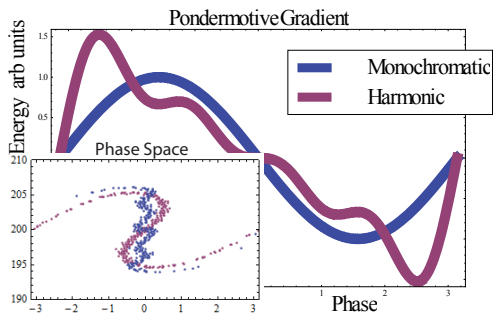

Figure 3: IFEL pondermotive gradients. The harmonic potential includes the first 4 harmonics of the fundamental radiation. The longtidunal phase space (lower left) illustrates the phase space of each gradient.

Harmonic Microbuncher

For the harmonic microbuncher, the novel change is the addition of multiple harmonics of the fundamental radiation to copropogate with the electron beam [8]. The pondermotive potential is no longer limited by the nonlinearities experiences by the monochromatic buncher, but becomes more like an ideal simple harmonic oscillator with the addition of more harmonics (Figure 3) [2]. In theory, a combination of infinite harmonics can produce a perfectly linear restoring force and thus perfect bunching and infinite current, limited only by space charge [2].

Adiabatic Buncher

The adiabatic buncher is another proposed microbuncher that eliminates the nonlinearities of the pondermotive potential [7]. An appreciable quality of the adiabatic microbuncher over the other two is its ability to preserve longitudinal beam emittance [7]. In this interaction, the radiation power is slowly increased along the undulator to fulfill the adiabatic condition – to change the amplitude of the pondermotive gradient on time scales much longer than the synchrotron period in order to preserve beam quality. In practice, the adiabatic condition is challenging to implement but can be approximated by utilizing the diffraction dominated regime of a gaussian wave and a very long undulator [7]. Figure 4 illustrates the validity of the approximation and the output longtidudinal phase space.

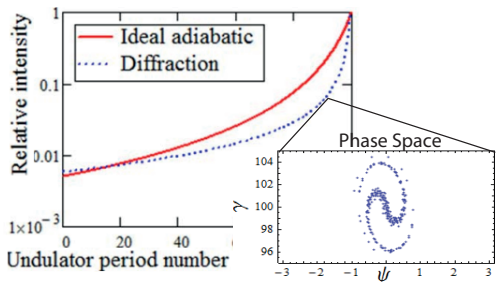

Figure 4: Fulfillment of the adiabatic condition and the approximation of the diffraction effects [7].

SIMULATION

Space Charge Approximation

The space charge fields are modeled by approximating each macroparticle as charged finite radial disks and summing the effects due all other macroparticles. In solving the coupled differential equations (2) and (3), we focus only on one bucket, with the assumption that all other buckets behave similarly. To evaluate the space charge effects, we must also account for the neighboring buckets and their contribution to the primary bucket.

Obtaining the electric field of one macroparticle on another and applying periodic boundary conditions, the electric field can be evaluated by:

$$E_0^{sc} = \epsilon \sum_{x}^{N} \sum_{b=-\infty}^{\infty} \operatorname{sgn}(\Delta_0 - b) \left(1 - \frac{1}{\sqrt{1 + \left(\frac{\Lambda}{\Delta_0 - b} \right)^2}} \right)$$

where $\epsilon = \frac{1}{2\epsilon_0} \frac{I_p \lambda}{Nc} \frac{1}{\pi \sigma_x^2}$, $\Delta_0 = \frac{\psi_x - \psi_0}{2\pi}$, $\Lambda = \frac{\sigma_x}{\lambda}$, I_p is the input peak current, N is the total number of macroparticles, b is the bucket, and σ_x is the transverse beam size.

When examining the sum over the buckets, we can see that contributions due to the buckets located to the left can be manipulated such that the buckets need only to be summed from $b = 0$ to $b = \infty$. In addition, because the

Copyright © 2013 CC-BY-3.0 and by the respective authors

sign function is defined to be 0 for $\mathrm{sgn}(0) = 0$, this avoids double counting of the particle in the bucket of interest. Then, the contribution of the electric field on the 0^{th} particle due to the x^{th} particle and its mirroring buckets can be written as:

$$E_0^{sc}(\psi_x) = \epsilon \,\mathrm{sgn}\,\Delta_0 \left(1 - \frac{1}{\sqrt{1+\left(\frac{\lambda}{\Delta_0}\right)^2}}\right) + \sum_{b=1}^{\infty} \frac{1}{\sqrt{1+\left(\frac{\lambda}{\Delta_0 - b}\right)^2}} - \frac{1}{\sqrt{1+\left(\frac{\lambda}{\Delta_0 + b}\right)^2}}$$

It is then possible to evaluate this sum for various phase positions, Δ_0, and use a n^{th} order fit function to replace this sum. This heavily simplifies the summation process by replacing an infinite sum to a simple polynomial function and reduces the space charge calculations to evaluating one sum that includes periodic boundary conditions.

Table 1: IFEL Monochromatic Bunching Parameters

Electron Beam	
Input Energy	100 MeV
Emittance	2 mm mrad
Peak Current	20000 Amps
Laser	
Power	50 TW
Wavelength	800 nm
Spot size $(1/e^2)$ at focus	3.56 mm
Rayleigh Range	50m
Undulator	
Undulator Length	0.96m
Undulator Period	.0639m
Undulator Parameter	.056

Verification of Simulation

The simulation, executed in Mathematica 8.0, was verified with the well-known FEL simulator, Genesis 1.3, developed by Sven Reiche [9]. This simulation is capable of modeling the conventional IFEL buncher, as well as the harmonic and adiabatic buncher.

In order to properly compare the models and the correctness of the space charge effects, we simulated in a particular case with parameters shown in Table 1. In this regime, the laser waist is much larger than the transverse size of the beam, reducing transverse effects and inducing a regime where 1-D simulations are justified. Additionally, in this regime, the gain length is much greater than the plasma length – that is $\frac{L_g}{L_p} >> 1$. This ensures that there is no radiation gain, which would otherwise counteract the space charge effects. Thus, we can clearly compare the effects of the pondermotive potential as well as space charge effects between the simulation and the Genesis 1.3 simulation without erroneous contributions existing in other particle simulators.

We found that the solutions of the equations of motion as well as the space charge calculations are consistent in the Mathematica simulation in comparison with Genesis 1.3. The bunching factors for space charge on and off are shown in Figure 5, showing the consistency between the models.

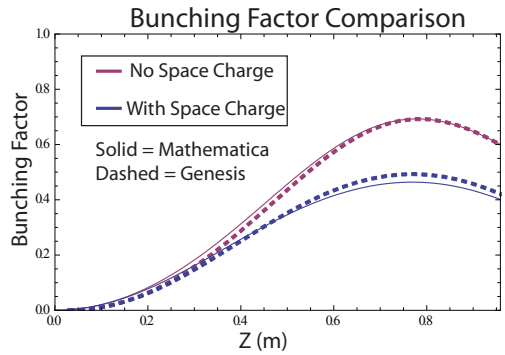

Figure 5: Comparison of Bunching Factor of monochromatic microbuncher between the simulations.

CONCLUSION

Verification with Genesis 1.3 and isolation the space charge effects validates the use of this simulation to adequately compare the different type of bunchers as well as the space charge effects.

Future plans include comparing the benefits and drawbacks of each – their experimental feasibility, bunching capabilities, and effects on the beam's final emittance, energy spread, peak current. Because space charge effects become much more dominant in the harmonic and adiabatic buncher, considerations of the extent of its affects on beam quality will also be analyzed.

IREAP, University of Maryland, College Park, MD, USA

Abstract

We report on experiments and simulations of beam lifetime at the University of Maryland Electron Ring (UMER) for an emittance as well as a strongly space-charge dominated beam. We note the presence of expected (and strong) integer resonances for both beam currents and the absence, for moderate envelope mismatch, of some half-integer resonances for the high current beam only. The observations are related to particle-tracking simulations with the matrix code ELEGANT. The simulations employ a simple incoherent space charge model for a continuous beam, as well as lattice and magnet errors.

INTRODUCTION

The operation of all circular accelerators rely on careful selection of the betatron tunes for optimal beam quality and lifetime. In addition, when collective effects are an important factor, systematic study of current-dependent phenomena, e.g. envelope resonance conditions, is required. The basis for our investigation is the University of Maryland Electron Ring (UMER), a low-energy, high-current compact machine dedicated to beam physics research [1, 2]. We discuss the use of a simple computer model and show that the results are consistent with the main features of experimental beam lifetime charts, i.e. charts that display the surviving fraction of injected beam current at a given turn as a function of betatron bare tunes. Of particular interest is to compare the beam lifetimes of emittance-dominated and space-charge dominated beams.

When space charge is a factor, realistic 6D computer simulations of beam evolution over even a few turns is very computer intensive. Customarily, particle-in-cell codes are employed for tracking hundreds of thousands or even million of macroparticles. Other calculations with space charge such as transverse rms envelope matching are performed with matrix codes such as TRACE3D [3] which employ a linear space charge model and do not allow particle tracking. By contrast, the matrix code ELEGANT [4] can be adapted to do particle tracking in the presence of strong transverse space charge including non-linearities. The ELEGANT model of transverse space charge is only approximate but has yielded satisfactory results in envelope as well as dispersion calculations in UMER [5].

EXPERIMENTS

We have conducted experiments with two electron beams, 0.6 mA and 6.0 mA, both at 10 keV. The initial normalized rms emittances are 0.4 μm (0.6 mA) and 1.3 μm (6.0 mA); the bunch duration is 100 ns for both beams. In one set of experiments, all 70 DC magnetic ring quadrupoles are powered with currents varying from 1.65 to 2.10 A in 10 mA steps, while the injection (pulsed) quadrupoles (YQ and QR1) are kept fixed at the nominal operating currents. For each operating set of quad currents, the transmitted peak beam current is measured with a wall-current monitor located roughly half-way around the ring. In the second set of experiments, the value of one of the injection quads (QR1) is also varied so its focal length equals the corresponding one for the ring focusing quadrupoles. The other injection quadrupole (YQ) could not be varied because it plays a critical role for the injection angle into the closed orbit.

Figure 1a displays the results of beam lifetime at the 10th turn as a function of *estimated* bare tunes for the 0.6 mA beam (emittance dominated) when varying the strength of QR1. Deep red in the figures indicates 90-100% transmission while deep blue or purple near complete loss. The overall beam transmission for the 0.6 mA beam at the 10th turn is slightly improved by varying QR1 (the results with fixed QR1 are not shown), particularly far from the nominal operating point (I_F, I_D) = (1.826,1.826)A, indicated in Fig. 1a by "0". "$I_{F,D}$" refer to the currents of focussing and defocussing ring quadrupoles. Also worth noting is that good transmission for 0.6 mA occurs for $\nu_{0x} \gtrsim 6.5$, but it is greatly reduced for $\nu_{0x} \lesssim 6.5$.

Figures 1 b-c illustrate the beam lifetime results for the 6.0 mA beam (space-charge dominated at injection). The results of varying QR1 are more dramatic for the 6.0 mA beam. In this case, the beam losses near the nominal horizontal bare tune ν_{0x} = 7.5 are markedly reduced. Further, significant beam transmission occurs for highly asymmetric focusing, around (ν_{0x}, ν_{0y}) = (5.5, 8.5), unlike the case for 0.6 mA (Fig. 1a.) Finally, beam transmission for 6.0 mA displays an asymmetry around the line defined by $\nu_{0x} + \nu_{0y}$ = 13, corresponding to a sum resonance. Notice that beam transmission, overall, is noticeably better for the 6.0 mA beam than for the 0.6 mA, with e.g. no visible beam loss at ν_{0x} = 6.5 for the former.

The *estimated* bare tunes in Fig. 1 are determined through a transformation of the quadrupole current space, which is square [(1.65, 2.09) A×(1.65, 2.09) A in 10 mA steps], into the trapezoidal tune space using an effective quadrupole peak gradient per amp of g_0 = 3.95 G/cmA and standard matrix formulas (specifically, the inversion of eqs. 18-ab in Ref. [6].) The choice of g_0 corresponds to a calibration to the observed integer-resonance bands for the *low-current* beam (Fig. 1a). Another model of UMER in ELEGANT based on fitting g_0 to match results from response matrix measurements leads to a slightly different tune calibration [7]. We stress the fact that the plots in Fig. 1 are meant mostly as a guide to study beam lifetime

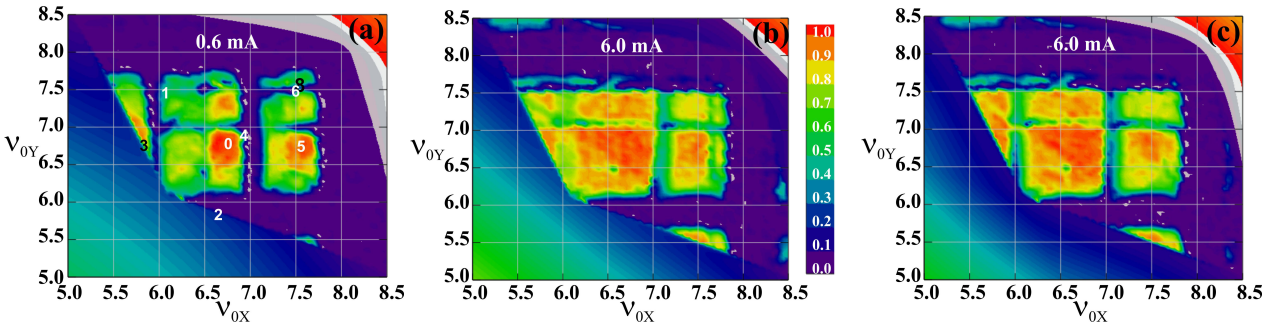

Figure 1: Beam lifetime charts at 10th turn as a function of estimated bare tunes (x: horizontal, y: vertical): (a) 0.6 mA beam (emittance dominated) with varying strength of injection quadrupole QR1 (see text ant Table 1); (b) 6.0 mA beam (space charge dominated) with fixed strength of QR1; and (c) 6.0 mA beam with varying strength of QR1. The green and red areas on opposite corners are artifacts of the graphics.

as a function of tunes, and that a more accurate calculation of tunes requires inclusion of all magnets. In fact, including the injection quadrupoles, and especially a realistic model of the main bending dipoles is important. The dipoles are used also as orbit correctors in UMER; the corrections compensate for the action of the vertical earth's field, the quadrupole radial displacement errors, and the machine imperfections.

Image forces also modify the tunes by values measured to be -0.003 and -0.03 for 0.6 and 6.0 mA beams, respectively, at the default operating point of 1.826 A [8]. The effect of image forces is seen by comparing Figs. 1a and 1b: e.g. the occurrence of the resonance at $\nu_{x0} = 7.0$ is shifted to an *apparently higher* value for the 6.0 mA beam relative to the 0.6 mA beam.

COMPUTER SIMULATIONS

The lattice model in ELEGANT employs hard-edge focusing and bending elements following the model described in [6], 3 injection elements (2 wide-aperture quadrupoles and one dipole), and a uniform 0.4 G earth's B-field pointing downward. A small quadrupole focusing term K1 = 3.45 m^{-2} is also included at every dipole; this arises from the presence of a sextupole component and the sagitta effect of particle orbits. Furthermore, *symplectic* quadrupoles and dipoles are employed.

We include magnet alignment and strength errors for the calculations: displacement errors of (rms) amplitude $(DX, DY) = (0.3, 0.1)$ mm; ring quadrupole strength error of amplitude $\Delta K1 = 1.0$ m^{-2}; and 2 mrad quadrupole and dipole tilt angle errors. The distribution of errors is Gaussian in all cases, with a cutoff of 2σ. Furthermore, we link the radial (DX) alignment errors of ring quadrupoles in groups of 4 as in the actual ring sections. We also implement a simple model of incoherent *transverse* space charge for a *continuous* beam [5], but image forces and momentum errors are *not* included. Also missing in the model are a number of vertical-steering corrector magnets.

The simulations are run over 10 turns with initial *beam* Courant-Snyder parameters that correspond to near rms-envelope matched conditions, and particle tracking is performed with 10K particles. We limit the simulations to 10 turns mainly because effects from debunching are not included. These effects, which manifest after about 20 turns for the 6.0 mA beam, render ineffective the measurement of the AC component of the beam current which is key for quantifying the beam lifetime as a function of tunes.

Out of the more than 2,000 operating tunes represented in Figs. 1, we focus our attention on a small number for tune measurements and for calculations in ELEGANT. The tunes are obtained by doing sinusoidal fits to 3 sets of difference orbits (for 6.0 mA); the resulting errors are 0.03 to 0.1. We calculate the small-amplitude tunes in ELEGANT by running a simple lattice model, with no magnet errors, over one turn. The Table below summarizes the results for 9 operating points; these are also indicated as numerals in Fig. 1a. The calculated and measured tunes agree in all cases but one to better than 0.08.

Table 1: Calculated (ELE.) and Measured (EXP.) Horizontal (x) and Vertical (y) Betatron *Linear* Tunes. Injection quad YQ is fixed at $K1 = -99.86$ m^{-2} (6.0 mA beam) for most points, while injection quad QR1 is varied (see text and Fig. 1a.)

[2] Inj. quads: (YQ,QR1) = (−114.43,114.43) m^{-2}
[3] Inj. quads: (YQ,QR1) = (−115.00,115.00) m^{-2}

At operating points like 0 and 5 in Table 1 and Fig. 1a, beam transmission at the 10th turn is essentially 100%. The magnet and lattice errors assumed (see above) lead in calculations to centroid oscillations of maximum amplitude of close to 6 mm and 10 mm in the horizontal and vertical planes, respectively, at point 0. At point 5, the calculated centroid oscillations are 4 mm and 10 mm, maximum amplitude. The magnitude of the oscillations in the vertical plane is about a factor of 2 larger than observed in beam-position-monitor data and also in results from simple calculations. Also regarding operating point 5, we note the

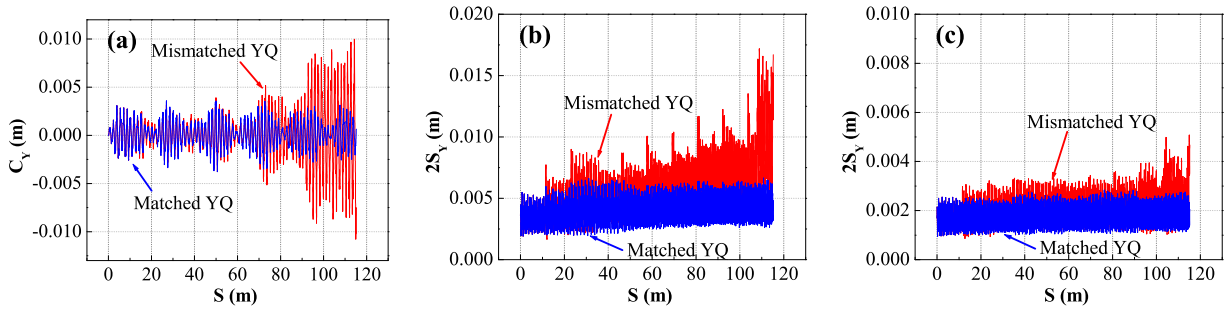

Figure 2: Results of calculations (*with* incoherent transverse space charge) in ELEGANT over 10 turns at (1.99, 1.99)A operating point in UMER: a) Vertical component of centroid motion for either 0.6 or 6.0 mA beams; b) 6.0 mA beam's vertical 2×rms semi-axis; and c) 0.6 mA beam's vertical 2×rms semi-axis. The strength of injection quadrupole YQ is increased by ∼15% to yield near-matched envelope conditions past $\nu_{0y} = 7.5$. The vacuum pipe radius is 0.025 m.

proximity to $\nu_{0x} = 7.5$, but the fact that beam transmission is unaffected at the 10th turn (Fig. 1c). Furthermore, envelope calculations with the "unmatched" original strength of the injection quad QR1, corresponding to Fig. 1b, show a steep increase in the 2×rms horizontal envelope of the 6.0 mA beam to almost 16 mm before the 10th turn, but only a modest increase for the 0.6 mA under the same conditions. Thus, retuning of QR1 in calculations makes a far more noticeable difference for high current than for low current, as in the experiment.

At four operating points (1, 2, 4, and 6 in Table 1), the beam circulates for 5 turns or less, insufficient to allow us to measure the tunes accurately at all these points. In ELEGANT, point 1 corresponds to tunes near (ν_{0x}, ν_{0y}) = (6.0, 7.5), while point 2 leads to tunes near (6.5, 6.0). The large centroid excursions seen in calculations for point 1 can explain the almost complete beam loss after only a few turns. Point 4 has (ν_{0x}, ν_{0y}) near (7.0, 7.0) and leads to the largest centroid oscillations and also to steep envelope growth after only 5 turns. Lastly, point 6 leads to an unstable vertical orbit and corresponding growing vertical centroid oscillations and envelope growth.

In Fig. 2a, we show the results of vertical centroid motion for two values of the strength of the injection quad YQ corresponding to "mismatched" and "matched" focal lengths, i.e. points 6 and 7 in Table 1. Also shown (Fig. 2b) are the vertical envelopes (2×rms semi-axis) for the 6.0 mA beam. These results are consistent with experiment: point 6 yields only 5 turns while point 7 recovers almost 80% beam transmission. A simple calculation using $\Delta\nu_0 = (4\pi)^{-1}\bar{\beta}(\Delta k_0)L$, where $\bar{\beta} = 0.22$ m, $\Delta k_0 = +15$ m^{-2}, $L = 7.45$ cm, shows that retuning YQ, as described above, leads to $\Delta\nu_{0y} = +0.020$, compared with $\Delta\nu_{0x} = -0.010$ from Table 1 (ELE.) However, no conclusive change in tunes can be measured because of the large errors, at least ± 0.05 near $\nu_{0y} = 7.5$.

Figure 2c shows the vertical 2×rms semi-axis of the 0.6 mA beam for "matched" and "mismatched" cases. The difference between the two cases is smaller than for the 6.0 mA beam. This example and results for a few additional operating points are in qualitative agreement with experiment, as little difference is seen in the beam lifetime chart for the 0.6 mA beam if the injection quad QR1 is adjusted to match the ring quads.

Naturally, without image forces in the model, the results for centroid motion do not change for the lower current beam, but those for the rms beam size yield about half the amplitude as for 6.0 mA because of the reduced incoherent space charge. At point 1, about half the peak beam current survives in the experiment at low current (Fig. 1a), unlike the case for 6.0 mA. Smaller envelope excursions, differences in orbit steering corrections and detuning from image forces may explain the different beam lifetimes.

To summarize, calculations of linear tunes with the code ELEGANT using a simple model are in good agreement with measurements in UMER. Further, calculated centroid and beam envelope evolution over 10 turns relate well to observed beam losses at points near integer and half-integer tunes. Other than reasonable assumptions for the magnitudes of magnet and lattice errors, the model has only one adjustable parameter, i.e. the transfer function of ring quadrupoles. The beam lifetime charts from experiments show that the emittance-dominated beam behaves more coherently than the space-charge dominated beam. Additional work for the near future includes more realistic modeling of lattice errors, improved tune measurements, and calculations and measurements of incoherent tunes.

We acknowledge helpful assistance from D. Brosius with typesetting the manuscript.

EXPERIMENTAL DETECTION OF ENVELOPE RESONANCE IN A SPACE-CHARGE-DOMINATED ELECTRON RING*

W.D. Stem, T.W. Koeth, I. Haber, B. Beaudoin, IREAP, University of Maryand, College Park, MD 20742, USA

Abstract

Linear perturbation analysis of the RMS envelope equations predicts a frequency splitting of the transverse envelope modes with the onset of space charge. The resulting resonances are a potential source of beam degradation for circular particle accelerators and storage rings encountering space charge. Following WARP simulations that predict measurable consequences of these resonances, an experiment has been designed for their direct detection. This paper provides a detailed description and preliminary results of an experiment to study envelope resonances in the beam at the University of Maryland Electron Ring (UMER), a scalable high intensity electron storage ring.

INTRODUCTION

In a particle beam, the set of particles that make up the transverse extremes of the beam at any given time is called the envelope. Because each particle oscillates sinusoidally in and out of the bulk, the envelope make-up changes in time. Independently of these particle oscillations, the envelope itself oscillates as described by the K-V equations [1,2,3]. These oscillations can be two different types as shown in Figure 1. The first type is called the breathing or even mode, in which the envelope oscillates in an azimuthally symmetric sense. The second is called the quadrupole or odd mode, in which the oscillations of the envelope are 90 degrees out of phase.

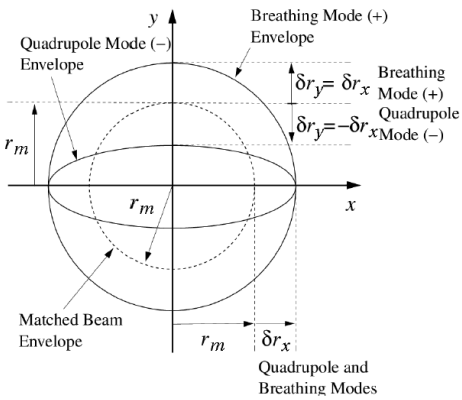

Figure 1: Transverse picture of the envelope modes [4].

At high energies, these envelope oscillations have the same frequency. This frequency occurs at a half-integer resonance, naturally determined from the geometry of the accelerator ring. At the onset of space charge a frequency splitting occurs and we can observe each of these oscillations independently. This frequency splitting is shown for UMER operating parameters in Figure 2.

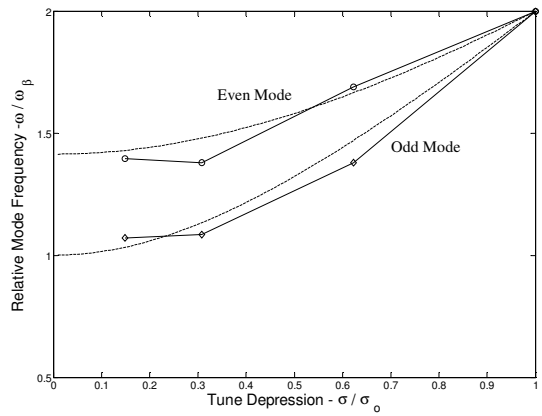

Figure 2: Relative envelope mode frequencies as a function of the tune depression for UMER operating parameters, plotted next to a calculation for the smooth approximation (dashed lines).

If we apply the appropriate perturbation to the envelope in phase with the mode we are trying to identify, the envelope will magnify in amplitude. This amplitude magnification results in the formation of a beam halo as shown in WARP simulation results [5]. After applying the perturbation, we can image the beam halo using a phosphor screen. Sweeping across frequencies, we can identify the resonant frequency of the oscillation as it will be proportional to the formation of beam halo. Applying the breathing mode perturbation may be possible with UMER's existing beam position monitors (BPMs), but the quadrupole mode requires the addition of an electrostatic quadrupole. This paper details the design, fabrication, and bench testing of the electrostatic quadrupole.

QUADRUPOLE DESIGN

In order to apply a quadrupole perturbation to the beam envelope, it is necessary to create a time-varying quadrupole field to match the oscillation frequency of the mode. To accomplish this, we create a resonant LC circuit using the quadrupole as a capacitor. The circuit design is shown in Figure 3.

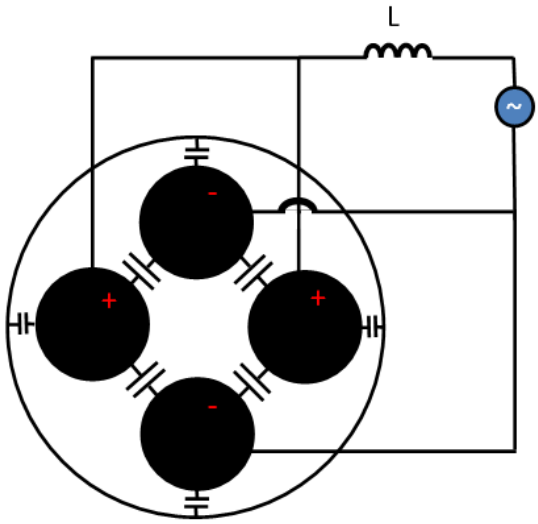

Figure 3: Circuit design for the electrostatic quadrupole. There is an undesired parasitic capacitance as the quadrupole interacts with the beam pipe wall.

Ideally, electrodes for a quadrupole field should have a hyperbolic cross section. However, fixing the ratio between the radius of the aperture and the radius of the electrode at 1:1.1468, a circular cross section approximates a hyperbolic cross section [6].

The quadrupole will replace an existing BPM in a BPM chamber. Due to the close proximity of the beam pipe wall, there exists a parasitic capacitance between the electrodes and the beam wall. To reduce this parasitic capacitance, the quadrupole's electrodes were designed to be half cylinders. The electric fields were simulated using a program developed by the Los Alamos Accelerator Code group called Poisson/Superfish [7]. The simulation is shown in Figure 4.

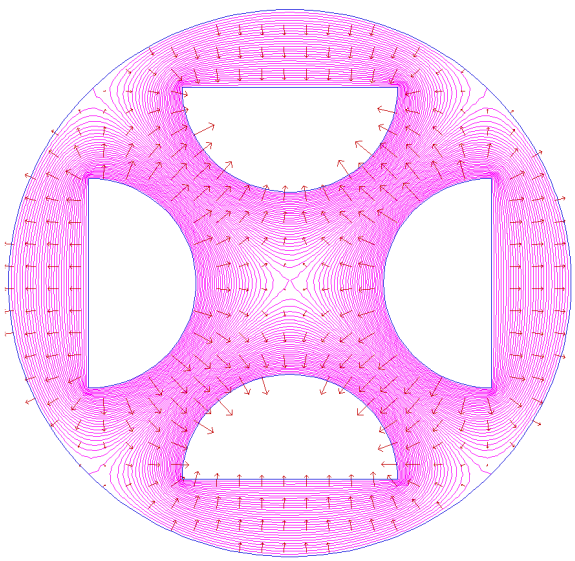

Figure 4: Poisson/Superfish electrostatic quadrupole simulation.

Since the opposing electrodes need to carry an identical, symmetrical voltage, the quadrupole was designed so that each group of opposing electrodes is in electrical contact through the base. Then the electrode pairs are attached by an insulating material. The CAD design for the quadrupole is shown in Figure 5.

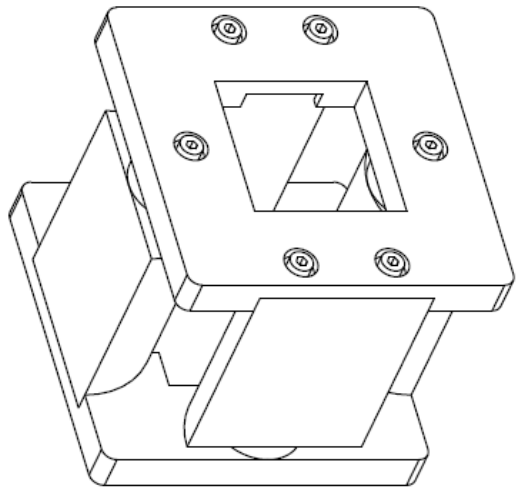

Figure 5: Pro/E diagram of machined quadrupole. Material is aluminum except for the insulating washers and insulating screws.

BENCH TESTS

Having machined the quadrupole to the CAD design in Figure 5, we proceeded to take measurements. By connecting a variable inductor to the bases of the quadrupole using the circuit design shown in Figure 3, a resonant circuit was formed. Using an MFJ-259B SWR Analyzer, the resonant frequency of the resonant circuit was measured. By finding the resonances for several values of inductance, we could plot the resonant frequency versus inductance and extract the capacitance according to the following equation:

$$C = \frac{1}{L(2\pi f_0)^2} \quad (1)$$

where f_0 is the resonant frequency of the circuit. This value was checked against a direct measurement of the capacitance using an SR715 LCR Meter. Initially, we used a stack of Mylar washers an inch in diameter for the insulating standoff. However, with a large area and a dielectric constant of 3.1, the capacitance between the electrodes and the base across the insulating gap was too great and it dominated the capacitance value between the electrodes. Instead, we opted for thinner, hollow plastic tubes to be used in place of the washers. Also, the base was unnecessarily large, so we fabricated new bases in the second bench model design shown in Figure 6.

Copyright © 2013 CC-BY-3.0 and by the respective authors

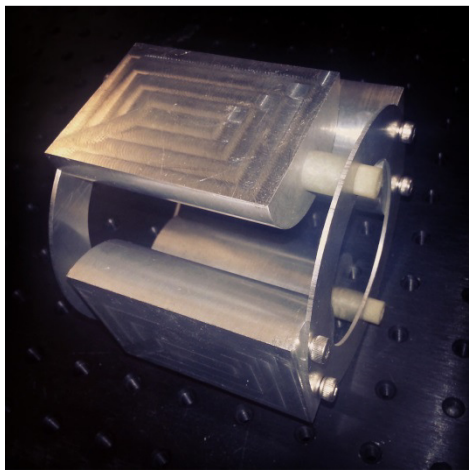

Figure 6: Finished bench model design using updated bases and insulating standoffs.

After completing a workable model of the quadrupole, we placed the quadrupole inside three sheets of wrapped sheet metal with a 6.9" inner diameter to simulate the parasitic capacitance from the beam pipe. Taking an S11 measurement with a network analyzer, the frequency spectrum for the resonant circuit was determined as shown in Figure 7. By perturbing the resonance in different ways, we have determined that the resonant peak for this circuit is just above 60 MHz. This of course can be varied by changing the value of the inductance in the LC circuit.

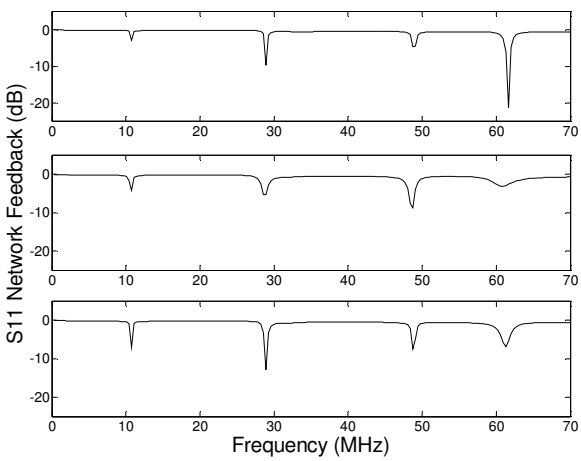

Figure 7: Frequency spectrum of the quadrupole from the network analyzer untouched (top) and touching each electrode (middle and bottom, respectively).

Using Matlab, the resonant peak was analyzed. The following formula was used to determine a Q of 444 for our resonant peak:

$$Q = \frac{f_0}{(f_{3dB} - f_{-3dB})} \qquad (2)$$

where f_{-3db} and f_{3db} represent the 3 dB bandwidth points. Using this analysis, we can verify that the parasitic capacitances from the beam pipe do not interfere with the capacitance of the quadrupole.

CONCLUSIONS

Envelope perturbations arising from resonant modes are present in space-charge-dominated particle accelerators and storage rings. It is important to understand these resonances when building and operating a high intensity accelerator to avoid emittance growth and beam loss. These modes can be observed experimentally using perturbative electric fields generated by an electrostatic quadrupole. After building a prototype and performing bench tests, we are certain that we can produce the fields necessary to induce envelope resonance in the beam. In the future, we plan to install a vacuum-ready electrostatic quadrupole into UMER and experimentally observe and manipulate high intensity envelope modes.

ACKNOWLEDGMENT

Thanks to John Pyle and Nolan Ballew of IREAP for their assistance in the fabrication of the electrostatic quadrupole. Also thanks to Timothy Ayo-Ajayi who assisted in the Pro/E CAD designs. Finally, we thank Alex Friedman, Dave Grote, and Jean-Luc-Vay for their support of the WARP code.

MEASUREMENT OF PLASMA WAVE SPEED FROM ELECTRON BEAM END EROSION*

D. F. Sutter and B.L. Beaudoin, Institute for Research in Electronics and Applied Physics, University of Maryland, College Park, MD 20742, USA

Abstract

The University of Maryland Electron Ring (UMER) normally injects a beam that is square in longitudinal profile (constant line density), filling one half the ring. When operating without longitudinal focusing, the beam head and tail erode at a constant plasma wave speed. Because the beam is very long (580 cm) compared to the beam pipe diameter (5 cm), the two eroding edges remain sharply defined until they meet. This paper describes how the plasma wave speed in the beam can be obtained experimentally by measuring only the initial pulse length, the time it takes for the eroding ends to meet and the kinetic energy. The plasma wave velocity can then be used to get an estimate of the average beam radius during the erosion time. Experimental results are compared to theoretical predictions.

INTRODUCTION

The University of Maryland Electron Ring (UMER) was built to explore the physics of non relativistic, space charge dominated beams that would be relevant for an ion accumulator ring of the type originally envisaged for application in heavy ion fusion. While the operating kinetic energy of 10 keV is very low, it is sufficient at the range of available operating currents, 0.6 to 100 mA, to serve as a good analog model for such accumulator rings. Moreover, because the relativistic gamma factor is only 1.02, there also exist a whole range of non neutral plasma phenomena that cannot be so easily observed in a highly relativistic beam. One of these is the ready generation and observation of plasma density waves. In UMER the beam can be operated with or with out longitudinal confinement [1]. When there is no longitudinal confinement, the initially almost square ends of the injected pulse begin to immediately disperse, or "erode" in a characteristic debunching pattern as shown in Figure 1. The electrons at the leading edge are pushed forward, gaining kinetic energy from the potential energy stored in the electrical potential of the beam charge, and electrons at the trailing edge are decelerated, in effect losing kinetic energy. The edges where the beam is actively eroding into the constant line charge density in the longitudinal beam center retain a sharp definition up to the point where the two edges come together in what is called the "breakpoint" in Figure 1. The rate at which each edge moves toward the center is the plasma wave velocity, c_s, and that is what is measured in this experiment.

accelphys@aol.com

PHYSICS OF THE EXPERIMENT

Boundary Conditions

The general operating parameters of UMER have been described elsewhere [2] as has the generation of density waves and solitons [3][4][5][6]. The specific properties that support the non neutral plasma experiments and modelling with cold fluid equations for space charge dominated beams are, the very long bunch length compared to the beam pipe diameter, the low beam velocity, the presence of strong space charge (for beam currents > 1 mA), and a beam density that is approximately constant over the radius. As a consequence, the radial component of the electric field, E_r, points outward and $E_z = 0$ in the region between the eroding edges. In the region between an eroding edge and the head or tail end point, E_z is proportional to the gradient in z of the line charge density, which is no longer constant. Of particular importance to the present technique, the 10 keV beam injected into UMER has an almost rectangular, constant initial line charge density profile with rise and fall times of a few nanoseconds, and a flat top of adjustable pulse length (~20 to 145 ns).

Computing the Wave velocity

The wave velocity, usually referred to as the "sound velocity" of the density wave because it is analogous to the ion acoustic velocity in neutral plasma, can be computed from [4],

$$c_s = \sqrt{\frac{e}{4\pi\varepsilon_0}\frac{1}{m_0 v_{bm}}\frac{g}{\gamma^5} I_{bm}} \quad , \text{ where } \quad g = 2\ln\frac{b}{a} \qquad (1)$$

for space charge dominated beams [3]. Noting that the classical radius of the electron r_e and the "characteristic current" I_0 are defined, respectively, by

$$r_e = \frac{e^2}{4\pi\varepsilon_0 m_0 c^2} \text{ and } I_0 = \frac{e\,c}{r_e},$$

Equation (1) can be rewritten in a more convenient form as

$$c_s = c\sqrt{\frac{1}{\beta\gamma^5}\frac{I_{bm}}{I_0} 2\ln\frac{b}{a}}, \qquad (2)$$

where c is the velocity of light, β and γ are the usual relativistic parameters, b is the beam pipe inner diameter and a is the beam radius. Given a set of beam radii corresponding to the relevant operating parameters,

Copyright © 2013 CC-BY-3.0 and by the respective authors

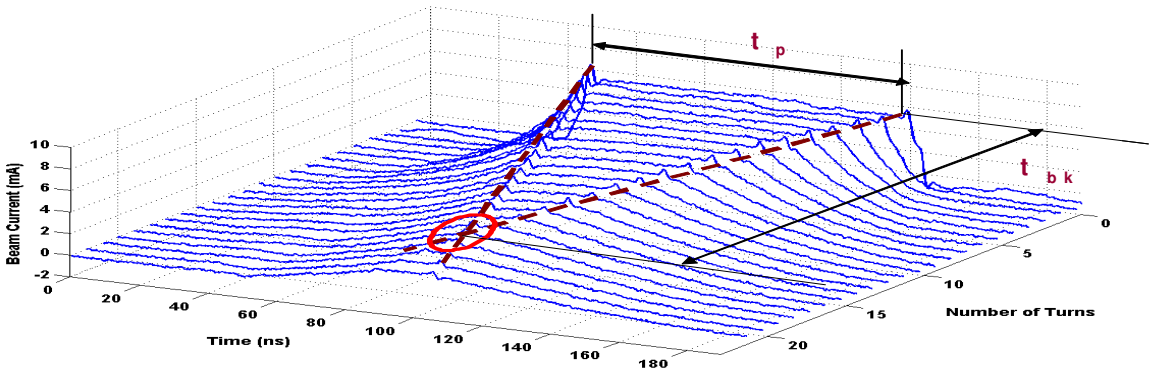

Figure 1: Mountain top plot of UMER 6 mA beam debunching past the "Break Point."

including the emittance at injection, and beam currents, equation (2) is used to compute the set of predicted values of c_s, shown in Table 1, column 3, corresponding to the initial beam radii shown in column 6. Solving equation (2) for the beam radius,

$$a = b\,e^{-A\frac{c_s^2}{I_{bm}}}, \text{ with } A = \frac{\beta\gamma^5 I_0}{2c^2} \qquad (3)$$

Equation (3) can then be used to compute a value of average beam radius based on the independent measurement of c_s described in the following section.

Sound Speed from Times

If the length of a beam pulse is t_p, and the velocity of the 10 keV beam is v_{bm}, the beam has a physical length l = $v_{bm}t_p$. But since the two edges are moving towards each other at the sound speed c_s, the edges will cover the same distance l in $2c_st_{bk}$, where t_{bk} is the break point time that it takes the two edges to come together. Since the distance is the same, $v_{bm}t_p = 2c_st_{bk}$ and

$$c_s = \frac{1}{2} v_{bm} \frac{t_p}{t_{bk}} \qquad (4)$$

So to measure the sound speed, it is only necessary to know three quantities: kinetic energy (to get v_{bm}) and the two times, the initial pulse length and the time to breakpoint. To compute the average beam radius for a measured c_s using equation (3), the corresponding beam current must also be measured.

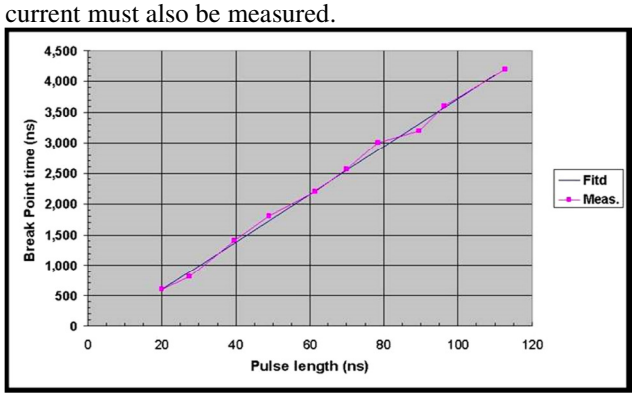

Figure 2: A plot of the measured values of t_{bk} vs t_p for a 6.0 mA beam.

MEASUREMENTS

In order to get a more accurate determination of the sound speed, t_{bk} was measured over a range of pulse lengths, and this was done for three different beam currents, I_{bm} = 0.6, 6.0 and 20.0 mA. The injected beam current is measured using a calibrated Bergoz integrating current monitor in the injection line and the values t_p and t_{bk} from a wall current monitor in the ring that displays the circulating beam current on a Tektronix DPO7254 oscilloscope. A plot of a typical data set is shown for the 6.0 mA beam in Figure 2. A linear fit is then made to the data which gives the slope and related errors as standard deviations. The fit also defines a linear relation

$$t_{bk} = mt_p + d\,,$$

where m is the slope and d the offset at $t_p = 0$, that can be used to predict t_{bk}. Using equation (4), the measured value of c_s in column 2 of Table 1 is computed from

$$c_s = \frac{1}{2}\frac{v_{bm}}{m}, \; where\; m = \left\langle \frac{t_{bk}}{t_p} \right\rangle_{fit}. \qquad (5)$$

Each of the measured values of c_s is an average over the time t_{bk}; so equation (5) gives a sort of "average of averages" of c_s over the t_{bk} versus t_p data sets.

All of the measurements were made with a beam kinetic energy of 10.000 keV giving a value of v_{bm} = 5.846 cm/ns, calculated from the special relativity relation for v_{bm} as a function of kinetic energy and electron rest energy. This was done to avoid a systematic error of ~ 1.4 % that would occur by using the nonrelativistic relation. The systematic error in equation (5) is calculated from,

$$\Delta c_s = \frac{1}{2m}\left(\Delta v_{bm} - \frac{v_{bm}}{m}\Delta m\right); \qquad (6)$$

Δm is the standard deviation of m obtained from the linear fitting routine. The results for three beam currents are shown in Table 1.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Table 1: Results of measuring the sound speed in the core of the UMER beam for several beam currents. The predicted radii in column 6 are based on the computed emittance of the beam generated at the exit of the electron gun [7]. These emittances have been confirmed by independent measurements using tomographic techniques [8]. The predicted radii are used to compute the predicted c_s values in column 3.

Beam Current (mA)	Meas. c_s (cm/ns)	Pred. c_s (cm/ns)	Percent Difference	Est. Beam Radius(mm)	Pred. Beam Radius (mm)	Percent Diff.
0.58	0.0274 ± 0.0002	0.0276	0.7	1.78 ± 0.01	1.71	4.0
6.0	0.0750 ± 0.0015	0.0752	0.3	3.69 ± 0.04	3.64	1.4
20.5	0.1282 ± 0.0040	0.1223	3.5	4.87 ± 0.34	5.64	13.6

The average beam radii in column 5 of Table 1 are computed from equations (3). The contribution to the error in the exponential is dominated by the errors from values for c_s and $I_{bm;}$ so the much smaller error in A is ignored in the following expression for the error in measured beam radius,

$$\Delta a = \left\{ \frac{\Delta b}{b} - \left[2\frac{c_s}{I_{bm}}\Delta c_s - \left(\frac{c_s}{I_{bm}}\right)^2 \Delta I_{bm} \right] A \right\} a \quad (7)$$

We have used the following values in calculating the entries in table 1: b= 24.89 ± 0.089 mm, $\Delta \mathbf{I_{bm}}$ = ± 0.2 mA for all beam currents and v_{bm} = 5.846 ± .006 cm/ns based on our best estimate for momentum spread, Δp = ± 20 eV.

CONCLUSIONS

The derivation of equation (1) for c_s using the one dimensional fluid model in the cited references assumes that the electron beam is space charge dominated. The 0.6 mA beam, although it exhibits lots of serious space charge effects, is considered emittance dominated. So using the definition of equation (1) instead of the non space charge definition,

$$g = \left(\frac{1}{2} + 2\ln\frac{b}{a}\right),$$

was a question. The results in Table 1 confirm that the space charge dominated form of g works for 0.6 mA. Based on operating experience with UMER, there have been problems of beam blow up with the 0.6 mA beam, associated with injection line quadrupole settings, over the ~50 turns required to reach t_{bk}. We have found only a few sets of injection quad settings that reduce the blow up, and the presented results confirm the effectiveness of the settings used for the measurements. The lack of significant blow up for these quad values has been confirmed by kicking the 0.6 mA beam out, turn - by – turn, onto a phosphor screen for a direct, but laborious, measurement of beam radius.

Beam loss has a variety of causes, and all of these can change the assumed constant line charge density in the flattop region of the beam pulse. There are also a variety of potential causes of emittance blow up implying a corresponding radial size blow up. This experiment cannot distinguish among such causes, but the measured results for average c_s and a_{avg} for the 0.6 and 6.0 mA beams indicate that such effects are minimal over the corresponding times to t_{bk} (~50 turns for 0.6 mA and ~18 turns for 6.0 mA at t_p = 100 ns) and the machine operating parameters in place during the measurements. Beam and emittance blow up are known issues for the more strongly space charge dominated 20 mA beam. So the measured results are better than expected, but then the number of turns to t_{bk} is only ~10 or 11- not a very long sample of beam behaviour.

In summary, the work presented shows that the use of this simple c_s measurement technique is a quick and easy way to get an estimate of beam behaviour over the store time from injection to the breakpoint and is easier than the beam knockout and phosphor screen method that is our only other present alternative.

PRELIMINARY ACCELERATOR DESIGN OF A CIRCULAR HIGGS FACTORY IN CHINA

Q. Qin, J.Y. Tang, Y.W. An, S. Bai, J. Gao, H.P. Geng, Y.Y. Guo, D. Wang, S. Wang, Y.W. Wang, M. Xiao, G. Xu, S.Y. Xu, T. Yue, J.Y. Zhai, C. Zhang, Institute of High Energy Physics, Chinese Academy of Sciences, P.O. Box 918-9, Beijing 100049, P. R. China

Abstract

Since the Higgs boson was announced to find at LHC in CERN last July, many labs around the world have showed their interests on building electron positron colliders as Higgs factories to investigate the features of the Higgs boson. IHEP also proposed a circular Higgs factory last Sept. with a circumference of 50 – 70 km, and can be converted to a super proton-proton collider, which can be a discovery machine for new particles and physics. A preliminary design of circular electron positron collider as a Higgs factory is given here.

INTRODUCTION

On July 4, 2012, CERN announced that the Higgs boson was found at the Atlas and CMS experiments of LHC. The mass of the Higgs boson is about 125 GeV, which is only 20 GeV higher than the maximum beam energy LEP reached. After that moment, concept of Higgs factory were proposed, including circular e^+-e^- collider, linear collider, muon collider and γ-γ collider. Among these machines, the international linear collider has been studied by global efforts for more than 10 years, with the TDR [1] just released, but the accelerator technologies of circular machine seem more mature after being developed during the past decades. Muon and γ-γ colliders are also considered as the candidates of Higgs factory, but some of their technologies are still under development. Reviews of these machines can be found in [2].

As the development of future high energy accelerator , a circular e^+-e^- collider (CEPC) as the Higgs factory was proposed in IHEP, China, last Sept. with a circumference of 50–70 km. It can also be converted to a super p-p collider (SppC), with the beam energy of 50 TeV or more, as a discovery machine in the far future. Figure 1 shows a schematic graph of the whole machine (CEPC+SppC).

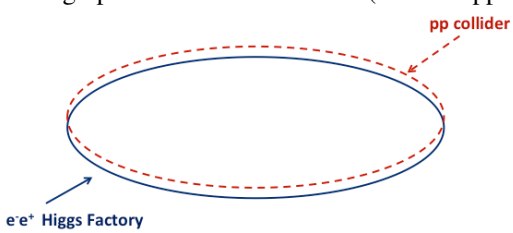

Figure 1: Schematic graph of the CEPC+SppC.

In this paper, we will first describe the determination of beam and machine parameters of the CEPC. Then, the linear lattice of the main ring will be given. The preliminary linear lattice design of the possible SppC converted from the CEPC by using the same tunnel is also presented. Some problems, covering both accelerator physics and technologies, are discussed at last.

PARAMETER DETERMINATION

In this section, main parameters for such a high energy collider will be given, after considering some important effects of beamstrahlung and the limit of synchrotron radiation power.

Beam Energy, Circumference, and Luminosity

As to a collider, beam energy and peak luminosity are the most important parameters.

Since the mass of Higgs particle is 125 GeV, the beam energy of CEPC can be set in the range of 120 – 125 GeV. In such a high energy region, beamstrahlung due to very strong synchrotron radiation (SR) when the two beams interact at IP, will be the main reason of the beam energy spread increase and thus the luminosity reduction. Under this concerning, we choose the lower limit of the Higgs particle, say 120 GeV, as the design energy of the storage ring of CEPC. Figure 2 shows the crossing-section of the Higgs at this energy region [3], from which we can see that though the lower beam energy was taken, the cross-section doesn't decrease too much.

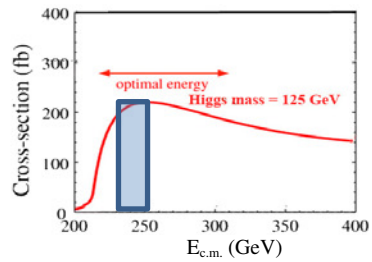

Figure 2: Cross-section at the Higgs energy region.

If we take cross-section of 200 fb and we need 20000 Higgs events per IP every year, we can easily get that the average luminosity will be $1\times10^{34}cm^{-2}s^{-1}$, which is then the design value for the CEPC.

The circumference of the CEPC storage ring can be determined by the future super p-p collider, converted from the CEPC. So the maximum proton beam energy, for example, E_{cm}=50–90 TeV, will be the energy of SppC, and thus we take 50–70 km as the circumference of the CEPC. Here we first use 50 km as the input parameter.

Considering the operation experience of LEP, we take the design value of vertical beam-beam parameter ξ_y as large as 0.1 for the CEPC, and 0.004 for the SppC. Besides these restrictions, another limit comes from the synchrotron radiation power of beam, which is taken as large as 50 MW. As to the 50 km circumference ring, if

Copyright © 2013 CC-BY-3.0 and by the respective authors

we take the filling factor of bending magnets around the ring as 0.78, we can get the bending radius of dipoles as ρ = 6.2 km. With these parameters, we can get the beam current from the following equation

$$P[kW] = 88.5\frac{E^4[GeV]}{\rho[m]}I[mA], \quad (1)$$

as $I = k_b I_b$ = 16.9mA. If we don't consider the hour glass effect, or beamstrahlung, the luminosity is expressed as

$$L[\mathrm{cm^{-2}s^{-1}}] = 2.17\times10^{34}(1+r)\xi_y\frac{E[\mathrm{GeV}]I[\mathrm{A}]}{\beta_y^*[\mathrm{cm}]}, \quad (2)$$

where r is the aspect factor, β_y^* the vertical beta function at IP, and I the beam current. With Eq. (2), we can get the luminosity can reach 4.42×10^{34}cm^{-2}s^{-1}if we take β_y^*=1mm.

Energy Spread, Emittance and Aspect Factor

Beamstrahlung plays an important role in such a high energy e$^+$-e$^-$ collider when two beams interact at the IP. Theories on how beamstrahlung affects beam parameters and the corresponding formulae can be found in [4]. Beam energy spread and lifetime are seriously influenced with the following equations

$$\delta_{BS} = \frac{2r_e^3N_e^2\gamma F}{3\sigma_x\sigma_y\sigma_z}, \quad R = \frac{\sigma_x}{\sigma_y}, F(R=1)=0.325, F(R>>1)\approx\frac{1.3}{R}, \quad (3)$$

and

$$\tau = \frac{20C\sqrt{6\pi}r_e\gamma}{\alpha^2\eta c\sigma_z}u^{3/2}e^u, \; u = \frac{\alpha\eta\sigma_x\sigma_z}{3r_e^2\gamma N_e}, \quad (4)$$

where C is the circumference, r_e the classical electron radius, N_e the number of particles per bunch, γ the relativistic energy factor, η the energy acceptance, and σ_x, σ_y and σ_z the 3-D bunch sizes. With some typical beam parameters, we can get the beam lifetime is about 10–20 min, which is much shorter than the existing or previous colliders. So the top-off injection should be adopted in the future CEPC.

Combining beam-beam parameter ξ_y with Eqs. (3) and (4), we can have the beam energy spread due to beamstrahlung as

$$\delta_{\mathrm{BS}} \equiv \frac{\langle\Delta E_{\mathrm{BS}}\rangle}{E\sigma r} = 0.864r_e^3\gamma\left(\frac{N_e}{\sigma_z(\sigma_x+\sigma_y)}\right)^2\beta_y \quad 0.864r_e^3\gamma\frac{r}{\sigma_z^2}\frac{2\pi\gamma}{e}\xi_yN_e \quad . \quad (5)$$

If we take ξ_y = 0.1, we will have $N_e = 5.26\times10^{19}\varepsilon_x$. From the above equations, one can find that small N_e can reduce the beam energy spread δ_{BS}, but one has to increase bunch number and decrease the horizontal emittance to keep the luminosity as high as possible. So, 50 bunches per beam can be adopted with the particle number of 3.52×10^{11} per bunch and the horizontal emittance of 6.69 nm.rad. Eq. (6) shows the luminosity concerning the beamstrahlung effect and limit of synchrotron radiation power.

$$L_{\mathrm{limit}} = 0.4565\times10^{34}\,\mathrm{cm^{-2}s^{-1}}\frac{\rho(\mathrm{km})P_{\mathrm{SR}}(100\mathrm{MW})\sqrt{\delta_{\mathrm{BS}}(0.1\%)}}{(E/100\mathrm{GeV})^{4.5}\sqrt{\varepsilon_y(\mathrm{nm})}}$$

$$= 0.4565 \quad 10^{34}\,\mathrm{cm^{-2}s^{-1}}\frac{\rho(\mathrm{km})P_{\mathrm{SR}}(100\mathrm{MW})}{(E/100\mathrm{GeV})^{4.5}}\times\frac{\sqrt{\delta_{\mathrm{BS}}(0.1\%)}}{\sqrt{r\varepsilon_x(\mathrm{nm})}} \quad . \quad (6)$$

Here, we can take the aspect factor, r, as small as 0.005, which was already realized in the existing particle factories, like KEKB, DAFNE and BEPCII.

Longitudinal and RF Parameters

Energy spread and acceptance due to synchrotron radiation are main parameters in longitudinal, together with bunch length and momentum compaction. Beam lifetime due to beamstrahlung as a function of V_{rf} at different RF frequency can be got and shown as Fig. 3.

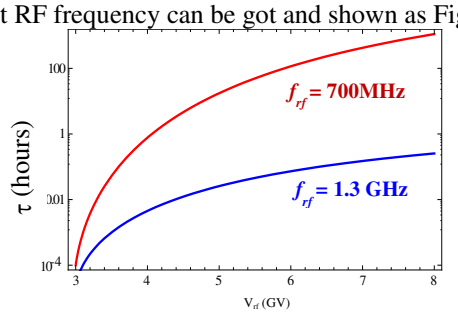

Figure 3: Beam lifetime as a function of RF voltage at different RF frequency.

If we take some typical values of σ_z<3mm, ν_s<0.3, δ_{BS} <σ_e/3, η<0.05 and τ>10 min, the correlation between α_p and V_{rf} can be got and shown as Fig. 4.

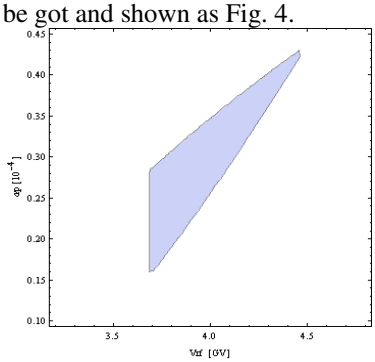

Figure 4: Momentum compaction vs. RF voltage (Grey: stable area).

If we choose the simplest FODO cell, as the basic unit of the arc, the momentum compaction can be got from

$$\alpha_p = \frac{\varphi^2}{4}\left(\frac{1}{sin^2\frac{\mu}{2}} - \frac{1}{12}\right), \quad (7)$$

and

$$\varepsilon_x = \frac{1-\frac{3}{4}sin^2\frac{\mu}{2}}{sin^3\frac{\mu}{2}cos\frac{\mu}{2}}C_q\gamma^2\frac{\varphi^2}{4}. \quad (8)$$

With ε_x = 6.69 nm.rad, we can choose $\alpha_p = 0.4\times10^{-4}$. Then from Fig. 4, we can get the total RF voltage V_{rf}= 4.2GV. The 5-cell RF cavity can be the candidate of the RF system, so we can take the acceleration field E_{acc}=10 MV/m with V_c=2 MV for each cavity. The total number of RF cavity will be 420.

Table 1 lists all the main parameters of the CEPC. The L_{limit} means the luminosity with the beamstrahlung effect. The luminosity with the beamstrahlung effect will be about half of the calculated luminosity. Here we take the hourglass coefficient as 0.6.

LINEAR LATTICE DESING OF CEPC

As we mentioned in previous section, the FODO cell is chosen as the basic unit of arcs. The phase advance of each cell is 60 degree for both horizontal and vertical

Copyright © 2013 CC-BY-3.0 and by the respective authors

planes. 16-folder symmetry is used for the whole ring and RF sections are distributed in each folder. A booster is assumed to be in the same tunnel as the main ring, with the energy range from 6 – 120 GeV. A 6-GeV linac is hoped to be the injector of the booster. For more IPs around the ring, pretzel scheme can be adopted. Figure 5 shows the Twiss functions for the standard cell in arcs.

Table 1: Main Parameters of the CEPS Storage Ring

Para.	Unit	Value	Para.	Unit	Value
Energy	GeV	120	Circum.	km	50
N_e	1E11	3.52	N_b/beam		50
Beam current	mA	16.9	SR power /beam	MW	50
Dipole field	T	0.065	Bending radius	km	6.2
$\varepsilon_{x,y}$	nm	6.69, 0.033	σ_x/σ_y	μm	36.6/0.2
β_{IP} (x/y)	mm	200/1	SR loss	GeV/ turn	2.96
$\xi_{x,y}$		0.1, 0.1	σ_z	mm	3
α_p	1E-4	0.4	IP No.		1
V_{rf}	GV	4.2	f_{rf}	GHz	0.7
ν_s		0.13	Harmonic		116747
δ_{SR}		0.0013	δ_{BS}		0.00014
η	%	2.7	τ_{BS}	hr	1.6
L_0/IP (10^{34})	/cm^2/s	2.65	L_{limit}/IP (10^{34})	/cm^2/s	1.26

To promote the luminosity at the same SR power, one has to increase the circumference of the ring. Another scheme with the circumference of 70 km is under design. Option for pretzel scheme is kept for more IPs, which can also have the luminosity enhanced, but not linearly with the number of IP. The final focusing system in the interaction region (IR) is still in its design, which will be one of the most difficult and critical parts of the machine.

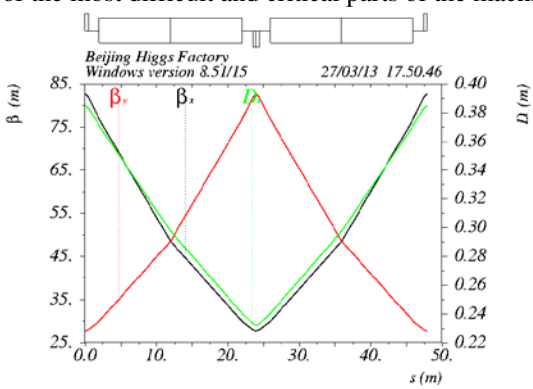

Figure 5: Twiss functions of a 60 degree cell.

The SppC, which will be constructed as a discovery machine using the tunnel of CEPC, can also have two scenarios with different circumferences, 50 km or 70 km. The maximum proton beam energy could reach 45 TeV, if the dipole field is about 20 Tesla using superconducting magnets. The energy limit mainly comes from the dipole field. The arc can also apply the standard cell with a phase advance of 60 or 90 degree.

With the empirical value of beam-beam parameter, say ξ_y = 0.004, beam current = 0.5mA, vertical beta function at the IP = 0.1m, we can get the luminosity of the SppC can be 2-3×10^{35}cm^{-2}s^{-1}. Table 2 gives the main parameters of SppC for 2 scenarios of 50 and 70 km circumference.

Table 2: Main Parameters of SppC for Two Schemes

Para.	SppC-1	SppC-2
Beam Energy (TeV)	20	45
Circumference (km)	50	70
No. of IPs	2	2
SR loss/turn (keV)	440	4090
N_p/bunch (10^{11})	1.3	0.98
Bunch No.	3000	6000
Beam current (mA)	0.5	0.405
SR power/ring(MW)	0.22	1.66
Dipole field (T)	12	19.24
Bending radius (km)	6.9	7.8
Momentum compaction (10^{-4})	3.5	2.5
β_{IP} x/y (m)	0.1/0.1	0.1/0.1
Norm. Trans. emit, x/y (μm.rad)	4	3
Geo. Lumi. reduction factor	0.8	0.9
L_0/IP (10^{35} cm^{-2}s^{-1})	2.15	2.85

DISCUSSION AND CONCLUSION

Although we have the preliminary design of the storage ring, but still a lot of problems remain. The accelerator physics related topics, such as dynamic aperture, low emittance ring design with pretzel orbits, beamstrahlung effect, design of the interaction ragion, beam background, beam polarization, collective effect and heat loading due to SR power, machine and detector interface (MDI), etc., are all very important to the machine design, and can influence the hardware system of the whole machine. Meanwhile, accelerator technology towards such a future machine needs to be developed too. The technique of very low field dipole and very high gradient quadrupole will be critical. Ultra-high field dipoles, such as 20 T, will be difficult for both superconducting and cryogenics system. How to realize the beam polarization at such a high beam energy, will be a challenge to both accelerator physics and technology.

In a word, the CEPC is very promising in physics, with some mature technologies. It could be converted to a p-p collider as a discovery machine. Some technologies need R&D, and accelerator physics studies need more efforts.

AC DIPOLE BASED OPTICS MEASUREMENT AND CORRECTION AT RHIC*

X. Shen†, S. Y. Lee, Indiana University of Bloomington, IN, 47405, USA

Abstract

Independent component analysis (ICA) was applied to the AC dipole based optics measurement at RHIC to extract beta functions as well as phase advances at each BPM. Existence of excessive beta-beat was observed in both rings of RHIC at polarized proton store energy. A unique global optics correction scheme was then developed and tested successfully during the RHIC polarized proton run in 2013. The feasibility of using horizontal closed orbit bump at sextupole for arc beta-beat correction was also demonstrated.

INTRODUCTION

Accurate optics measurement and efficient optics correction schemes are highly demanded to provide more precise optics manipulation for further improvement of RHIC luminosity as well as its polarization performance.

ICA FOR AC DIPOLE BASED OPTICS MEASUREMENT

At RHIC, AC dipole has been routinely used to excite sustained coherent beam motion with large amplitude and preservation of beam emittance to facilitate acquisition of 1024 turn by turn beam position data at the beam position monitors (BPMs) [1]. Optical functions can then be extracted from the recorded BPM data by the technique of independent component analysis (ICA). ICA is more efficient than principle component analysis (PCA) because, in addition to correlations of data from all BPMs, it takes advantage of the time correlation between independent components to extract source signals with non-overlapping spectra [2]. From the spatial functions of source signals corresponding to AC dipole driven oscillation, one may extracted the modified betatron amplitude function β_d and phase advance ψ_d, which are related to the optical functions β_f and ψ_f of free betatron oscillation as [3]:

$$\beta_d = \frac{1+\lambda^2-2\lambda\cos[2(\psi_f-\pi\nu)]}{1-\lambda^2}\beta_f, \quad (1)$$

$$\tan(\psi_d-\pi\nu_d) = \frac{1+\lambda}{1-\lambda}\tan(\psi_f-\pi\nu_f), \quad (2)$$

where $\lambda = \sin[\pi(\nu_d-\nu_f)]/\sin[\pi(\nu_d+\nu_f)]$, ν_d is the driving tune of the AC dipole, and ν_f is the betatron tune of free oscillation. In Eq. (1) and (2), the reference point for phase advance is at the location of the AC dipole. In order to reconstruct the β_f and ψ_f, an accurate and efficient method was developed for routine operation. This method averages optical functions from two measurements in which ν_d is set on either side of ν_f with a distance of 0.01 to minimize the systematic errors from AC dipole driven oscillation. Details about the robustness of this averaging method against BPM errors can be found in Ref. [4].

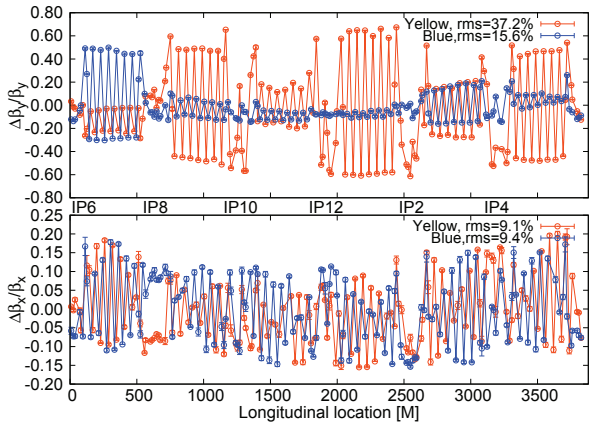

Figure 1: Measured beta-beat with error bars in the horizontal (bottom) and vertical (top) plane for both rings at RHIC. 15% peak beta-beat was observed in the horizontal plane for both rings. A 30% vertical peak beta-beat was found in the Blue ring and 60% in the Yellow ring

Figure 1 shows the beta-beat for the 255 GeV polarized proton beams in the Blue and Yellow rings during RHIC operation in 2013. In both rings, the horizontal peak beta-beat is approximately 15%. In the vertical plane, the peak beta-beat reaches 30% in the Blue ring and 60% in the Yellow ring. The excessively large beta-beat requires efficient correction to be explored.

BETA-BEAT RESPONSE MATRIX CORRECTION METHOD

The problem of beta-beat correction can be described by the following model:

$$\mathbf{WB} = \mathbf{WRK}, \quad (3)$$

where $\mathbf{B}^T = (\frac{\Delta\vec{\beta}_x}{\beta_x}, \frac{\Delta\vec{\beta}_y}{\beta_y}, \Delta\nu_x, \Delta\nu_y)$ is composed of the beta-beat vectors and tune variations, $\mathbf{K}^T = (\Delta K1L_1, \Delta K1L_2, \ldots, \Delta K1L_N)$ represents the change of integrated strength of N quadrupoles, and the superscript T means a transpose. $\mathbf{R}$ is the $M \times N$ beta-beat

† xiaoshen@indiana.edu

Copyright © 2013 CC-BY-3.0 and by the respective authors

response matrix. $\mathbf{W}$ is a diagonal matrix containing the weighting factors w_i $(i = 1, \ldots, M)$. To avoid beam loss and polarization loss, the tune variations receive high weights to be minimized. Beta-beat from noisy BPMs are assigned low weights. In reality, the number of independently powered quadrupoles is often very limited, i.e., $M \gg N$, such that Eq. (3) describes an overdetermined system in which the weighted measured beta-beat is minimized with the constraint of zero tune shifts. The required correction strength $\mathbf{K}_{\mathrm{cor}}$ is computed by using the generalized inverse $(\mathbf{WR})^{\dagger}$ of the weighted response matrix from singular value decomposition (SVD) as:

$$\mathbf{K}_{\mathrm{cor}} = -(\mathbf{WR})^{\dagger}\mathbf{WB}. \qquad (4)$$

Since the response matrix $\mathbf{R}$ is calculated from the ideal model, multiple iterations of correction based on Eq. (4) are necessary in the event of large beta-beat.

Based on the method discussed above, systematic computations were carried out to determine optimum correction for both rings of RHIC, in which a total of 72 triplet and trim quadrupoles in the interaction regions (IRs) with independent power supply are used as beta-beat correctors and two families of arc quadrupoles are included for tune compensation.

Figure 2 shows the relative correction strength for the Blue ring. All relative changes are below the maximum capability of power supplies. The large changes in trim quadrupoles are because the trim quadrupoles are initially set at a low field. Figure 3 shows the measured beta-beat with and without correction. The horizontal peak beta-beat was successfully reduced from 15% to 8%, while the vertical peak beta-beat was reduced from 40% to 14%. The experimental results were in good agreement with predictions.

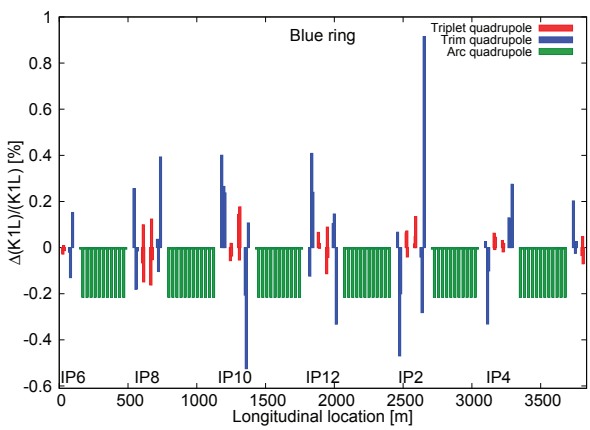

Figure 2: Relative changes of quadrupole integrated strength as a function of quadrupole locations in the Blue ring.

Due to the excessively large beta-beat in the vertical plane of the Yellow ring, two iterations of correction were implemented within the limited beam time. Figure 4 shows the computed relative corrections for the Yellow ring for the first and second iteration. Figures 5 and 6 show the

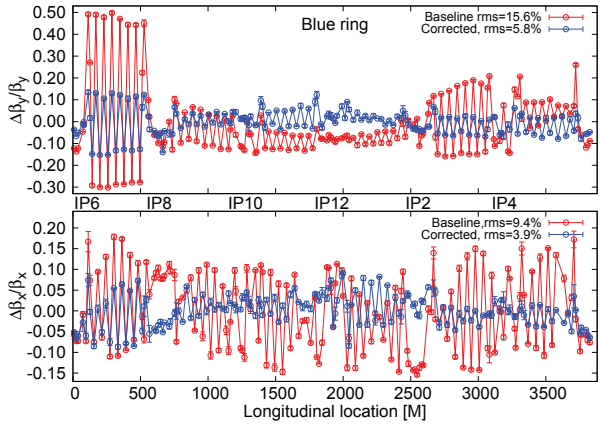

Figure 3: Baseline and corrected horizontal (bottom) and vertical (top) beta-beat with error bars for the Blue ring. Horizontal peak beta-beat was corrected from 15% to 8%, while vertical peak beta-beat from 40% to 14%.

measured horizontal and vertical beta-beat in the Yellow ring with and without corrections ,respectively. After the first iteration, the horizontal peak beta-beat was reduced to 12% which is consistent with the prediction, while the vertical peak beta-beat was reduced to 20% which still deviates quite much from the computation. Good agreement between experiment and prediction was found after the second iteration and peak beta-beat in both planes were reduced to 10%.

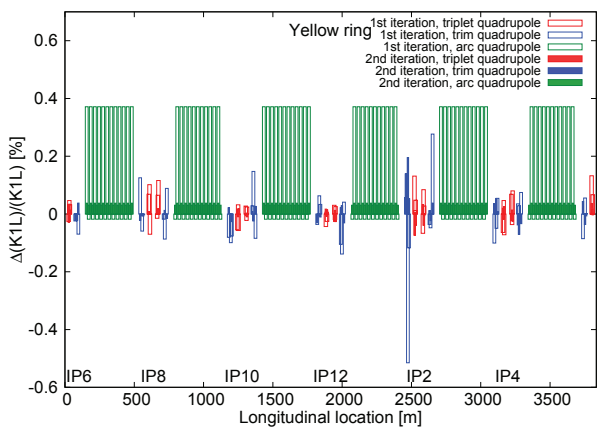

Figure 4: Relative changes of quadrupole integrated strength as a function of quadrupole locations in the Yellow ring for the first iteration (hollow bars) and second iteration (solid bars), respectively.

ARC BETA-BEAT CORRECTION USING CLOSED ORBIT BUMP AND SEXTUPOLE

In RHIC, there are no independently powered quadrupoles in the arcs such that gradient errors in these regions cannot be effectively corrected. However, feed-down normal quadrupole field from horizontal closed orbit bump at sextupole can be included as additional correctors to reduce beta-beat in these regions. This technique also provides capabilities of more precise optics

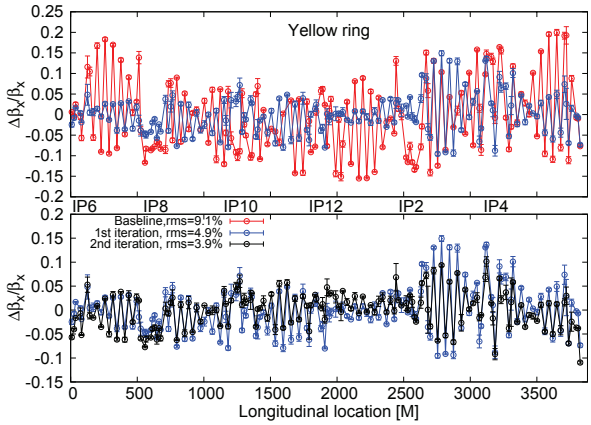

Figure 5: Baseline and corrected horizontal beta-beat with error bars for the Yellow ring. The peak beta-beat was reduced from 15% to 12% after the first iteration of correction, and further reduced to 10% after the second iteration.

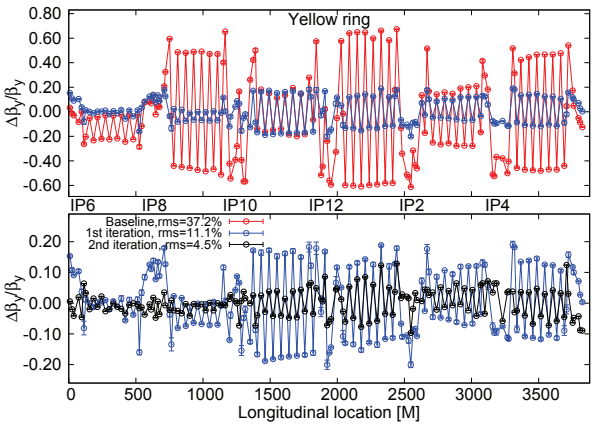

Figure 6: Baseline and corrected vertical beta-beat with error bars for the Yellow ring. The peak beta-beat was reduced from 60% to 20% after the first iteration of correction, and further reduced to 10% after the second iteration.

control to facilitate demanding optics manipulations. A proof-of-principle experiment of this technique was successfully carried out during the 2013 RHIC polarized proton operation.

Figure 7 shows the computed horizontal closed orbit required for arc beta-beat correction as well as the measured horizontal closed orbit. The computed and measured closed orbit are well matched in the arcs. The mismatches at around the interaction points (IPs) do not affect the correction performance because there are no sextupoles in these regions. The correction results are shown in Fig. 8. In the horizontal plane, beta-beat reduction was seen clearly in the arc between IP10 and IP12 as well as the arc between IP4 and IP6. In the vertical plane, significant beta-beat reduction was observed in the four arcs between IP10 and IP4. Overall, the peak beta-beat was reduced to 7%.

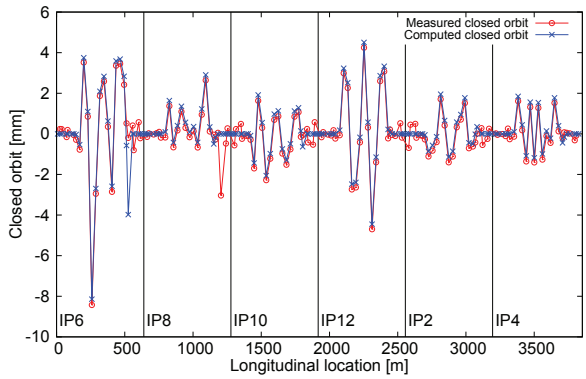

Figure 7: Measured and computed horizontal closed orbit for correction of arc beta-beat in the Yellow ring.

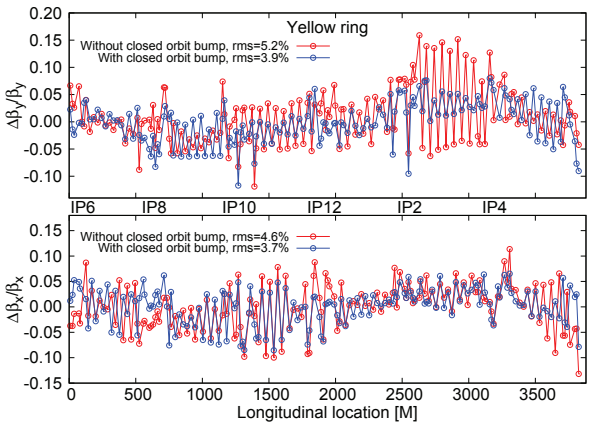

Figure 8: Horizontal (bottom) and vertical (top) residual beta-beat with and without the horizontal closed orbit bump displayed in Fig. 7 for the Yellow ring. Peak beta-beat was reduced to 7% for both planes with the closed orbit bump.

CONCLUSION

ICA was by the first time applied to RHIC to accurately extract optical functions from turn by turn BPM data of AC dipole driven betatron oscillation. With limited number of quadrupole correctors, a global correction scheme using beta-beat response matrix method was experimentally demonstrated to reduce the peak beta-beat to 10%. Peak beta-beat was further reduced to 7% during a proof-of-principle experiment of arc beta-beat correction using horizontal closed orbit bumps at sextupoles.

ACKNOWLEDGMENT

The authors would like to thank S. Tepikian for his help in providing RHIC design model, and the engineers in the beam instrumentation group as well as RHIC operators for their technical support.

IMPLEMENTATION OF OPTICS CORRECTION ON THE RAMP IN RHIC*

C. Liu†, A. Marusic, M. Minty, BNL, Upton, NY 11973, USA

Abstract

In this report we describe and present experimental results from correction of the accelerator optics during acceleration and preparation for collisions at the Relativistic Heavy Ion Collider (RHIC) at BNL. Past experiences with beam optics correction at RHIC have concentrated on measurements and corrections at store beam energies. While well-corrected store beam optics is desirable for maximizing beam and polarization lifetime, well-corrected beam optics during the ramp is also desirable for example to reduce the strength of depolarizing resonances. With optics measurements on the ramp at every 2 or 4 seconds, corrections were computed for several fixed points on the ramp using a well-tested weighted Singular Value Decomposition algorithm. Successful implementation of correction on the second part of the ramp (rotator ramp), together with some observations on the first part of the ramp (the energy ramp) will be presented.

INTRODUCTION

Analysis of depolarizing resonances on the ramp and dynamic aperture study are part of the ramp optics design nowadays in RHIC [1]. Acceptable intrinsic resonance strength and dynamic aperture are ensured by design. With optics errors, both of these quantities are hard to predict. Most likely the machine performance in both aspects will degrade to some extent with optics errors. Therefore, it is desirable to correct the optics on the ramp for better polarization and intensity transmission efficiencies.

Besides continuous efforts for improving TbT (turn-by-turn) BPM data quality over the years [2], there are two developments in 2013 that make ramp optics correction feasible. One of the developments is the precision optics measurement based on ARTUS kicker [3] which is critical for ramp optics analysis. Firing the AC dipole for optics measurement is operational and robust at injection and store energies [4], however, it has not been demonstrated on the ramp during acceleration. Exciting the beam periodically with the ARTUS tune meter kicker has been done previously for the purpose of ramp chromaticity control, however, no successful effort has been applied to extract accurate linear optics information along the ramp. The other development is the successful demonstration of global optics corrections based on both the ARTUS kicker and the AC dipole [5, 6].

† cliu1@bnl.gov

RAMP OPTICS MEASUREMENT

By firing the ARTUS kicker every 2 or 4 seconds on the ramp, TbT BPM data of free betatron oscillations can be recorded in both planes [2]. The timing of the excitations in the two transverse planes is shifted by 510 turns to reduce coupling effects. Special care was taken to avoid interference between TbT and average orbit data taking. The option of 1k, 2k and 4k turns TbT orbit is available. The option of 1k is chosen for the ramp optics measurement since usually the oscillation lasts less than 500 turns due to decoherence. Examples of TbT BPM data are shown Fig. 1.

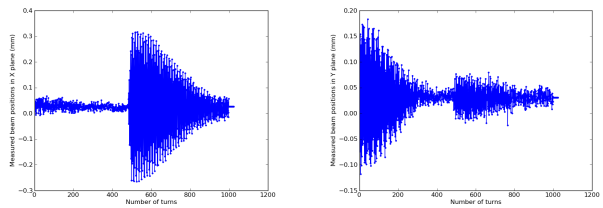

Figure 1: Turn by turn BPM positions in the horizontal (left) and the vertical (right) plane from ramp optics measurement, residual coupling (right) appears in the vertical plane where the horizontal oscillation starts.

As with usual optics analysis, beta functions and phase advances are determined for both planes from TbT BPM data. The analysis technique adopted by the author favors the data in the horizontal plane for better measurement resolution [3]. Therefore, the data in the vertical plane was shifted backwards by 500 turns (data after 500 turns being discarded) before windowed FFT being applied, which also reduces the impact of the residual coupling in the vertical plane after ∼500 turns.

The beta beats and phase errors at 289 s into the ramp are shown in Figs. 2 and 3. The whole ramp takes 320 s. Similar analyses were performed with data acquired every 4 seconds in the Blue ring and every 2 seconds for the Yellow ring. The overall trend of the optics errors is similar for both rings. As beam is being accelerated, the optics error decreases to its minmum in the middle of the ramp. Then the error goes up as beta stars are being squeezed.

RAMP OPTICS CORRECTION SCHEME

For the polarized proton program at RHIC in 2013, the ramp has two parts. The first one, during which the energy is ramped up and beta stars are squeezed, is called energy ramp. The second ramp, during which the rotator magnet ramps up, is called rotator ramp. There are 32 fixed points

Copyright © 2013 CC-BY-3.0 and by the respective authors

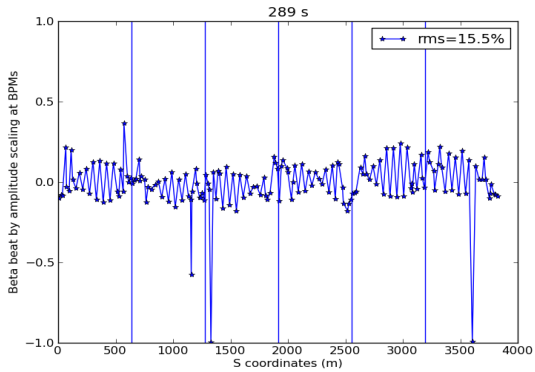

Figure 2: Beta beats at 289 s into ramp in the horizontal plane from ramp optics measurement.

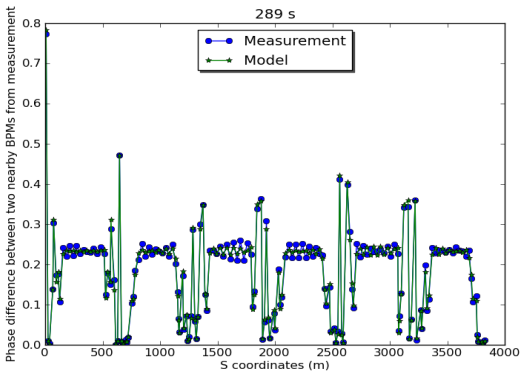

Figure 3: Phase errors at 289 s into ramp in the horizontal plane from ramp optics measurement.

(stepstones) for the energy ramp where magnet strengths are controllable for the energy ramp. The magnet strengths are interpolated between these stepstones. The rotator ramp has fewer stepstones since the optics is smoothier.

TbT orbits near stepstones are picked for optics analysis for the availability of optics models. Then corrections using the 72 trim quads are calculated based on the principle presented in [5]. Two scripts are designed for ramp optics correction. One of them goes through all the picked orbits for analyzing optics in both planes. The second one implements the corrections in RampEditor for all relevant stepstones. Due to the fact that the beam is not perfectly centered in quadrupoles, the closed orbit will vary with implementation of correction. Therefore, orbit feedback was turned on to keep the orbit stable. Besides that, tune feedback was used as well to avoid beam loss due to resonances. Chromaticity changes due to optics corrections were predicted by the online model (OptiCalc), which was then manually corrected before activation of corrections.

TEST ON ROTATOR RAMP

The concerns regarding ramp optics correction implementation are mostly related to the beam loss and beam emittance dilution. As a test, correction on a rotator ramp with fewer bunches (12 by 12) was attempted to study these effects. The test ramp was the same as a physics ramp except for the fewer bunches. The optics for the rotator ramp is considered as smooth regardless of the ramping of the rotators. Therefore, corrections calculated for the full energy were applied to all stepstones of the rotator ramp except the very first one. It means the correction strengths ramp up from the first to the second stepstone.

Beam loss of the test ramp and a physics ramp are shown in Fig. 4. The rising of beam loss around 1300 s in the Blue ring was due to other beam study. The oberservation is that the beam loss was slightly better for the test ramp during the rotator ramp and after beam collision. The IPM

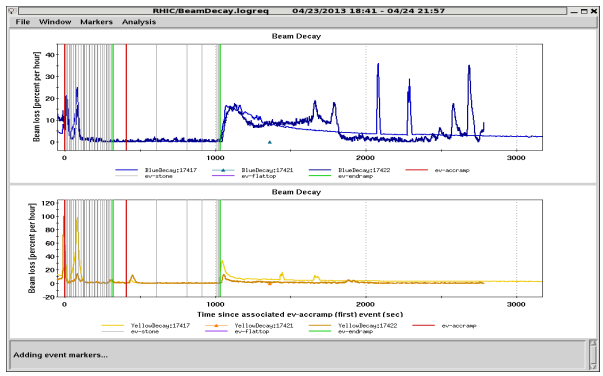

Figure 4: Comparison of beam loss between the test ramp and a physics ramp for both rings.

(Ionization Profile Monitor) reported emittance for the test ramp and a physics ramp are shown in Fig. 5. They are similar except for the large error bars due to fewer bunches. In addition, the calculated beam emittance inferred from beam collision signals are as good as in a good physics store.

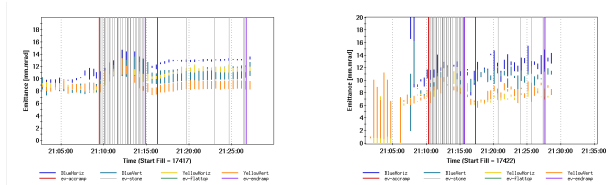

Figure 5: IPM measured emittance in a physics ramp (left) and the test ramp (right) for both rings.

The collision rate was expected to reach 1070 kHz at STAR by scaling beam intensities, which is ∼15% increase of luminosity.

The results of the test eliminate the concern of adverse effects of ramp optics corrections. Later on, the correction for the rotator ramp was implemented operationally for the physics program in the Yellow ring only due to other changes being made in the Blue ring. The rest of the program has been running with corrected optics without any complication.

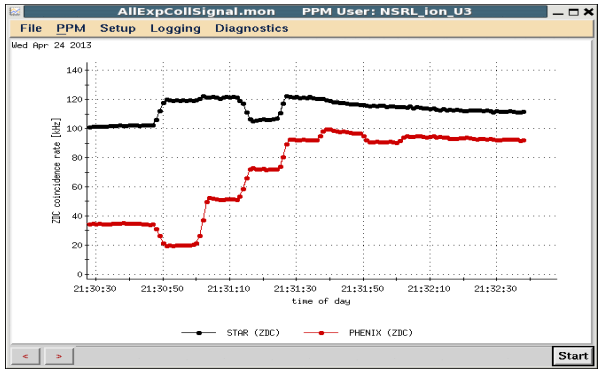

Figure 6: Beam collision signals in the test ramp for both experiments.

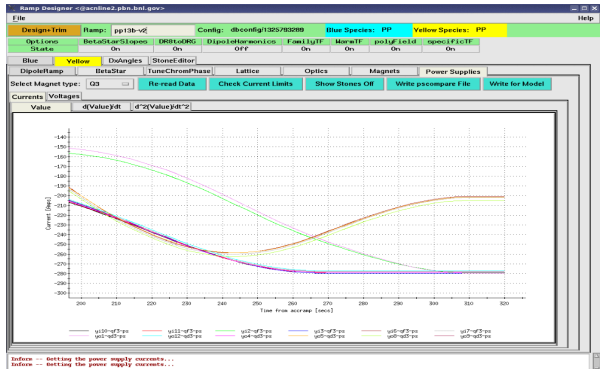

Figure 7: Current curves for selected magnets without ramp optics correction.

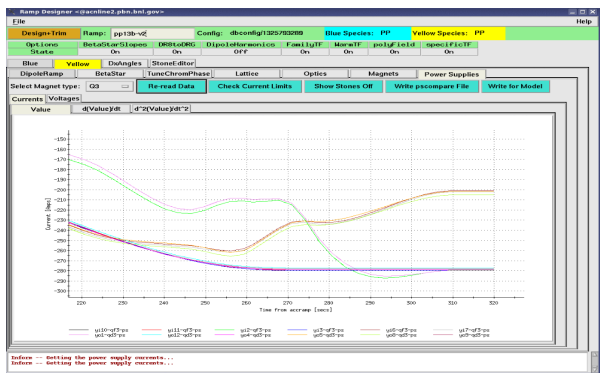

Figure 8: Current curves for selected magnets with ramp optics correction.

TEST ON ENERGY RAMP

Ramp optics correction for the energy ramp has been tested twice in 2013. We ran a 12 by 12 ramp for ramp optics measurement, ran a script to select the TBT orbit files near the stepstones and calculate optics corrections, ran script to send correction strengths to RampEditor and activated corrections. We were not able to ramp again for ramp optics measurement to verify the correction due to time limitations.

The problem encountered in the first attempt was that, each time a set of strengths were sent to a stepstone in RampEditor, the online model recalculated all relevant magnet strengths for the whole ramp which was too time-consuming. The solution was to send all correction strengths for a stepstone once, not separately. The other way around is to fix magnet strengths (anchoring) for the relevant stepstones so interpolation of magnet strengths will not occur after implementing correctons. The two ways are similar because changing strengths for a stepstone would anchor it as well. The problem encountered in the second attempt was that, anchoring stepstones changes the current curves for magnets dramatically, which caused magnets to exceed limits. The selected current curves before and after anchoring stepstones are shown in Figs. 7, 8. The ongoing effort is to change the RampManager code so that anchoring stepstones only fix the magnet strengths, but does not change the derivatives of the current curves.

SUMMARY

Precision analysis of the linear optics based on TbT BPM data by the ARTUS kicker opened out the possibility of ramp optics measurement at RHIC. Breakthrough of global optics correction added the critical piece for implementing ramp optics correction. Ramp optics correction for the rotator ramp has been implemented operationally at RHIC. Ramp optics correction for the energy ramp is in progress.

GLOBAL OPTICS CORRECTION IN RHIC BASED ON TURN-BY-TURN DATA FROM ARTUS TUNE METER*

C. Liu†, M. Blaskiewicz, K.A. Drees, A. Marusic, M. Minty, BNL, Upton, NY 11973, USA

Abstract

Deviation of the optical functions from the model may result in reduced dynamic aperture, luminosity and beam polarization all of which are of particular interest in the polarized proton program at RHIC. Peak to peak beta beats as large as +/- 80% have been observed. In Run-13, we demonstrated that the optical functions can be corrected globally by two different approaches, either beta beat or phase error correction. The optics measurement, correction algorithm and beta beat and phase error measurements before and after correction will be presented.

INTRODUCTION

RHIC (Relativistic Heavy Ion Collider) has been running with large beta beat over the years for both heavy ion and polarized proton programs. The impact on dynamic aperture and beam polarization from optics error are expected, however hard to quantify. The optics errors manifest themselves as beta beats (relative error of beta functions), or as phase advance errors, and as the integral, the tune errors. Usually, the luminosity decreases because of enlarged β^* from the presence of beta beat. Therefore, luminosity is expected to benefit from optics correction even though many other parameters contribute as well. Model optical functions are usually used in correction in accelerators, like orbit, tune and chromaticity corrections [1] since calibration of optical functions is non-trivial. The errors in optics obviously set a limitation on the best performance of the corrections. In addition, many critial diagnostics rely on model optics as well. For instance, IPM (Ionization Profile Monitor) uses model beta functions to calculate the beam emittance. The accuracy of all these diagnostics are expected to be improved with the measurement of optical functions and correction. The above facts justify the need of a robust fast turn-around optics measurement and correction scheme.

OPTICS MEASUREMENT

In RHIC, two types of TbT (turn-by-turn) BPM data can be acquired for optics measurement. One is the betatron oscillation driven by the AC dipole [2]; the other is the free betatron oscillation initiated by the ARTUS kicker [3] (tune meter). The oscillation caused by the AC dipole is adiabatical and renders high signal to noise ratio. The ARTUS kicker affects only one bunch, so it is more robust in practice. All measurments and corrections in this paper are based on TbT BPM data acquired using the ARTUS kicker.

* The work was performed under Contract No. DE-AC02-98CH10886 with the U.S. Department of Energy.

† cliu1@bnl.gov

TbT data analysis techniques, whether it is a time domain, frequency domain or any statistical method, should in principle deliver similar measurement resolutions provided they are employed to their best capacities. The author adopted a frequency domain method which produces ~0.2 deg phase measurement resolution [4] at RHIC.

In addition to measurements at BPM locations, beta functions at various critical devices can be interpolated based on the measured beta functions at nearby BPMs. First, one calculates the transfer matrices between the device and the upstream and downstream BPMs based on model optical functions. Then two equations can be established which relate the unknown beta and alpha at the device and the measured betas at the two BPMs.

$$\begin{cases} \beta_1 = R_{11}^2\beta_0 - 2R_{11}R_{12}\alpha_0 + R_{12}^2\frac{1+\alpha_0^2}{\beta_0} \\ \beta_2 = r_{11}^2\beta_0 - 2r_{11}r_{12}\alpha_0 + r_{12}^2\frac{1+\alpha_0^2}{\beta_0} \end{cases} \quad (1)$$

Here β_1, β_2 are the measured beta functions at BPM 1 and 2. R and r are the transfer matrices from the device to BPM 1 and 2 respectively. β_0 and α_0 are the unknown Twiss parameters at the device.

CORRECTION SCHEME

Global beta beat correction has been implemented on various accelerators successfully [5]. However, global phase error correction has been proposed but not demonstrated successfully [6]. The basics of the two corrections being applied in RHIC are similar. Suppose $(e_1, e_2, \ldots, e_m)'$ is the optics error (beta beat or phase error) being measured, M is the response of optics errors to quadrupole strength variationd in form of a matrix. The correction can be obtained by solving the following equations:

$$-\begin{pmatrix} e_1 \\ e_2 \\ \vdots \\ e_m \end{pmatrix} = \begin{pmatrix} M_{11} & M_{12} & \cdots & M_{1n} \\ M_{21} & M_{22} & \cdots & M_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ M_{m1} & M_{m2} & \cdots & M_{mn} \end{pmatrix} * \begin{pmatrix} k_1 \\ k_2 \\ \vdots \\ k_n \end{pmatrix} \quad (2)$$

The optics error on the left side are from both planes, on which proper weights can be applied based on the scale of the errors. The correction knobs in RHIC are the 72 quadrupoles with trim power supplies which all reside in the interaction regions [7].

The response matrix for beta beat correction can be calculated either by an optics program (MAD-X) simulation or analytically based on the online model (OptiCalc) optical functions. The analytical formula are presented

Copyright © 2013 CC-BY-3.0 and by the respective authors

in Eq. 3. Betas in Eq. 3 are for the quadrupoles. The quadrupole integrated strength is assumed.

$$\begin{cases} M_{ij,x} = -\frac{\beta_{i,x}}{2\sin\pi\mu_x}\cos\left(2\pi\mu_x - 2|\phi_{i,x} - \phi_{j,x}|\right) \\ M_{ij,y} = \frac{\beta_{i,y}}{2\sin\pi\mu_y}\cos\left(2\pi\mu_y - 2|\phi_{i,y} - \phi_{j,y}|\right) \end{cases} \quad (3)$$

The results from both calculations were compared for RHIC at both the injection and store energies. Because of the fact that gamma-t quads are implemented in OptiCalc but not in the MAD-X model, the response matrices differ considerably from each other at injection energy. At full energy, the two results agree very well with each other since the contribution of gamma-t quads decreases with energy.

The response matrix for the phase error correction was only simulated with MAD-X. Therefore, the error in the phase response matrix is expected to be non-negligible due to the missing gamma-t quads at injection. At full energy, the impact of gamma-t quads on the phase response matrix should be minimal just like for the beta beat response matrix.

OPTICS CORRECTION

Due to time limitations and the known error in the model, a phase error correction was only attempted briefly at injection energy. With one iteration of corrections, the phase errors before and after correction at injection are shown in Figs. 1, 2, 3 and 4.

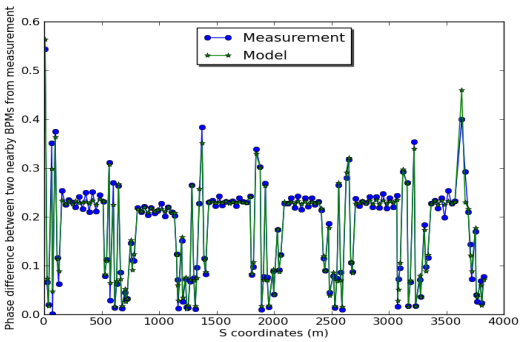

Figure 1: The measured and model phase advance in the horizontal plane before phase correction (in units of 2π).

The corresponding rms beta beat was reduced from 17.3% to 9.3% in the vertical plane, from 7.8% to 5.2% in the horizontal plane with the phase error correction.

Beta beat corrections were demonstrated in both rings at full energy. The beta beat before and after correction in the Blue ring are shown in Figs. 5 and 6. The applied integrated trim strengths for all 72 quads are shown in Fig. 7.

The phase measurement and correction has certain advantages over the beta beat correction. First, the phase measurement is model independent; secondly, the phase measurement is mostly immune to BPM calibration errors; and lastly, the phase correction will not introduce additional tune changes which have to be corrected. Phase error

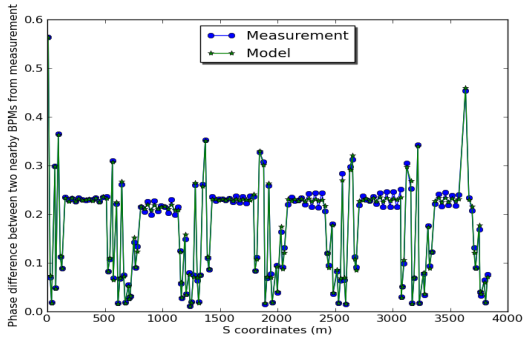

Figure 2: The measured and model phase advance in the horizontal plane after phase correction (in units of 2π).

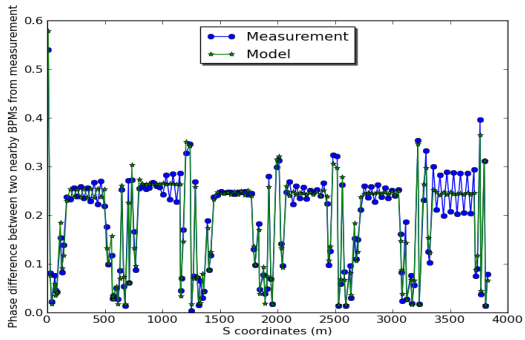

Figure 3: The measured and model phase advance in the vertical plane before phase correction (in units of 2π).

correction has been demonstrated successfully in RHIC at injection energy, however, not to its full capacity.

The beta functions at IPs (Interaction Points) are interpolated from the measurements before and after beta beat correction. The results are shown in Table 1 and 2. The numbers in parenthesis are the design values for the β^*.

SUMMARY

Both global optics correction schemes (beta beat and phase error correction) have been demonstrated successfully at RHIC based on ARTUS TbT BPM data. The beta

After	0.66(0.64)	0.63(0.61)	0.69(0.63)	0.73(0.64)

Table 2: β^* at IPs in the Yellow Ring Before and After Beta Beat Correction

	β_x **(IP6)**	β_x **(IP8)**	β_y **(IP6)**	β_y **(IP8)**
Before	0.6	0.79	0.62	0.75
After	0.63(0.66)	0.66(0.6)	0.68(0.67)	0.70(0.68)

beat correction has since then been implemented operationally at store. The benefit on luminosity was observed [8]. The correction of β^* was verified by measurements after correction. Even though the phase response matrix has certain errors due to the missing gamma-t quads in the MAD-X model, phase error correction was demonstrated successfully at injection energy. Further studies are planned for the future. The result of a phase error correction is expected to be no worse than the beta beat correction.

DYNAMIC APERTURE MAXIMIZATION WITH HEAD-ON BEAM-BEAM COMPENSATION IN RHIC*

Y. Luo, W. Fischer, S. White
Brookhaven National Laboratory, Upton, NY USA

Abstract

To reduce the large beam-beam tune spread and to compensate the beam-beam non-linear resonance driving terms, two electron lenses are being installed in the RHIC tunnel for head-on beam-beam compensation. In this article we discuss the approaches to maximize the proton dynamic aperture by adjusting the phase advances between beam-beam interaction points and the electron lenses. We present the beam-beam compensation lattice design, dynamic aperture calculation results, and comparisons between the lattices used in the previous RHIC proton operation.

INTRODUCTION

The working point in the polarized proton collision operation in the Relativistic Heavy Ion Collider (RHIC) is constrained between 2/3 and 7/10 to achieve a good beam lifetime with beam-beam interaction and to preserve the proton polarization on the energy acceleration and at the physics store. To further improve the luminosity, with an upgraded polarized proton source, the proton bunch intensity will be increased from currently 1.8×10^{11} up to 3.0×10^{11}. However, with such a high bunch intensity, there is not enough tune space between 2/3 and 7/10 to accommodate the large beam-beam tune spread.

To reduce the large beam-beam tune spread and compensate the large beam-beam resonance driving terms (RDTs), head-on beam-beam compensation with electron lenses (e-lenses) is adopted in RHIC [1]. Figure 1 shows the layout of RHIC head-on beam-beam compensation. The two proton beams collide at IP6 and IP8. Two e-lenses are being installed on either side of IP10, one for the Blue ring and one for the Yellow ring. To cancel the non-linear beam-beam RDTs from collision at IP8, we require the betatron phase advances between IP8 and the e-lens center to be $k\pi$, where k is an integer.

For the next 100 GeV polarized proton run, we will commission head-on beam-beam compensation for the first time in RHIC. To best utilize head-on beam-beam compensation and to maximize the proton dynamic aperture, we redesigned the proton lattices for both RHIC rings. On top of the above $k\pi$ phase advances between IP8 and the e-lenses, we also attempt to maximize the off-momentum dynamic aperture by adjusting the phase advances between the two collisional IP6 and IP8. In the following, we first discuss the phase requirements for head-on beam-beam compensation, then present the newly designed lattices and the calculated proton dynamic apertures compared with the previous RHIC proton operation lattices.

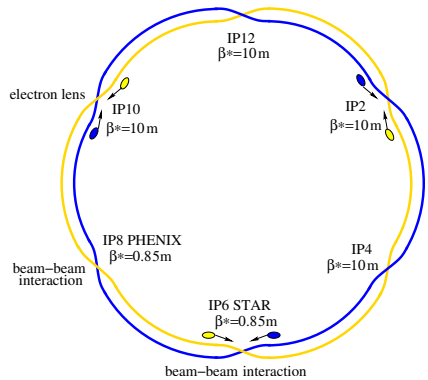

Figure 1: Layout of RHIC head-on beam-beam compensation. Proton beams collide at IP6 and IP8. E-lenses are located on both sides of IP10.

PHASE ADVANCE CONSIDERATIONS

For head-on beam-beam compensation in the proton operation in RHIC, simulation results show that full compensation gives a lower dynamic aperture than that with half beam-beam compensation. With half beam-beam comnpensation, if the phase advances between IP8 and the center of e-lenses is $k\pi$, k being an integer, the non-linear beam-beam RDTs from beam-beam interaction at IP8 will be exactly compensated by the e-lens at IP10 to the first order. For this purpose, we added two shunt power supplies to the main quadrupoles in the arc between IP8 and IP10.

In the previous proton runs, we observed that the particle loss at store took place in the transverse plane with beam-beam interaction. The proton loss rate was found to be proportional to the particle leakage rate from the proton bunch center to the tail. Since the particles in the bunch tail have bigger momentum errors, we concluded that the proton loss at store was caused by the low off-momentum dynamic aperture [2]. To improve it, we need to compensate the chromatic effects and compensate the higher order chromaticities.

In the early studies, we identified that the non-linear chromaticities for the RHIC proton lattices are mainly contributed by the triplet quadrupoles in the two interaction regions IR6 and IR8 where βs are much bigger than other non-collisional interaction regions [3]. From the

$\xi^{(2)}_{x,y}$	(-119,-60)	(-4160,-1045)
$\Delta\Phi_{x,y}\vert_{\rm IP6->IP8}$	(7.5π, 11.5π)	(8.3π, 11.0π)
$\Delta\Phi_{x,y}\vert_{\rm IP8->elens}$	(11π,9π)	(10.7π,8.8π)

perturbation theory, the second order contributions from quadrupoles are mostly determined by the first order off-momentum β-beat $d\beta/d\delta$, $\delta = dp/p_0$. Therefore, for the asymmetric optics at IP6 and IP8 in RHIC, we can minimize $d\beta/d\delta$ at the triplet quadrupoles by adjusting the phase advances between IP6 and IP8 to be $(p+1/2)\pi$, with p an integer [4].

OPTICS DESIGN

For the next RHIC proton run, the particle energy will be 100 GeV. According to the operational experiences in the previous RHIC 100 GeV proton runs, to obtain acceptable store beam lifetime, we choose $\beta^* = 0.85$ m, the same as in the 2012 100 GeV proton run. The luminosity gain will mainly come from the increased proton bunch intensity. With half beam-beam compensation with e-lenses, we expect that the maximum proton bunch intensity at store exceeds 2.5×10^{11}.

Table 1 shows the main optics parameters for the new lattice design for beam-beam compensation, together with the lattices used in the previous RHIC proton runs. For simplicity, we name the previous RHIC run lattices "standard lattices" and the newly designed lattices for beam-beam compensation "e-lens lattices". From Table 1, the e-lens lattices meet all above phase advance requirements: $k\pi$ between IP8 and e-lens and $(p+1/2)\pi$ between IP6 and IP8.

As an example, Figure 2 shows the fractional vertical tunes versus dp/p_0 for the e-lens lattices and the standard lattices. With the phase advances between IP6 and IP8 being $(p+1/2)\pi$, the second order chromacticities are largely reduced. Figure 3 shows the RDTs of $3Q_x$ along the ring. Large $3Q_x$ RDTs affect negatively the beam lifetime at injection and cause beam loss and emittance growth on the energy and rotator ramps. From Figure 3, for the e-lens lattices, the RDTs of $3Q_x$ in the Yellow ring are bigger than that from the Blue ring. To meet these phase advance requirements, the e-lens lattices reduce the arc FODO cell's phase advances from optimum 90° to 74° and generate extra β and dispersion beats between IP8 and IP10 with shunt qudrupole power supplies between them.

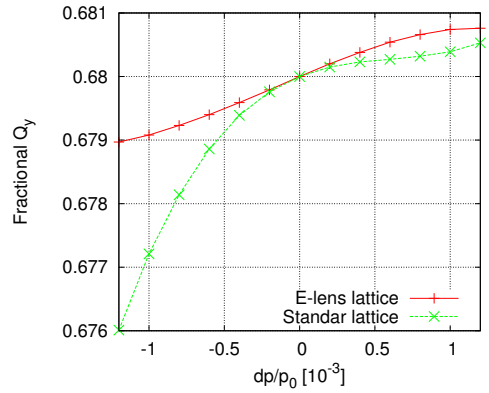

Figure 2: Yellow vertical tunes versus dp/p_0. Phase advances $(p+1/2)\pi$ between IP6 and IP8 reduce $\xi^{(2)}_{x,y}$. The Yellow vertical plane shows the largest nonlinear chromaticity in the standard lattice (Table 1).

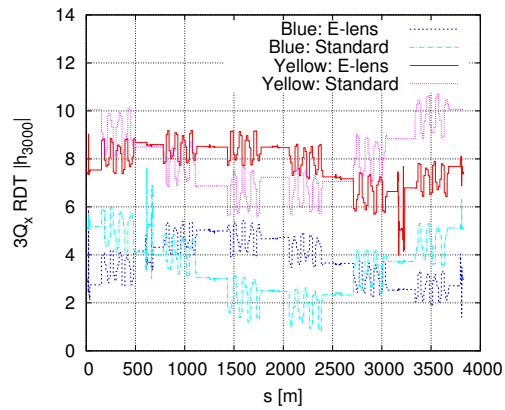

Figure 3: RDTs of the $3Q_x$ resonance for e-lens and standard lattices. $3Q_x$ RDTs are bigger in Yellow than Blue rings.

DYNAMIC APERTURE CALCULATIONS

Figure 4 shows the proton dynamic aperture without beam-beam interaction at store energy. The zero-amplitude tunes are scanned along the diagonal in the tune space. In this study, the vertical tune is always lower than the horizontal tune by 0.01. The Blue e-lens lattice gives a bigger dynamic aperture than the Yellow e-lens lattice when the tunes are close to 2/3. The Yellow standard lattice gives the lowest dynamic aperture in the scan, which is due to its large $3Q_x$ RDT and negative vertical second order chromaticity.

Figure 5 shows the dynamic aperture with beam-beam interaction at IP6 and IP8. The zero-amplitude tunes are (0.68,0.67). The dynamic aperture for the e-lens lattices are above 5 σ when the proton bunch intensity is below 2×10^{11}. The Yellow e-lens lattice gives a larger dynamic aperture than the standard Yellow lattice. The dynamic aperture begins to drop for all cases when the proton bunch intensity is above 2×10^{11}, which justifies head-

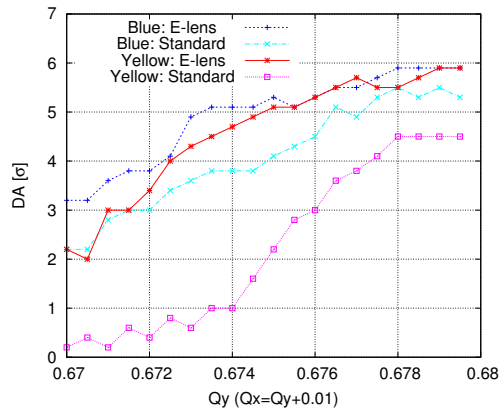

Figure 4: Dynamic aperture without beam-beam interaction at store. The initial $dp/p_0 = 12.5 \times 10^{-4}$.

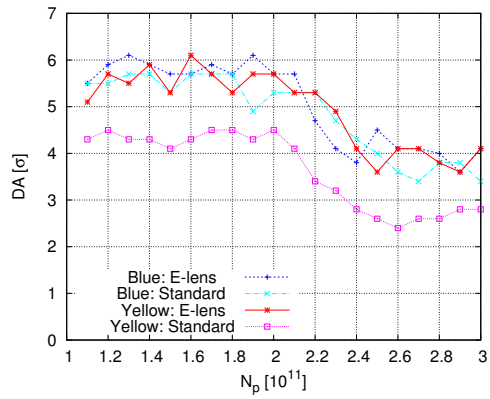

Figure 5: Dynamic aperture with beam-beam interaction at store. The zero-amplitude tunes are (0.68,0.67).

on beam-beam compensation for proton bunch intensities above 2×10^{11}.

Figure 6 shows the dynamic apertures with half head-on beam-beam compensation (HBBC). With HBBC the e-lens lattices give a bigger dynamic aperture than the standard lattices. For the Blue e-lens lattice the dynamic aperture is about 5 σ for all bunch intensities. While for the Yellow e-lens lattice, it is above 4.5σ for bunch intensities between 2.0-3.0$\times 10^{11}$.

The Yellow e-lens lattice gives a lower dynamic aperture than the Blue e-lens lattice when bunch intensities are below 2×10^{11}. One possible reason is the large Yellow $3Q_x$ RDT. Here we correct all the first order sextupole resonance driving terms with 12 sextupole families. The focusing or defocusing sextupoles in each arc are grouped into one family. With correction, the $3Q_x$ RDT is reduced by more than half and the second order chromaticties are still below 400. Figure 7 shows the dynamic apertures with the sextupole first order RDT correction. The dynamic aperture of HBBC with correction improves slightly but is still low when the proton bunch intensity is below 2.0$\times 10^{11}$.

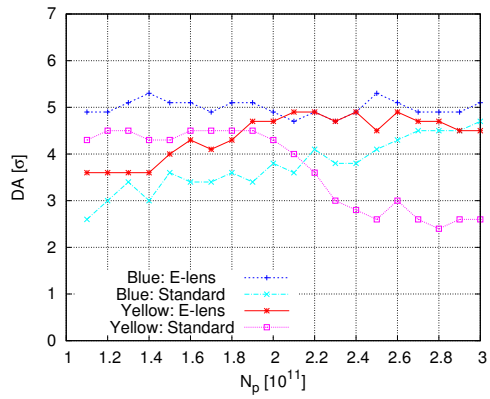

Figure 6: Dynamic aperture with half beam-beam compensation at store.

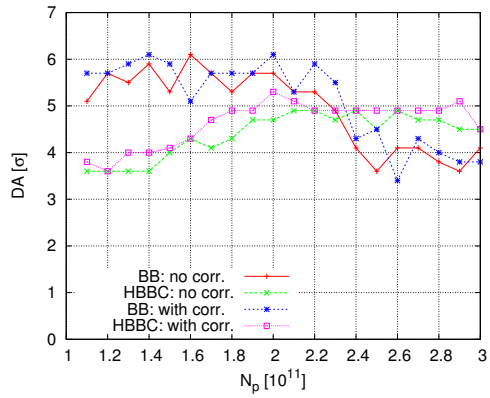

Figure 7: Dynamic aperture for the Yellow e-lens lattice with $3Q_x$ correction.

SUMMARY

We re-designed lattices for the head-on beam-beam compensation with e-lenses in RHIC. Phase advances between IP8 and the e-lenses are set to $k\pi$ to compensate non-linear beam-beam RDTs and the phase advances between IP6 and IP8 are set to $(p + 1/2)\pi$ to reduce the second order chromaticities. Dynamic aperture calculations show that the dynamic aperture is improved with e-lens lattices without and with beam-beam compensation, compared to the previous RHIC proton run lattices.

MEASUREMENT OF BEAM OPTICS DURING ACCELERATION IN THE RELATIVISTIC HEAVY ION COLLIDER

M. Minty#, K.A. Drees, R. Hulsart, C. Liu, A. Marusic, R. Michnoff, P. Thieberger
Brookhaven National Laboratory, Upton, NY 11973, U.S.A.

Abstract

Measurements of the beam optics during acceleration have been performed at the Relativistic Heavy Ion Collider (RHIC). The results were used to obtain a measure of the maximum amplitude of the beta-beat envelope during acceleration which are of interest in the context of emittance and polarization preservation. The measured beta functions were then interpolated to locations of beam profile monitors for more accurate determination of the transverse beam emittances during the energy ramp. In this report we summarize recent improvements in the experimental methods, describe the measurement procedure and present experimental results.

INTRODUCTION

Optics measurements during acceleration are here based on excitation of the beam using pulsed kicker magnets (from the RHIC tune measurement system, ARTUS [1]) as opposed to driven excitations using AC dipoles [2], which are not well suited for measurements during the energy ramp. The response of the beam's change in centroid position was measured using beam position monitors (BPMs). Compared to measurements made previously [3] using the ARTUS kicker magnet [1], the measurement precision has been substantially improved by numerous enhancements made in the BPM and data delivery systems and by the application of continuously operating orbit and tune/coupling feedback [4] used to ensure reproducible and stable conditions during acceleration. For beam optics measurement during the energy ramp, a coherent beam oscillation was excited and single-bunch turn-by-turn (TBT) BPM measurements were acquired. These were carefully interleaved with average orbit measurements used by the orbit feedback. The TBT data were acquired at a selectable maximum rate possible (depending on whether acquisitions were desirable in both RHIC accelerators simultaneously) as limited by the data delivery times. The results were analyzed using slightly modified adaptations of existing frequency-based analyses [5-7] as described in Ref. [8].

In this report we summarize the improvements leading to reliable and robust measurements, describe the measurement procedure and present experimental results.

TURN-BY-TURN BEAM POSITION MEASUREMENTS

Past beam optics measurements in RHIC were sometimes compromised by poor BPM performance [9]. During the early years of RHIC operation, modifications (e.g. electronics relocation, gain relay modifications) were made and automated timing scans were developed which contributed to substantially improved performance [10, 11]. Then several issues specific to the turn-by-turn BPM system were resolved: timestamp errors were eliminated (2008), FireWire (IEEE serial bus interface) error checking and staggering using software loop delays were implemented (2009), a RAM data corruption source was located in the integrated front end of the signal processing electronics and corrected (2009), changes were made to interrupt priorities (2009), and Sederta-card memory corruption was identified and eliminated (2010).

DETERMINISTIC DATA DELIVERY

During the shutdown before the RHIC FY11 run, a digital test mode was developed to ensure reliable and robust delivery of TBT BPM data and executed over many months. For each of the ~650 BPMs in RHIC, a test pattern was set at a 0.25 Hz rate in the TBT data array of the local signal processing unit. The received patterns, as logged by the RHIC control system, were subtracted from the expected patterns to detect data handling errors. While the symptoms of data delivery errors were varied (values missing, values repeated, etc.), it was found that they were primarily due to stale data being read back (if overloaded, the Sederta card lost a portion of data and delivered data previously saved in the circular buffer). The errors were solved by further staggering of data transmitted over FireWire using now the RHIC beam sync link turn counter to more precisely stagger the delays to prevent data transmission time overlaps between BPMs. After these modifications, error-free data delivery using the digital test mode was demonstrated: >100,000 acquisitions were performed, where 1 acquisition corresponds to readout of 1024 turns from all BPMs, or about 70 billion readings, with no errors.

ACQUISITION METHODOLOGY

Measurements of the beam optics were made reproducible by ensuring reproducible beam orbits and betatron tunes using the now standard beam feedback systems during acceleration. While orbit and tune

Copyright © 2013 CC-BY-3.0 and by the respective authors

feedback operate independently, the BPM measurements used by orbit feedback and the turn-by-turn BPM measurements share the same networks for data delivery. The timing of the delivery of beam position measurements for these two systems was therefore carefully staggered to avoid data corruption.

A conceptual sketch showing the data acquisition methodology is shown in Fig. 1. Orbit feedback operated at its standard 1 Hz rate. We allowed 200 ms corresponding to an upper limit on the time to transmit all (4 planes from both accelerators) the average orbit BPM data well in excess of the 150 ms required based on previous measurements [12]. After delivery of the data for orbit feedback, the beam was excited in one plane followed a short time later by excitation in the other plane, where the spacing between applied excitations was set (~ 500 turns) to be longer than the decoherence time.

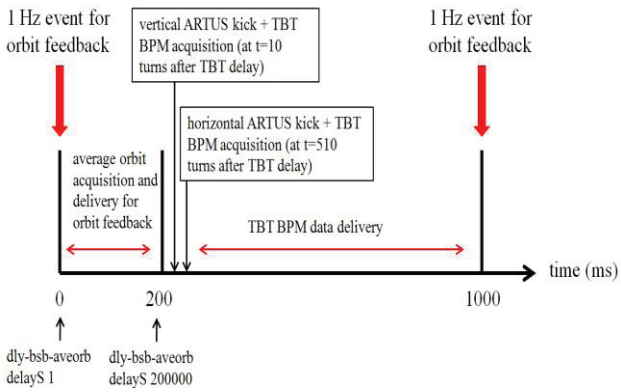

Figure 1: Conceptual sketch of carefully orchestrated timing to allow for turn-by-turn BPM acquisitions interleaved with BPM acquisitions required by orbit feedback during beam acceleration.

MEASUREMENT RESOLUTION

Following the above changes, the resolution of the turn-by-turn BPMs was first quantified using data acquired with continuous excitations provided by AC dipoles [13]. The resolution is here defined as the rms of the difference between the measurement and a sinusoidal fit to the measurement. In Fig. 2 is plotted in histogram format this rms for all BPMs for both transverse planes in both accelerators. Note that the resolution defined here represents an upper bound on the instrumental resolution; a correlation between poor resolution and large beta function (on either side of each interaction region) was determined by Fourier analysis to be due to residual oscillations of the beam (of about 10 Hz [11, 14], which for even higher precision analyses could be fit and removed from the data arrays).

APPLICATIONS

The Run-13 [15] ramp optics data were initially used [16] to determine the betatron tune spread along the energy ramp, which is important in the context of preservation of the proton beam polarization during acceleration. At that time a new beam optic designed for operation of new electron lenses [15,17] was being developed. An unexpected observation, namely reported shrinking beam emittances while establishing beams (i.e. "squeezing") for collision was observed in the yellow ring which provided motivation for interpolation of the beta function measurements [18] to the locations of the ionization profile monitors (IPMs, [19]) which measure the transverse beam sizes.

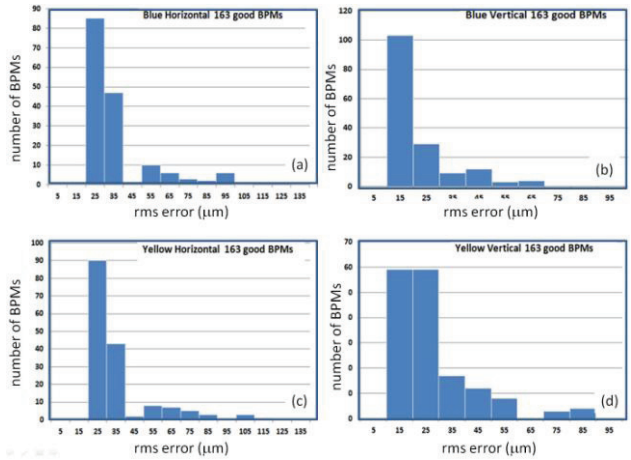

Figure 2: Resolution of turn-by-turn BPM measurements in histogram format for the blue/yellow ring horizontal plane (a)/(c) and vertical planes (b)/(d).

To investigate this further, ramp optics measurements were acquired. Shown in Fig. 3a/b are the model and measured beta functions at the IPMs in the two transverse planes. For reasons that are not yet understood the measured local beta function was observed to decrease while the model beta function, which is assumed for conversion of the beam size to emittance for online reporting, increased. The emittances (95%, normalized) derived using the model and measured beta functions are plotted in Figs. 3c/d. Using the measured beta functions, the emittances were constant - certainly not decreasing. These results are consistent with those acquired at the same time from the fluorescence monitor [20] which also indicated constant beam size while the model beta function increased.

Another example of beta function measurements at the RHIC IPMs is shown in Fig. 4 acquired with the lattice used for most of the FY13 run. The data shown here were acquired with a 1 Hz acquisition rate (ref. Fig. 1) in both accelerators. In all four planes the agreement between model and measured beta functions was observed to be best about midway during the acceleration cycle (which happens to be consistent with the tune errors seen by the tune feedback loops).

The evolution of the beta- and phase-beats during acceleration as measured by all BPMs was evaluated (and available in movie-style format). The amplitude of the envelope of the beta-beating in the accelerator arcs was consistent with those shown in Fig. 3.

SUMMARY

Numerous improvements in the BPM system have been completed over the years including most recently dedicated tests resulting in guaranteed error-free delivery of TBT data. The resulting resolution of the BPMs was measured and found to be excellent. This motivated further application of ARTUS-based beam optics measurements during beam acceleration in RHIC. With careful management of the transmission of BPM data used for orbit feedback and for TBT acquisitions, beta- and phase-beating were measured during the energy ramp and during the final beta squeeze in before collisions.

The results revealed that the presently used approach to optics correction based on fixed energy correction at injection and store with corrections propagated forward and backward, respectively, into the energy ramp [7,18] is appropriate. The measurements were also applied to better understand the beam emittances with measurement errors dominated by the uncertainty in the beta functions.

Efforts continue to utilize these ramp optics measurements for both validating corrections and for development of new methods for directly applying corrections during acceleration [21].

ACKNOWLEDGEMENTS

These beam optics studies – both measurement and analysis – result from many years of development and dedication of many individuals. Here thank M. Bai and C. Montag for use of the data obtained with the AC dipole for evaluation of the BPM resolution. We thank also the C-AD Operations and AP groups for their support.

Abstract

Hydrodynamic behavior of high power targets for future particle accelerators, in particular for the proposed neutrino factory and muon collider, has been investigated via numerical simulations. The target will contain a series of mercury jet pulses of about 1 cm in diameter, interacting with intense proton pulses in 15 – 20 T magnetic fields. Simulations used a smoothed particle hydrodynamics code designed to accurately resolve free surface 3D hydrodynamic flows. Simulation results have been compared with existing experimental data and previous simulations performed with the front tracking code FronTier. New target parameters have also been investigated.

INTRODUCTION

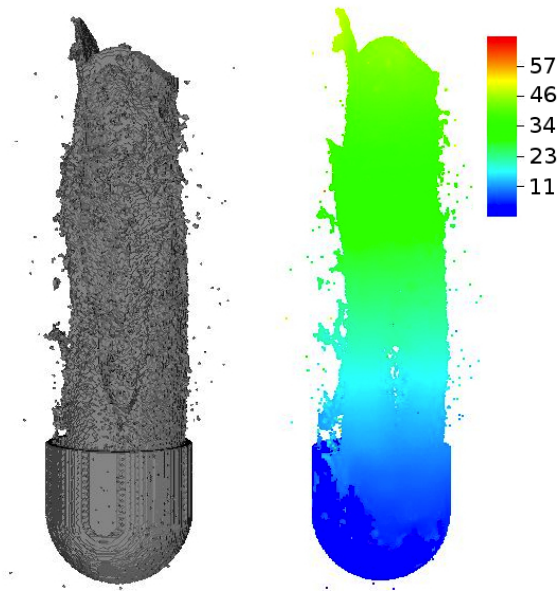
The key element of the target system being designed for the future muon collider and / or neutrino factory is a liquid mercury jet interacting with powerful proton pulses inside a 15 – 20 T magnetic solenoid. The stability of the mercury jet after the proton pulse disruption is a major concern for the target design. The proof-of-principles experiment for high-power mercury target system was conducted at CERN in 2007 [1].

The problem of the slow distortion of the mercury jet entering the solenoid has been evaluated numerically using the FronTier code [2, 3]. FronTier is a hydro- and magnetohydrodynamic code that resolves material interfaces using the method of front tracking. FronTier simulations of the mercury jet cavitation and disruption caused by interaction with proton pulses were presented in [4] and previous works referenced therein. Previous studies have demonstrated that modeling of cavitation and surface dynamics is critical for the simulation of the mercury jet interaction with proton pulses. Cavitation is intrinsically a multiscale phenomenon involving scales from micron-size at the cavitation onset to global scales in later phases of the evolution of bubbles. In FronTier, cavitation was modeled by creating numerically grid-dependent initial cavitation bubbles with tracked surfaces in rarefaction waves of critical strength. Such a cavitation model depends on a number of artificial parameters and makes it difficult to resolve small scales typical for clouds of cavitating bubbles. It is also non-conservative in nature as it removes the liquid and replaces the corresponding volume with gas bubbles. Difficulties with cavitation models prevented us from simulating long time dynamics of mercury jets in 3D.

To improve the modeling of small scales and simulation of long time dynamics of free surfaces flows, we have developed a parallel code based on the smoothed particle hydrodynamics (SPH) [5]. The code has been applied for the simulation of mercury jet targets in the parameter range typical for the muon collider, neutrino factory, and other experimental designs. The present paper only deals with hydrodynamic effects. The study of influence of MHD on the mercury jet cavitation and disruption using particle methods is in progress and will be reported in forthcoming work.

NUMERICAL METHODS

SPH [5] is a Lagrangian particle method in computational fluid dynamics in which deforming Lagrangian cells are replaced with particles. SPH eliminates the main mesh tangling difficulty of the original Lagrangian method while retaining many of its advantages. Due to its Lagrangian nature, SPH is strictly mass-preserving and capable of robustly handling interfaces of arbitrary complexity in the simulation of free surface and multiphase flows. It has known accuracy issues in the numerical approximation of differential operators but these are compensated by the SPH properties of nonlinear stability and conservation, enabling successful usage of SPH for a wide class of problems. We have also developed necessary physics models pertinent to the mercury target problem.



To model properties of mercury, we use the stiffened polytropic equation of state (EOS) [6]

$$P = (\gamma_l - 1)\rho(E + E_\infty) - \gamma_l P_\infty$$

with the adiabatic exponent $\gamma_l = 6.0$ and the stiffening constant $P_\infty = 47$ kbar . The stiffened polytropic EOS extends the range of pressure to negative values in order to account for the transient effect of tension in liquids. When the pressure falls below the cavitation threshold, the interaction between the corresponding particles is eliminated. This causes internal liquid breakups or cavitation. Using this method, cavities can appear on particle-scale length. The particle interactions are resumed if the pressure equilibrates and particles move close to each other causing the merger of fluid fragments.

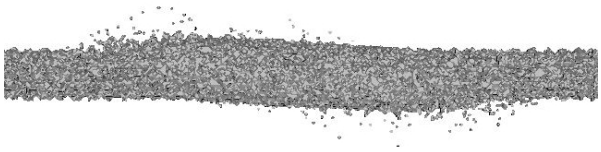
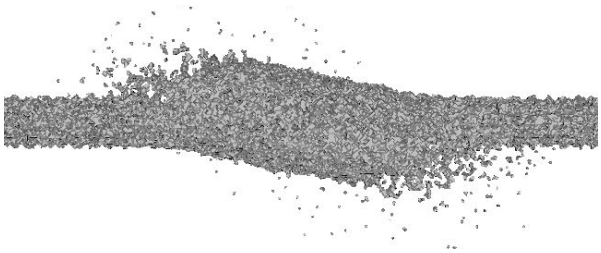
RESULTS AND DISCUSSION

Mercury Thimble Experiments



We have validated SPH simulations of the interaction of mercury with proton pulses using data of the mercury thimble experiments [7]. The volume of the thimble excavated in a stainless steel bar is 1.3 cm^3. It consists from bottom to top of a half sphere (r = 6 mm) and a vertical cylinder (r = h = 6 mm). The mercury has a free surface in up-direction, where it can expand to. The proton pulse has approximately Gaussian distribution and the intensity range of $0.6 - 17 \cdot 10^{12}$ protons at energy 24 GeV. We have performed numerical simulations of the thimble splash and observed that the splash velocity is sensitive to the value of the critical pressure used in the capitation model. Good agreement with experimental data was obtained for the critical pressure of 100 bar. This value was then used in all mercury jet simulations. Figure 1 depicts the shape of the mercury column in the thimble simulation.

Mercury Targets for Neutrino Factory and Muon Collider



In this section, we report simulation results of the mercury jet interaction with proton pulses in the neutrino factory and muon collider power regimes. The 4 MW beam of 8 GeV protons will be delivered in 150 bunches per second for the neutrino factory and in 15 bunches per second for the muon collider. 20.8 teraproton bunches arrive at the neutrino factory target with the 6.67 ms interval that is large compared to hydrodynamic time scales of the mercury splash. In the case of the muon collider, 208 teraproton bunches arrive with the time interval of 66.7 ms. Therefore, it is sufficient to consider the interaction of the mercury jet with only one proton pulse. We use the corresponding energy deposition tables calculated at FNAL with the Monte Carlo code MARS. Assuming the isochoric regime of the energy deposition (the deposition time scale is mush smaller than the hydrodynamic time scale), the peak pressure is approximately 110 kbar in the muon collider target and 11 kbar in the target for the neutrino factory. Figure 2 shows the increase of pressure in mercury with the increase of internal energy. The proton pulse enters the jet under small angle and the energy deposition is not axially symmetric. The pressure profile in the jet is shown in Fig. 3.

After the energy deposition, strong pressure wave propagates to the jet surface and reflects from the mercury - vacuum interface as a rarefaction wave. Rarefaction waves focus in the center of the jet, break the liquid and create an extensive cavitation zone. After the jet is disintegrated by cavitation and surface instabilities, fragments of jet freely fly apart. The velocity of the neutrino factory target splash is in the range of 15 - 35 m/s, with some small droplets reaching velocities of the order of 40 - 50 m/s. These velocities are in the same range as ones observed in MERIT experiments. The exact comparison is not possible because of uncertainties in the energy deposition and spot sizes. In the muon collider case, main jet fragments disperse with the velocity of 90 - 110 m/s with some droplets reaching much higher velocities (see Fig. 4).

Evaluation of Gallium Targets

The targetry group of the MAP collaboration is interested in evaluating the performance of lower-Z materials as targets for future accelerators / storage rings. We performed initial hydrodynamic simulations of the interaction of gallium jets with proton pulses. The density of gallium is $6.1\,g/cm^3$ and the sound speed is 2879 m/s. Detailed thermodynamic properties of gallium were not available at the time of simulations. Based on lower gallium density, we assumed that the pressure and internal energy density increase will be 50% of that in mercury for the same proton pulse. Using the muon collider proton beam parameters, the dispersal of the gallium jet was similar to that of the mercury jet (see Fig. 5). This observation is consistent with a simple extimate using the energy balance law. For the case of the neutrino factory proton beam, the jet expansion velocities were lower compared to the mercury jet and the gallium jet exhibited little distortion at 1 ms. This result could have been affected by inaccurate thermodynamic properties of gallium and the cavitation model. This issue will be addressed in the future work.

Figure 5: Gallium jet dispersal after proton beam energy deposition.

CONCLUSIONS AND FUTURE WORK

Hydrodynamic response of high power mercury targets interacting with proton pulses have been studies computationally using a smooth particle hydrodynamics (SPH) code. The mercury thimble experiments have been used for the validation of physics models, in particular cavitation, implemented in the SPH code. Simulated velocities of the mercury splash agree with experimental values. Furthermore, the sensitivity of the splash velocity to the value of the critical pressure has again demonstrated the importance of cavitation modeling for target simulations. With the critical pressure selected in the benchmark process, simulations of the neutrino factory and muon collider targets have been performed and mercury dispersal velocities have been calculated. Preliminary studies of gallium targets have also been performed. Future work will focus on MHD effects using the SPH code and its modifications.

IMPACT OF THE INITIAL PROTON BUNCH LENGTH ON THE PERFORMANCE OF THE MUON FRONT END*

H.K. Sayed,† H.G. Kirk, J.S. Berg, Brookhaven National Laboratory, Upton, NY 11973, USA
K.T. McDonald, Joseph Henry Laboratories, Princeton University, NJ 08544, USA

Abstract

The dependence of the performance of the Front End of a Muon Collider/Neutrino Factory on the proton-beam bunch lengths of 0-20 ns is explored for beam kinetic energies of 3 and 8 GeV.

INTRODUCTION

Some of the requirements on the proton driver for a staged Neutrino Factory based on muons beams [1] are listed in Table 1. Efficient capture of muons in the Buncher of the Front End [2] of the Neutrino Factory favors very short proton bunch lengths. However, meeting the requirement of an intense proton bunch of length only 2 ns is challenging at 3-GeV beam energy because of space-charge effects [3]. We present here a study of the impact of a longer proton bunch on the performance of the Front End.

In the course of related studies [4], an advantage in capture efficiency was found in using a short "taper" to the profile of the capture-solenoid magnetic field, down from the 20 T peak at the target to 1.5-3.0 T at the beginning of the Decay Channel some 4-6 m downstream. Shorter tapers were found to deliver muon beams with smaller time spread at the Buncher for a given proton bunch length at the pion-production target, corresponding to increased capture efficiency of the Buncher. In this study we examined the performance of such short tapers, as well as long adiabatic ones, for proton bunches of 2-20 ns length.

The beam-dynamics simulations were performed using the ICOOL code [5], with input spectra of secondary particles produced at the proton-beam target as modeled by MARS15(2012) [6]. Figure 1 shows examples of pion beams at the end of the target, of length from 2-10 ns, before being tracked through the tapered capture-solenoid, Decay Channel, Buncher, Phase Rotator and Ionization Cooling sections.

CAPTURE EFFICIENCY VERSUS TARGET SOLENOID TAPER LENGTH

Pions (which later decay to muons) are generated at the target with a wide spread in transverse momentum, largely uncorrelated with their longitudinal momentum As they move through the high target solenoid field they develop a correlation between the longitudinal velocity and the initial transverse momentum. The higher the field integral $\int Bdl$ of the target solenoid leads to a larger time spread (*i.e.*, more muons sent out of the longitudinal acceptance of the buncher and rotator). Figure 2 shows the longitudinal phase space of muon beam at the end of the Decay Channel for a short taper of 4'm and a much longer adiabatic one of 40 m. The shorter solenoid taper delivers muon beam with smaller time spread at a fixed longitudinal momentum p_z to the Buncher. Consequently the short taper has an advantage over the more adiabatic long taper as it manages to pack more muons within the longitudinal acceptance of the buncher and phase rotation channels. Figure 3 shows the muon beam time spread at the end of decay channel (50 m from target) for various taper solenoid profiles.

Pions (later muons) produced off the target were tracked through the Front End starting from the end of the target, through the tapered solenoid, Decay Channel, Buncher,

Table 1: Proton-driver requirements for the final and initial stages of a Neutrino Factory.

Parameter	Final Stage	Initial Stage
Proton energy [GeV]	8	3
Beam power [MW]	4	1
Rep. frequency [Hz]	50	70
Bunch length [ns]	2 $\pm$1	2 $\pm$1

Phase Rotator and Ionization Cooling channels. Fig. 4 shows the number of captured muons versus the solenoid taper length for various target solenoid configurations. The peak field of the target solenoid increases the transverse capture of the pions, as shown in Fig. 4. As the field tapers down to the constant field within the Buncher and Phase Rotator, the faster the taper the smaller the time spread and the better the performance. Increasing the taper-end field strength increases the acceptance of the Front End, as can be seen in Fig. 4).

(a) Short solenoid taper of 4 m.

(b) Long solenoid taper of 40 m.

Figure 2: Longitudinal phase space of pions and muons at the end of the Decay Channel, 50 m from the target.

As the initial pion bunch length gets longer the advantage of the short taper in preserving the time spread will not be the dominant effect on the performance of the Buncher and Rotator. To find the bunch-length limit over which the short solenoid taper holds its advantage, we tracked pions (muons) with bunch lengths varying from 1 to 30 ns through the Front End, Figure 5 shows the number of positive muons at the end of the Front End tracked through solenoid tapers of lengths 6, 20 and 40 m in case of

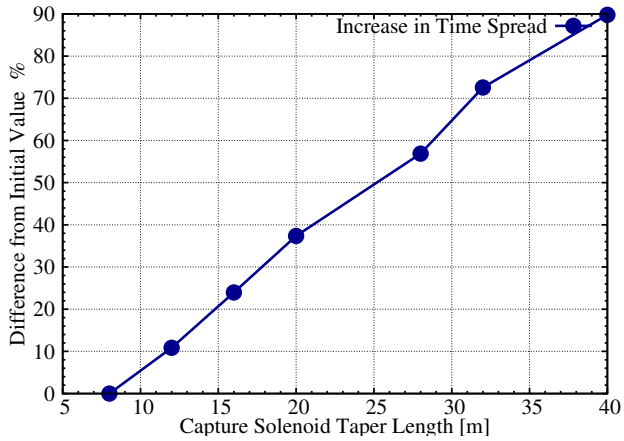

Figure 3: Relative increase in the time spread of the muon beam at the end of the Decay Channel as a function of the taper length. The distance from target to end of Decay Channel is constant.

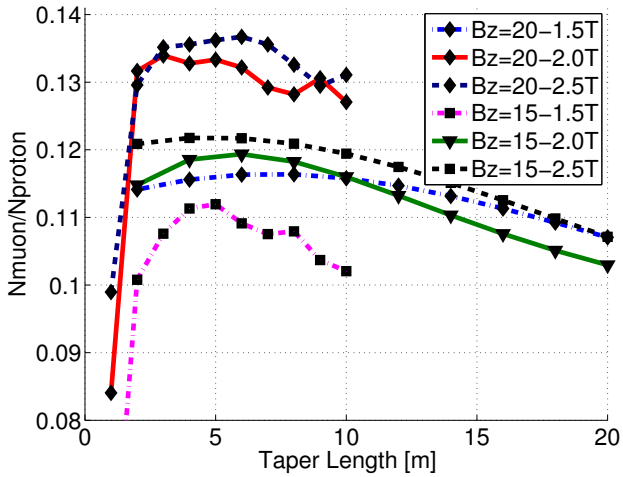

Figure 4: Muon yield after the transverse Ionization Cooling Channel, within the acceptance of the following accelerator chain, *vs.* the target solenoid taper length. Optimum yield is at taper length of 4-6 m.

an 8-GeV proton beam incident on a Hg-jet target, with solenoid-field profile tapering from 20 down to 2.5 T. The short taper looses its advantage gradually as bunch lengths increase from 1 to 20 ns. Bunches with length of 20 ns and longer will not benefit from the short-taper effect.

A similar study was carried for an initial Neutrino Factory with a 3-GeV proton beam on a graphite target and peak solenoid field of 15 T, with results shown in Fig. 6. The tracking study was done for a target solenoid taper length of 4 m and end field of 2.5 T. For this case the loss is $\approx 5\%$ per 1 ns increase in bunch length.

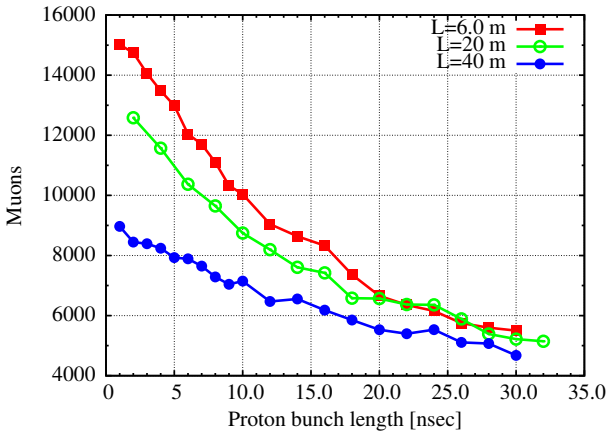

Figure 5: Number of positive muons within the accelerator chain acceptance *vs.* the initial proton bunch length for 8 GeV proton beam on a Hg-jet target. The tracking study was done for different target solenoid taper length of 6, 20, 40 m (red, green, blue). The short taper loses its advantage gradually as the bunches get longer.

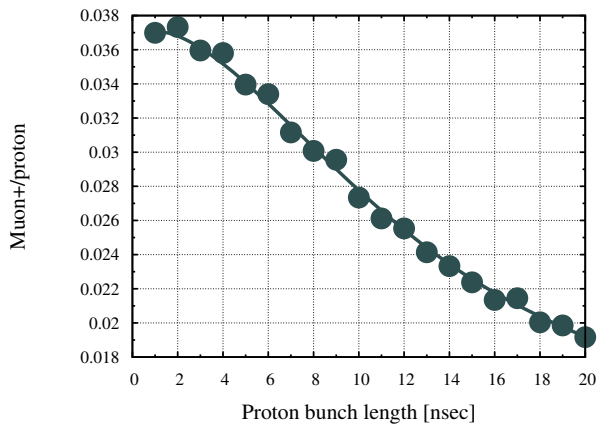

Figure 6: Number of positive muons within the accelerator-chain acceptance *vs.* the initial proton bunch length for 3-GeV proton beam on a graphite target. The tracking study was done for a target solenoid peak field of 15 T, taper length of 4 m, and end field of 2.5 T. For this case the loss is $\approx 5\%$ per 1 ns increase in bunch length.

PERFORMANCE OF THE DESIGN BUNCH LENGTH 2-8 NS

The performance of the Front End at various design bunch lengths of 2, 5, 8 ns *vs.* the target-solenoid taper length is shown in Fig. 7. For bunch lengths of interest for a Muon Collider and Neutrino Factory (2-8 ns), the short taper holds its advantage. The difference in performance of the front end between a 2 and 8 ns decreases gradually with the taper length.

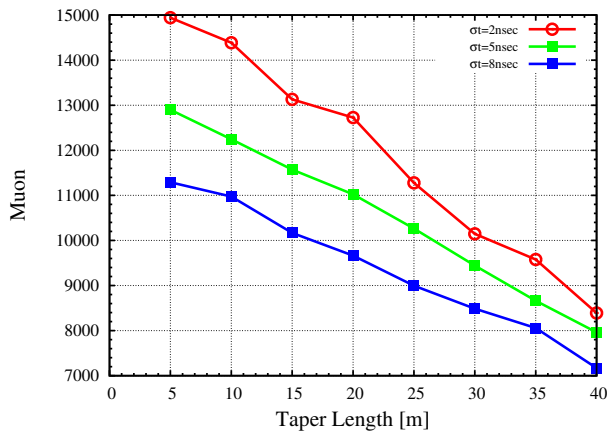

Figure 7: Number of positive muons within the accelerator-chain acceptance *vs.* the target solenoid taper length at three different bunch lengths of 2, 5, 8 ns.

Abstract

The baseline design for the Front End of a Neutrino Factory and Muon Collider consists of a five major components, namely the Target System, Decay Channel, Buncher, Phase Rotator, and the Ionization Cooling Channel. Although each of the mentioned systems has a complex design which is optimized for the best performance with its own set of local objectives, the integration of all of them into one overall system requires a global optimization to insure the effectiveness of the local objectives and overall performance. This global optimization represents a highly constrained multi-objective optimization problem. The objectives are the number of muons captured into stable bunches of specified transverse and longitudinal emittances, as constrained by the momentum-and dynamic-acceptance of the subsequent acceleration systems in addition to the overall cost. A multi-objective global evolutionary algorithm is employed to address such a challenge. In this study a statement of optimization strategy is discussed along with preliminary results of the optimization.

INTRODUCTION

The capture efficiency of muon Front End [1] of a Neutrino Factory and Muon Collider [2] determines the luminosity of both machines. In the Neutrino Factory scenario only a 4D transverse Cooling Channel is considered, while in the Muon Collider a charge separation follows the Front End before the 6D Ionization Cooling.

The muon beam is produced by bombarding a pion-production target with a 4-MW proton beam that is pulsed at 50 Hz. Produced pions travel through a constant-field solenoid Decay Channel where they decay into muons. Following the Decay Channel, muons go through bunching, phase rotation, cooling, and acceleration sections. Previous studies [3] have shown that using the global Front End performance as the figure of merit in the optimization of local systems improves the performance in a significant way. In this study we identify the parameters in each of the major subsystems of the Front End major that have an impact on the integrated performance, then we optimize the design accordingly.

TARGET AND MUON FRONT END

The Target System is designed to deliver intense muon beam of 10^{14} muons/sec from an incident beam of 10^{15} protons/s. In the baseline design a liquid-mercury jet target intercepts the 8-GeV proton beam inside a solenoid field that peaks at $B_i = 20$ T at the target and tapers down to $B_f = 1.5$ T over a distance of $L_{\rm taper} = 15$ m. The portion of the mercury jet disrupted by the proton beam is replaced before the arrival of the following proton pulse. This baseline configuration produces 0.8 muons/proton at the end of the Target System.

After the particles leave the tapered target solenoid they are transported in the Decay Channel, Buncher, and Phase Rotator in a constant solenoid field, nominally 1.5 T. At the end of the Decay Channel, $\approx$ 70 m from the target, most pions have decayed into muons and the beam is about 15 m long. The beam is then bunched over $\approx$ 33 m in a sequence of RF cavities with frequencies from 320 to 230 MHz that capture muons with kinetic energy ranging from 50-400 MeV. The bunching cavities RF voltage increases linearly along the channel from 3.4 to 9 MV/m.

In the 42-m-long phase-rotation section, lower-energy muons are accelerated and higher-energy ones are decelerated, until at the end of the Rotator the central momentum is 232 MeV/c, and the original 15-m-long bunch of muons of both signs has been formed into a 48-m-long train with 33 bunches of μ^+ interleaved with 33 bunches of μ^-. The muon beam is then matched into the alternating, 2.8-T solenoid field in the Cooling Channel.

OPTIMIZATION STRATEGY

In this section we identify the parameters in each subsystem that we consider in the global optimization. In the next section we will show the improvement on the performance after optimizing each of those parameters.

Capture Solenoid

The target-solenoid field is parameterized in three variables, the peak initial field at the target location, the taper length, and the end solenoid field. For this study the peak field was either 20 or 15 T The effect of solenoid field profile on the phase space density and distribution of the captured muons was studied by simulating the particles produced at the target and transported through the rest of the Front End. The target-solenoid field profile was shown to

Copyright © 2013 CC-BY-3.0 and by the respective authors

have a significant effect on the performance of the front end [4]. Here, we consider optimizing the capture efficiency as a function of the final asymptotic end field and the length of the taper as well.

Decay Channel, Buncher and Phase Rotator

Muons are confined in the Decay Channel, Buncher, and Phase Rotator by a series of constant-field focusing solenoid coils.

The muon/pion bunch lengthens as it drifts through the Decay Channel, developing a high-energy head and a low-energy tail which depends on the Channel length. We considered a multivariable optimization of the target-solenoid taper length, RF phase and the Decay Channel length at various taper end-field values. Figure 1 shows the process of optimizing the Decay Channel length with the figure of merit being the total number of muons within the acceptance cuts of the accelerator [5].

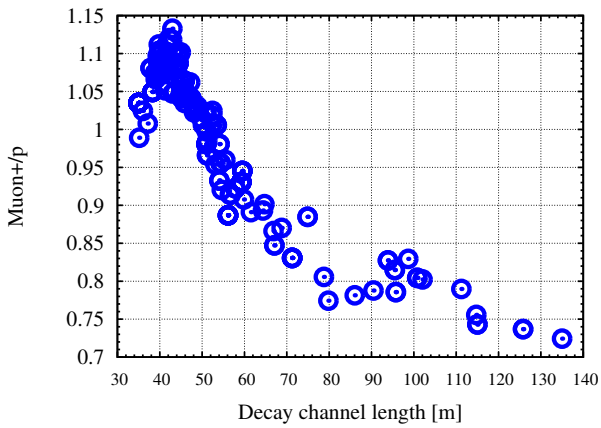

Figure 1: Optimizing the Decay Channel length using a differential evolution algorithm.

The effect of the solenoid field strength on the performance of the Front End was studied, including dynamic losses due to resonances ("stop bands") in the periodic field structure. The coil design was optimized to suppress those dynamic losses.

As the taper length of the target solenoid was optimized, the RF phases of the Buncher and Phase Rotator were also varied to find the optimal working point. Figure 2 illustrates an optimization of overall RF phase.

Broadband Match to Ionization Cooling Channel

While the muons are confined with a constant solenoid field starting from the Decay Channel to the end of the Rotator, the field in the Cooling Channel is generated by alternating solenoid coils of ± 2.8 T strength. The muon-beam phase-space ellipse would experience filamentation and emittance growth without matching between the region regions of constant and alternating solenoid fields. The muon beam out of the Phase Rotator has a large momentum spread, as shown in Fig. 3. A set of 9 solenoid coils

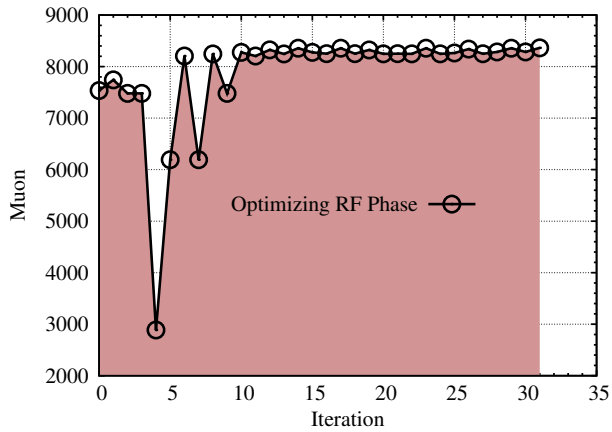

Figure 2: Optimization of the phase of the Buncher and Rotator RF cavities. Each iteration represent a trial value of the RF phase.

were considered to perform the match between the Rotator and the Cooling Channel. The objective of this optimization was constructed as a sum of the emittance magnification factor [6], eq. (1), at various momenta weighted by the number of muons within the vicinity of a central momentum,

$$EM = \frac{1}{2}\left[\frac{\beta_b}{\beta_s} + \frac{\beta_s}{\beta_b} + \left(\sqrt{\frac{\beta_b}{\beta_s}}\alpha_s - \sqrt{\frac{\beta_s}{\beta_b}}\alpha_b\right)^2\right], \quad (1)$$

where β_b and α_b are the beam ellipse parameters and β_s and α_s are the periodic solution for the Cooling Channel. Figure 4 shows the number of accepted muons along the Front End before and after the match.

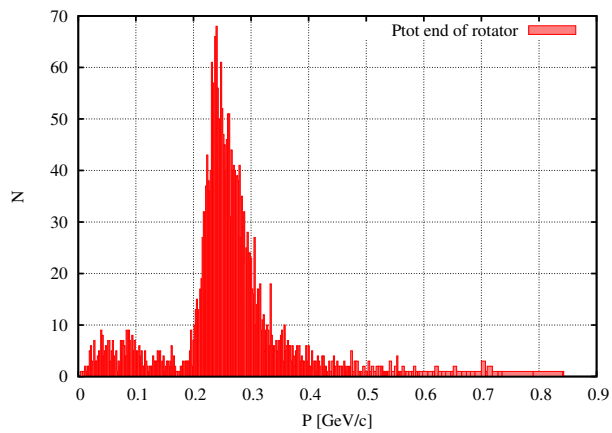

Figure 3: Muon beam momentum distribution at the end of the Phase Rotator.

HIGH PERFORMANCE COMPUTING OPTIMIZATION TECHNIQUES

A set of parallel, differential-evolutionary-optimization algorithms working on a CRAY based architecture [7] were

utilized and integrated with a parallel, Monte-Carlo-based, ionization-cooling-and-transport code ICOOL [8].

RESULTS

A first round of the global optimization of the Front End (which included parameters from the target solenoid taper, Buncher and Rotator RF phases, Decay Channel length and field strength, broadband matching to Cooling Channel) showed significant improvement of the performance of the Front End. Figure 5 shows the optimized performance of the Front End *vs.* the constant solenoid field, with an improvement of 15% above the unoptimized baseline field of 1.5 T, increases to 60% improvement at 3.5 T. An increase of the focusing field from 1.5 T to 2 T would improve the performance by 40% which represents a substantial increase in the performance of a mild rise in the cost.

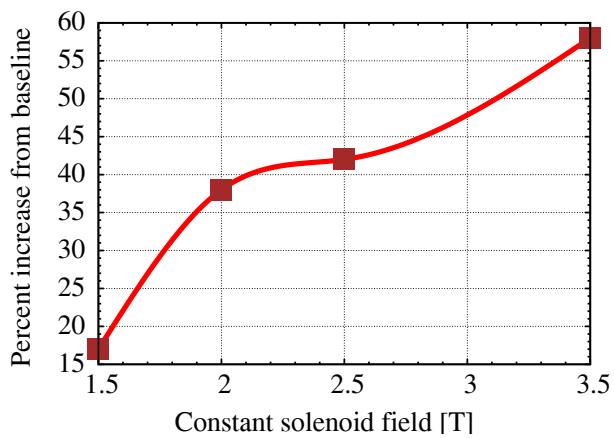

Figure 5: Optimized performance of the Front End *vs.* the constant solenoid field in the Decay Channel, Buncher, and Phase Rotator.

SUMMARY AND FUTURE WORK

A global optimization strategy for the muon Front End was presented. The first round of the multivariable optimization showed improvement by $15 - 60\%$ over the current baseline. Future work will include optimization of parameters of the Ionization Cooling Channel (focusing field, RF phase and RF gradient, absorber configuration).

DESIGN OF THE ILC RTML EXTRACTION LINES FOR THE RENOVATED TWO-STAGE BUNCH COMPRESSOR

S. Seletskiy#, NSLS, BNL, Upton, NY 11973, U.S.A.
N. Solyak, FNAL, Batavia, IL 60510, U.S.A.

Abstract

The renovated two-stage bunch compressor (BC) in the International Linear Collider (ILC) Damping Ring to the Main Linac (RTML) beamline requires new design for the extraction lines (ELs). The ELs located downstream of each stage of the BC will be used for both an emergency abort dumping of the beam and the tune-up continuous train-by-train extraction. They must accept both compressed and uncompressed beam with energy spread of 1.4% and 0.1% respectively. In this paper we report the design that allowed minimizing the length of such extraction lines while offsetting the beam dumps from the main line by 5 m distance required for acceptable radiation level in the service tunnel. Proposed extraction lines can accommodate beams with different energy spreads at the same time providing the beam size suitable for the aluminum ball dump window.

INTRODUCTION

It was decided [1-3] to incorporate a two stage bunch compressor [4] into the final design of the ILC [5]. The renovated two-stage BC compresses 6 mm long beam to 0.3 mm. The beam energy and energy spread after the first stage of the BC are 4.8 GeV and 1.4 % respectively. The beam energy after the second stage is 15 GeV and the beam energy spread, while it depends on the ILC operational mode, is 1.26 % at maximum.

The two extraction lines (ELBC1 and ELBC2) considered in this paper are located downstream of respective stages (BC1 and BC2) of the bunch compressor. The ELs can be used for either an emergency beam abort or for a train-by-train extraction. Since these ELs might receive both compressed and uncompressed beam, they must accept beams with both low and high energy spread.

Each extraction line is equipped with the 220 kW aluminum ball dump, which corresponds to the power of the continuously dumped beam with 5 GeV energy.

EXTRACTION LINES REQUIREMENTS

There are multiple requirements to the extraction lines:

- Due to the requirements of acceptable radiation levels in the service tunnel, horizontal offset of the dump from the main beamline must be at least 5 m center-to-center [6].
- The beam size on the dump window must be at least $\pi\sigma_x\sigma_y$=12 mm^2. Such beam size allows the use of an aluminum window on the dump.
- The beamline apertures have to be large enough to accommodate the beam. The RMS energy spread of the beam can be as large as 1.4% (for ELBC1). Additionally, a reasonable limit for the horizontal β-function is about 5 km. Since one might want to run beams with energy spread of 0.04% (for ELBC2 taking 15 GeV uncompressed beam) to the dump the beam size due to dispersion is no help in maintaining the required beam size on the dump window.
- The elements of the straight-ahead beamline and the extraction beamline must have enough transverse clearance.
- One has to arrange for both the train-by-train extraction and emergency abort of the beam, i.e., the emergency abort kicker has to ramp from zero to full strength in less than the minimum bunch spacing of 150 nsec.
- The magnets must be physically realizable. Here we limit ourselves to 1 T pole-tip fields for the quads, 1.5 T fields for the bends, and 0.05 T fields in septum magnets [6].
- The extraction line must be made as short as possible.

Requirements to the ELs in the final RTML are similar to the requirements specified in [6]. As a matter of fact the extraction system of new ELs is copied from 2008 solution.

EXTRACTION SYSTEM

The abort extraction of the beam is performed by four 2 m long fast kickers, which are powered to 35 G with a rise time of about 100 ns. Routine tune-up beam extraction is performed by a single 1 m long pulsed bend located between two central kickers. The bend is excited to 280 G to make its bending angle compatible with the cumulative angle provided by four fast kickers.

EXTRACTION LINES IN LINEAR APPROXIMATION

To satisfy aforementioned requirements, the linear lattices of ELBC1 and ELBC2 are designed in accordance with the concept considered in details in [6].

To decouple the dispersion and beam size issues we use Double Bend Achromats (DBA) as EL bending blocks. The extraction line is built of the cells, which have periodic solution for the Twiss parameters, and consist of DBA and focusing quads. Number of cells is determined by requirement to sufficient separation between the beam

#seletskiy@bnl.gov

dump and the main line.

The linear solutions for the ELBC1 and ELBC2 are presented in Fig. 1 and 2 respectively.

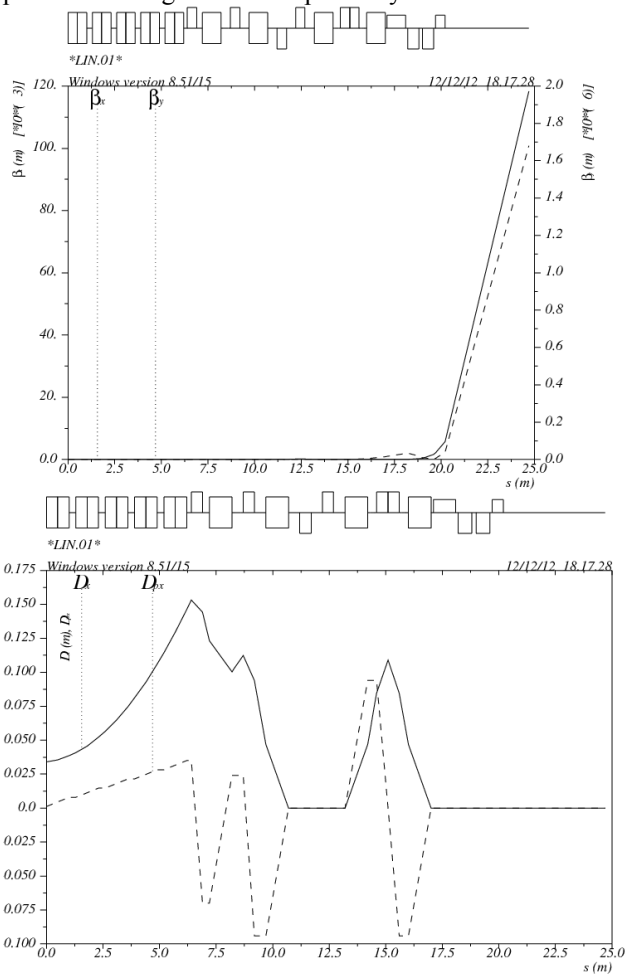

Figure 1: Twiss parameters and dispersion in ELBC1.

The extraction is initiated by a set of septum magnets (5 for ELBC1 and 6 for ELBC2) deflecting the beam from the main beamline by distance large enough to accommodate regular bends and quads. The septa are followed by a dispersion matching section consisting of two bends and two quads, which are tuned to zero the dispersion at the exit of the section.

The periodic cells (one for ELBC1 and two for ELBC2) following the dispersion matching section separate the dump from the main line by required distance. The quads at the end of the dump line are used to blow up the beam size on the dump window to the specified requirements. The resulting lengths of ELBC1 and ELBC2 are 24.7 m and 45.8 m respectively.

BEAM DUMP

The 220 kW aluminum ball dump [6] will be used for each of the lines. A nominal dump window diameter is 12.5 cm.

Calculations show that an aluminum window using a 1 mm thick hemispherical design is feasible for a suggested aluminum sphere dump. It has the promise of long term safe operation, with beam spot area on the dump window larger than 12 mm^2. There are no steady state heat transfer issues to reject the energy deposited by the beam to the cooling water.

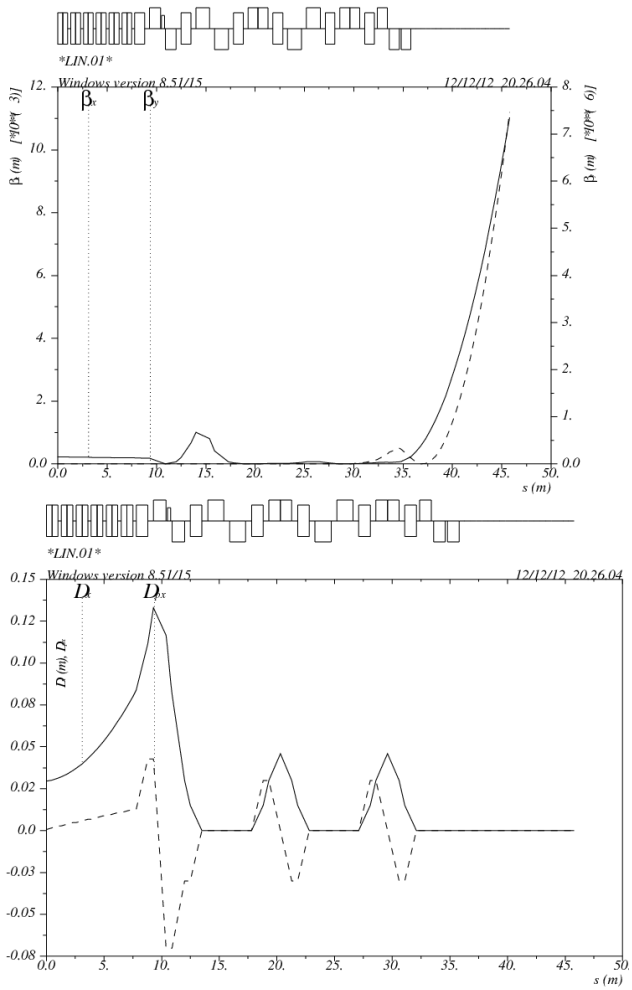

Figure 2: Twiss parameters and dispersion in ELBC2.

NONLINEAR EFFECTS

For a beam with a high energy spread there is a substantial blow-up of beam size at the end of the ELs. In Y direction the growth of the beam halo is due to chromatic aberrations, while in X direction it is because of both chromatic aberrations and nonlinear dispersion.

While the beam with small energy spread is contained within the envelope of reasonable size, the high energy spread beam explodes in horizontal size making the optical solution for the EL obtained in linear approximation unfeasible.

In the previous designs of the 2-stage BC extraction lines a number of solutions that mitigate the nonlinear halo were considered, including collimators, superconducting quads of large aperture and large diameter dump window. On the other hand, for the single stage BC there was found an extraction line solution [7] that uses relatively weak sextupoles for containing the nonlinear halo and doesn't require any additional beam collimation.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Following the recipe adapted from single stage BC EL solution, we found that for ELBC1 the two sextupoles can contain the nonlinear hallo of the high energy spread beam. Such beam can be accommodated by the dump window of nominal 12.5 cm diameter, and there is no need in additional collimation. As Fig, 3 demonstrates, both high energy and low energy beam sizes are within the limits allowing for transporting through the EL and for utilization of nominal size dump window.

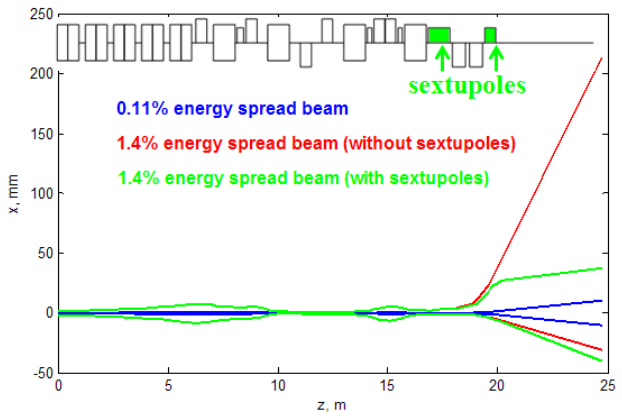

Figure 3: The horizontal beam size evolution through the extraction line for 1.4% (red – without sextupoles, green with sextupoles) and 0.11% (blue) energy spread beams.

In case of ELBC2 we found that the high energy spread beam can be contained with the help of only one sextupole strategically placed at the location of highest dispersion. Figure 4 shows that sizes of both low- and high-energy spread beams allow utilizing aluminum ball beam dump with a dump window of 12.5 cm diameter.

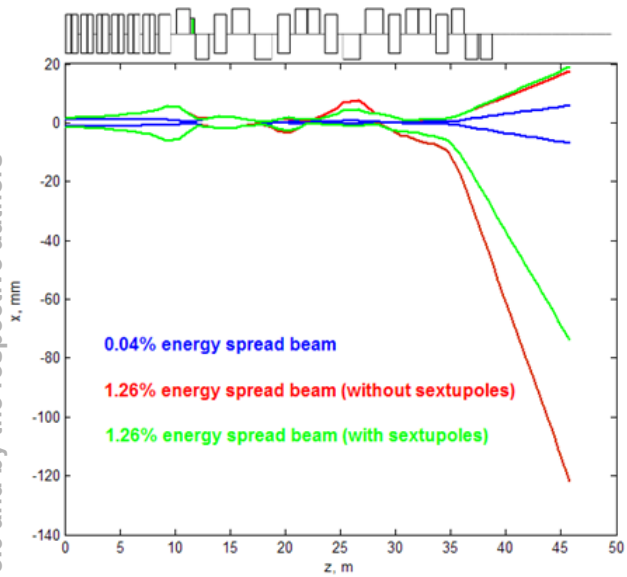

Figure 4: The horizontal beam size evolution through the extraction line for 1.26% (red – without sextupoles, green with sextupoles) and 0.04% (blue) energy spread beams.

CONCLUSION

We described the final design of the ILC RTML extraction lines located downstream of each stage of the renovated two-stage bunch compressor. The extraction lines are only 24.7 m and 45.8 m long. They are capable of accepting and transmitting 220 kW of beam power. The ELs can be used for both fast intra-train and continual extraction, and are capable of accepting both low- and high-energy spread beams.

NS-FFAG FOR ELECTRON-ION COLLIDER IN RHIC (ERHIC)*

D. Trbojevic, J. S. Berg, S. Brooks, O. Chubar, Y. Hao, V. N. Litvinenko, C. Liu, W. Meng, F. Meot, B. Parker, V. Ptitsyn, T. Roser, N. Tsoupas, and W. T. Weng, BNL, Upton, New York, USA

Abstract

A future electron ion collider "QCD test facility" is designed in the present Relativistic Heavy Ion Collider (eRHIC) tunnel. Electron acceleration and de-acceleration is preformed with energy recovery linac with multiple passes. We report on a combination of a multi-pass linac with the Non-Scaling Fixed Field Alternating Gradient (NS-FFAG) arcs. A single NS-FFAG arc allows electrons to pass, in the first stage of eRHIC, through the same structure with an energy range between 1.28 and 10 GeV. The NS-FFAG is placed in the existing RHIC tunnel. The 100 MeV injector bring the polarized electrons to the 0.9 GeV superconducting linac. After three passes through the linac 2.8 GeV electrons enter NS-FFAG arc and after 8 passes reach the energy of 10 GeV. After collisions the beam is brought back by the NS-FFAG, decelerated to the initial energy and directed to the dump.

INTRODUCTION

The eRHIC, future "QCD factory", will provide collisions between polarized electrons and: polarized protons in an energy range of 100-250 (325) GeV; light ions (d, Si, Cu); heavy ions 50-200 (130) GeV/u; and, polarized He^3 215 GeV/u. Electrons will circulate in the present RHIC tunnel as shown in Figure 1.

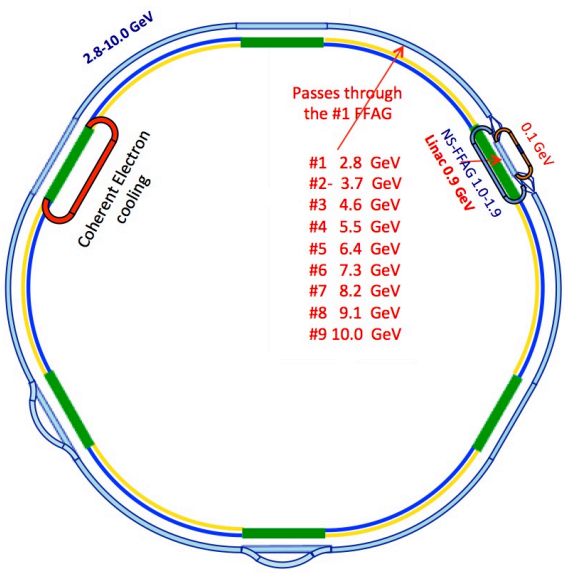

Figure1: Schematic layout of the electron NS-FFAG in the RHIC tunnel – blue and yellow superconducting ion rings are shown, as well as the position of the coherent electron cooling.

The Energy Recovery Linac (ERL) is proposed due to the beam-beam tune shift limitation in the ring-ring case for achieving higher luminosities and due to ability to recover the energy of ~1 GW with a dump energy equal to the injection energy. To reduce the cost and number of elements in the tunnel, a single NS-FFAG ring is proposed with an energy acceptance between 2.8-10 GeV for the first stage of eRHIC.

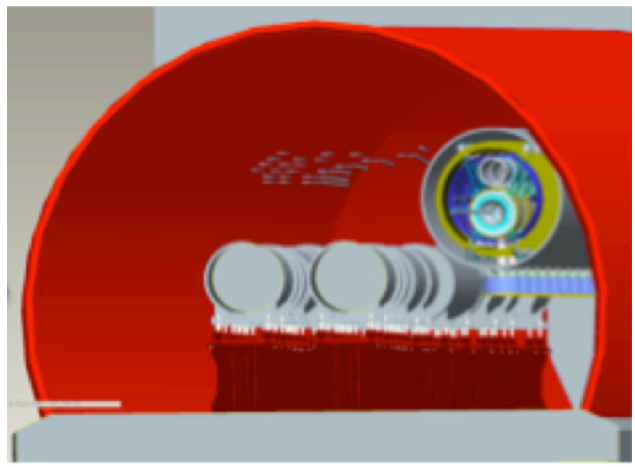

Figure 2: Two RHIC rings with electron linac on the right side above.

Non-Scaling FFAG

Revival of the Fixed Field Alternating Gradient (FFAG) accelerators previously developed in fifties [1,2,3] is very evident. They have very large momentum acceptance with beam accelerated under a constant magnetic field. The scaling FFAG have been mostly built in Japan: started with a the proof of principle (POP) proton accelerator at KEK, the 150 MeV proton accelerator (presently at the Kyushu University), 150 MeV accelerator at Osaka University, and many electron scaling FFAG's built for different applications. Although the scaling FFAG's have an advantage of the fixed magnetic field the synchrotrons are dominant accelerators in spite of magnetic field variation with energy. This is mostly due to significantly smaller aperture requirements. Large aperture magnets accommodate for the large orbit offsets. The aperture size is significantly reduced with the Non-Scaling FFAG's (NS-FFAG) [4]. The maximum of the orbit offsets are -18.6 mm$<\Delta x<0$ in the example presented. The NS-FFAG has fixed magnetic fields designed for the reference momentum. The maximum electron energy of 10 GeV, in the first stage of eRHIC, is selected for the reference energy with circular beam orbit. This is to reduce the synchrotron radiation, as the radius of the curvature is r=318 m.

NS-FFAG 2.8-10 GEV

The electron ring follows the shape of the RHIC tunnel and six arcs have 132 identical NS-FFAG cells. Each cell

* Work performed under Contract Number DE-AC02-98CH10886 with the auspices of the US Department of Energy

Copyright © 2013 CC-BY-3.0 and by the respective authors

is made of three combined function magnets: the central 1.25 m long is a defocusing magnet with a gradient of G_D=-17.9 T/m and dipole field of B_D=0.1T, while the two surrounding, 0.5m long, are focusing magnets with a gradient of G_F=23.7 T/m and dipole field of B_F=0.1 T. Properties of a NS-FFAG cell are shown in Figure 3.

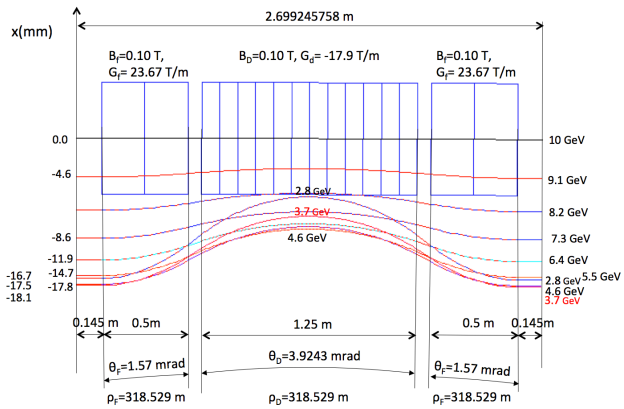

Figure 3: Basic NS-FFAG cell properties.

The tune dependence on energy is shown in Figure 4.

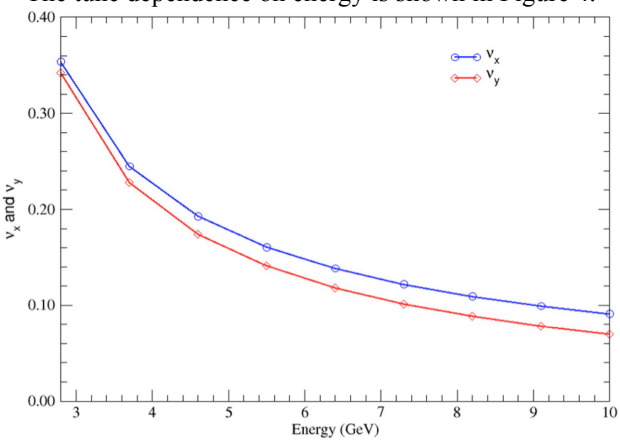

Figure 4: Betatron tunes dependence on energy.

The path length in NS-FFAG has a parabolic function with respect to the beam energy range with a minimum corresponding to the momentum compaction or transition energy equal to zero. A relation ship between bending angles Ratio=θ_F/θ_D of the two magnets defines the shape of the parabola as shown in Figure 5. The ratio of Ratio=θ_F/θ_D =0.4 was selected to allows for almost symmetric dependence in the time of flight with respect to the medium energy of E=6.4 GeV and the largest bending radius to reduce the synchrotron radiation.

A connection of the NS-FFAG to the linac is presented in Figure 6. The spreaders on one side of the linac and combiners on the other side allow at the same time adjustment of the time of flight for each energy so the bunches arrive at linac at the top of the linac RF wave or if they are decelerated to the bottom of it.

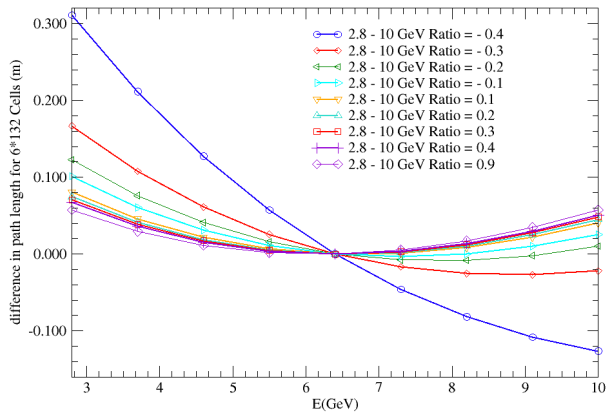

Figure 6: The six arcs time of flight dependence on the ratio between to angles of bending of the two magnets.

The maximum orbit offset dependence on the ratio between the two magnets is presented in Figure 7.

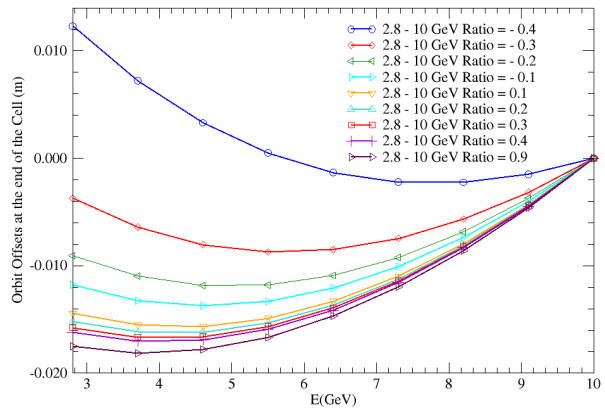

Figure 7: Maximum of the orbit offsets dependence on energy for different ratios of the bending angles θ_F/θ_D.

2.8-10 GeV Magnet Design

The defocusing combined function magnet made of combination between the permanent magnet SmCo is shown in Figure 8.

A magnet design for the focusing combined function magnet is shown in Figure 9.

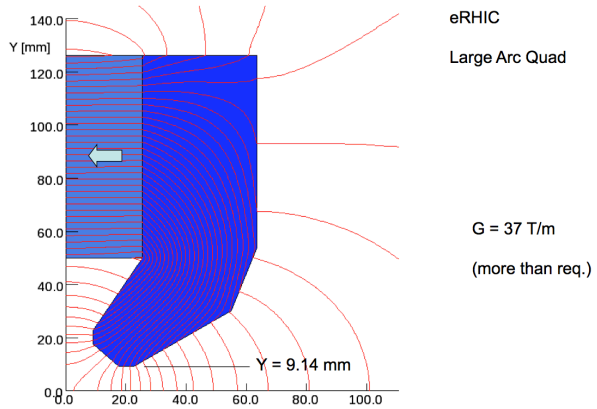

Figure 9: Focusing combined function magnet.

1-1.9 GEV NS-FFAG

The area around interaction region at 4 o'clock is selected for placement of the linac, injector and the NS-FFAG racetrack for two passes of electron beam with energy of 1 and 1.9 GeV. The 90 MeV injector receives electrons with energy of 10 MeV from the polarized electron source as schematically shown in Figure 10.

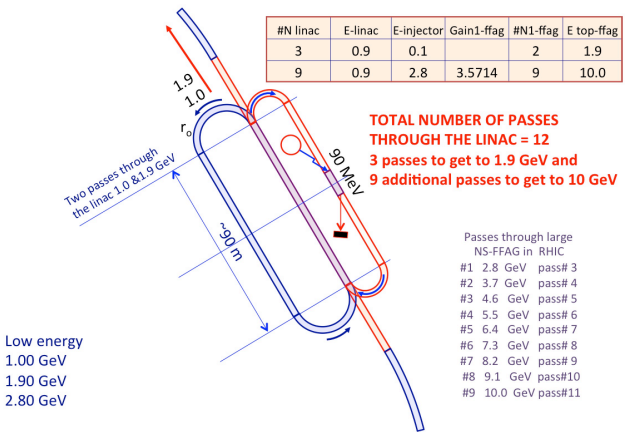

Figure 10: Schematic presentation of the linac with the injector, polarized electron source, and small NS-FFAG.

The new civil construction will be necessary for the small NS-FFAG ring as shown in Figure 11.

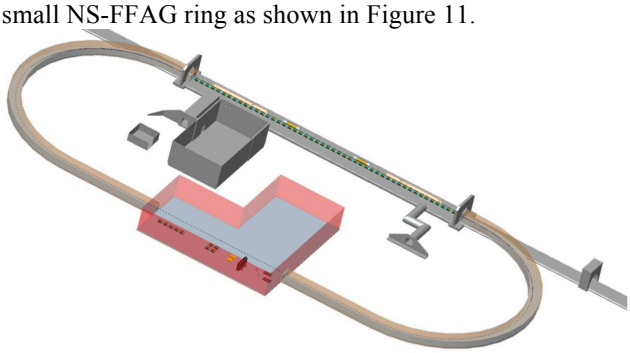

Figure 11: Linac and small NS-FFAG layout.

The basic NS-FFAG cell for the two passes with energies of 1 and 1.9 GeV is shown in Figure 12.

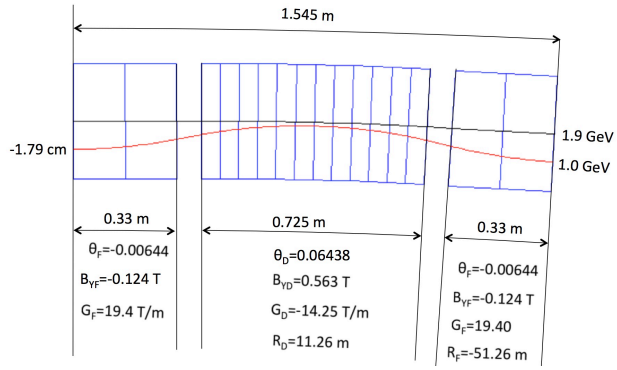

Figure 12: The NS-FFAG cell with two passes and 30 m radius of a curvature.

ORBIT CORRECTION

A random misalignment of the magnets, with a Gaussian distribution with maximum errors of 50, 100, and 150 μm, was implemented. Orbit for all energies were recorded and corrected with two correctors per cell.

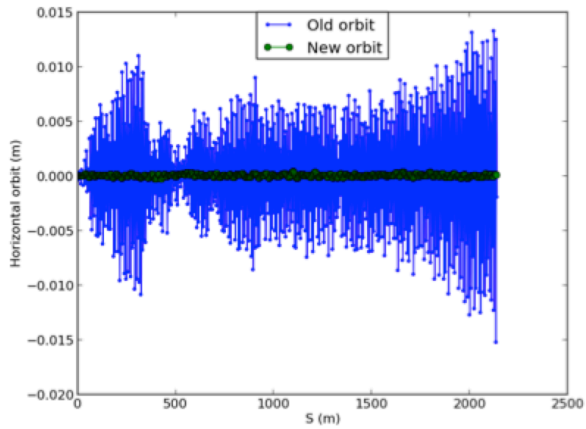

Figure 13: Correction of the orbit due to misalignment.

SUMMARY

A new approach of the NS-FFAG electron lattice design for the ERL eRHIC project is being studied. Two 2.8-10 GeV and 1-1.9 GeV NS-FFAG's lattices are designed and studied. Magnet design and beam dynamics studies are in progress.

DYNAMICAL BETA-SQUEEZE FROM 80 TO 40 CM AT RHIC*

Dejan Trbojevic, Jing Yichao, and Yun Luo, BNL, Upton, New York, USA

Abstract

Relativistic Heavy Ion Collider (RHIC) has been achieving record luminosities during the last decade. The latest stochastic cooling of the heavy ions, like uranium, achieved the largest luminosity at RHIC during the last heavy ion run. A betatron squeeze method, already used at LHC CERN, where a betatron wave is created through the arc up to the interaction region is applied at RHIC. When the heavy beam size is reduced due to stochastic cooling a dynamical beta squeeze is possible to apply in RHIC where the existing 75 cm value of beta-star could be reduced to 45 cm. This could be achieved by introducing the betatron wave in both planes throughout the arc before and after the interaction region. Higher values of dispersion and betatron functions in the arc, with a 90° degrees phase difference per FODO cell allow easier higher order chromatic corrections.

INTRODUCTION

The RHIC stunning discoveries in quark-gluon plasma in recent years went above any expectations that have captured worldwide attention. First and foremost was the unexpected "perfect"-liquid nature of the 4-trillion-degree quark-gluon plasma that permeated the early universe. RHIC is now closing in on the transition from this hot quark-gluon plasma into ordinary matter made of protons and neutrons—namely everything we see in today's world. This is a report on an attempt to improve on the RHIC existing large luminosity by dynamically squeezing the beam size as the stochastic cooling succeeds in reducing all three emittances. The stochastic cooling has already shown tremendous success during the previous RHIC runs. Under this assumption an additional step might be possible in an attempt to increase further the luminosity by additional beta squeeze at the interaction point (IP). This would be possible as the emittances are reduced and the triplet aperture would not present the aperture limitation anymore – as the beam is getting smaller at the IP the maximum of the betatron functions become larger at the focusing triplet quadrupoles. A complex of the RHIC accelerators used to make the latest achievements is shown in Figure 1.

RHIC 90° Lattice

Advantages of the 90° degrees per cell lattice have been well known [1]. The LHC chromatic and other non-linear compensations [2] were followed for the RHIC lattice chromatic corrections after encouraging results in the eRHIC lattice design.

* Work performed under Contract Number DE-AC02-98CH10886 with the auspices of the US Department of Energy

Figure 1: The RHIC accelerator complex shows the major components Linac, Booster, Alternating Gradient Synchrotron (AGS), and RHIC. The Electron Beam Ion Source EBIS is an additional important element.

Major advantage of the 90° lattice is not only reduction in the intra-beam scattering effect but easier linear and non-linear chromatic correction as there are 24 sextupole circuits available in RHIC. The sextupole correction has already shown very impressive results in dynamical aperture improvements during the eRHIC lattice study. The betatron functions of the 90° RHIC lattice with β^*=75 cm is shown in Figure 2.

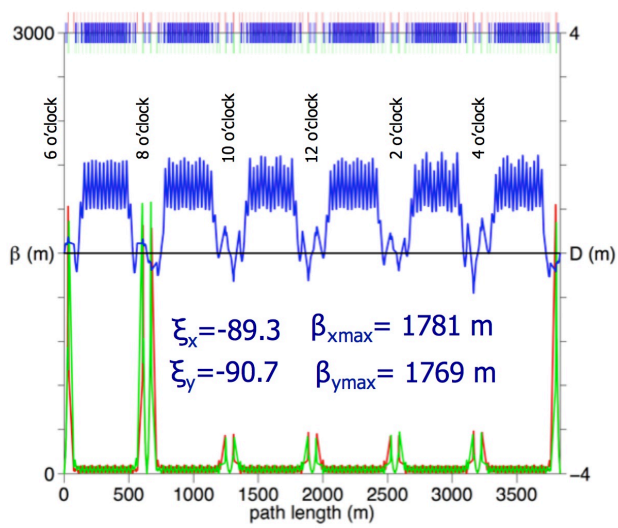

Figure 2: Betatron functions of the RHIC 90° degrees lattice with the β^*=80 cm. Two interaction regions at 6 and 8 o'clock have the same beam size.

Details of the lattice functions around one of interaction regions are shown in Figure 3. The maximum of the dispersion function is D_{max}=1.78 m. The lattice parameters

in both cases with the β^*=75 cm and β^*=45 cm are shown in Table 1.

Table 1. Betatron Functions for β^*=75 and 45 cm

β^*(cm)	β_{xmax}(m)	β_{ymax}(m)	ζ_x	ζ_y	D_{xmax}	D_{xmin}
75	1781	1769	-89	-91	1.76	-0.6
40	2985	3317	-108	-119	2.52	-2.6

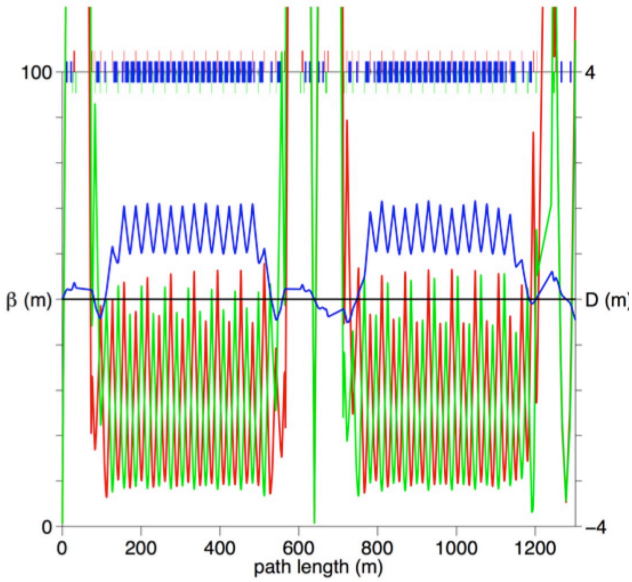

Figure 3: Details of the betatron functions around the IP for the β^*=75 cm.

The RHIC 24 sextupole circuits are shown in Figure 4.

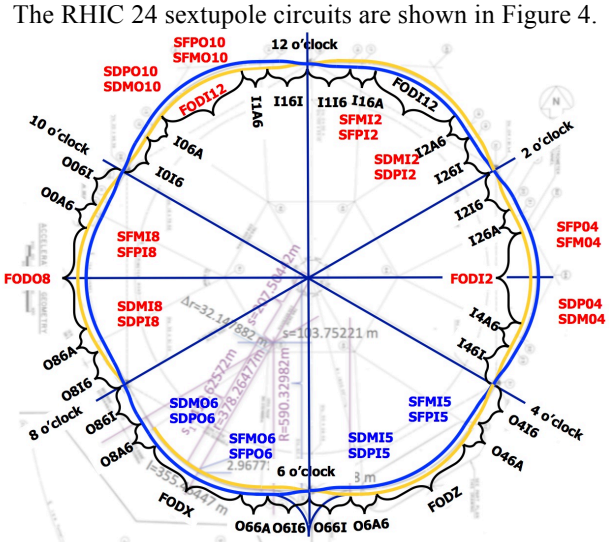

Figure 4: RHIC 24-sextupole circuits schematic.

Two pairs of quadrupoles are used around on each side of the interaction point IP-6 to induce the betatron wave through the IP6. At the end of the arc after the IP-6 there are two additional pairs in both horizontal and vertical plane used to cancel the wave, placed at correct betatron phase. A schematic presentation of the quadrupole pairs used in beta squeeze is shown in Figure 5. The quadrupoles in the pair are 90° degrees apart. The first quadrupole of the pair has a decrease in the gradient of ΔG=-7% while the second one has an increase of ΔG=+7%. The opposite is valid for the other plane at the beginning of the arc before the IP.

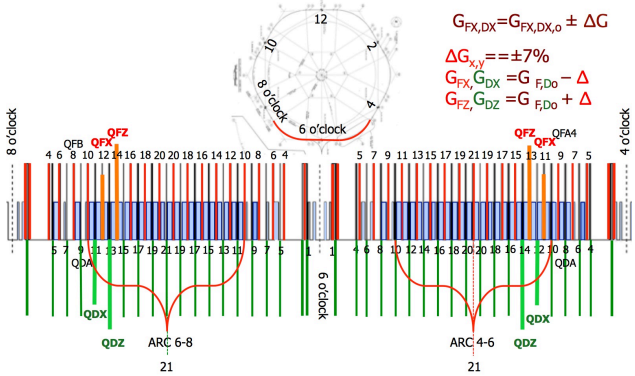

Figure 5: The quadrupole pairs to induce the beta wave are labeled QFX and QFZ, and QDX and QDZ at the beginning and end of the arcs.

The betatron functions in RHIC after introduction of the beta wave and beta squeeze is shown in Figure 6.

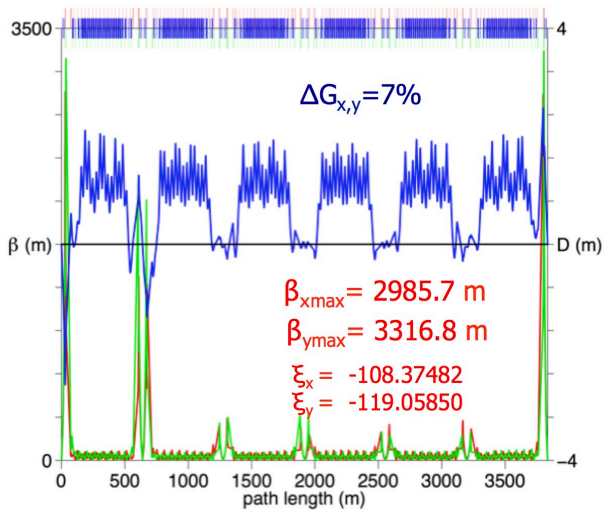

Figure 6: Betatron functions after the betatron wave is created through the IP 6.

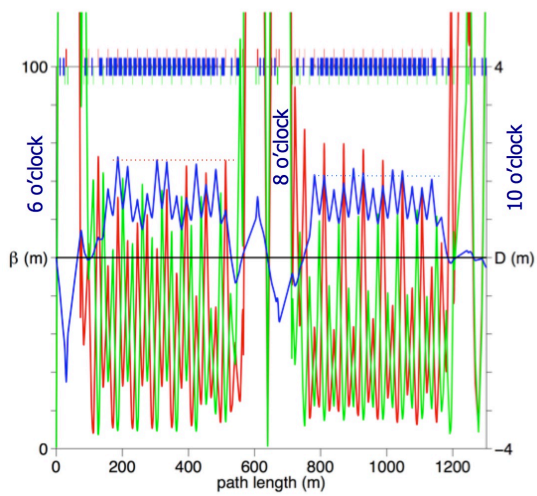

Figure 7: Details of the beta squeeze.

Details of the beta squeeze from β^*=75 cm to β^*= 45 cm in two arcs around the IP-6 are shown in Figure 7.

SUMMARY

The stochastic cooling in RHIC has showed incredible success getting to the point that almost all beam loss comes from collisions with other beam. As the cooling reduces emittances in all three dimensions it would be possible to gain more in luminosity by dynamically squeezing the size at the collisions as the beam gets cooled, as the maximum of the betatron functions at the triplets are not a limitation any more. This is a study with the lattice design trying to double the luminosity. The LHC [2] method was followed. A betatron wave through the interaction point IP-6 succeeded in reducing the β^* from β^*= 75 cm to β^*= 45 cm with the beta wave creation through the two neighboring arcs. The larger betatron functions and dispersion in the arcs will allow easier chromatic correction as the correction is given by $\sim K_2 \beta D_x$. The dynamical aperture study in this case is in progress.

ERHIC INTRACTION REGION AND LATTICE DESIGN*

D. Trbojevic, E. C. Aschenauer, V. N. Litvinenko, Y. Luo, Jing Yichao, B. Parker, and V. Ptitsyn
BNL, Upton, New York, USA

Abstract

A proposal for the new high luminosity L=10^{34} $s^{-1}cm^{-2}$ polarized electron proton/3He and other un-polarized heavy ions eRHIC based on Electron Recovery Linac (ERL), assumes a location in the existing tunnel of the operating Relativistic Heavy Ion Collider (RHIC). Requests of the experiments for the interaction region are very challenging: allow detection of neutrons, allow deep virtual scattering for protons-electron collisions, detection of partons with lower momentum, etc. We present an interaction region (IR) design with a vey high focusing where at the collision point IP of 5 cm, and a 10-mrad collision angle between electrons and ions using the crab cavities. We are introducing a combined function magnet for the first element in the high focusing triplet configuration to provide neutron and the lower energy parton detection, and allow at 4.5 cm distance passage of electrons through free magnetic field region. The 200 T/m gradient quadrupoles provide very small beam size at the IP and allows a passage with a very small magnetic field for electrons.

ERHIC PHYSICS

The RHIC stunning discoveries in quark-gluon plasma in recent years went above any expectations that have captured worldwide attention. First and foremost was the unexpected "perfect"-liquid nature of the 4-trillion-degree quark-gluon plasma that permeated the early universe. RHIC is now closing in on the transition from this hot quark-gluon plasma into ordinary matter made of protons and neutrons—namely everything we see in today's world. Continuation of the RHIC success will be a new polarized electron-polarized proton/He^3 and electron-ion collider the QCD lab (the quantum chromodynamics describes the strong forces). It would be determining quark and gluon contribution to the proton spin, what is the polarization of gluons, and what is the flavor decomposition of the polarized sea, what is the spatial distribution of quarks and gluons in nuclei, and to explore the strong forces – understand in detail the transition to the non-linear regime of strong gluon fields and the physics of saturation, and have a probe to study deep inelastic scattering.

IR LATTICE FOR HIGH LUMINOSITY

A choice for ERL in the eRHIC is due possibilities of obtaining higher luminosity as the beam-beam effect represents a limitation the ring-ring option. From an injector the beam is accelerated by the superconducting linac using several passes and reaching energies up to 20-30 GeV to be able to reach luminosities of L=10^{34} $s^{-1}cm^{-1}$. We describe an ion lattice and Interaction Region (IR) design to allow small beam sizes with β^*= 10 and 5 cm. It is assumed that coherent electron cooling will reduce the ion beam emittances, allowing very short bunches in the longitudinal space. The strong focusing is possible by placing the first magnet of the triplet at 4.5 m distance from the IP. The IR design is being developed together with the detector physicist designers. The IR in RHIC is made to be symmetric as shown in Figure 1 and in more detail in Figure 2.

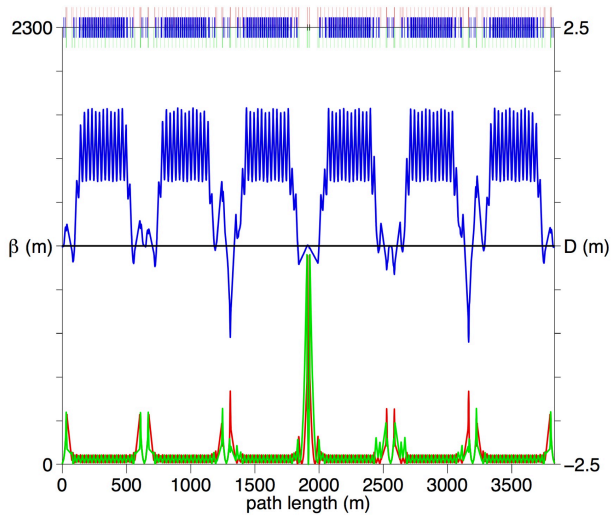

Figure 1: eRHIC lattice design with the β^*=10 cm at the single interaction region at 6 o'clock IP.

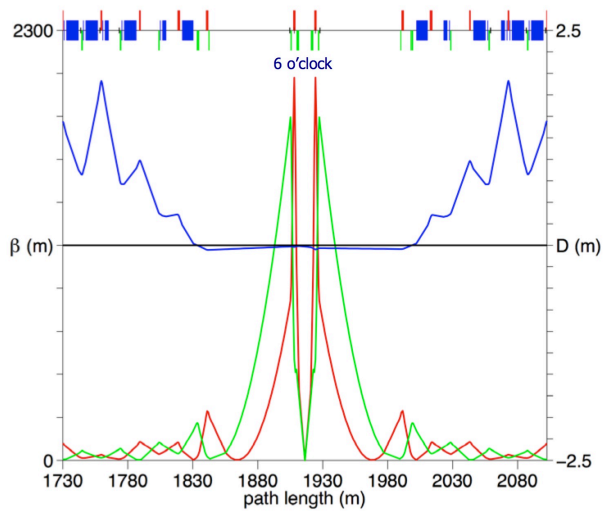

Figure 2: Details of betatron functions in the IR.

The maximum of the betatron function in the triplet magnets, the dispersion function, the chromaticities, and tunes for the β^*=10 cm are shown in Table 1. It is

* Work performed under Contract Number DE-AC02-98CH10886 with the auspices of the US Department of Energy

Copyright © 2013 CC-BY-3.0 and by the respective authors

important to note that the natural chromaticities of the ion eRHIC lattice are smaller than the RHIC chromaticities at RHIC the operating conditions.

Table 1. Betatron Functions for β^*=10, 5 cm

β^*(cm)	β_{xmax}(m)	β_{ymax}(m)	ζ_x	ζ_y	D_{xmax}	D_{xmin}
10	1100	1103	-89	-83	1.56	-1.1
5	2209	2210	-134	-113	1.94	-1.6

The layout of the interaction region in eRHIC is schematically presented in Figure 3.

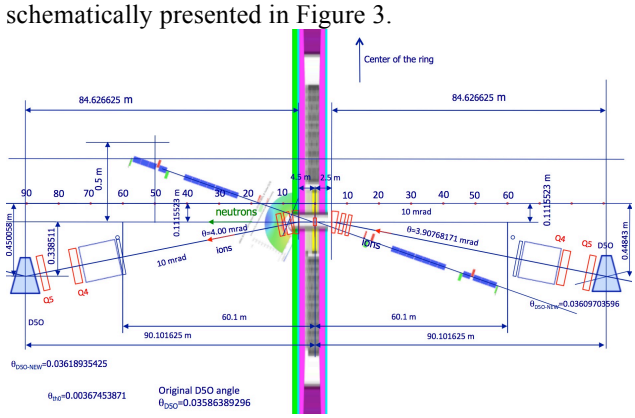

Figure 3: Layout of eRHIC interaction region.

Schematic presentation of the interaction region magnets downstream of the electron-ion or polarized proton or He^3 collisions is shown in Figure 4. The solid angle of neutron is obtained by use of a combined function magnet – (shown in orange color). The electron beam passes through the zero field region of the combined function magnet as shown in Figure 5.

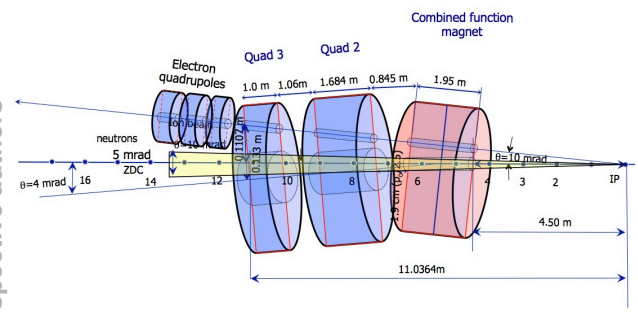

Figure 4: The triplets for both electron and ion lattice eRHIC IR layout with neutron solid angle (yellow).

A dipole coils are added to the solenoid of the detector to allow bending of electrons for an angle of 10 mrad. The combined function magnet is followed by the 200 T/m gradient quadrupoles. The combined function magnet bends the beam for 4.5 mrad allowing neutron detection downstream. The vertical axis in Figure 3 is centimeters while the horizontal axis is in meters. The detector is shown in looks distorted as due to different scale.

The RHIC lattice in the arcs is made of 90° phase difference per cell in the arcs. The LHC chromatic corrections were used in his design. The beam squeeze with a β^*=10 cm does not result in a very large natural chromaticities as shown in Table 1. The beam squeeze from 10 cm to 5 cm is realized by introduction of the betatron waves in both planes. The wave is created by changing the quadrupole gradients (ΔG= 7% with respect to the regular arc quadruple gradients) in two quadrupole pairs at the beginning of the arc before the IP.

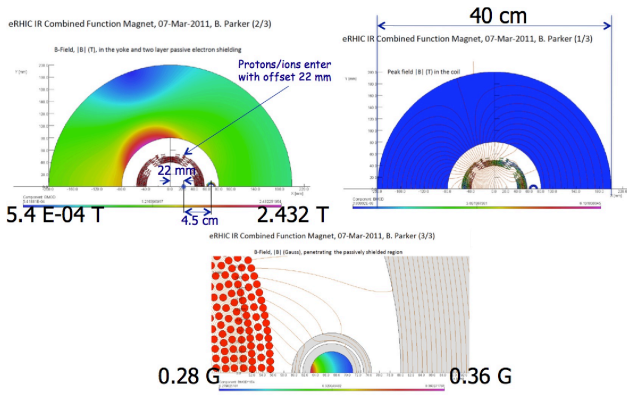

Figure 5: Combined function magnet with three different functions at the same time: bend the ions for 4.5 mrad, field free region for electron passage, and neutron detection downstream.

The layout of the sextupoles in the eRHIC ion lattice is shown in Figure 6.

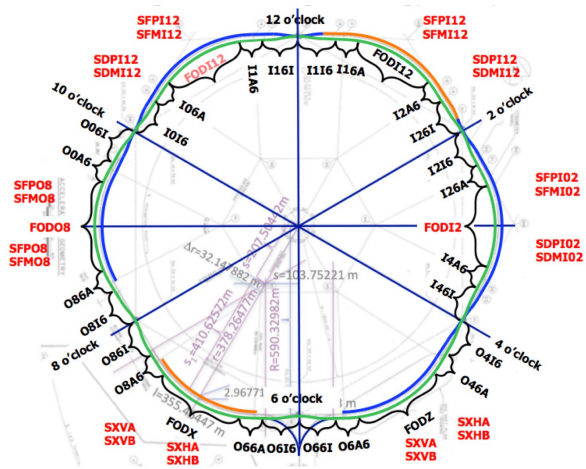

Figure 6: 24 families of sextupoles in the 90° degrees lattice are able to correct the first and higher orders of chromaticitiies in eRHIC lattice.

The betatron wave, as in the LHC design [1], not only achieves a reduction of the β^* from β^*=10 to β^*=5 cm, but also allow easier chromatic correction as the beta functions in the arcs before and after the IP are increased, as well as the dispersion function, reducing the strength of the sextupoles. The betatron functions after the beta squeeze to β^*=5 cm are shown in Figure 7 with detail of the sextupoles in the arcs in Figure 8.

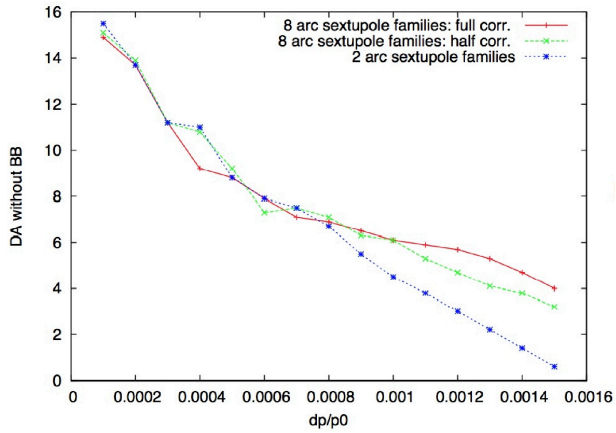

Figure 10: The dynamical aperture with 8 families of sextupoles.

The dynamical aperture after 24 families sextupole correction is shown in Figure 11.

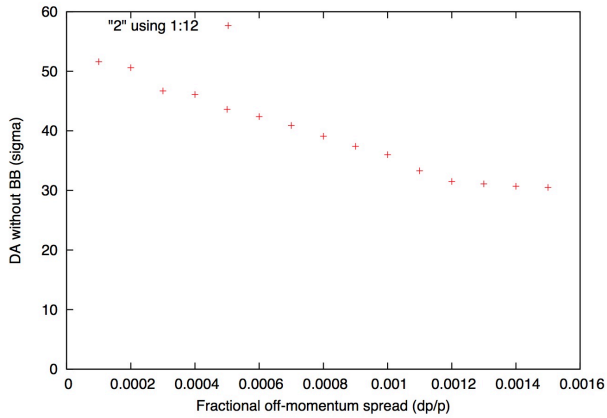

Figure 11: The dynamical aperture in the eRHIC lattice with β^*=10 cm after 24 family of sextupole correction.

SUMMARY

The eRHIC interaction region design with lattice design is presented. The LHC [1] beta squeeze was used as driving idea of the eRHIC lattice design. Initial results of the dynamical aperture are very favorable. A study of the dynamical aperture with the β^*=5 is in progress. Improvement in the interaction region design, with new superconducting triplet magnet design will follow.

nuSTORM PION BEAMLINE DESIGN UPDATE*

A. Liu†, A. Bross, D. Neuffer, Fermilab, Batavia, IL, 60510, USA
S.Y. Lee, Department of Physics, Indiana University, Bloomington, IN, 47405, USA

Abstract

A facility producing neutrinos from muons that decay in a racetrack ring can provide extremely well understood neutrino beams for oscillation physics and the search for sterile neutrinos. The "neutrinos from STORed Muons"(nuSTORM) facility based on this idea has been introduced by Bross, Neuffer et al. The design of the nuSTORM facility and the particle tracking have been presented in the paper of Liu, et al. This paper demonstrates the recent optimization results of the pion beamline, with G4beamline simulations. The optimum choice of pion beam center momentum, a new algorithm on fitting bivariate Gaussian distribution to the pion phase space data at the downstream side of the horn, and the comparison of the beamline performance with the optics designed based on Graphite and Inconel targets are also described.

INTRODUCTION

The overview of the nuSTORM project can be found in the nuSTORM Fermilab proposal [1]. A possible nuSTORM facility design was described in the paper of Liu, et al. [2]. An overview of the facility is displayed in Figure 1. In order to obtain as many useful muons from pion decay as possible, the pion beamline is designed to capture and transport pions within a $P_0 \pm 10\%$ GeV/c momentum range, where P_0 is the design momentum of the pion beamline [3]. P_0 is chosen to maximize the muon flux within a $3.8 \pm 10\%$ GeV/c range. This paper finds P_0=5 GeV/c, as determined by G4Beamline[4] simulations. We also inspect the possibility of using an Inconel target where the pion productivity is checked and compared with the graphite target scenario we proposed in our previous papers.

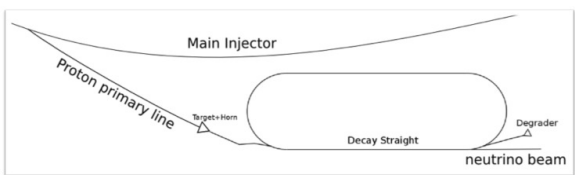

Figure 1: Overview of the nuSTORM facility. The Fermilab Main Injector places proton beam on a target, producing a large spectrum of secondary pions that are transported and injected into the decay ring. The pions then decay within the decay straight to muons , which are captured by the ring. Muons decay and produce neutrino beams with known flux and flavor in the decay straight.

* Work supported by DOE under contract DE-AC02-07CH11359
† aoliu@fnal.gov, also affiliated to Indiana University, supported in part by DE-FG02-12ER41800 and NSF Phys 1205431

Pions are produced by protons hitting the target, collected by a magnetic horn, transported and injected into the ring by a Beam Combination Section (BCS) and transmitted to the end of the decay straight until extracted. The beamline from the downstream end of the horn to the end of the racetrack ring decay straight is called the pion beamline of nuSTORM. A schematic drawing of the pion beamline in G4Beamline is shown in Figure 2.

PION PRODUCTION AND COLLECTION

nuSTORM is designed to use a 100 kW target station. A proton pulse with approximately 10^{13} protons at 120 GeV and pulse length of 1.6 μs will be extracted from the Fermilab Main Injector and bombarded onto a solid target. The target is partially inserted into a NuMI-like, 300 cm long magnetic horn to collect the pions produced from the target. The horn shape and length are designed to optimize the acceptance of pions within a momentum range of $P_0 \pm 10\%$. A schematic drawing of the horn with the target is shown in Figure 3

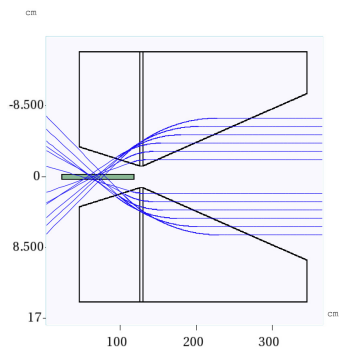

Figure 3: Schematic drawing of the nuSTORM horn and target (middle rod). Protons hit the target from the left.

Selecting The P_0 of The Pion Beam

The probability density of having a muon with momentum p_μ from the decay of a highly relativistic pion is $1/(2\gamma p'_\mu)$ for $0.573 P_0 \leq p_\mu \leq P_0$, where γ is the relativistic gamma of the pion, and $p'_\mu = 29.8$ MeV/c is the muon momentum in the rest frame of the pion. Assuming the pion beam has a uniform momentum distribution over the range $[0.9P_0, 1.1P_0]$, the probability of having a muon with momentum p_μ from this pion beam has a maximum constant value

$$f(p_\mu) = \int_{0.9P_0}^{1.1P_0} \frac{1}{0.2P_0} \frac{m'_\pi c}{2p_\pi p'_\mu} dp_\pi = \frac{2.35}{P_0} \left(\frac{\text{muons}}{\text{MeV/c}}\right)$$

Copyright © 2013 CC-BY-3.0 and by the respective authors

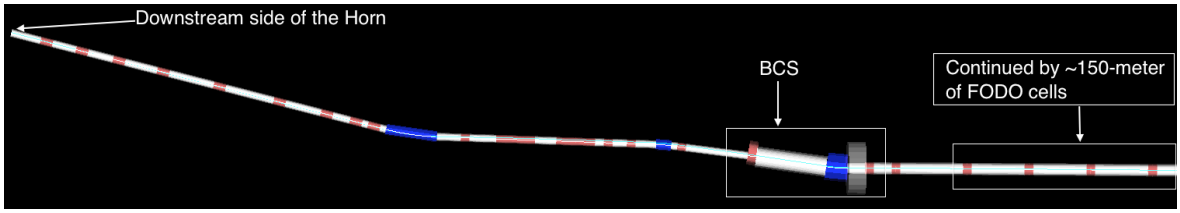

Figure 2: A schematic drawing of the pion beamline. The pions move from the downstream side of the horn (left) to the end of the decay ring straight section (right, not shown all).

for $0.63P_0 \leq p_\mu \leq 0.90P_0$. m'_π=139.6 MeV/c is the pion mass in the rest frame of the pion. This implies that the momentum distribution of the muons within the 3.8±10% GeV/c momentum acceptance of the ring is uniform as long as $P_0 \in$[4.644, 5.426] GeV/c. In addition, the value $2.35/P_0$ of the flat top of $f(p_\mu)$ is smaller when P_0 is larger. Having a lower P_0 will result in more muons within $3.8 \pm 10\%$ GeV/c, whereas having a higher P_0 will reduce the requirement on dispersion, D_x, created by the BCS and will reduce the emittance growth from pion decay. Figure 4 shows the trade-off by plotting the number of muons in the momentum acceptance with $\sigma_{x'}$ and $\sigma_{y'}$, which are the rms angle width of the muons. The smaller $\sigma_{x'}$ and $\sigma_{y'}$ are, the easier the muon beam can be captured. The criteria are well-balanced when P_0 is 5 GeV/c.

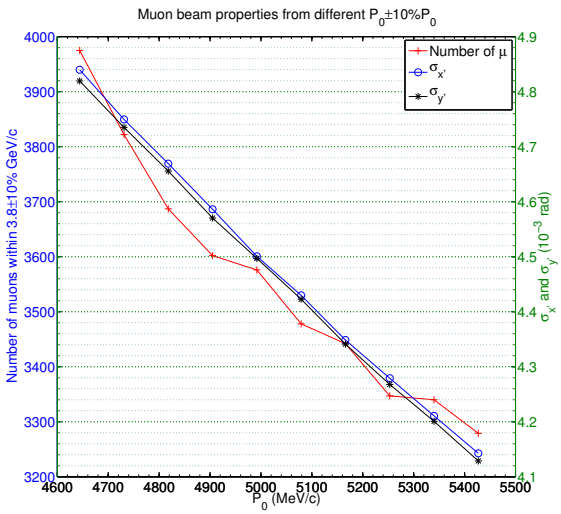

Figure 4: Number of muons within $3.8 \pm 10\%$ GeV/c from the decay of pion beams with different $P_0 \pm 10\% P_0$ (In red crosses, left vertical axis), $\sigma_{x'}$ and $\sigma_{y'}$ (In blue circles and black stars, right vertical axis) v.s P_0. The number of pions in each simulation bin is 10^4.

Target and Horn

We use a 95 cm graphite target (about two interaction lengths), with a radius of 3 mm as a baseline in our design. A 39 cm Inconel target (also two interaction lengths), with the same radius has also been considered and with it we obtain more pions within the above momentum range. The engineering prospects of the Inconel target are under study. The number of pions within 5±10% GeV/c we collect after the horn is 0.139 and 0.157 pions per POT for the graphite and Inconel targets, respectively.

Algorithm for Fitting a Gaussian Function to the Pion Distribution

In order to design the pion beamline optics, the TWISS parameters need to be matched at the downstream side of the horn. Because the pion distribution in the transverse phase space is dramatically distorted from an ideal Gaussian beam, we need to find an algorithm to fit a bivariate Gaussian distribution to the phase space data. One way to do so is by using a thorough scan on the TWISS parameters and including the maximum number of pions with the acceptance ellipse. However, this scan efficiency is greatly limited by its step size and the initial starting point of the parameters. We implemented the Gauss-Newton method of minimizing the sum of squared function $Q(\vec{\alpha}) = \sum_{i=1}^{n} r_i^2(\vec{\alpha})$ where $\vec{\alpha} = (\mu_t, \mu_{t'}, \sigma_t, \sigma_{t'}, \rho_{t,t'})$ represents a list of variables in the function r_i, which in our fitting purpose represents the residuals of $r_i(\vec{\alpha}) = \ln z(t,t')_i - \ln f((t,t')_i, \vec{\alpha})$. t and t' represent the transverse phase space coordinates in either x or y direction, $z(t,t')_i$ is the real bivariate probability density value at $(t,t')_i$ and $f((t,t')_i$ is the Gaussian function value at that point. The vector $\vec{\alpha}$ is optimized by iterating on m in the expression $\vec{\alpha}^{(m+1)} = \vec{\alpha}^{(m)} - (\vec{J}^\top \vec{J})^{-1} \vec{J}^\top \vec{r}(\vec{\alpha})$ until the difference of $\vec{\alpha}^{(m+1)}$ and $\vec{\alpha}^{(m)}$ has decreased to a critical value. Once the $\vec{\alpha}$ is found, we can use the covariance matrix to get the TWISS parameter values.

The direct Gauss-Newton method still has large inaccuracy because we include all the pions in the phase space in the fitting. However, some of those particles are far outside the 2×10^{-3}m·rad acceptance ellipse of the pion beamline. Thus we did another iteration on the Gauss-Newton method, where each time we discard a number of pions having the largest phase space emittance. The iteration is repeated until the rms phase space emittance of the beam has shrunk to 2×10^{-3}/6 m·rad, which is the conventional way of defining the relation between rms emittance and acceptance.

The comparison of the fitting results from the parameter scan method and the iterative Gauss-Newton method are shown in Figure 5, taking the pions produced by the

Copyright © 2013 CC-BY-3.0 and by the respective authors

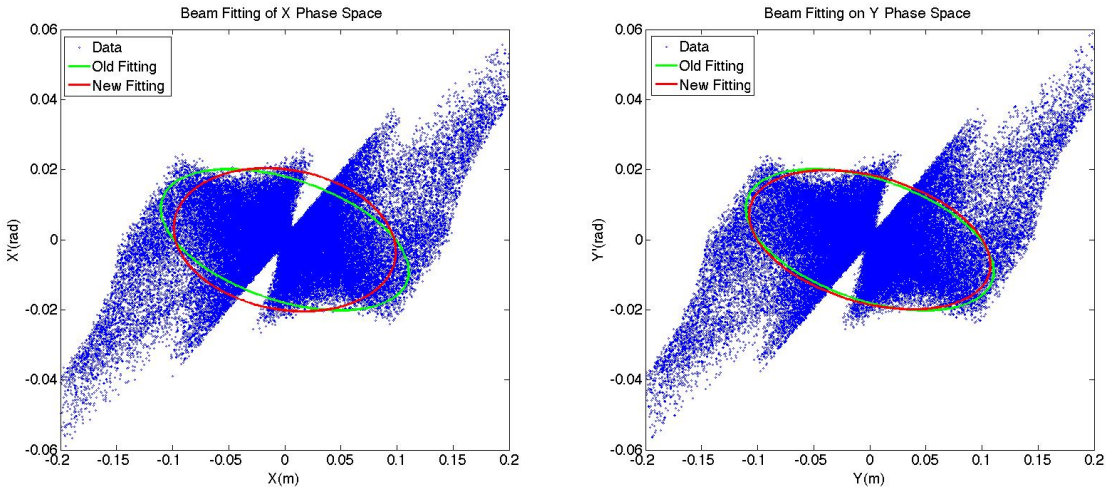

Figure 5: Comparison of acceptance ellipses in the horizontal phase space (left) and vertical phase space (right) using different fitting methods. The old scanning method and the new Gauss-Newton method are plotted in green and red, respectively.

graphite target as an example. The new acceptance ellipse contains approximately 1% more pions than the previous one does. The TWISS parameters from the direct Gauss-Newton method, parameter scan method, and the iterative Gauss-Newton method are shown in Table 1.

Table 1: TWISS Parameters from Different Fitting Methods

method	α_x(1)	β_x (m)	α_y (1)	β_y (m)
Direct Gauss-Newton	-0.21	5.28	-0.58	6.32
Parameter Scan	0.5	6.13	0.5	6.13
Iterative Gauss-Newton	0.17	4.91	0.38	5.8

Pion Beamline Performance

After the TWISS parameters are found at the downstream side of the horn, the optics of the pion beamline can then be matched to the racetrack ring decay straight, where the periodic TWISS parameters were set by optimizing a series of design criteria [5]. The performance comparison of pion beamlines designed based on the optics of pions from graphite and Inconel targets is shown in Table 2.

SUMMARY

The nuSTORM pion beamline design has been updated. The optimization of the beamline confirms an optimum center momentum of the pion beam at 5 GeV/c, and a new algorithm of particle distribution fitting has been tested. The yield of muons within 3.8±10% GeV/c within the first pass of the decay straight is about 0.008 for graphite target and 0.013 for Inconel target, per 120 GeV POT.

Table 2: Pion Beamline Performance Comparison

Target	π^+ at the downstream side of the horn (per POT)	π^+ at the end of the decay straight (per POT) (without decay)
Graphite	0.140	0.081
Inconel	0.157	0.114

Target	$\mu+$ in 3.8±10% GeV/c at the end of the decay straight (per POT) (with decay)
Graphite	0.008
Inconel	0.013

ACKNOWLEDGMENT

We thank the APC colleagues who provided comments and suggestions on the design of the nuSTORM facility.

Abstract

Muon-based facilities offer a unique potential to provide capabilities at both the Intensity Frontier with Neutrino Factories and the Energy Frontier with Muon Colliders ranging from the Higgs energy to the multi-TeV energy range. They rely on novel technology with challenging parameters, for which the feasibility is currently being assessed by the U.S. Muon Accelerator Program (MAP) [1]. A realistic scenario for a complementary series of staged facilities with increasing complexity and significant physics potential at each stage has been developed. It takes advantage of and leverages the capabilities already planned at Fermilab, especially Project X and LBNE. Each stage is defined in such a way as to provide an R&D platform to validate the technologies required for subsequent stages. The rationale and sequence of a realistic staging process are presented.

INTRODUCTION

The major discoveries made in 2012, namely the large flavour mixing angle θ_{13} measured at Daya Bay in China and the Higgs boson by the LHC at CERN dramatically modified the Particle Physics landscape. Although the Higgs discovery corresponds to a splendid confirmation of the Standard Model (SM) and no sign of new physics Beyond the Standard Model (BSM) has (yet) been detected at LHC up to at least 1 TeV, BSM physics is necessary to address basic questions which the Standard Model cannot address especially the dark matter, the matter-antimatter asymmetry and the neutrino mass. Therefore the quest for BSM physics constitutes a high priority for the future of High Energy Physics. It requires facilities at both high energy and high intensity frontiers. Neutrino oscillations are irrefutable evidence for BSM physics with the potential to probe up to an extremely high energy range. Neutrino Factories with an intense and well defined flux of neutrinos from muon decay provide an ideal tool for high precision flavour physics at the high intensity frontier. At the high energy frontier, a multi-TeV lepton collider will be necessary as a precision facility to complement the LHC, if and when confirmed, for Physics exploration beyond the Standard Model.

THE BEAUTY AND CHALLENGES OF MUON-BASED FACILITIES

Muon-based facilities [2] offer the unique potential to provide the next generation of capabilities and world-leading experimental support spanning physics at both the Intensity and Energy Frontiers. Building on the foundation of Project X at FNAL, muon accelerators can provide that next step with a high-intensity and precise source of neutrinos to support a world-leading research program in neutrino physics. Furthermore, the infrastructure developed to support such an Intensity Frontier research program can also enable the return of the U.S. high energy physics program to the Energy Frontier. This capability would be provided in a subsequent stage of the facility that would support one or more Muon Colliders, which could operate at center-of-mass energies from the Higgs resonance at 126 GeV up to the multi-TeV scale.

An ensemble of facilities built in stages is made possible by the strong synergies between Neutrino Factories and Muon Colliders, both of which require a high power proton source and target for muon generation followed by similar front-end and ionization cooling channels. These muon facilities rely on a number of systems with conventional technologies whose required operating parameters exceed the present state of the art as well as novel technologies unique to muon colliders. An R&D program to evaluate the feasibility of these technologies is being actively pursued within the framework of the U.S. Muon Accelerator Program (MAP) [1] with impressive R&D results already achieved and a definitive answer expected by 2018 as to whether or not muon-based facilities built in stages can be realistically contemplated.

RATIONALE FOR A STAGED APPROACH

The feasibility of the technologies required for Neutrino Factories and/or Muon Colliders must be validated before a facility based upon these could be proposed. Such validation is usually made in dedicated test facilities which are rather expensive to build and to operate over several years. They are therefore difficult to justify and fund, given especially that they are usually useful only for technology development rather than for physics.

Copyright © 2013 CC-BY-3.0 and by the respective authors

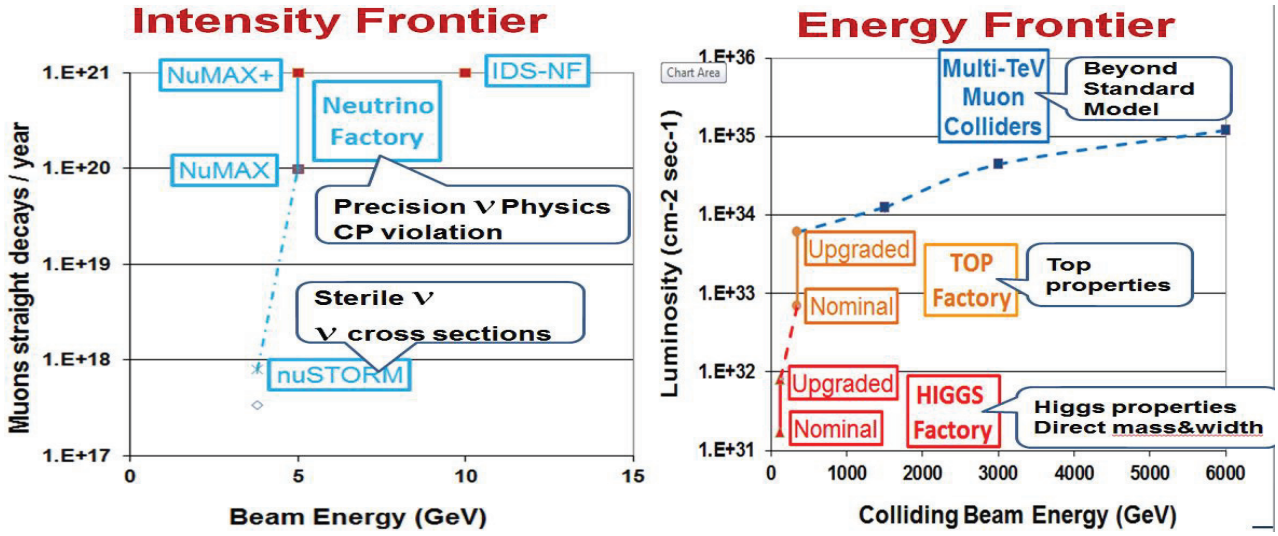

Figure 1: Performance and Physics of muon-based facilities over two frontiers and a wide energy range.

An alternative approach is proposed here. It consists of a series of facilities built in stages, where each stage offers:

- Unique physics capabilities such that the corresponding facility obtains support and is funded.
- In parallel with the physics program, integration of an R&D platform to develop, test with beam, validate and get operational experience with a new technology that is necessary for the following stages.
- Construction of each stage as an add-on to the previous stages, extensively reusing the equipment and systems already installed, such that the additional budget of each stage remains affordable.

Such a staging plan [3] thus provides clear decision points before embarking upon each subsequent stage. It is especially attractive at FNAL building on, and taking advantage of, existing or proposed facilities, specifically:

- Existing tunnels and other conventional facilities;
- Project X as the MW-class proton driver for muon generation;
- SURF as developed for the LBNE detector, which could then house the detector for a long-baseline Neutrino Factory.

It consists of a series of facilities with increasing complexity, each with performance characteristics providing unique physics reach (Fig.1):

- nuSTORM [4]: a short-baseline Neutrino Factory-like facility enabling a definitive search for sterile neutrinos, as well as neutrino cross-section measurements that will ultimately be required for precision measurements at any long-baseline experiment.
- NuMAX: an initial long-baseline 5GeV Neutrino Factory, optimized for a detector at SURF, affording a precise and well-characterized neutrino source that exceeds the capabilities of conventional superbeams.
- NuMAX+: a full-intensity Neutrino Factory, upgraded from NuMAX, with performances similar to IDS-NF [5] as ultimate source to enable precision CP-violation measurements in the neutrino sector
- Higgs Factory: a collider capable of providing between 3500 (startup) and 13,500 Higgs events per year (10^7 sec) with exquisite energy resolution enabling direct Higgs mass and width measurements.
- Multi-TeV Collider: if warranted by LHC results, a multi-TeV Muon Collider, with an ultimate energy reach up of to 10 TeV, likely offers the best performance and least cost and power consumption for any lepton collider operating in the multi-TeV regime.

Their main parameters are described in Table 1. A complex integrating all of the above facilities in a staged approach on the FNAL site is shown in Figure 2.

TENTATIVE STAGED SCENARIO AND SCHEDULE

Three major items on the critical path have been clearly identified: i) MAP technology feasibility demonstration with results expected by 2018, ii) 6D cooling performance with beam validation by 2022 possibly using nuSTORM as an R&D platform in complement to the cooling principle and feasibility demonstration at MICE [6], iii) Proton beam power availability of 3 MW at 3 GeV from Project X (phase 2) by 2024 and 4MW at 8 GeV (phase 4) by 2032. A technically limited schedule could then be tentatively defined.

nuSTORM as the first stage could be launched as soon as funding is available since it does not require any technology development. A first beam could be provided by the end of the decade. It would serve as an R&D platform to test and validate the 6D cooling with a 10^8 muon beam. NuMAX which does not require any cooling could be launched by 2018 when the MAP technology feasibility will have been demonstrated. It would initially be driven by a proton beam power of 1MW at 3 GeV provided from 2024 by Project X phase 2 in parallel with its other users. This facility would then be upgraded to NuMAX+ by adding a limited amount of 4D cooling validated in NuMAX when used as an R&D platform with a beam of 10^{11} muons and by increasing the proton driver to the full power of 3 MW provided by Project X phase 2 at 3 GeV. The NuMAX+ injector & acceleration up to 5 GeV could then be used to drive a Muon Collider at the energy and luminosity as required by Physics at the time, possibly a Higgs factory, which could be launched by 2025. It would have to be upgraded by i) implementing a 6D cooling previously validated at full intensity using NuMAX+ as an R&D platform with a beam of 10^{12} muons, ii) upgrading the proton driver to 4 MW by the project X phase 4 at 8 GeV available from 2032, iii) extending the acceleration system up to 62.5GeV. A multi-TeV muon collider could then be launched if and when required by Physics for BSM studies by using the previously built injector system and adding the necessary final cooling, acceleration system and collider ring.

CONCLUSION

A staging approach for muon-based facilities has been developed with physics interest and technology validation at each phase taking advantage of the present and proposed facilities at Fermilab. Each stage is built as an addition to the previous stages, reusing as much as possible the systems already installed such that the additional budget of each stage remains affordable. Thanks to the great synergies between Neutrino Factory and Muon Collider technologies, these facilities are complementary and allow capabilities and world-leading experimental support spanning physics at both the Intensity and Energy Frontiers. Rather than building an expensive test facility without physics use, the approach uses each stage as an R&D platform at which to test and validate the technology required by the following stage. The critical issues of this novel and promising technology are thus all addressed in the most efficient and practical way within reasonable funding and scheduling constraints.

As deduced from the components on the critical path and a technically limited schedule, such a staging approach with integrated R&D would allow informed decisions by 2020 about Neutrino Factories at the Intensity Frontier and by 2025 about Muon Colliders at the Energy Frontier.

BEAM-BEAM STUDIES FOR HL-LHC*

A. Valishev#, FNAL, Batavia, IL 60510, USA, D. Shatilov, BINP, Novosibirsk 630090, Russia
T. Pieloni, CERN, Geneva, Switzerland, D. Banfi, J. Barranco, EPFL, Lausanne

Abstract

The analysis of beam-beam effects for the High Luminosity LHC upgrade is in progress as a part of HiLumi LHC Design Study. We report on the current status of beam-beam simulations with the particular emphasis on single and multi-particle weak-strong tracking studies. We evaluate the LH-LHC performance scenarios, and outline the plan of further research.

MOTIVATION AND APPROACH

A major upgrade of the Large Hadron Collider aiming at a significant increase of its luminosity beyond the design value is planned for around 2020. The machine configuration, called High Luminosity LHC (HL-LHC) will incorporate a number of technological advances bringing the beam intensity, brightness and overall accelerator precision to an unprecedented level. The global HiLumi LHC Design Study is in progress with the goal of delivering an integrated design to facilitate the upgrade [1]. Quite naturally, the examination of beam dynamics aspects constitutes an essential part of the effort. In the HiLumi structure, Work Package 2 covers accelerator physics subjects and combines the following Tasks: Coordination and Communication; Optics and Layout; Intensity Limitations; Beam-Beam Effects; Beam Parameter and Luminosity Optimization. The Tasks work in close collaboration with each other to enable the development of a coherent view on the beam dynamics. The goal of Beam-Beam Task is to evaluate the possible performance limitations arising from beam-beam interactions, to define key parameters such as minimum required beam separation and maximum acceptable beam brightness values and to identify optimum beam configurations for the different operating scenarios.

The studies of beam-beam interactions at HL-LHC are grouped into two categories: the weak-strong (incoherent) and the strong-strong (coherent) effects. The proposed values of beam brightness at HL-LHC suggest that the weak-strong effects are more likely to result in performance limitation through the creation of resonances causing particle losses and emittance growth. As such, the incoherent effects are the focus of the present report. For the strong-strong effects see e.g. Ref. [2, 3].

PERFORMANCE SCENARIOS

A detailed description of the baseline HL-LHC scenario can be found in Refs. [4, 5]. Here we present the parameters relevant to the simulations reported further.

The so-called 'stretched' baseline HL-LHC scenario presumes that at the beginning of a high-energy run (fill), the beams collide at IP1 and IP5 (Atlas and CMS experiments) at the full crossing angle of 590 μrad. Due to the large geometrical reduction, the total beam-beam tune shift is quite moderate and does not exceed 0.015 for the case of 3 head-on collisions. The transverse separation at long-range collision points is 12.5 beam sigma. As the beam intensity decays due to the luminosity burn-off, the bunches are gradually tilted with respect to the reference trajectory (crabbed) using RF crab cavities, which results in a head-on collision at the end of the fill. This achieves a constant (leveled) luminosity of 5×10^{34} cm^{-2}s^{-1}, thus allowing to maximize the luminosity integral. The beta-function at IP1/5 during leveling remains constant at 15 cm.

Table 1: 'Stretched' Baseline HL-LHC Parameters for 25ns Bunch Spacing

Parameter	Value
Protons/bunch	2.2×10^{11}
Number of bunches	2808
Crossing angle	590 μrad
β*	15 cm
Normalized emittance	2.5 μm
Energy spread	1.2×10^{-4}
Bunch length	7.5 cm
Beam-beam tune shift per IP	0.0033

In the baseline HL-LHC scenario the luminosity is leveled such that the number of events per crossing (pile-up) does not exceed the limit set by experiments. However, it was recently recognized that the longitudinal pile-up density (the number of events per unit length or unit time) also needs to be limited. This can be achieved through maximizing the length of luminous area by keeping the bunches always colliding fully head-on (crabbed). The luminosity leveling in this scheme is performed by the transverse offset or change of beta-function, i.e. β*=70 cm at the beginning of a fill, and then is gradually reduced to 15 cm.

SIMULATION TOOLS

The weak-strong beam-beam simulations for HL-LHC were performed with two particle tracking codes: SixTrack [6] and Lifetrac [7]. Both codes have been extensively used for the development of such colliders as the Tevatron, DAFNE, and LHC, and have been well tested against available experimental data. Nevertheless, we performed additional benchmarking in order to ensure consistency of simulations. For example, Fig. 1 presents the Dynamic Aperture (DA) simulation for HL-LHC lattice with multipole errors in the absence of beam-beam interactions.

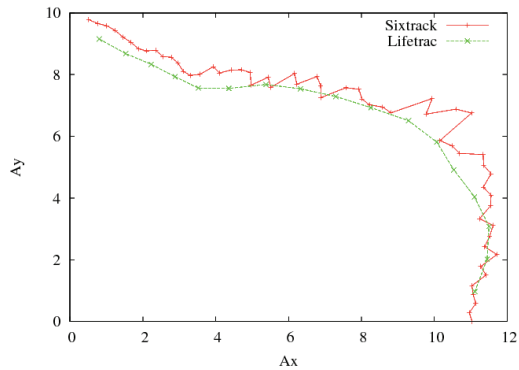

Figure 1: Dynamic aperture (Ax, Ay in units of beam σ) for HL-LHC lattice with multipole errors without beam-beam, simulated with two codes. Sixtrack data courtesy of M. Giovannozzi.

The two codes treat machine lattice with a symplectic thin-lens approach, and account for full set of machine features, including the focusing chromaticity and high-order multipole errors. The beam-beam kicks are realized through analytical formulae (the so-called Hirata formalism).

The standard figure of merit for the evaluation of performance is the dynamical aperture for particles with momentum deviation of 2.7×10^{-4}, based on 10^6 turns of tracking. However, a recent application of the Frequency Map Analysis [8] to beam-beam interactions [9,10] provides a useful insight into the dynamics of a system with much less intensive simulations. Throughout the report we provide comparisons of the two approaches.

BASELINE SCENARIO RESULTS

Figures 2, 3 present simulation results for the baseline scenario. The color on FMA plots depicts the tune variation along a particle's trajectory over 2^{12} turns (momentum deviation for these FMA simulations was zero). The logarithmic scale is provided in Fig. 2 on the right. One can see that the tune footprint is small and is not densely populated with resonances. The DA results based on 10^6 turns generally agree well with area in FMA plots where tune jitter is large, and resonances overlap (Chirikov criterion [11]).

Figure 4 shows the DA for various options of HL-LHC optics as a function of crossing angle (slhcv3.1b optics, 10^6 turns). The target minimum DA for a robust design is 6 σ, which determines the choice of crossing angle for the baseline scenario.

BETA-FUNCTION LEVELING SCENARIO

The alternative leveling scenario is more demanding with respect to beam-beam interaction due to a relatively large beam-beam tune shift at the beginning of a fill (ξ=0.034). However, the results in Figs. 5, 6 suggest that at least for the case of machine without multipole imperfections, the first studies with Lifetrac show that DA is not reduced below 6 σ. The 7th order resonance does not cause significant diffusion of the core particles. The overlapping 10th and 13th order resonances cause some emittance growth, which reduced the luminosity lifetime to approximately 20 hours. However, it is likely the effect of these resonances could be mitigated by a careful choice of the betatron tune working point. We also explored the possibility to reduce the crossing angle towards the end of a fill, when the bunch intensity decays to Np=0.95×10^{11}, to 480 μrad (10 σ separation), and found that DA in this case remains over 6.5 σ.

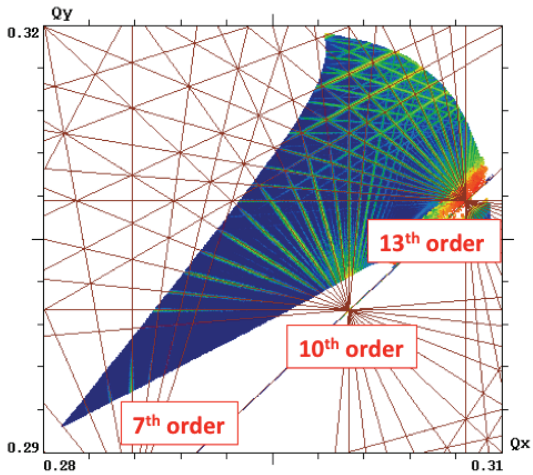

Figure 5: FMA plot in tune space for full head-on collision at IP1/5. β*=15 cm, crossing angle 590 μrad (12.5 σ separation).

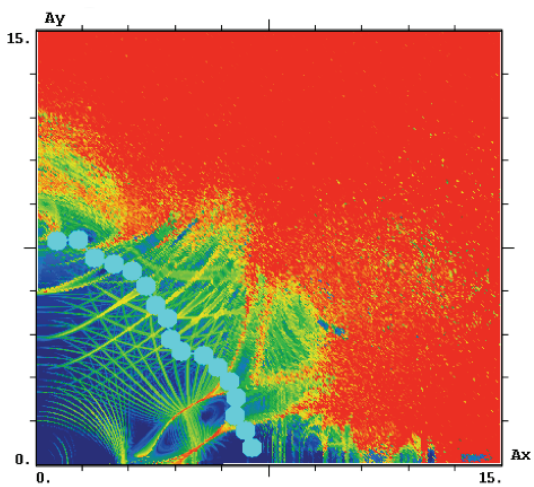

Figure 6: FMA plot in amplitude space for full head-on collision at IP1/5. Cyan points – 10^6 turns DA.

SUMMARY AND OUTLOOK

The weak-strong simulations of beam-beam effects in HL-LHC using two particle tracking codes demonstrate robustness of the baseline operational scenario. The dynamic aperture predicted by both codes is over the reference value of 6 σ for a machine with no multipole imperfections. Studies of an alternative luminosity leveling scenario making use of beta-function leveling and full head-on interactions, predict that despite the significantly larger beam-beam parameter in this scheme, the dynamical aperture is well within the specified limit. The alternative scheme may allow a decrease of the crossing angle and, consequently, the required crab-cavity voltage.

Future effort will be concentrated on the studies of sensitivity of the proposed schemes to machine imperfections. We also plan to investigate other options of achieving lower pile-up density, such as longitudinal beam density shaping.

ACKNOWLEDGMENTS

The authors would like to thank the experts of HiLumi Work Package 2, and Beam-Beam Task in particular, for numerous enlightening discussions. We are grateful for the support by SixTrack team. We are indebted to S. Fartoukh for his constant encouragement and attention to this work.

COHERENT INSTABILITY DUE TO BEAM-BEAM INTERACTION IN HADRON COLLIDERS*

S. Paret, J. Qiang, LNBL, Berkeley, CA, 94720, USA

Abstract

Beam-beam effects can excite coherent modes in circular colliding beams and can thereby cause coherent instabilities. Nevertheless the beams in LHC have been well behaved and no fundamental limitation to the beam-beam parameter has been found in head-on collisions. In this paper we consider beams with much higher intensities than ever collided in any hadron collider. By virtue of 3D strong-strong computer simulations, we investigate the coherent stability and emittance growth of proton beams in head-on collision. The impact of a crossing angle between the beams and of a transverse damper is examined.

INTRODUCTION

In lepton colliders, a changed scaling of the luminosity and the beam-beam parameter with intensity has been observed when the intensity exceeded a threshold [1]. The dynamics of colliding hadron beams differs qualitatively from that of electron beams because radiation damping is negligible for hadrons. Therefore hadron beams are assumed to be more prone to instabilities. In the LHC however, the intensity or beam-beam parameter have not been limited by beam-beam effects due to head-on collisions [2]. Beam-beam effects at the highest beam-beam parameter achieved in LHC are discussed in Ref. [3, 4]. In this paper we consider the coherent stability at intensities well beyond the performance of present colliders to identify possible inherent beam-beam limitations for future colliders.

Analytic models of the coherent stability apply only to simplified cases, like assuming linear self-fields and no crossing angle [5, 6]. These models predict unstable regions in the parameter space. Head-tail modes, on the other hand, have been found to be generally stable as long as impedances are neglected [7]. The computer simulations discussed here are not subject to the limitations of the analytic models. In the next section the setup of our simulations is outlined. A discussion of results and conclusions follow in the subsequent sections.

SETUP

The beam parameters chosen for our simulations loosely follow the LHC setup, except for the intensity. The intensity of the beams in our simulations was increased until strong coherent effects were observed. Table 1 lists the simulation parameters. Initially, the particle distribution was Gaussian. One pair of bunches collided once per turn. The corresponding beam-beam parameter without crossing angle is 0.067. According to the linear model developed in Ref. [6], these bunches will experience a quadrupolar instability.

Table 1: Simulation Parameters

Parameter	Value	Unit
N	21×10^{11}	-
ϵ	0.512	nm

σ_L	0.077	m
δ_p	1.11×10^{-4}	-
Q_x, Q_y, Q_z	0.31, 0.32, 0.00212	-
E	7	TeV
N_m	1,000,000	-
Slices	10	-

Table 2: The Four Cases Discussed in This Paper

Case	Crossing angle	Damper
A	0	off
B	0	on
C	0.15 mrad	off
D	0.15 mrad	on

The beam-beam kicks were computed self-consistently using a Green's function method [8]. The numerical noise in self-consistent simulations can drive emittance growth [9, 10]. However, in the cases considered here, the physical emittance growth is so large that the numerical contribution is negligible. In fact, using 4 times more macro particles in a simulation of case D changed the emittance growth by about 3 % only. Impedances and electron clouds have been neglected because they would obscure the pure beam-beam effects.

Collisions with and without crossing angle as well as with and without transverse damper are discussed. In the following section these 4 cases will be referred to by the letters specified in Tab. 2. The damper model is described in Ref. [10].

RESULTS

First we consider the case A. The offset and emittance are shown as a function of time in Fig. 1. The centroid motion is unstable and the emittance grows by several 10 %/s. From 12,000 to 50,000 turns, the horizontal oscillation is damped while the emittance growth is accelerated. A list of emittance growths after different time intervals for all cases is provided in Fig. 3. For either plane, the average growth of both beams is given.

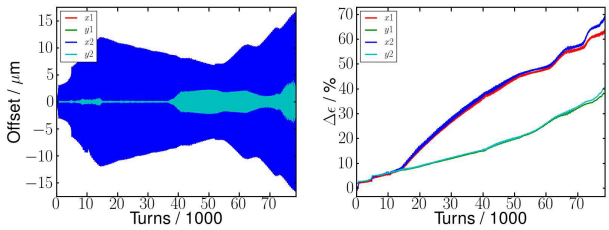

Figure 1: Case A, offset (left) and emittance growth (right) versus time.

Table 3: Emittance Growth (with respect to initial value) at Different Times for Cases A Through D. The simulation of case C did not arrive at 70,000 turns.

Turns	5000	25,000	70,000
A, hor.	8 %	26 %	61 %
A, ver.	7 %	13 %	35 %
B, hor.	33 %	35 %	41 %
B, ver.	13 %	16 %	21 %
C, hor.	7 %	43 %	-
C, ver.	6 %	22 %	-
D, hor.	78 %	116 %	134 %
D, ver.	43 %	70 %	81 %

The envelope spectrum of 2048 turns at the beginning of the simulation and after 30,000 turns is shown in Fig. 2. At the beginning there are peaks at 0.2 and 0.4, indicating a 5^{th} order envelope resonance. These peaks disappear, however, within 10,000 turns and several peaks close to 0 and 0.5 rise. Due to the large beam-beam parameter, the tune footprint is quite large and spreads over many resonance, as Fig. 3 illustrates.

Setting the damper gain to 0.02 (case B) stabilized the centroid, as Fig. 4 demonstrates. Larger gains yielded more emittance growth. The horizontal oscillation is quite large initially, with an amplitude of about 10 μm, and damped very slowly, though. The difference between the planes is attributed to the tunes since all other parameters are equal in both planes. There is a rapid emittance growth initially, which suddenly slows down, as shown in Fig. 4. The final growth rate is on the order of 1 %/s, presumably due to diffusion. Compared with case A, the emittance growth

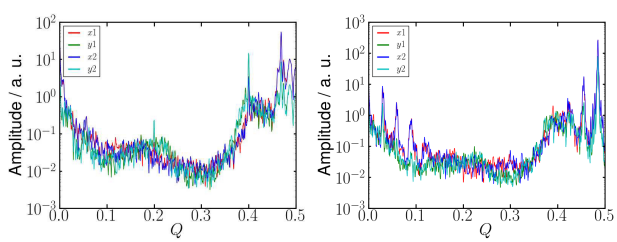

Figure 2: Case A, envelope spectrum after at the beginning and after 30,000 turns.

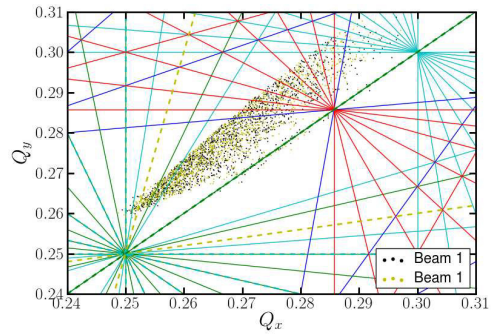

Figure 3: Case A, tune footprint. The visible resonance lines include 4^{th} order (cyan dashed), 6^{th} order (yellow dashed), 7^{th} order (red), 8^{th} order (green), 9^{th} order (blue) and 10^{th} order (cyan solid).

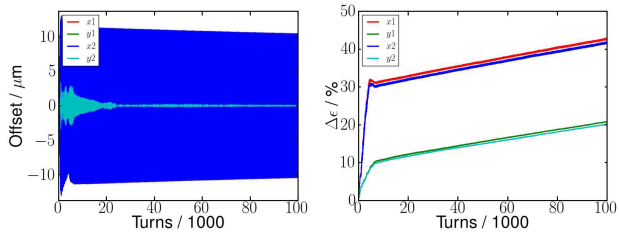

Figure 4: Case B, offset (left) and emittance growth (right) versus time.

is enhanced initially (s. Tab 3), but after a short time the damper proves beneficial.

The spectra of the offsets and envelopes during the fast growth period are shown in Fig. 5. There is a series of peaks in the spectra, indicating the excitation of the beams. After a few 1000 turns, when the beams stabilized, they mostly disappear. As a consequence of coupling, the spectra look all quite similar, despite the differences between the vertical and horizontal planes in the time domain.

Next we let the bunches collide with the nominal crossing angle, without damping (case C). The resulting centroid motion and emittance growth are displayed as a function of time in Fig. 6. The beams obviously suffer a dipolar instability. The emittance grows modestly at the beginning but accelerates as the instability evolves.

The spectrum of the centroid motion is shown in Fig. 7.

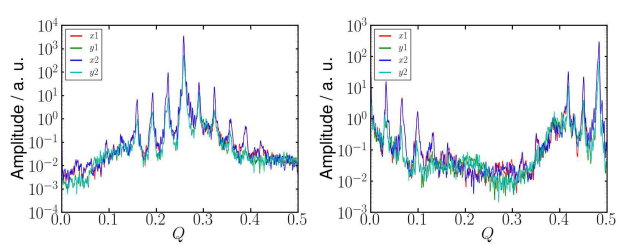

Figure 5: Case B, offset and envelope spectrum after 3000 turns.

Copyright © 2013 CC-BY-3.0 and by the respective authors

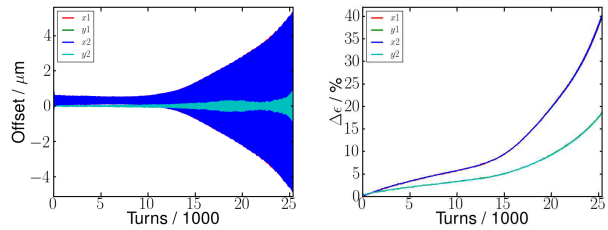

Figure 6: Case C, offset (left) and emittance growth (right) versus time.

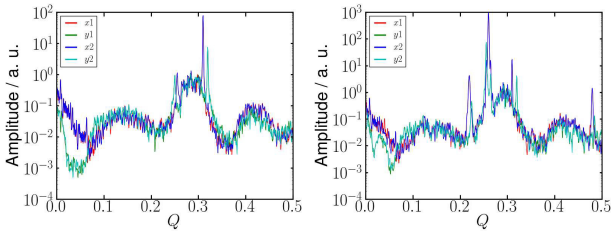

Figure 7: Case C, offset spectrum after 1000 turns and 20,000 turns. The π and σ beam-beam modes are clearly visible.

The spectra clearly reveal the σ (at Q_x and Q_y, respectively) and π (at lower frequency) BB modes. As the instability progresses, the π modes increase, which proves that they are driving the oscillation, but also new modes appear.

Finally the damper was turned on while the beams were colliding with crossing angle (case D). In this case the damper gain was set to 0.2. The corresponding offset and emittance are shown in Fig. 8. The damper stabilizes the centroids within 30.000 turns. By this time the emittance has already grown by 40 % to 50 %, respectively, in each plane. After the offset is under control, the emittance keeps growing at a decreasing rate. Similarly to the situation without crossing angle, the damper accelerates the initial emittance growth but mitigates it later on. The growth rate will possibly converge towards a constant determined by diffusion.

The spectra of the offset and envelope are shown in Fig. 9. Here we see one coherent mode at $q \approx 0.262$ in both planes. It appears that the π mode of both planes coupled to an oscillation with a single frequency while the damper completely suppresses the σ mode. The envelope spectrum features peaks at q, $1-2q$ and a broad band around $1-2$ times the working point.

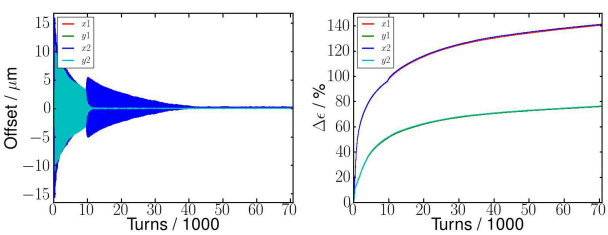

Figure 8: Case D, offset (left) and emittance growth (right) versus time.

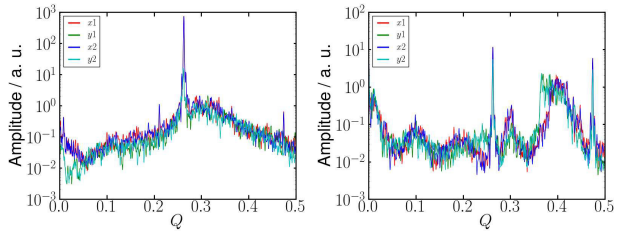

Figure 9: Case D, offset (left) and envelope (right) spectra after 20,000 turns.

CONCLUSIONS

At extremely high intensity beams colliding head on experience dipolar instabilities in our simulations. A transverse damper has proven able to suppress these instabilities, although the damping time can be very long. Employing the damper causes a short, drastic emittance growth, several 10 % within a few 10,000 turns, and cannot avert a subsequent continuous emittance growth with a rate of about 1 %/s. Although a crossing angle (without crab cavities) reduces the effective beam-beam parameter, the beams are stronger affected by beam-beam effects with a crossing angle. At a sufficiently large intensity, beam-beam effects severely challenge the control of the beams even in the absence of external perturbations.

Abstract

The next generation of future linear colliders (LC) demands nano-meter beam sizes at the interaction point (IP) in order to reach the required luminosity. The final focus system (FFS) of a LC is meant to deliver such small beam sizes. The Accelerator Test Facility (ATF) aims to test the feasibility of the new local chromaticity correction scheme which the future LCs are based on. To this end the ATF2 nominal and ultra-low beta* lattices are design to vertically focus the beam at the IP to 37nm and 23nm, respectively if error-free lattices are considered. However simulations show that the measured field errors of the ATF2 magnets preclude to reach the mentioned spot sizes. This paper describes the optimization of high order aberrations of the ATF2 lattices in order to minimize the detrimental effect of the measured multipole components for both ATF2 lattices. Specifically three solutions are studied, the replacement of the last focusing quadrupole (QF1FF), insertion of octupole magnets and optics modification. By applying the mentioned cures the design vertical beam size at the IP is almost recovered for both ATF2 lattices.

INTRODUCTION

The International Linear Collider (ILC) [1] and the Compact Linear Collider (CLIC) [2] projects are designed to deliver a luminosity at the interaction point (IP) above $10^{34}\mathrm{cm}^{-2}\mathrm{s}^{-1}$ by colliding e^+e^- beams of vertical sizes in the nanometre scale. The final focus system (FFS) provides the required beam focusing by means of two strong quadrupole magnets, so called Final Doublet (FD), which are located at a distance L* upstream the collision point. The FD generates chromaticity due to the inherent energy spread of the particle beam which needs to be corrected in order to preserve the vertical IP beam size.

The ATF2 [3] beam line is the extension of the Accelerator Test Facility (ATF) meant to validate the feasibility of the final focus systems (FFS) based on the local chromaticity correction scheme, first proposed in [4]. To this end the ATF2 nominal and ultra-low lattices are designed to obtain a σ_y^* of 37 nm and 23 nm respectively. The nominal lattice is the scaled-down version of the FFS of ILC while the ATF2 ultra-low β^* lattice [5] features a β_y^* a factor 4 smaller than nominal, in order to increase the chromaticity to a value similar to that of the CLIC FFS. This challenging optics explores the feasibility of ultra-low β^* lattices.

Reducing the value of β_y^* imposes tight constraints on the magnetic field tolerances of the FFS magnets, particularly for those magnets located at high beta regions, e.g. FD. The lattice design that recovers the design vertical spot size σ_{y0}^* for both ATF2 lattices is described in the following.

LATTICE DESIGN

In order to overcome the destructive impact in terms $\sigma_{x,y}^*$ of the multipole components of the ATF2 magnets, described in [6], different solutions have been considered in [7]. These include replacing the FD, reducing the vertical emittance or increasing the β_x^*. Reducing the vertical emittance is not a cost effective solution. Increasing the value of the β_x^* by a factor 4 effectively reduces the impact of the multipole magnets for both ATF2 lattices, yet it is not the preferred solution since it deviates from the IP beam aspect ratio that the ATF2 nominal lattice was designed for to mirror that of the ILC FFS. In 2012 it was decided to insert 4 skew sextupole magnets [8] meant to compensate for the skew sextupole components of those quadrupole magnets that do not meet the required tolerances, see [9]. Further the focusing quadrupole magnet of the FD was replaced by a 4Q17 type recycled from the PEP-II ring, due to its better field quality. As a result of these beam line modifications the impact of the multipole components becomes negligible for the ATF2 nominal lattice. Although these modifications also minimise the impact of the multipole components for the ATF2 ultra-low β^* lattice, they are not sufficient. The σ_y^* obtained is still 30% larger than design value. The analysis of the high order aberrations of the IP beam size carried out in [10] by the MAPCLASS code [11] determines that a chromatic third order (octupole) component is the main contributor to the calculated $\Delta\sigma_y^*$. The insertion of a pair of octupole magnets is proposed in [10] as an effective solution for compensating this particular aberration.

Octupole Magnets

Two octupole magnets located at dispersion and dispersion-free regions of the ATF2 beam line, namely OCT1FF and OCT2FF respectively, counteract the effect of the chromatic octupole aberration on the vertical IP beam size. It is found that these octupole magnets can reduce the σ_y^* down to 24 nm. More details can be found in [10].

In terms of field quality, the tolerances have been evaluated for both decapole and dodecapole components, Table 1 summarises the tolerances for both octupole magnets. Tighter tolerances are found for the OCT1FF which is located at the dispersion region but all of them are easily achievable from the point of view of magnet design. CERN has taken the initiative to design and construct a pair

OCT2FF	7	4	6	12

of octupole magnets to be inserted in the ATF2 beam line, see [12] for more details.

TUNING PROCEDURE

The tuning procedure consists in bringing the accelerator to its design performance under realistic error imperfections. When errors are included into simulations, the IP beam sizes are well above their design values. The tuning procedure is applied to compensate for the IP beam size aberrations caused by the machine imperfections. The tuning determines the feasibility of a lattice. The procedure of tuning ATF2 consists of an initial alignment of the ATF2 magnets using the beam itself, so called BBA. This technique centres the beam at the magnetic center of the magnets within 100 μm [13]. The typical σ_y^* at this stage is of the order of a few μm respectively, see Fig. 1. The final IP spot tuning after the BBA is based on a set of orthogonal tuning knobs that target the residual beam size aberrations at the IP.

Tuning Errors Conditions

The error conditions considered in this simulation are transverse misalignments, rotations along the longitudinal axis and strength errors of the magnetic fields. 100 simulated machines are set up with different initial error conditions. Each error is assigned to the quadrupole, sextupole and octupole magnets following a random Gaussian distribution of width σ_{error}. Also the measured multipole content of the ATF2 magnets and a measurement error of the IP beam size monitor are included into the tuning study. Table 2 summarises the values of σ_{error} for each error.

Table 2: Errors σ_{error} Assumed for the Tuning Simulation Study.

Error	σ_{error}
Horizontal misalignment [μm]	100
Vertical misalignment [μm]	100
Tilt along s-coordinate [μm]	300
Strength [%]	0.1
IP measurement [%]	10

Tuning Knobs

The available 5 normal sextupole magnets of ATF2 are used to construct 8 linear knobs that target the waists α_x^*, α_y^* (longitudinal displacement of the focal point), energy dispersions η_x^*, η_y^* and $\eta_y'^*$ and couplings between x and y ($< x, y >$), p_x and y ($< p_x, y >$) and p_x and p_y (p_x, p_y) at the IP. Each knob uses different combinations of transverse displacements of the normal sextupole magnets. Since the orthogonality may not be fully guaranteed it is common practise to scan the whole set of knobs a few times. Figure 1 shows the evolution of the mean of the vertical IP spot size $< \sigma_y^* >$ (solid line) over 100 different seeds, after each scan of the linear knobs.

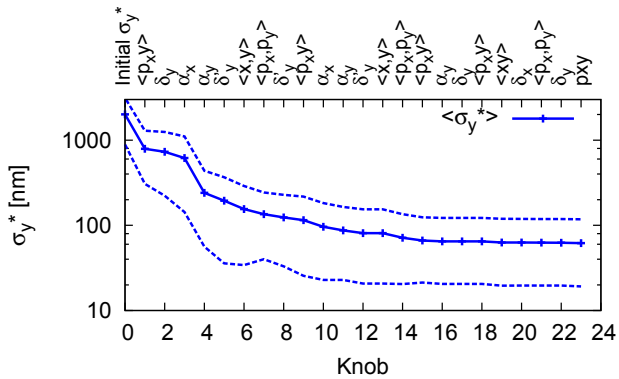

Figure 1: Evolution of $< \sigma_y^* >$ after scanning each of the linear knobs shown in the upper axis. The solid line refers to the mean value of σ_y^* of the 100 simulated machines and the upper and lower dashed curves represent the mean $\pm$ rms error, respectively.

The linear knobs bring σ_y^* from a few μm down to $\approx$ 100 nm in about ten knob scans, after that the tuning speed decreases notably and the beam size converges to above 60 nm after scanning the set of linear knobs 3 times. This $< \sigma_y^* >$ represents almost a factor 3 above the design value. In terms of the confidence level, only 33 % of the simulated machines reach a final $\sigma_y^* < 1.2\ \sigma_{y0}^*$ as shown by the red curve in Fig. 3.

At this stage, further study of the higher order aberrations of σ_y^* of the 100 different machines after scanning the linear knobs is conducted using the MAPCLASS code in combination with MADX [14]. MADX evaluates the map from the entrance of ATF2 to the IP to the desired order. MAPCLASS uses this map to transport a Gaussian distribution meant to represent the beam at ATF2. The study reveals that the 2$^{\text{nd}}$ order aberrations that contribute most to $\Delta\sigma_y^*$ using the so called *transport notation* are related to: $T_{y,p_x,y}$, T_{y,x,p_y}, $T_{y,\delta,\delta}$ and $T_{y,x,x}$ coefficients. In addition to these aberrations, it is also worth noting the contributions from the 3$^{\text{rd}}$ order which are more severe than those of the second order, the most notable being related to the coefficients: $U_{y,x,x,x}$, $U_{y,x,\delta,\delta}$, $U_{y,x,x,y}$, U_{y,x,x,p_x} and $U_{y,x,y,\delta}$, as shown in Fig. 2. The two line-points shown in Fig. 2 represent the average contribution to $\Delta\sigma_y^*$ over

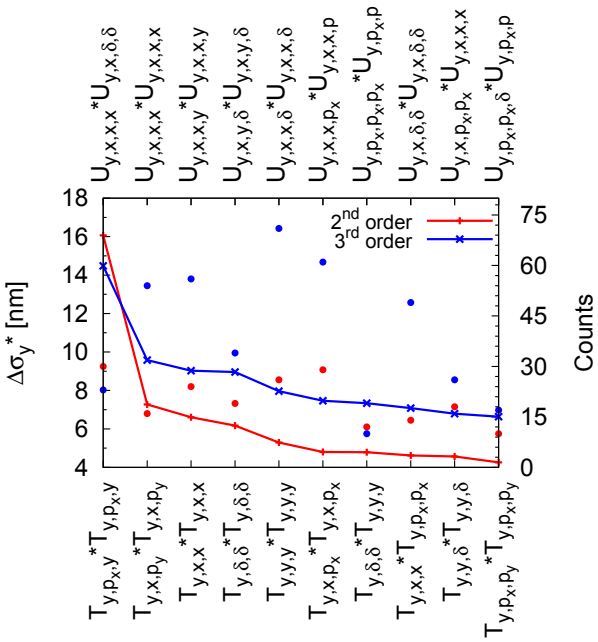

Figure 2: Most relevant high order aberrations that remain after applying the linear tuning knobs. Red curve refers to the 2nd order aberrations, namely $T_{i,j,k}$ (lower axis). Blue curve represents the 3rd order aberrations, namely $U_{i,j,k,l}$ (upper axis)

the simulated machines from the aberration labelled on the horizontal axes. The lower and upper axes show the 2nd (red) and 3rd (blue) order coefficients. The number of occurrences of each aberration is shown by the single points using the same color code, and should be read on the right axis.

Taking advantage of the 4 skew sextupole magnets installed along the ATF2 beam line, a set of 4 knobs are constructed in order to compensate for the above mentioned $T_{i,j,k}$ aberrations. The 2 octupole magnets are used to obtain 2 additional knobs for taking care of the $U_{y,x,x,x}$ and $U_{y,x,\delta,\delta}$ aberrations. These knobs are based on strength variations. The number of machines that reach a $\sigma_y^* < 1.2\ \sigma_{y0}^*$ increases from 33% to 54% after applying the linear and 2nd order knobs. When the octupole knobs are included into the tuning procedure, the percentage of tuned machines with $\sigma_y^* < 1.2\ \sigma_{y0}^*$ increases to 63% as shown in Fig. 3. Figure 3 compares the confidence level of the tuning strategies, namely linear knobs (red), linear plus 2nd order knobs (green) and linear plus 2nd order plus octupole knobs (blue). The confidence level represents the number machines that reach a $\sigma_y^* < 1.2\ \sigma_{y0}^*$.

SUMMARY

The present multipole content of the ATF2 magnets increases the vertical beam size at the IP by less than 5% when the ATF2 nominal lattice is considered in simulations. By contrast, the impact of these multipole errors

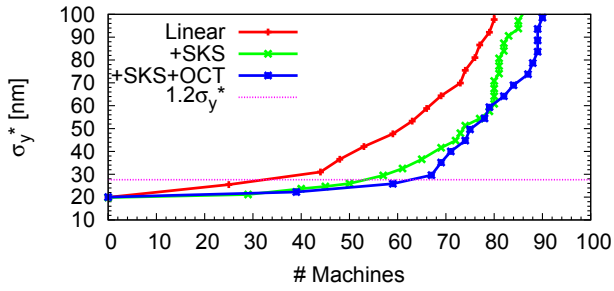

Figure 3: Confidence curves obtained for the 3 tuning strategies. The magenta line indicates the $1.2\ \sigma_{y0}^*$ value.

increases σ_y^* by 30% for the ATF2 ultra-low β^* design. Simulation shows that 2 octupole magnets can effectively reduce the impact on the beam size by less than 5%. The calculated tolerances of the magnetic field errors of these octupole magnets do not represent any difficulty from a magnet design point of view. An additional benefit is found when studying the tuning performance of the ultra-low β^* lattice under realistic error imperfections. Thanks to the knobs based on these octupole magnets, the percentage of machines that reach a final $\sigma_y^* < 1.2\ \sigma_{y0}^*$ increases from 54 % up to 63 %.

COUPLING SPIN RESONANCES WITH SIBERIAN SNAKES*

Nermeen Khalil†, Stony Brook University, Stony Brook, NY 11794, U.S.A.
V. Ptitsyn, Brookhaven National Laboratory, Upton, NY 11973, U.S.A.

Abstract

The polarization of proton beam during the acceleration process in a particle accelerator is affected by the existence of spin resonances. Coupling spin resonances can be excited in the presence of the betatron coupling introduced by rolled quadrupoles and solenoids. A corresponding algorithm has been developed and added to the ASPIRRIN code to include the calculation of the first-order intrinsic resonance harmonics in the case of arbitrary strong betatron coupling and in the presence of Siberian Snakes and spin rotators.The analysis of the coupling resonance harmonics excited in RHIC collider is presented.

INTRODUCTION

Accelerating high energy polarized proton beams in a circular accelerator is complicated with the presence of depolarizing resonances. With the application of the various kind of spin rotating devices (like Snakes and spin rotators) the stable spin axis on the design closed orbit may deviate from the vertical, and an algorithm should be realized which would calculate the spin resonance harmonics with this complex configuration of the magnetic field on the design orbit. Main features of this algorithm for calculating the spin resonance strength were presented in [1]. In the work presented in this paper the algorithm has been extended to include the calculation of horizontal and vertical intrinsic spin resonance amplitudes for the case of strong betatron coupling, caused by rotated quadrupoles and solenoidal fields. We consider, as an example, the betatron coupling in RHIC accelerator which is originated mostly due to rolls of quadrupoles at the RHIC interaction regions and compensated using the local skew quadrupole correctors. In order to calculate the undesired coupling effects on the spin resonance strength an algorithm has been modified in ASPIRRIN [2] code to include the horizontal and vertical intrinsic spin resonance amplitude calculation for arbitrary rotated quadrupole in presence of the Siberian Snakes. In RHIC two Siberian Snakes are installed in each of the two RHIC rings [3].

ALGORITHM DESCRIPTION

In order to describe the spin motion which is initiated by the arbitrary rotated quadrupole , we would need to introduce the calculation of the spin perturbation in general. We consider the spin perturbation due to betatron oscillations as the linear form in the orbit variables $w_j = T_{iq}X_q$. The orbital coordinates and momenta of a particle will be defined as $X^T = (x, p_x, y, p_y)$, where x and y are the horizontal and vertical coordinates of a particle, and p_x and p_y are their conjugate momenta. The linear orbital motion can be defined as $X_q = F_{qr}A_r$ where F_{qr} is the matrix compiled from the complex eigenvectors of the orbital motion, and A_r is the vector of the betatron amplitudes.

Here we are considering the spin perturbation theory in the coordinate system $(\mathbf{l}, \mathbf{m}, \mathbf{n_0})$, where $\mathbf{n_0}$ is the stable spin solution on the design orbit. In this coordinate system a spin vector on the design orbit rotates with the constant spin precession tune ν around $\mathbf{n_0}$. The vector $\mathbf{k} = \mathbf{l}+\mathbf{im}$ is related with the spin eigenvector $\mathbf{k_0}$ by $\mathbf{k} = \mathbf{k_0}\cdot e^{i\nu\theta}$, where θ describes the accelerator azimuth. In Eq. 1 the first-order spin resonances are defined as the coefficients of Fourier decomposition of the spin perturbation term

$$\mathbf{w}\cdot\mathbf{k} = \sum_{r,p}\epsilon_{rp}e^{i(p+Q_r)\theta} = \sum_{r,p}A_r\tilde{v}_{rp}e^{i(p+Q_r)\theta} \qquad (1)$$

where p are integer numbers and Q_r present components of the orbital betatron tune vector $(Q_I, -Q_I, Q_{II}, -Q_{II})$. Q_I and Q_{II} are tunes of two betatron oscillation modes. In order to calculate $\tilde{v}_{rp}$ in the program the integral over one turn is taken doing element-by-element integration [1].

$$\tilde{v}_{rp} = \frac{1}{2\pi}\int_0^{2\pi} e^{i\delta_{rp}\theta}\sum_{j,q}T_{jq}\mathcal{F}_{qr}k_{0j}d\theta \qquad (2)$$

where $\delta_{rp} = \nu - (p + Q_r)$ describes detuning of the spin tune from a resonance tune.

In order to obtain $\tilde{v}_{rp}$ for rotated quadrupole we start with considering the following equations of motion of particle in arbitrary rotated quadrupole:

$$x'' = -g_c x - \kappa_c y \qquad y'' = g_c y - \kappa_c x \qquad (3)$$

where $g_c = g\cdot cos(2\phi)$ and $\kappa_c = g\cdot sin(2\phi)$ are defined by the quadrupole rotation angle ϕ and the quadrupole field gradient g.

From (3) we can get the expressions for the orbital motion eigenvectors which will be used later in the paper :

$$F_{3r} = -AF''_{3r} + BF''_{1r} \qquad F_{1r} = AF''_{1r} + BF''_{3r} \qquad (4)$$

Here:

$$A = -cos(2\phi)/g \qquad B = -sin(2\phi)/g \qquad (5)$$

The components of horizontal and vertical components of the spin perturbations in a quadrupole are given by:

$$w_x = (1+\nu_0)y'' \qquad w_y = -(1+\nu_0)x'' \qquad (6)$$

* Work supported by Brookhaven Science Associates, LLC under Contract No. DE-AC02-98CH10886 with the U.S. DOE
† nermeen.khalil@stonybrook.edu

Copyright © 2013 CC-BY-3.0 and by the respective authors

where $\nu_0 = G\gamma$, with magnetic moment anomaly G and relativistic factor γ. From (1) and (6) the contribution to a spin resonance harmonic produced by a betatron mode oscillating with the tune Q_r from a quadrupole can be formulated as the following:

$$\tilde{v}_{rp}^{quad} = (1+\nu_0)(k_{0x}I_3 - k_{0y}I_1) \quad (7)$$

where I_1 and I_2 are the integrals defined as

$$I_1 = \int_{\theta_1}^{\theta_2} F_{1r}^{''} e^{i\delta_{rp}\theta} d\theta \quad (8)$$

$$I_3 = \int_{\theta_1}^{\theta_2} F_{3r}^{''} e^{i\delta_{rp}\theta} d\theta \quad (9)$$

and θ_1 and θ_2 correspond to the entrance and the exit of the quadrupole.

To find the integrals (8) and(9) one can apply twice the integration by parts and the expressions (4) to get the set of linear equations for I_1 and I_3. Resolving the equations one gets the solution in the matrix form:

$$\begin{pmatrix} I_1 \\ I_3 \end{pmatrix} = M^{-1} \begin{pmatrix} C_1 \\ C_3 \end{pmatrix} \quad (10)$$

where M, C_1 and C_3 are expressed as

$$M = \begin{pmatrix} 1 + A\delta_{rp}^2 & B\delta_{rp}^2 \\ B\delta_{rp}^2 & 1 - A\delta_{rp}^2 \end{pmatrix} \quad (11)$$

$$C_3 = \left[(F_{3r}^{'} - i\delta_{rp}F_{3r}) e^{i\delta_{rp}\theta} \right]_{\theta_1}^{\theta_2} \quad (12)$$

$$C_1 = \left[(F_{1r}^{'} - i\delta_{rp}F_{1r}) e^{i\delta_{rp}\theta} \right]_{\theta_1}^{\theta_2} \quad (13)$$

Then the final formula which defines the contribution from an individual rotated quadrupole to the spin resonance harmonic is:

$$\tilde{v}_{rp}^{quad} = Y[k_{0x}(\delta_{rp}^2 \sin(2\phi)C_1 + (g - \delta_{rp}^2\cos(2\phi))C_3) - k_{0y}((g + \delta_{rp}^2\cos(2\phi))C_1 + \delta_{rp}^2 \sin(2\phi)C_3)] \quad (14)$$

where

$$Y = g(1+\nu_0)/(g^2 - \delta_{rp}^4) \quad (15)$$

Summing these contributions from all quadrupoles gives us the full spin resonance harmonic defined by r and p.

Using similar technique the spin resonance harmonics contribution from a solenoid was derived as:

$$\tilde{v}_{rp}^{sol} = \frac{(G-\nu_0)K_s}{\delta^2 - (GK_s)^2}(-i\delta_{rp}[e^{i\delta_{rp}\theta}((F_{2r} + \frac{1}{2}K_sF_{3r})k_{0x} + (F_{4r} - \frac{1}{2}K_sF_{1r})k_{0y})]_{\theta_1}^{\theta_2} + GK_s[e^{i\delta_{rp}\theta}((F_{2r} + \frac{1}{2}K_sF_{3r})k_{0y} - (F_{4r} - \frac{1}{2}K_sF_{1r})k_{0x})]_{\theta_1}^{\theta_2}) + \frac{(1+\nu_0)K_s}{2}\left[e^{i\delta_{rp}\theta}(F_{1r}k_{0x} + F_{3r}k_{0y})\right]_{\theta_1}^{\theta_2} \quad (16)$$

where K_s is the normalized field of the solenoid and the last term describes the contribution from the solenoid ends.

CALCULATIONS FOR THE BETATRON COUPLING AT RHIC

We would show some tests which have been done by ASPIRRIN after modifying it with the new algorithm. The main motivation for our calculation was to test the code ability of calculating the resonance strength amplitude in the general case for the betatron oscillation coupling. The calculations were done for the RHIC lattice with two Siberian Snakes, which had uncoupled tunes $Q_x = 27.685$, $Q_y = 29.673$ with betatron amplitudes of $10\mu m \cdot rad.$ in both planes.

The spin tune in RHIC with the Siberian Snakes is equal to 0.5. because of that in all plots in this section we show the result for resonance harmonics which are closest to 0.5 value (that is with the resonance tunes in $[0-1]$ range). Moreover, we add together the amplitudes of the two spin resonance harmonics, one below and other above 0.5, corresponding to the same betatron tune (Q_I or Q_{II}). That gives the resonance amplitude of the linear resonance harmonic, which is more natural when considering an accelerator with the Siberian Snake [1].

First we started by varying the field strength of different IR skew quadrupoles correctors, which are used to compensate for the coupling caused by the rolled quadrupoles, and observing how the spin resonance harmonics depend on the betatron coupling, which is characterized by minimum betatron tune split ΔQ_{min}. In figure 1 a typical behavior of the vertical and horizontal resonance harmonics are shown by varying the gradient strength of skew-quadrupole (SQ06C2B), the horizontal resonance amplitude would increase non linearly while the vertical amplitude would behave the opposite.

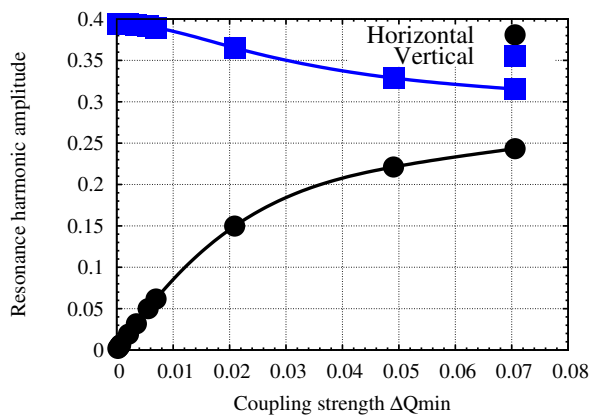

Figure 1: Dependence of the vertical and horizontal resonance harmonic amplitudes on the coupling strength when varying a skew quadrupole corrector. $G\gamma = 422.3$.

Figure 2 demonstrates another typical feature of the resonance harmonic dependence observed during the skew quadrupole variation studies. While the vertical and horizontal harmonics changes the sum of their squares remains approximately constant: $\tilde{v}_{hor}^2 + \tilde{v}_{ver}^2 \approx const.$ This in-

Copyright © 2013 CC-BY-3.0 and by the respective authors

dicates a rotational type transformation between the horizontal and vertical resonance harmonics when the betatron coupling is introduced.

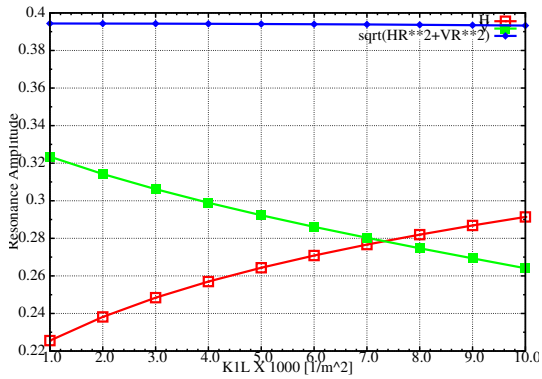

Figure 2: Conservation of the sum of squares of the horizontal and vertical resonance harmonic amplitudes when varying a skew quadrupole corrector(SQ08C2B). $G\gamma = 422.3$.

Next, we considered actual coupling errors present in RHIC, where strong sources of the the betatron coupling are due to the rolls of the IR quadrupoles. These quad rolls are well known from the beam-based and magnetic measurements. Thus, we applied the known rolls and well as local skew quadrupole corrector strengths used at RHIC operation [4]. Figure 3 shows the calculated values of the vertical resonance amplitudes versus $G\gamma$ in a region of strong resonances in RHIC. The figure shows some reduction of the values of vertical harmonics amplitude after applying the quad rolls and skew quad correction.

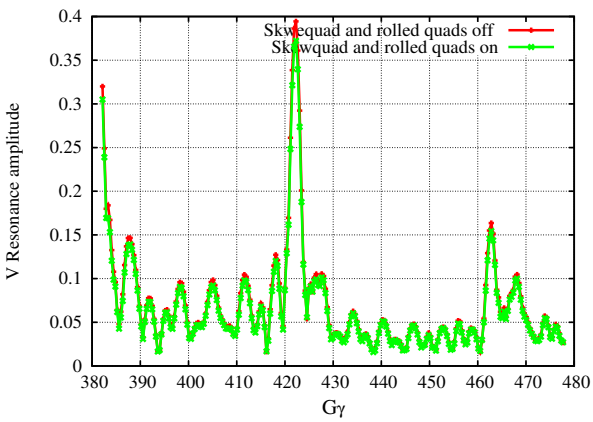

Figure 3: Calculated vertical spin resonance harmonics with and without the actual RHIC IR quadrupole rolls and local IR skew corrections.

Figure 4 shows the calculated values of the the horizontal resonance amplitude versus $G\gamma$ and it is observed that the horizontal resonance amplitudes are excited up to 0.15 when the actual quadrupole rolls and skew quad corrector strengths are used (in this case $\delta Q_{min} \approx 0.01$). After that we used optimized values for certain local skew quadrupole gradients, which reduced the δQ_{min} coupling parameter to 0.001. The horizontal resonance harmonics are clearly reduced in this case. The plot also shows that the horizontal resonance amplitudes are suppressed to zero when the skew quadrupoles are turned off and the quadrupole rolls are 0.

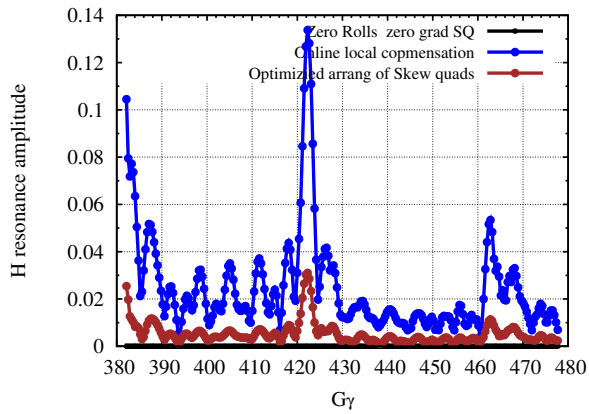

Figure 4: Calculated horizontal spin resonance harmonics with and without the actual RHIC IR quadrupole rolls and local IR skew corrections. The result for optimized corrections is also shown.

SUMMARY

The calculation of spin resonance harmonics with coupled transverse betatron motion was implemented in the ASPIRRIN code. We noticed a rotation-type transformation of the resonance strength of vertical and horizontal harmonics when introducing the betatron coupling. The local coupling correction for actual values of quad rolls and IR skew quad correctors at 6 Interaction regions in RHIC results in exciting the horizontal resonance strength up to 0.15 at $G\gamma$ of value of 422.3. Optimizing the skew quadrupoles arrangement for better compensation of the local coupling helps to reduce the horizontal spin resonance amplitudes even before applying the global coupling correction.

Abstract

To commission some of the hardware and software for the RHIC electron lenses (e-lenses), we built a test bench based on BNL's EBIS test stand. Over several months, we tested the electron gun, the collector, the high-voltage gun-modulator, the instrumentation, the partial control system, and several software applications. A nominal DC-beam current of 0.85 A was demonstrated. And the electron beam transverse profiles were verified as being Gaussian with a small flat top. We also evaluated some e-lens power-supplies and the electronics for measuring current on our bench. The properties of the cathode and the profile of the beam were assessed. In this paper, we present some of our experimental findings.

INTRODUCTION

To improve the luminosity of the polarized protons in the Relativistic Heavy Ion Collider (RHIC), we are installing two electron lenses (e-lenses) in IR10 [1-4] to compensate for the head-on beam-beam effect. We designed an e-lens test bench to test some elements of the e-lens hardware, its controls, and some application software [5]. Figure 1 illustrates the layout of e-lens test bench; it encompasses an electron source, a beam-propagation system, an electron collector, and some instruments for beam diagnostics.

The electron source is an electron gun with a cathode designed to generate a beam with transverse Gaussian profile [3, 6]. After manufacturing it, we measured the actual shape of the cathode (its cross-sectional profile), then simulated the beam profile resulting from the cathode profile with the 2D program TRAK, and compared it to the obtained beam profile with the measured beam.

The system that propagates the beam encompasses a 4.6 T superconducting solenoid, a collector coil, gun dipoles, main dipoles, collector dipoles, and a drift tube.

When the electron beam arrives at the collector, we measured its current with the DCCT and the pulse CT [7]. The maximum temperature on the collector was determined by Resistance Temperature Detectors (RTDs) at the highest DC load. The eight RTDs on the cylindrical surface of the electron collector were arranged in two groups. Each group consisted of four RTDs in one longitudinal plane; the four thermocouples of one group were separated azimuthally by 90 degrees, while the two groups were separated longitudinally by 70 mm.

After several months of operation, we tested the electron gun, the collector, the high-voltage gun modulator and most of the instrumentation on the test bench. We also qualified parts of the control system and several software applications. The nominal pulse and the DC beam current of 0.85 A were demonstrated, and the electron beam transverse profiles were verified as being Gaussian. Some e-lens power supplies and the electronics for measuring the current were also assessed. The properties of the cathode and the profile of the beam were evaluated.

THE ELECTRON GUN AND BEAM

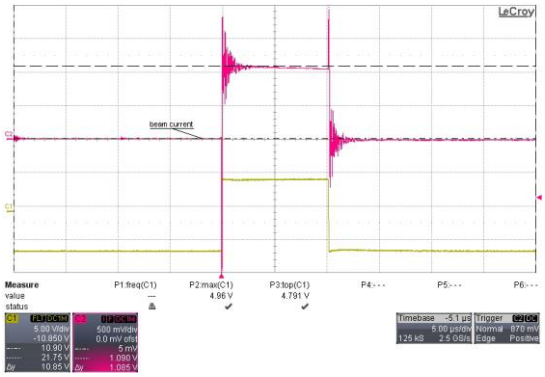

Figure 2: Example of the measurements of the 1085 mA current of the electron beam (yellow) and the anode voltage (red).

We demonstrated the capability of the electron gun on the test bench. Figure 2 shows an example of the measurements of the electron beam current (yellow) and the anode voltage (red). For the current, it is 500 mA/div; for the anode voltage, it is 5 kV/div; the pulse length is 5 μs/ div.

For the pulsed electron-beam, we used the gun-side pulse CT (Fig. 1) and obtained the anode voltage locally via the Tek P6015A probe. To obtain information on the beam loss, we evaluated the electron beam current on the collector side CT, and compared it with a similar measurement from the gun-side CT.

THE COLLECTOR

The temperature of the collector was recorded while the DC beam current was being increased to 1 A.

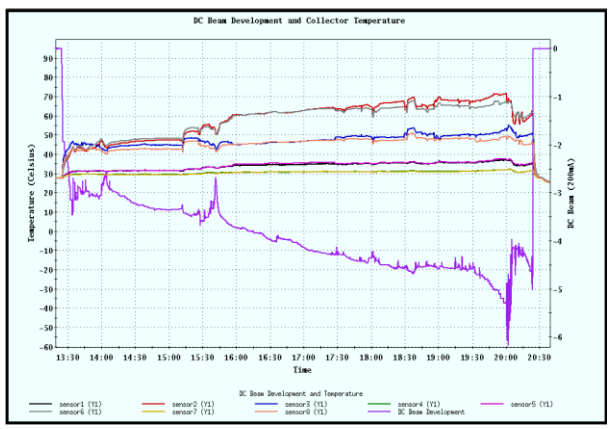

Figure 3: Collector temperature and DC beam.

Figure 3 shows the DC beam current (purple) and the RTDs temperature read-backs (other colors). The DC current is $I = 5.04 \times 200$ mA $= 1080$ mA, and the collector voltage is about 5 kV. The total beam power is 5.4 kW and the maximum temperature is about 70°C on the temperature sensor 2.

As it is apparent from Fig. 3, the eight temperature sensors yield four similar groups of readings, implying that the electron beam may be off-axis or not parallel to the collector axis. Similar readings were obtained from pairs of sensors located at the same angle along the beam, but at two different longitudinal positions.

THE MODULATOR

Figure 4 shows results from the modulator running at 80 kHz with a 10 kV anode voltage. The yellow waveform is the anode voltage, while the red waveform represents the electron beam current measured by the gun-side of the pulse current transformer. The two spikes on both sides of each pulse seemingly reflect the charging and discharging current between the modulator and the anode.

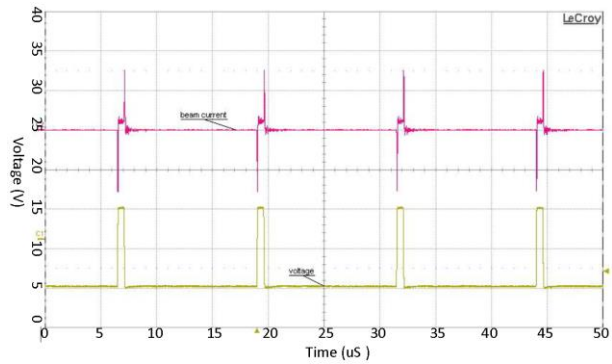

Figure 4: 80 kHz modulator test with beam-current pulse (red), and the anode-voltage pulse (yellow).

The BPMs will play a critical role in meeting the ambitious requirements for commissioning and operating the electron lenses. Two BPMs in the e-lens will measure the positions of both the proton and the electron beam. To assure beam alignment within 10% beam sigma precision for a 300-μm electron beam, we designed the modulator with a rise and fall time of only 50 ns.

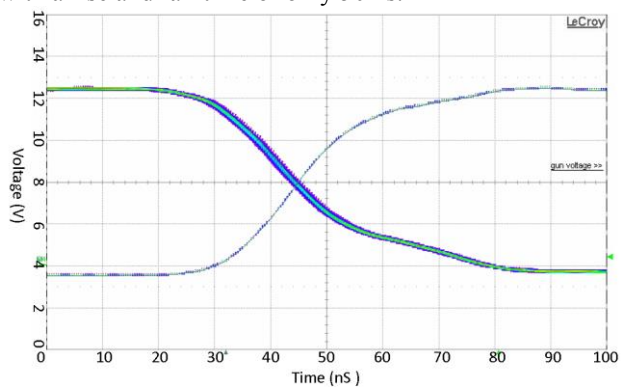

Figure 5: Rise and fall times of the electron beam measured via the anode voltage.

Although the beam current is a non-linear function of the voltage, the rise and fall times of the current signal are very close to the rise and fall times of the anode's voltage signal. Therefore, at first, we measured the electron beam rise and fall times via measuring those of the anode voltage.

Figure 5 plots the beam rise and fall time, measured with a waveform persistence setup; it reveals that the

Copyright © 2013 CC-BY-3.0 and by the respective authors

rising edge of the beam is more stable than the falling edge. The frequency is 80 kHz, and the anode voltage is 10 kV.

The rise and fall times for 98% of the amplitude are 60 ns and 70 ns, respectively. We located the Behlke switch of the anode modulator about 0.6 m away from the anode because of the test bench structural limitations. We will reduce the contribution of the capacitance and inductance of the connecting cable to the transitions of the modulator pulses in the e-lens by positioning the Behlke switch much closer, i.e., 10 cm, to the anode feed-through.

PINHOLE SCANNER AND YAG SCREEN

The pinhole scanner was fully tested, evaluated, and calibrated. By adding a bias voltage on the pinhole we found that the behaviour of the secondary electrons play an important role in the total signal at the integral pinhole scanner.

Figure 6 shows the beam profile, acquired by the pinhole scanner for a beam of 200 mA. The profile has a flat top at the center, and lesser intensity at the edges of the beam, as predicted by the 2D program TRAK with a measured cathode profile.

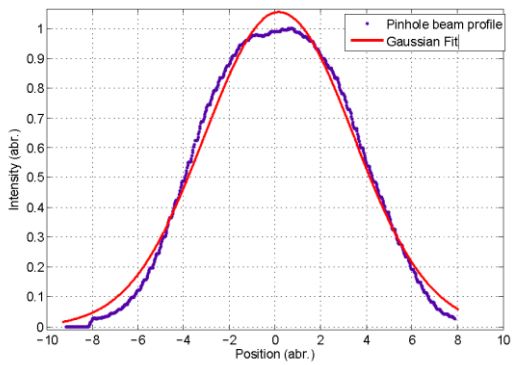

Figure 6: Beam profile obtained using pinhole scanner.

We also developed a YAG screen and camera system for measuring the beam profile. Our findings for a 144 mA electron beam are plotted in Fig. 7; the profile is similar to that depicting the pinhole results.

The YAG screen can obtain the beam profile within seconds. We acquired many beam profiles for different system configurations. However, caution is required here because the YAG screen is very fragile and can be damaged by unwanted beam current.

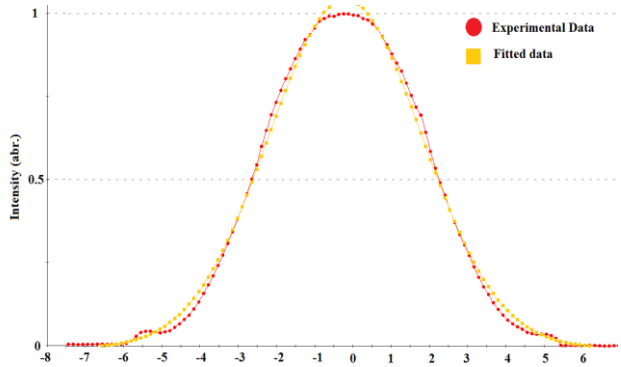

Figure 7: Beam profile from YAG screen, showing the correspondence between the experimental and fitted data.

SUMMARY

We tested and improved the electron gun, collector, some instrumentation, and some power supplies on the e-lens test bench. The software- and the machine-protection system were also prototyped. All of these tests resulted in a considerable savings in time for commissioning the 2013 e-lens, and later on.

SINGLE PASS ELECTRON COOLING SIMULATIONS FOR MEIC*

G. I. Bell†, I. V. Pogorelov and B. T. Schwartz, Tech-X Corp, Boulder, CO, 80303, USA
Yuhong Zhang and He Zhang, Jefferson Lab, Newport News, VA, 23606, USA

Abstract

Cooling of medium energy protons is critical for the proposed Jefferson Lab Medium Energy Ion Collider (MEIC). We present simulations of electron cooling of protons up to 60 GeV. In the beam frame in which the proton and electrons are co-propagating, their motion is non-relativistic. We use a binary collision model which treats the cooling process as the sum of a large number of two-body collisions which are calculated exactly. This model can treat even very close collisions between an electron and ion with high accuracy. We also calculate dynamical friction using a δf PIC model. The parallel code VSim (formerly Vorpal) is used to perform the simulations. We compare the friction rates with that obtained by a 3D integral over electron velocities which is used by BETACOOL.

ELECTRON COOLING

In the simplest form of electron cooling [1], an electron beam is created with the same γ as a relativistic ion beam which we wish to cool. The two beams are then made to co-propagate over a section of a storage ring, the **cooling section**. In the **beam frame** traveling with the average velocity of the particles, their velocities are non-relativistic, and the particles interact by means of Coulomb collisions.

This paper explores the amount of dynamical friction which can be obtained in an (unmagnetized) cooling section of the Jefferson Lab Medium Energy Ion Collider. The particles to be cooled are protons with $\gamma = 65.4$. The cooling section is $s = 60$ m long. These simulations are done in 3D, where x and y are transverse coordinates and z is the direction of beam propagation.

The bunched electron beam is non-uniform, but suppose we consider a small region only a few Debye lengths wide in the center of the electron bunch. In this region, the electron density is nearly constant. We consider a distribution of electrons which is uniform in space and has a Maxwellian distribution in velocity

$$f_0(\vec{v}) = \frac{n_e}{(2\pi)^{3/2}\sigma_x\sigma_y\sigma_z}\exp\left[-\frac{v_x^2}{2\sigma_x^2}-\frac{v_y^2}{2\sigma_y^2}-\frac{v_z^2}{2\sigma_z^2}\right], \quad (1)$$

where n_e is the density in the center of the electron bunch. In the beam frame the RMS velocities $\vec{\sigma}$ are non-relativistic, specific values are given in Table 1. Note that

Table 1: Electron Beam Parameters Used in the Simulations, all Parameters are in the Beam Frame

parameter	symbol	value	unit
electrons per bunch		2.5	10^9 elec.
peak density	n_e	1.32	$10^{15}e/m^3$
plasma freq.	ω_p	3.26	10^8/sec
plasma per.		3.07	nanosec
interaction time	τ	3.06	nanosec
trans. RMS bunch size	r_x	303	μm
long. RMS bunch size	r_z	1.3	m
trans. RMS velocity	σ_x	2.35	10^5 m/sec
long. RMS velocity	σ_z	0.36	10^5 m/sec
trans. Debye length	λ_x	114	μm
long. Debye length	λ_z	17.5	μm

z is the direction of beam propagation, and because this is an accelerated beam it is not isotropic, and $\sigma_z < \sigma_x = \sigma_y$.

Consider now a single ion moving at velocity $\vec{v}_{ion}$, and let $\vec{v}_{\rm rel} = \vec{v}_{ion} - \vec{v}$ be the velocity of each electron relative to the ion. Assuming each collision is symmetric in time, the dynamical friction force on the ion can be calculated by the 3D integral over the electron velocity space [2]

$$\vec{F}_{\|} = -\frac{n_e Z^2 e^4}{4\pi\epsilon_0^2 m_e}\int_{-\infty}^{\infty}\Lambda\,\frac{\vec{v}_{\rm rel}}{|\vec{v}_{\rm rel}|^3}f_0(\vec{v})\,d^3\vec{v}. \quad (2)$$

Here Z is the ion charge number (for protons, $Z = 1$), $e < 0$ is the electron charge, and m_e is the electron mass. In the simplest case, the Coulomb logarithm

$$\Lambda = \log(\rho_{max}/\rho_\perp), \quad (3)$$

where ρ_{max} and $\rho_\perp$ are often called "the maximum and minimum impact parameters". This terminology is unfortunate, because equation (2) actually includes contributions from collisions with arbitrarily small impact parameters [2]. $\rho_\perp$ is the impact parameter for 90 degree scattering

$$\rho_\perp(\vec{v}_{\rm rel}) = \frac{Ze^2}{4\pi\epsilon_0 m_e|\vec{v}_{\rm rel}|^2}. \quad (4)$$

In the actual beam, collisions with arbitrarily small impact parameters can occur. In simulations, the problem is that very small impact collisions are rare, and there may not be enough of them to accumulate good statistics. Therefore, in simulations it is advantageous to introduce a cutoff

ρ_c, and to ignore collisions with impact parameter less than ρ_c. A modified Coulomb logarithm for equation (2), which can take into account ρ_c as well as the finite interaction time is given by [2]

$$\Lambda = \frac{1}{2}\log\left[\left(\frac{\rho_{max}^2+\rho_\perp^2}{\rho_\perp^2+\rho_c^2}\right)\left(\frac{\rho_c^2+d^2}{\rho_{max}^2+d^2}\right)\right], \quad (5)$$

where $d = |\vec{v}_{\rm rel}|\tau/2$ and $\tau = s/(\gamma\beta c)$ is the interaction time in the beam frame. Note that the Coulomb logarithm (5) reduces to (3) in the case where $\rho_c = 0$ and $d \gg \rho_{max} \gg \rho_\perp$.

In general, the Coulomb logarithm Λ is different for each electron because of the dependence of $\rho_\perp$ and d on $\vec{v}_{\rm rel}$. We cannot hope to calculate the integral (2) analytically, but it is easily calculated numerically because the velocity distribution $f_0(\vec{v})$ decays exponentially.

If $\omega_p = (n_e e^2/(m_e\epsilon_0))^{1/2}$ is the plasma frequency, then the Debye lengths in x, y and z, respectively, are $\lambda_x = \sigma_x/\omega_p$, $\lambda_y = \sigma_y/\omega_p$ and $\lambda_z = \sigma_z/\omega_p$. For this accelerated beam the longitudinal Debye length is considerably less than the transverse Debye length.

Over one passage through the cooling section, suppose we need to accumulate more than N_c collisions of impact parameter less than ρ_c in order to get good statistics on these collisions. In [2] it is shown that for the isotropic case, N_c and ρ_c are related by the formula

$$\rho_c = \sqrt{\frac{N_c}{\langle|\vec{v}_{\rm rel}|\rangle\tau\pi n_e}}, \quad (6)$$

where $\langle|\vec{v}_{\rm rel}|\rangle$ is the average magnitude of the relative velocity over all electrons. This equation can be used in the numerical models to set the cutoff impact parameter ρ_c.

To estimate the dynamical friction in the actual beam, we numerically evaluate the friction (2) using the Coulomb logarithm (5) with $\rho_c = 0$ and $\rho_{max} = 3r_x$, where r_x is the transverse RMS bunch size. Figure 1 shows the friction force in eV/m obtained for protons moving at various velocities. If the electron velocity distribution were isotropic, Figure 1 would be radially symmetric in $|\vec{v}_{ion}|$. Instead it shows enhanced friction longitudinally, and the maximum friction force of 0.659 eV/m occurs for a proton moving purely longitudinally with $v_z = 0.90 \times 10^5$ m/s.

SIMULATION MODELS

Electron cooling is an extremely weak effect, and difficult to capture numerically. The Debye shielding cloud around one proton has a magnitude on the order of the proton charge, $|e|$. Therefore, the perturbation in the electron bunch due to the presence of a single proton is nine orders of magnitude smaller than the charge of the electron bunch, $(2.5 \times 10^9)e$.

The first model we consider is the **binary collision** model [2]. The Coulomb collisions are modeled as an n-body problem, although we ignore electron-electron interactions. The interaction between each ion and electron is calculated exactly as a 2-body problem, with the contributions summed over all particles. This produces an n-body solver which can accurately model any 2-body collision with a constant time step [2]. To accurately model 3-body and higher collisions the time step must be decreased during these interactions, however these collisions are rare and do not contribute appreciably to dynamical friction.

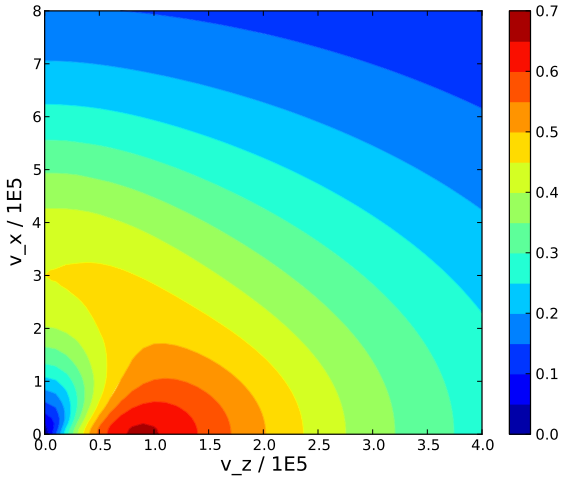

Figure 1: A contour plot of the friction force in eV/m as a function of the longitudinal and transverse ion velocity. This figure is only shown in one quadrant because it is symmetric in the other three.

In order to reduce the noise in these simulations, we add a positron over each electron with identical location and velocity. When an electron and positron interact with a proton, the diffusive velocity kicks cancel while the dynamical friction accumulates. Without this trick the dynamical friction would be dominated by particle noise.

Figures 2 and 3 show friction estimates from the binary collision model, the two figures are for purely longitudinal or transverse motion, the two axes of Figure 1. However, the theoretical curves are not the same as in Figure 1, because we have adjusted the theory to take into account the size of the numerical domain (L), and use a ρ_c corresponding to $N_c = 5$. The simulation domain is a cube $L = 800$ µm on a side, and in [2] it is shown that we should use $\rho_{max} = \min\{3r_x, 0.43L\}$ and $d = \min\{|\vec{v}_{\rm rel}|\tau/2, 0.43L\}$. These modifications of the Coulomb logarithm (5) reduce the friction by about 30% compared with the values in Figure 1. The theoretical friction values compare well with those predicted by the binary collision model. The error bars are derived by comparing friction rates for multiple ions. In the transverse case (figure 3) the errors can be large, probably because the electrons are hotter transversely ($\sigma_x > \sigma_z$).

The second model we consider is a **linear δf PIC model** [3–5]. We consider the shielding to be a perturbation from the equilibrium Vlasov-Poisson equation. The perturbation is modeled using weighted particles, where the particle weight represents the perturbation and all weights start at zero. The δf particles move in response to background

Copyright © 2013 CC-BY-3.0 and by the respective authors

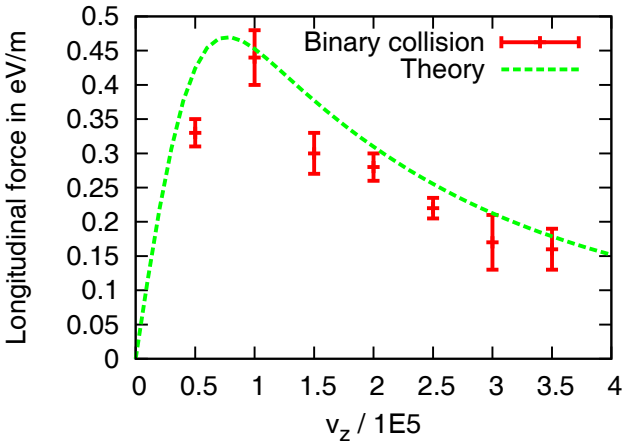

Figure 2: Theoretical longitudinal friction, eq. (2) versus that obtained from the binary collision model.

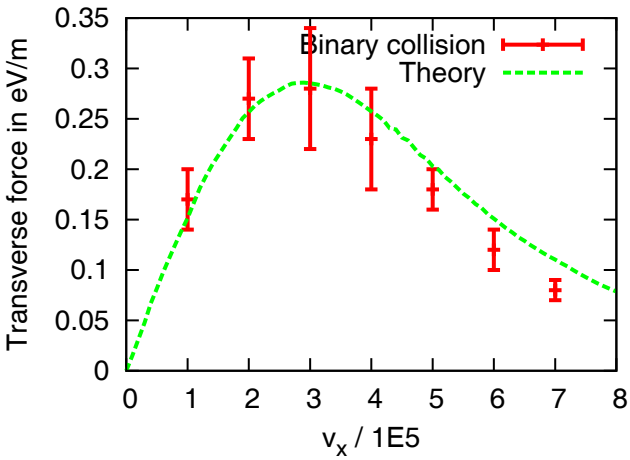

Figure 3: Theoretical transverse friction versus that obtained from the binary collision model.

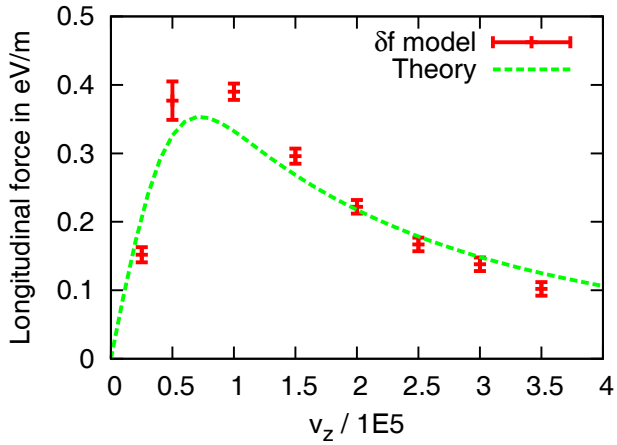

Figure 4: Theoretical longitudinal friction, eq. (2) versus that obtained from the δf model.

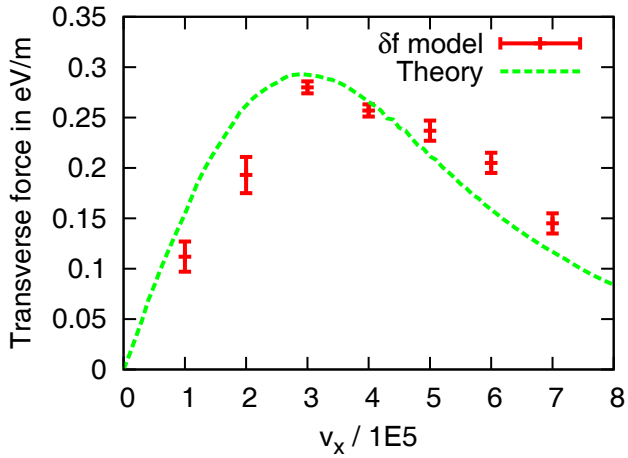

Figure 5: Theoretical transverse friction versus that obtained from the δf model.

fields, and their weights evolve to capture the shielding. The ions move in the electric field of the δf particles using the Boris push [6]. In all cases, the average force on each ion is calculated from the velocity change of the ion over the run. We note that a force of 0.5 eV/m results in a proton velocity change of 0.15 m/s over the cooling section, or about 1 part in 10^6 of the proton beam frame velocity.

Figures 4 and 5 show dynamical friction results for the δf model. The δf model uses a different domain size which is not cubical, therefore in the theoretical model we have inserted a different L. The error in the δf method is often very small, because different protons behave similarly. The δf method eliminates much of the particle noise present in the binary collision model.

SUMMARY

Theoretical estimates of dynamical friction (2) have been confirmed by two numerical simulations. The theoretical model includes effects from the finite interaction time τ, and also effects present in simulations such as finite domain size L and a lower cutoff in impact parameter, ρ_c. The numerical simulations agree well with the theoretical model when we insert appropriate values of these parameters.

MEIC ELECTRON COOLING SIMULATION USING BETACOOL*

He Zhang†, Yuhong Zhang, Jefferson Lab, Newport News, VA 23606, USA

Abstract

Electron cooling of ion beams is one critical R&D issue in Jefferson Lab's medium energy electron-ion collider (MEIC). In the present MEIC design concept, a multi-phase cooling scheme is adopted. In the ion pre-booster, a DC electron cooler is responsible for assisting ion beam accumulation and initial cooling. In the ion collider ring, the ion beams with energies up to 100 GeV/u are cooled by a high current bunched electron beam driven by an energy-recovery SRF linac assisted by a circulator ring. It is essential to understand how efficient that electron cooling is, particularly in the high energy range, and how the cooling electron bunches in the circulator cooler ring are affected by the cooling process and other collective beam effects, in order to confirm the feasibility of the design. Here we present first results of the simulation studies of electron cooling processes of MEIC using BETACOOL code.

INTRODUCTION

The MEIC is designed to deliver a peak luminosity above 10^{34} $\mathrm{cm}^{-2}\mathrm{s}^{-1}$ and covers a CM energy range up to 65 GeV. It offers an electron energy up to 12 GeV, a proton energy up to 100 GeV, and corresponding energies per nucleon for heavy ions with the same magnetic rigidity [1]. The MEIC ion complex consists of ion sources, a linac, two boosters and a medium energy collider ring, as shown in Fig. 1. The conventional electron cooling is chosen to assist cumulation of ions from the linac and to reduce and preserve the emittance of the MEIC ion beam. We propose to have electron coolers installed both in the pre-booster and in the collider ring, and our multi-phase electron cooling scheme includes the following steps: (1) low energy (up to 2 MeV) DC cooling at the pre-booster, (2) bunched electron cooling at the ion injection energy (up to 20 GeV/u) of the collider ring, and (3) bunched cooling at the top ion energy (100 GeV/u) of the collider ring. An important feature of this scheme is continuous electron cooling of the ion beams during their collision with the electron beam.

While the electron cooling mechanism is well developed and successfully tested with low energy DC beam applications world wide, we are challenged by the high density and high energy of the MEIC ion beam [2, 3]. The present design concept calls for an ERL for the high energy cooler in the collider ring for meeting the request of a very high RF power and additionally a circulator ring for mitigating the electron gun life time challenge [1]. There are a number of critical R&Ds for this design concept, for example, (1) what is the cooling efficiency at the high energy range with a bunched electron beam; (2) how the cooling electron bunches in the circulator cooler ring are affected by the cooling process and other collective beam effects; and further (3) how the cooling efficiency is affected by the continually (slow) degradation of the cooling bunches during circulation of the cooling. In the report, we present our initial results for the simulation studies of the first issue listed above. For simplicity, the coupling to the electron beam dynamics in the circulator cooler ring is ignored. The latter is currently also under studied [4]. In other words, the cooling electron bunches in the simulations are assumed ideal, fresh from the electron source, for each cooling, instead of being a real beam circulating in the cooler ring. At a later time, these two studies will be combined as we expect.

MODELS AND METHODS

Ideally a start-to-end simulation should be carried out for the entire process of MEIC ion beam formation and cooling, nevertheless, presently there is no such a code capa-

ble of taking such a task. Therefore, we simulate various physics processes independently.

To explore the capability and limitations of both the low energy DC cooler and high energy ERL cooler, we have performed simulations for the following three hypothetical cooling schemes: (1) only the DC cooler in the pre-booster, (2) only the ERL circulator cooler in the collider ring, and (3) using both the DC cooler in the pre-booster and the ERL circulator cooler in the collider ring. It is expected that such simulations will shed the lights of the nominal MEIC cooling design scheme.

The highest kinetic energy of protons in the pre-booster is 3 GeV, the corresponding energy of the cooling electron energy is about 2 MeV. Space charge effect of the DC electron beam is included. In the collider ring, a Gaussian bunched electron beam of 1.5 A is used to cool a coasting (very long bunch) proton beam at the injection energy (20 GeV), and the same electron beam is used to cool a Gaussian bunched proton beam at the collision energy (60 GeV for the nominal design point). The beam and cooler parameters for the different cooling schemes are presented in Table 1.

We utilized the well developed BETACOOL code, which provides various formulas for the intra-beam scatterings (IBS) effect and cooling force calculation, along with various models for dynamic simulations [5]. As to the following results, Martini model [6] is used for IBS effect calculation, the model beam method is for DC cooling simulation and the RMS dynamic method with single particle model is for bunched electron beam cooling simulation [5].

SIMULATION RESULTS

Cooling in Pre-booster Only

In the pre-booster, the initial normalized emittance of the proton beam is assumed to be 3.15 $\pi \cdot \mathrm{mm} \cdot \mathrm{mrad}$ in both transverse directions, which is limited by the space charge tune shift. The momentum spread dp/p is assumed to be 0.001. The radius of the electron beam is 0.832 cm, which is three times of the rms radius of the proton beam. The current of the electron beam is 3A. Fig. 2(a) shows the evolvement of the normalized emittance and the momentum spread of the proton beam during the cooling process. After about 600 s, the transverse emittance of the proton beam reaches the equilibrium at about (0.6, 0.2) $\pi \cdot \mathrm{mm} \cdot \mathrm{mrad}$. Because we need to stack five injections in the collider ring, 600 s is too long. We would like to stop cooling after 200 s, when the emittance was reduced to (1.18, 0.99) $\pi \cdot \mathrm{mm} \cdot \mathrm{mrad}$. After the pre-booster, we inject the proton beam into the large booster, accelerate it to 20 GeV, and then inject it to the collider ring. The first long bunch needs to wait 800 s for the following four bunches before we accelerate them together to 60 GeV. During this 800 s, the horizontal emittance of the proton bunch will increase up to 1.45 $\pi \cdot \mathrm{mm} \cdot \mathrm{mrad}$ due to the IBS effect, which is shown in Fig. 2(b). After being accelerated to 60 GeV, without cooling the horizontal emittance keeps increasing due to IBS effect. As Fig. 2(c) shows, after two hours the horizontal emittance will be about 3.8 $\pi \cdot \mathrm{mm} \cdot \mathrm{mrad}$. For both energy stages, the vertical emittance remains almost unchanged because the vertical IBS effect is much smaller than the horizontal one.

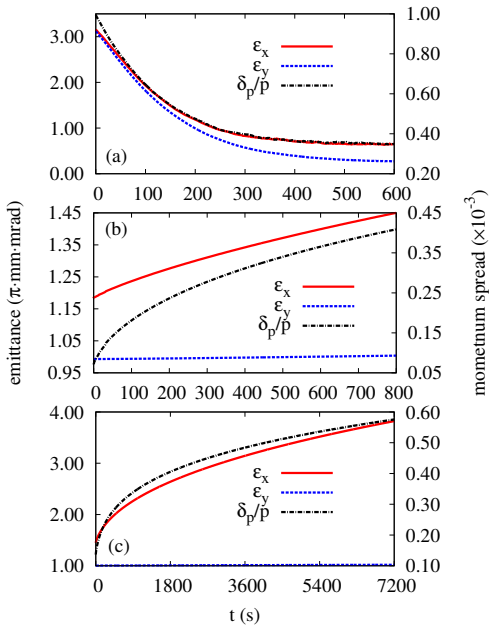

Figure 2: Cooling in the pre-booster (a) and IBS induced emittance and momentum spread expansion in the collider ring at 20 GeV (b) and 60 GeV (c).

Cooling in Collider Ring Only

Without cooling in the pre-booster, we assume the initial normalized emittance of the proton beam in the collider ring at 20 GeV to be 3.15 $\pi \cdot \mathrm{mm} \cdot \mathrm{mrad}$, limited by the space charge tune shift, and the momentum spread 3×10^{-3}. We will cool the coasting (very long bunch) proton beam at 20 GeV first, and then cool the bunched proton beam at 60 GeV. Cooling at 20 GeV turns out to be quite efficient as shown in Fig. 3(a). The emittance reaches the equilibrium within 250 s. When the proton beam is bunched at 60 GeV, its IBS effect is about two orders of magnitude higher in the horizontal direction than in the vertical direction, while the friction forces in both directions are roughly the same. Hence there is a tendency to over cool the beam in the vertical direction, which as a result of the over cooling makes the cooling in horizontal direction even more difficult. If the transverse motion of the proton beam is coupled, the emittance growth due to IBS effect will be redistributed in the two directions according to the coupling rate, which makes the cooling in the horizontal direction easier and also provides a way to control the transverse bunch sizes. Simulation results also support this hypothesis. If the emittance at 20 GeV is reduced to 0.30 $\pi \cdot \mathrm{mm} \cdot \mathrm{mrad}$, then at 60 GeV after the proton beam is bunched, the emittance can be further reduced to 0.17 $\pi \cdot \mathrm{mm} \cdot \mathrm{mrad}$ within 20 s with 100% coupling in trans-

Copyright © 2013 CC-BY-3.0 and by the respective authors

verse directions as shown in Fig. 3(b). Or the emittance can be reduced to (0.30,0.07) $\pi \cdot \mathrm{mm} \cdot \mathrm{mrad}$ with 40% transverse coupling as shown in Fig. 3(c), which provides a flat beam.

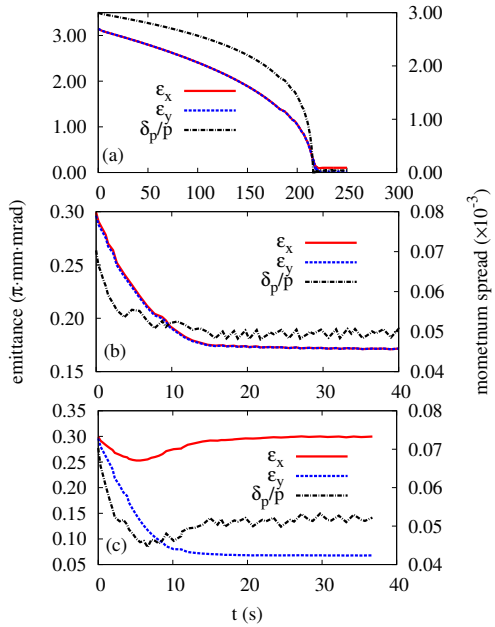

Figure 3: Cooling in the collider ring at 20 GeV (a) and at 60 GeV for 100% (b) and 40% (c) coupled p^+ beam.

Cooling in Pre-booster and Collider Ring

Now we consider both the DC cooling in the pre-booster and the ERL circulator Cooling in the collider ring. the DC cooling in the pre-booster is the same as shown in Fig. 2(a). Assuming the normalized emittance of the proton beam out of the pre-booster is (0.83,0.57) $\pi \cdot \mathrm{mm} \cdot \mathrm{mrad}$ and we start to cool from this emittance in the collider ring at 20 GeV, the evolvement of the emittance and momentum spread of the proton beam is shown in Fig. 4(a). Initially the longitudinal cooling is strong and the momentum spread reaches the lowest point within five seconds and then starts to increase again. When the emittance is reduced to about 0.3 $\pi \cdot \mathrm{mm} \cdot \mathrm{mrad}$, dp/p is in the order of 10^{-6} and it is increasing, according to Fig. 4(a), which means energy is transferring from the transverse directions to the longitudinal direction. If we stop cooling the coasting beam at this point, it is reasonable to assume dp/p will increase during the following accelerating and bunching process. In the following simulations for the cooling at 60 GeV, an initial dp/p of 3.7×10^{-4} is used. As Fig. 4(b) and Fig. 4(c) show, the emittance can be reduced to 0.23 $\pi \cdot \mathrm{mm} \cdot \mathrm{mrad}$ within 20 s when fully coupled in the transverse directions or (0.31,0.18) $\pi \cdot \mathrm{mm} \cdot \mathrm{mrad}$ within 30s when 50% coupled.

SUMMARY AND DISCUSSION

Preliminary simulation results suggest the design parameters of MEIC cooling system are achievable. We did simi-

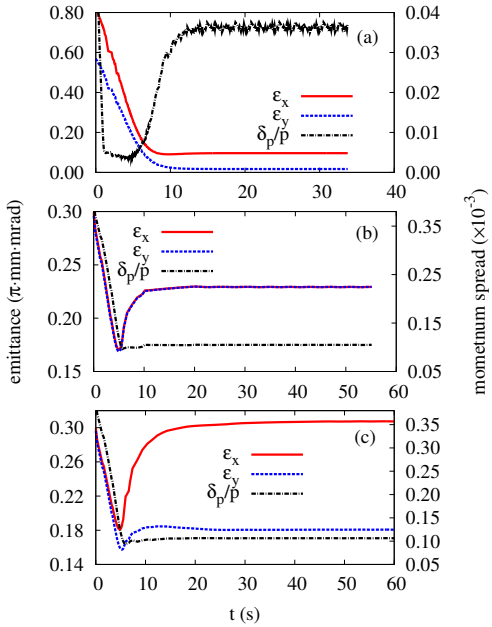

Figure 4: Cooling in the collider ring at 20 GeV (a) and at 60 GeV for 100% (b) and 50% (c) coupled p^+ beam.

lar simulations for heavy ions, the cooling of which turned out easier than that of protons. There are some points we want to note as follows. Transverse coupling is helpful for the cooling in the collider ring, but its dynamic effect needs to be studied. In the above simulations, we assume the ion beams always have Gaussian distributions. However, this is not necessarily true. We need to study how the ion beam distribution evolves in different cooling processes and how much it affects the results if the distribution deviates from Gaussian. Analytical formulas are used to calculate the friction force, and their accuracy under the MEIC parameters need to be checked and confirmed. We plan to use the electron bunches multiple times in cooling, so it is crucial to understand how the electron bunches are affected by the proton bunches, which is currently out of the ability of BETACOOL. New method, such as N-particle simulations, may need to be developed and applied.

STATUS AND FUTURE PLAN OF THE DEVELOPMENT OF A COMPACT X-RAY SOURCE BASED ON ICS AT LASER UNDULATOR COMPACT X-RAY (LUCX)*

M. Fukuda#, S. Araki, A. Aryshev, Y. Honda, N. Terunuma, J. Urakawa, KEK, Ibaraki, Japan
K. Sakaue, M. Washio, RISE, Tokyo, Japan

Abstract

We have developed a compact X-ray source via inverse Compton scattering (ICS) between multi-bunch electron beam and a laser pulse stacked in an optical cavity at Laser Undulator Compact X-ray (LUCX) accelerator in KEK. Since the autumn of 2011, we have begun X-ray imaging test. In the beginning, it had taken two hours to get an X-ray image because of low intensity of X-ray with 10^4 photons/pulse. To get a clear X-ray image in a shorter period of times, we have upgraded the accelerator, which consists of a 3.6 cell photo-cathode rf-gun, a 12cell standing wave accelerating structure and a 4-mirror planar optical cavity. The target intensity of an electron beam is 500nC/pulse with 1000 bunches at 30 MeV. The one of laser pulse is also 6mJ/pulse. The expected number of X-ray is $1.7\text{x}10^7$ photons/pulse with 10% bandwidth. We have already started the multi-bunch beam generation and X-ray imaging test after upgrade. The accelerator produces 26.8 MeV beam with the total charge of 380nC in 300 bunches per pulse. The aging process is also continued to increase energy and intensity. We will report the results of the beam test and future plan of the development of a compact X-ray source at LUCX.

INTRODUCTION

X-rays have various fields of application, such as medial application, biological science, material science etc. Synchrotron radiation produced by GeV order storage ring is commonly used for high brightness X-ray source. However the device is generally huge and expensive. On the other hand, the X-ray source based on ICS is compact and inexpensive because this method can decrease this energy of an electron beam by more than an order of magnitude when producing X-rays with the same energy.

We have constructed the LUCX accelerator at KEK in order to develop the compact X-ray source based on ICS. Since the autumn of 2011, we have begun X-ray imaging test and succeeded to take the X-ray image of fish bone[1]. However, it took two hours to get the image due to low intensity of X-ray with 10^4 photons/pulse.

We have upgraded this accelerator in order to increase the intensity of X-rays in last year. The 3.6cell rf-gun, 12cell booster and 4mirror cavity have been designed and constructed for this upgrade. The X-ray generation and the X-ray imaging are already started after upgrade[2]. We will report the current status and future plan of the X-ray experiment in the accelerator.

#mfukuda@post.kek.jp

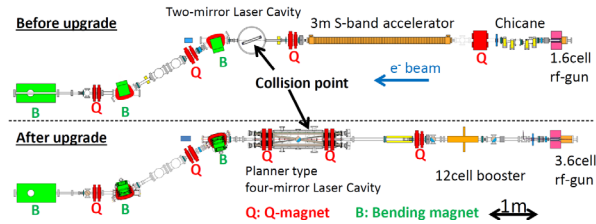

Figure 1: The beamline of the LUCX accelerator before/after upgrade.

LUCX ACCELERATOR

The upgraded beamline is shown in Fig. 1. A 3.6cell photo-cathode rf-gun generates an electron beam with the energy of 10MeV and then the beam is accelerated to 30MeV by a 12cell booster. After that, the beam is collided with a laser pulse in a 4-mirror planar optical cavity and then X-rays are generated by ICS. The X-rays are extracted into the atmosphere through a Be window with the thickness of 300μm. The electron beam is separated from the X-ray by a bending magnet and then is dumped to the beam dump.

3.6Cell Photo-Cathode Rf-Gun

An S-band 3.6cell rf-gun[3] has been installed instead of 1.6cell rf-gun to increase the beam energy. The cut view and the picture of the rf-gun is shown in Fig. 2. The cavity structure consists of smooth curves to increase the Q-value of the cavity and to reduce dark current from the surface. Cesium telluride (Cs_2Te) film is evaporated on the surface of the Mo cathode plug which is attached in the cavity by the load-lock system. An electron beam is emitted from the cathode by irradiating 266nm UV laser light. The beam is accelerated to 10MeV.

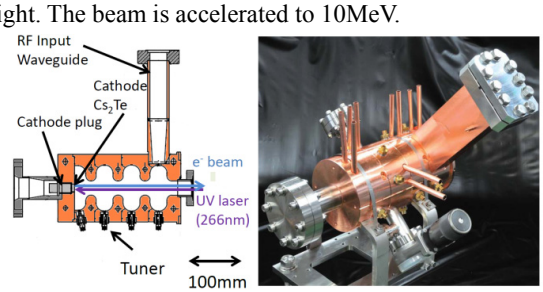

Figure 2: The cut view and the picture of 3.6cell rf-gun.

The cavity of the 3.6cell rf-gun has four resonance modes. Therefore the surface of the iris in the cavity has

Copyright © 2013 CC-BY-3.0 and by the respective authors

reduced 3mm rather than former in order to expand the mode separation. The separation between 2/3π mode and π mode is 2.8MHz. The size of rf input port is also enlarged to adjust the coupling β to close to 1. Table 1 shows the parameter of the rf-gun.

12Cell Booster

A 12cell booster[3], which is standing wave accelerating tube, has been installed instead of an S-band travelling wave accelerating tube in order to downsize the accelerator section. The length has been shortened from 5.7 to 2.5m. An electron beam is accelerated to from 10MeV to 30MeV here.

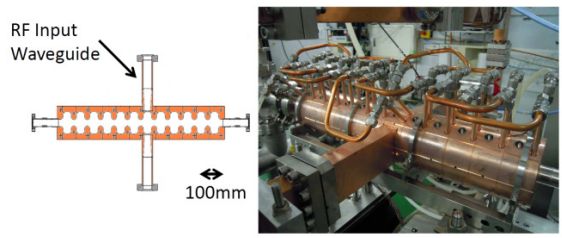

Figure 3: The cut view and the picture of the 12cell booster.

Figure 3 shows the cut view and the picture of the 12cell booster. The structure of the cavity is almost the same as that of the rf-gun. However, the accelerator has twelve resonant modes. Therefore the surface of the iris in the cavity has further reduced compared with that of the rf-gun to extend the mode separation. The separation between 10/11π mode and π mode is 1MHz. In addition, rf power is input through two input ports to obtain symmetrical electric field in a coupling cavity. The parameter of the 12cell booster is shown in Table 1.

Table 1: Parameters of the Rf-Gun and the Booster

	3.6cell rf-gun	12cell booster
Frequency(π-mode)	2856MHz	2856MHz
Q-value	15000	17800
Coupling β	0.99	1.1
R/Q	395Ω	420Ω
Mode separation	2.8MHz(π-2/3π)	1MHz(π-10/11π)

4-Mirror Planar Optical Cavity

A four-mirror planar optical cavity[2] is a four-mirror bow-tie ring resonator. The drawing is illustrated in Fig. 4. The cavity enhances the laser power and makes small laser size at the collision point. The spacing of laser pulses is equal to that of electron bunches. Therefore the laser pulses can collide with all bunches of multi-bunch electron beam.

To increase the luminosity of ICS by enhancing the stored power in the cavity and by bringing close to head-on collision, the 4mirror cavity is installed. The distance of the concave mirrors is made longer than former 2-mirror cavity to enhance the stored power and the laser size on the mirror is enlarged because the stored power is limited by the damage threshold of the mirrors. Moreover, the collision angle of an electron beam and a laser pulse is reduced to 7.5deg. The parameters are shown in Table 2.

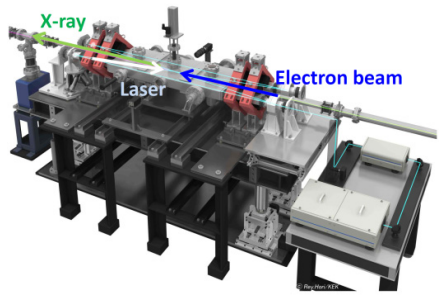

Figure 4: Drawing of the 4-mirror planar optical cavity.

Laser Master System

The length of 4-mirror cavity must be held in the accuracy less than angstrom to keep resonance. It is very difficult to also synchronize to the accelerator simultaneously with this. Therefore the master signal is generated from the signal of laser pulses injected to the cavity. That is to say the accelerator devices such as klystrons synchronize with the cavity and the rf frequency is determined by the length of the cavity. We call this method the laser master system, whose diagram is shown in Fig. 5. By using this method, the 4-mirror cavity should just maintain resonance and the stability has improved very much.

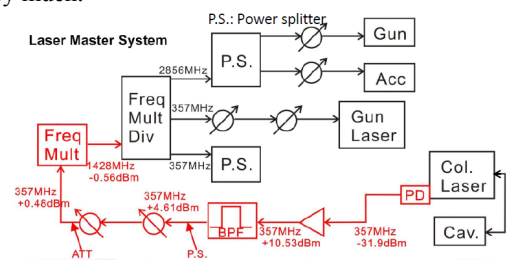

Figure 5: Diagram of the laser master system.

MULTI-BUNCH BEAM GENERATION

We have successfully generated the 300 bunches beam with 26.8 MeV and 380nC total charge now. The 3.6cell rf-gun produces 8.1MeV electron beam and the 12cell booster accelerates up to 26.8MeV.

The beam loading compensation is important issue when accelerating a multi-bunch beam. The loading effect is compensated by injecting the beam in the timing of the transition region when rf power is filled[4]. The compensation optimized by adjusting the timing between an electron beam and a rf pulse. In this upgrade, the accelerating tube is changed into the standing wave type cavity which has with the same Q-value as the rf-gun. This makes the compensation easy because these timings for the compensation become also almost same. Figure 6

Copyright © 2013 CC-BY-3.0 and by the respective authors

shows the measured energy of multi-bunch beam. The energy difference is within 1.2% (peak to peak). The energy spread(rms) of each bunch is also 0.1%.

Figure 7 shows the emittance when changing the solenoid field with the bunch charge of 1.25nC/bunch. The emittance at the solenoid current of 116A is about 5π mm mrad. The beam size at the collision point is also 80μm x 50μm.

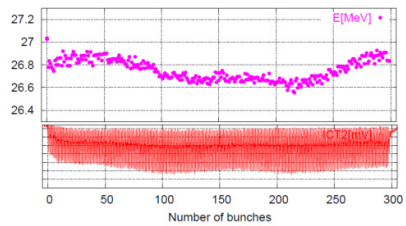

Figure 6: These graphs show the energy of multi-bunch beam and the current transformer waveform.

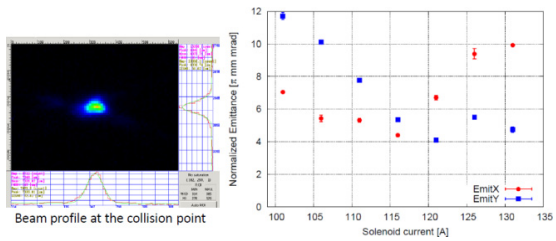

Figure 7: The left picture is the beam profile at the collision point. The right graph shows the result of emittance measurement.

X-RAY IMAGNING TEST

We already start to generate ICS X-rays and to take X-ray images after upgrade. A Micro-Channel Plate (MCP) and a Silicon-On-Insulator (SOI) pixel sensor[5] are used as X-ray detector. The MCP is utilized for measuring the intensity of X-rays. The SOI sensor can take the X-ray image with high spatial resolution because the SOI sensor has very small pixel size of 17μm. The sensor can also obtain the X-ray signal with high signal to noise ratio because the sensor can distinguish an X-ray and a high energy particle by measuring the deposit energy at each pixel or by checking whether the signal is detected along several pixel.

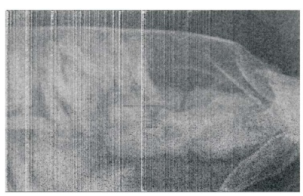

Figure 8: Captured image of chilli pepper by SOI sensor.

We have succeeded to obtain very clear image by the SOI sensor. Figure 8 shows the X-ray image of Chilli pepper[2]. The number of X-rays injected to SOI sensor is 5460 photons/pulse with the energy of 9keV. The number of total band is 5.1×10^5 photons/pulse. The total irradiated number of X-rays to the SOI sensor is 6.7×10^7 photons.

We are trying to increase the intensity of ICS X-ray by increasing the number of electron bunch and the intensity of a laser pulse after X-ray imaging test. Current number of X-rays in total band is 1.4×10^6 photons/train. It is about three times at the time of X-ray imaging test.

SUMMARY AND FUTURE PLAN

We have upgraded the LUCX accelerator and the laser cavity to increase the intensity of X-rays, which increased by about 10 times as compared with upgrade before. The clear image can also be obtained by the SOI pixel sensor.

Table 2 and 3 show the present and target parameters of an electron beam and a laser pulse respectively. The target intensity of X-rays is 1.7×10^7 photons/pulse 10%b.w. at the energy of 15keV in this upgrade. To achieve it, more number of electron bunch and higher energy electron beam is needed as the accelerator side. The target number of electron bunch is 1000bunches/pulse with 30MeV. Therefore we continue the rf processing of 3.6cell rf-gun and 12cell accelerating tube to expand the rf pulse width and to increase rf power. We will try X-ray phase imaging with Talbot-Lau interferometer if we could obtain the higher intensity of X-rays from now.

Table 2: Present and Target Parameters of Electron Beam

	Present	Target
Energy	26.8MeV	30MeV
Intensity	1.25nC/bunch	0.5nC/bunch
Number of bunch	300	1000
Beam size (rms)	33μm x 33μm	80μm x 50μm
Pulse length	15ps	---

Table 3: Present and Target Parameters of Laser

	Present	Target
Wave length	1064nm	---
Pulse energy	0.4mJ/pulse	6mJ/pulse
Beam size (rms)	89μm x 85μm	50μm x 25μm
Pulse length	7ps	---
Collsion angle	7.5deg	---

HIGH-CHROMATICITY OPTICS FOR THE MAX IV 3 GeV STORAGE RING

T. Olsson, S.C. Leemann, MAX IV Laboratory, Lund University, SE-22100 Lund, Sweden

Abstract

The ultralow emittance lattice of the MAX IV 3 GeV storage ring has a large negative natural chromaticity. This has to be corrected to positive values to prevent head-tail instabilities. On the other hand, high linear chromaticity can lead to a large tune footprint which limits Touschek lifetime. Therefore, the linear chromaticity is corrected to +1 in both planes with sextupoles while octupoles are used to further reduce the tune footprint. Studies indicate this design leads to threshold currents for resistive wall and transverse mode coupling instabilities beyond what is expected during regular user operation. However, since these are only preliminary studies based on approximations, the possibility of instability issues during commissioning needs to be considered. A short term solution is to operate the storage ring at a higher chromaticity. This paper describes the developed high-chromaticity optics for the MAX IV 3 GeV storage ring. It focuses on reduction of chromatic and amplitude-dependent tune shifts to maximize dynamic aperture and Touschek lifetime. A comparison between the performance of the new high-chromaticity optics and the design optics is also presented.

INTRODUCTION

The MAX IV facility is a 3rd generation state-of-the-art synchrotron light source currently under construction in Lund, Sweden [1]. The MAX IV 3 GeV storage ring has an ultralow emittance lattice with a large negative natural chromaticity in both planes [2]. To avoid head-tail instabilities, the linear chromaticity has to be corrected to positive values. On the other hand, a large linear chromaticity can lead to proximity to, or crossing of, potentially dangerous resonances, which can limit dynamic aperture and Touschek lifetime. To satisfy both constraints, the linear chromaticity in the design optics of the MAX IV 3 GeV storage ring has been corrected to +1 in both planes [2]. Initial instability studies indicate this design leads to threshold currents for resisitive wall instability and transverse mode coupling instability beyond what is expected during user operation [3]. However, since these are only preliminary studies based on initial estimates of the impedance budget the possibility of instability issues occurring during commissioning needs to be considered. The instability studies indicate that the threshold currents increase with chromaticity. A short term solution is therefore to operate the storage ring at a higher chromaticity. An alternate optics for the MAX IV 3 GeV storage ring with linear chromaticity +4 in both planes has therefore been developed [4]. This paper presents the performance of the newly developed high-chromaticity optics in comparison to the design optics. The challenges to achieve a high-chromaticity optics with sufficient performance are also described.

NONLINEAR OPTICS OPTIMIZATION

The MAX IV 3 GeV storage ring make use of strong sextupoles to correct the linear chromaticity, minimize chromatic tune shifts and tailor the chromatic tune footprint while minimizing first-order resonance driving terms. Octupoles are employed to minimize the amplitude-dependent tune shifts and further tailor the tune footprint. This approach is detailed in [5]. The same approach was used during the development of a high-chromaticity optics.

OPA [6] was used to correct the linear chromaticity to +4 in both planes using the two strongest chromatic sextupoles. All five sextupole families were then adjusted to optimize the chromatic tune footprint while constraining the linear chromaticities to +4.

The chromatic tune shifts for the high-chromaticity optics are displayed in Fig. 1. For both planes, the resulting chromatic tune shifts for the high-chromaticity optics are not unexpectedly larger than the corresponding tune shifts for the design optics across the entire range of interest.

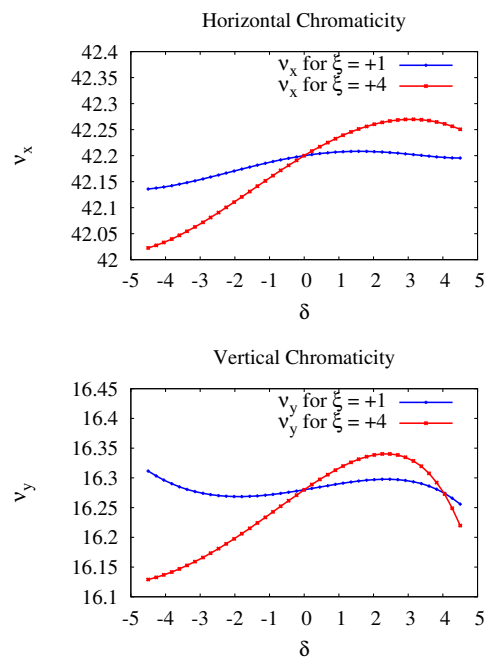

Figure 1: Chromatic tune shifts for the high-chromaticity optics calculated by TRACY-3 [7]. The chromatic tune shifts for the design optics are displayed for comparison.

Copyright © 2013 CC-BY-3.0 and by the respective authors

The chromatic tune footprint for the high-chromaticity optics is displayed in Fig. 2. The chromatic tune shifts were tailored with OPA to avoid the $\nu_x + 2\nu_y = 75$ resonance which is assumed to be potentially strongly driven. The resonances $\nu_x - \nu_y = 26$, $2\nu_x - \nu_y = 68$ and $3\nu_y = 49$ are all skew resonances. They were assumed to be weaker driven and less focus was put on avoiding them. The resulting chromatic tune footprint although not large, is not as compact as the chromatic tune footprint of the design optics detailed in [8].

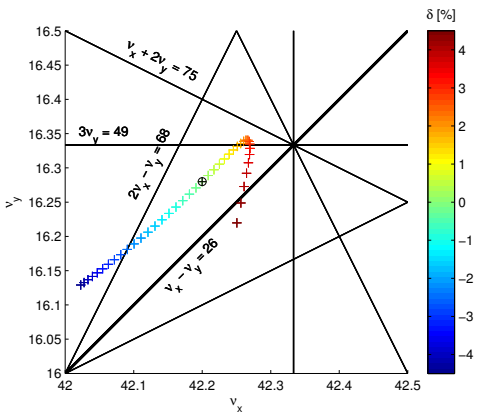

Figure 2: The chromatic tune footprint for the high-chromaticity optics calculated by OPA. Resonances up to third order are displayed.

The three families of octupoles were then used to tailor the amplitude-dependent tune shifts. The resulting amplitude-dependent tune shifts for the high-chromaticity optics are displayed in Fig. 3. It is evident that the amplitude-dependent tune shifts are larger for the high-chromaticity optics than for the design optics.

DYNAMIC APERTURE

The dynamic aperture for the high-chromaticity optics is displayed in Fig. 4. Comparison with the dynamic aperture for the design optics presented in [8] reveals that the dynamic aperture for the high-chromaticity optics is smaller. However, the required on-momentum dynamic aperture is achieved. The off-momentum dynamic aperture is smaller for $\delta = -4.5\%$ than for $\delta = +4.5\%$ which is a consequence of the chromatic tune shifts.

MOMENTUM ACCEPTANCE

The off-momentum diffusion map is displayed in Fig. 5. The momentum acceptance appears to be limited to within $\delta = -7\%$ and $\delta = +9\%$. Within the required momentum acceptance $\delta = \pm 4.5\%$ several areas with somewhat elevated diffusion and some bands and ring-shaped structures possibly indicating resonant behavior are visible. From frequency map analysis two resonances can be recognised, $4\nu_x = 169$ and $4\nu_y = 65$. These are both upright octupole resonances that are not expected to be driven strongly. For

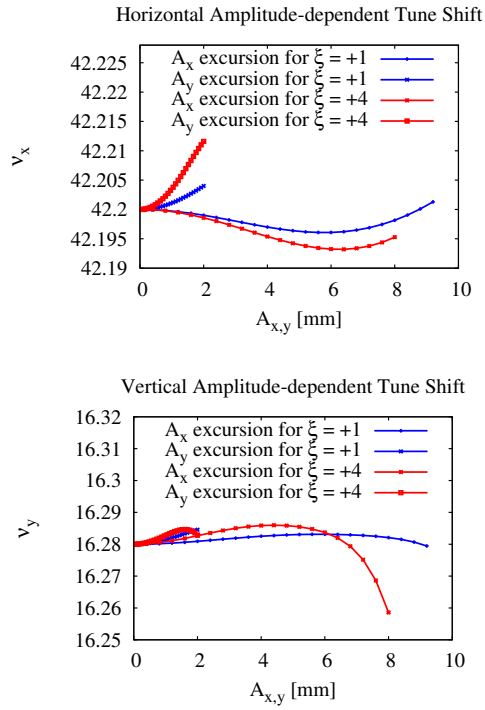

Figure 3: Amplitude-dependent tune shifts for the high-chromaticity optics calculated by TRACY-3. The amplitude-dependent tune shifts for the design optics are displayed for comparison.

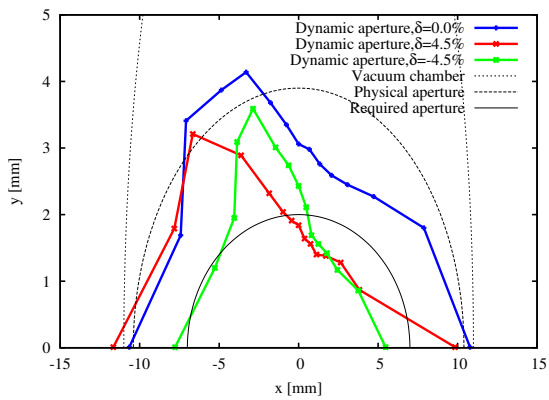

Figure 4: Dynamic aperture at the centre of the long straight sections for the high-chromaticity optics calculated by TRACY-3. The physical aperture originating from the vacuum chamber and the aperture required for injection and lifetime reasons are also shown.

$\delta < -5\%$ there appears to be an area with chaotic motion. Frequency map analysis indicates that this occurs close to the integer resonance.

TOUSCHEK LIFETIME

The Touschek lifetime of the high-chromaticity optics was determined by 6D tracking with TRACY-3 using actual

Copyright © 2013 CC-BY-3.0 and by the respective authors

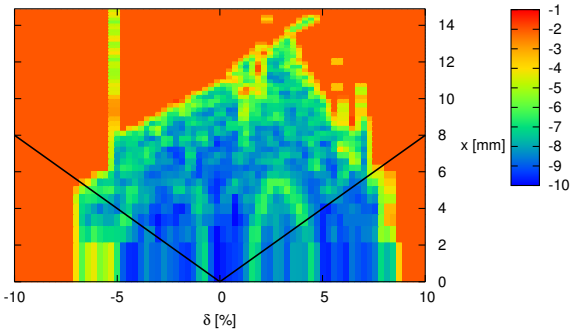

Figure 5: Diffusion map for off-momentum particles at the centre of the long straight sections for the high-chromaticity optics calculated by TRACY-3. Blue areas show low diffusion and red areas high diffusion. The vertical amplitude was set to +0.1 mm. The black line is an approximation of the maximum dispersive orbit.

vacuum chamber apertures. For the maximum stored beam current of 500 mA, vertical emittance 8 pm rad and maximum cavity voltage 1.8 MV, the Touschek lifetime was determined to be 8.98 hours. Neither the effects of IBS nor the Landau cavities present in the MAX IV 3 GeV lattice were included in this calculation. This is a reduction of roughly 5 hours compared to the corresponding Touschek lifetime of the design optics [8].

ERROR STUDIES

Initial error studies have been performed. These studies indicate that a lattice momentum acceptance of $\pm 4.5\%$ will not be achievable with the high-chromaticity optics, however an overall momentum acceptance of roughly $\pm 3.5\%$ is ensured. This will considerably reduce the Touschek lifetime. Initial estimates for the reduction of Touschek lifetime caused by magnet and alignment imperfections indicate that the Touschek lifetime could still be sufficient to allow the high-chromaticity optics to be used in the MAX IV 3 GeV storage ring as a short term solution should instability issues occur during commissioning. Further studies of the reduction of Touschek lifetime with errors need to be performed to fully validate this conclusion.

CHALLENGES FOR A HIGH-CHROMATICITY OPTICS

The correction of the linear chromaticity to +4 in both planes sets high demands on the nonlinear optics to achieve sufficiently large dynamic aperture to ensure an efficient injection process and sufficiently large Touschek lifetime. Since the linear chromaticity is set to +4 there is a need for strong sextupole magnets and skillful optimization of the chromatic tune footprint to accomplish small chromatic tune shifts which do not approach dangerous resonances. Because of the enlarged chromatic tune footprint caused by the increased linear chromaticity, the demand for small amplitude-dependent tune shifts is further increased.

The strong sextupole magnets and the need for small amplitude-dependent tune shifts call for strong octupole magnets. When the gradients of the octupole magnets are considerably enlarged they start to have a substantial effect on the chromatic tune shifts through higher order dispersion. Therefore, the chromatic tune shifts and the amplitude-dependent tune shifts have to be optimized with regard to each other. This results in a more complex design process. Several iterations and skillful design are required to achieve good performance. A possible alternative is to apply MOGA [9] to find a high-chromaticity optics with further improved performance.

CONCLUSIONS

A high-chromaticity optics with linear chromaticity +4 in both planes has been developed for the MAX IV 3 GeV storage ring. The high-chromaticity optics has a smaller dynamic aperture than the design optics, especially for off-momentum particles. The momentum acceptance of the high-chromaticity optics is therefore lower compared to the design optics. No major effect on the efficiency of the injection process is expected since the dynamic aperture requirements are fulfilled on-momentum. However, the reduction of momentum acceptance will result in a considerable reduction of Touschek lifetime. Initial estimates for the reduction of Touschek lifetime caused by errors indicate that the performance of the high-chromaticity optics should be sufficient to allow the optics to be applied in the MAX IV 3 GeV storage ring as a short term solution if instability issues occur during commissioning. Further studies are necessary to validate this conclusion. There also exist opportunities to revise the high-chromaticity optics and perhaps further improve its performance.

CREATION OF HIGH-CHARGE BUNCH TRAINS FROM THE APS INJECTOR FOR SWAP-OUT INJECTION*

C.-Y. Yao, M. Borland, L. Emery, L. Donley, F. Lenkszus, B.-X. Yang
Advanced Photon Source, Argonne National Laboratory, Argonne, IL 60439, USA

Abstract

A multi-bend-achromat (MBA) low-emittance lattice is being explored for a future APS Upgrade [1]. Due to its small dynamic aperture, the traditional injection scheme must be replaced with a "swap-out" scheme [2]. Several options were considered for the creation of a high-charge bunch train from the injector, and we selected an option that builds the bunch train in the existing particle accumulator ring (PAR). This option enables both single-bunch mode, which is necessary to support current APS operation, and bunch-train mode. This report provides a description of the injection process, simulation results, and specifications of injector timing, kicker, and rf subsystems.

INTRODUCTION

The APS injector consists of a 450-MeV electron linac, a particle accumulator ring (PAR), and a synchrotron booster. The PAR has a 9.77-MHz cw fundamental system (RF1) and a 117.3-MHz pulsed 12th-harmonic system (RF12). In the first 250 ms, beam is accumulated into the RF1 bucket and damped to a bunch length of ~0.86 ns. RF12 is turned on at 250 ms of the PAR cycle and compresses the bunch length to 0.3 ns. Bunch cleaning is performed at 350 ms, and beam is further damped and extracted at 483 ms. Currently the injector runs at a 2-Hz rate and provides a single bunch with a beam charge of up to 4 nC. For an APS MBA low-emittance lattice, the injection scheme would be replaced with a single-bunch or bunch train swap-out scheme. Several bunch fill patterns are being considered: a single-bunch high-charge mode with up to 4 mA per bunch, and a multiple bunch mode that consists of multiple bunch trains, each with up to 5 bunches per train.

HIGH-CHARGE SINGLE-BUNCH AND BUNCH TRAIN GENERATION

The APS MBA upgrade now under exploration envisions two types of fill patterns: a 48-singlet fill pattern with a single-bunch charge of up to 15 nC, and a multi-bunch-train fill pattern with up to 432 bunches.

For 48-singlet mode the injector would need to deliver up to a 20-nC single-bunch with an emittance of 30 nm-rad in the x and y planes. The rf gun, without major upgrade, can deliver about 1 nC per pulse with 30-Hz repetition rate. To reach 20 nC we would need to extend the PAR accumulation cycle from the current value of 0.5 second to 1 second or longer. Figure 1 shows a possible 1-second PAR accumulation cycle. During the first 633.33 ms, 20 linac pulses are accumulated, while the next 100 ms is used to damp the beam to about 0.8 ns in length. The 12th-harmonic rf is turned on around 733.33 ms, following which the beam is captured into the 12th-harmonic bucket and compressed to a bunch length of 0.3 ns. Bunch cleaning is then turned on for 20 ms. After a final damping of 100 ms, beam is extracted to the PAR-to-booster (PTB) beam transport line. The current rf system, with modest upgrades, can support this operating cycle.

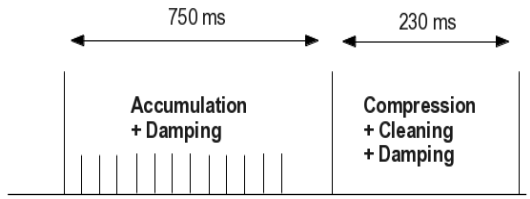

Figure 1: Accumulation of high-charge single-bunch beam in the PAR.

For the multiple bunch-train fill pattern, we consider 2 to 5 consecutive bunches per bunch train with a total of up to 432 bunches and flexible spacing between the trains. To build such bunch trains the PAR rf system must be replaced with a cw 352 MHz system. The bunches can be either accumulated one at a time with a linac micro-bunch length of less than 1.5 ns, or simultaneously with a long linac micro-bunch of up to 15 ns. In both cases a fast gun chopper with a rise time of ~1 ns is needed to accurately control the length of the linac micro-bunches. Bunch cleaning can be performed after accumulation to remove unwanted satellite bunches. Figure 2 shows one possible bunch-train fill pattern with 4 bunches per train.

Figure 2: A multiple bunch train fill pattern.

TIMING SYSTEM UPGRADE

The APS timing system would need to be upgraded to accommodate the new fill patterns and timing precision requirements. The "swap out" mode of operation and ns-level rise/fall time of the kickers requires much-reduced jitter time, estimated to be 50 ps or lower. The jitter time of the existing APS timing system, measured in the range of 200 to 500 ps, is apparently inadequate. A new timing infrastructure would need to be developed to achieve the required timing precision.

STORAGE RING KICKER UPGRADE

The swap out injection scheme [3] requires extracting an old bunch or an old train of bunches and replacing it with a new one. The spacing between the singlet bunches or bunch trains can be as short as two or three buckets, i.e., 5 to 8 ns. The rise time and fall times must be shorter than this spacing. Since traditional ferrite-based kickers would not provide such fast response, we are exploring the use of multiple striplines driven with very fast pulse generators, e.g., similar those made by FID GmbH [4]. For on-axis injection we would need a 3-mrad total kick angle. A set of seven striplines could be used for injection with a total length of 2.8 m. Another set would be used for extraction. Development work on the stripline kicker is underway. Table 1 lists the main parameters for the stripline kickers.

Table 1: Main Parameters of the Stripline Kickers

Impedance (Ω)	Drive voltage (kV)	Kick angle (mrad)	Total kick (mrad)	Total length (m)
50	±20	0.4	3.0	2.8

RF POWER AND DETUNING REQUIREMENTS FOR HIGH SINGLE-BUNCH CHARGE

At 20-nC single-bunch charge the PAR average current is 200 mA and we expect to see much stronger beam loading effects. Upgrades of rf amplifiers and tuning loops would be needed to compensate for the high beam loading. The booster rf system (RF5) would also need to handle a beam current of 17 mA. An estimated 450 kW of rf power is required at extraction, 50 kW more than the current value, and much higher detuning is required at injection. Table 2 lists the required rf power and detuning angle for the upgraded rf systems. Based on these estimates, the current cavities, the RF1 amplifier, and the RF5 klystron can support the required power. The amplifier for the PAR RF12 system would need to be upgraded, and the detuning range for the PAR cavities must be measured and re-evaluated. The booster cavity uses mechanical tuners that can only react to slow changes. The large detuning range between the injection and extraction of the booster beam may require a fast tuner. We are considering installing ferrite tuners through a coupler installed in one of the ports of the cavity. If that is not practical then direct rf feedback must be considered to stabilize the beam.

Table 2: Rf Power and Detuning Requirements

System	Gap Volt V(kV)	Shunt imp. Rs (MΩ)	Power P (kW)	Detuning ψ (deg)
RF12	30	0.22	4.2	40
RF1	40	0.37	4.8	40
RF5@inj	620	221	1.8	80
RF5@inj	9000	221	460	20

Figure 3 and 4 shows the estimated power and detuning for the PAR RF12 system.

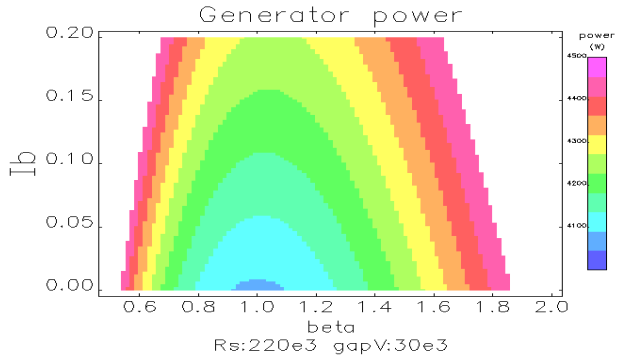

Figure 3: Power requirement as a function of beam current and coupling coefficient for RF12.

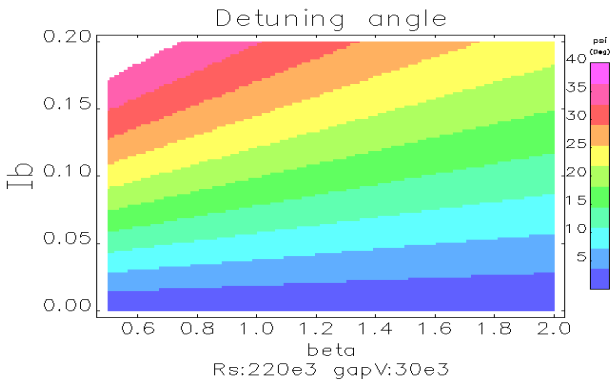

Figure 4: Detuning requirement as a function of beam current and coupling coefficient of the RF12 cavity.

BEAM INSTABILITIES

Resistive-wall, coupled-bunch, and ion instabilities are stronger with higher single-bunch charge. Chromaticity correction is perhaps the most effective compensation method. For the PAR, the sextupole magnets and corrector magnets are combined. A current limit of 4 A limits the chromaticity to 1 or 2 in both planes, even though the sextupole power supply can provide more than 10 A. We will perform magnetic measurements and evaluate the feasibility of increasing the sextupole current limit to 10 A, which will bring the chromaticity to 6 to 7. The booster sextupole magnets, especially the defocusing sextupoles (SD), are currently close to their power supply limit. We would need to upgrade these supplies to increase the sextupole field by a factor of 1.2 to 1.5. Pole-tip shimming is also being considered. Simulations show that adding 3-mm shims to the poles increases the sextupole field by 30%. Combining these two methods should give a 50% increase in booster sextupole strengths for a target chromaticity of ~7 in both planes.

Transverse feedback systems would need to be installed for both the PAR and booster in case dynamic aperture becomes a limiting factor with increased chromaticity.

BOOSTER BEAM EMITTANCE

The beam emittance of the booster 92-nm lattice, measured at the current energy of 7 GeV, is 72 nm-rad.

Copyright © 2013 CC-BY-3.0 and by the respective authors

The reduction in emittance is due to momentum offset caused by rf frequency change. At 6-GeV extraction energy of the APS MBA lattice, the booster emittance would be reduced to 53 nm-rad, much higher than the sub-100 pm MBA lattice emittance. Since the MBA lattice uses on-axis injection and also has nearly equal β-functions for both x- and y-planes, we can further reduce the effective booster emittance by full coupling. A study shows that full coupling can be realized by moving the booster tunes together along the ramp cycle. Figure 5 shows a tune measurement result. We measured a reduction of x-emittance by a factor of two. Hence, we anticipate that we can achieve a booster emittance of 30 nm in both planes.

BOOSTER RAMP SUPPLY UPGRADE

The booster ramp supplies employ 12-phase-SCR-based voltage regulation hardware. Current regulation is achieved with workstation-based ramp correction programs. The system runs well for normal operations. However the supplies, especially the dipole supply, are sensitive to AC line harmonic distortion and line voltage changes. To insure the stability and reliability of injector operation we may need to replace the power supply with switching-type power supplies with current regulation.

In addition, the corrector ramp control hardware would be upgraded to achieve a ramp update time of 1 to 2 seconds, which would enable us to run orbit correction with sufficient speed.

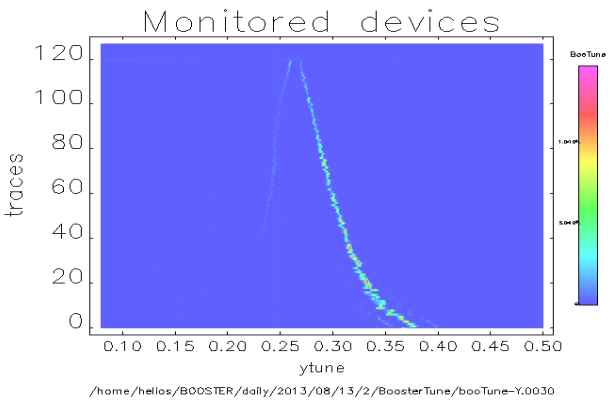

Figure 5: Tune plot of a fully coupled booster beam. The bright trace is the horizontal tune and the dim trace on the left is the vertical tune. Each trace represents 1.8 ms in time.

LINAC SYSTEM UPGRADE

The APS linac consists of dual thermionic rf guns and a photocathode gun, two non-SLEDed klystrons (L1 and L3), and three SLEDed klystrons (L3, L4, and L5) delivering a maximum beam energy of 450 MeV. During normal operations the linac delivers a 375-MeV beam. High single-bunch charge injection may require running the linac with more pulses per cycle and a beam energy of 450 MeV. This may impact linac reliability, so we may add a waveguide switching network so a spare klystron (L6) can be a hot spare for the L4 or L5 klystrons. A kicker that serves as a bunch length chopper, which has a rise/fall time of 50 ns, would be upgraded with a new power supply giving few-ns rise and fall times, in order to accurately control the linac micro-bunch length.

BEAM DIAGNOSTICS UPGRADE

The PAR beam position monitors (BPMs) have a strong beam intensity dependence and can only be used for slow orbit correction in a limited beam current range. New BPM electronics would be needed to increase the dynamic range of the BPMs. The new system would also provide turn-by-turn history capability for beam physics studies, e.g., analysis of instabilities and potential cures.

The booster BPM system was designed to read the average orbit at one time slot during a ramp. It can only be used to tune up beam orbit. A new booster BPM system would use the same BSP-100 module [5] used in the APS storage ring. The new system would provide averaged orbits for up to five time slots along the acceleration cycle, allowing orbit to operate continuously. The orbit correction program could be configured to treat each of the combinations of BPMs and time slots as an independent variable. Turn-by-turn histories would also be available for such tasks as injection trajectory correction, beam stability analysis, etc.

CONCLUSIONS

An MBA extreme low-emittance lattice is being explored for a future APS upgrade. A “swap out” scheme with a high-charge singlet fill pattern and a multiple-train hybrid fill pattern are under consideration. We considered the options and necessary upgrades in order to prepare the injection beam with the existing APS injector complex.

OBSERVATION OF +1 BUCKET BUNCH IMPURITY GROWTH AT THE APS STORAGE RING*

C.-Y. Yao, B.-X. Yang, M. Borland, ANL, Argonne, IL 60439, USA

Abstract

The APS storage ring has three fill patterns: a 24-singlet, a 1+8x7 hybrid with a leading bunch of 16 mA, and a 324-singlet. Bunch purity of better than 1×10^{-6} is required for +3 and higher bucket numbers for the first two fill patterns during user operations. A PAR bunch cleaning system is used to clean the satellite bunches. During top-up user operation, beam charge in satellite bunches grows due to the long lifetime of the low charge satellites. Recent storage ring developments, including operating with the bunch-by-bunch feedback system, reduction of chromaticity, and lattice correction, have increased the dynamic and momentum aperture of the storage ring. We observed unusual beam charge growth in +1 buckets, which indicates leakage of electrons from the main bunches to the +1 satellite buckets. This report describes the observation and the dependence of leakage on chromaticity settings, and gives a brief analysis.

OBSERVATION OF ABNORMAL +1 BUNCH GROWTH

Figure 1 shows the normal growth of the +1 satellite bucket relative counts in the 24-singlet fill of the RHB (reduced horizontal β-function) lattice, recorded in the first run period of 2013. It has a typical growth rate of ~2×10^{-8} per hour. Figure 2 shows an abnormal growth of the +1 bucket counts with a growth rate of ~3×10^{-6}, about 150 times higher than normal value. Typical injector bunch impurity for the +1 satellite bucket is at the 8×10^{-7} level and can not explain this abnormal growth. A test was conducted with injected beam turned off and top-up injection systems continuously running. We observed significant growth of net counts in the +1 satellites while the -1 buckets showing no growth. A plot of the result is shown in Figure 3. This test confirmed that the +1 bucket counts come from leakage of main bunches.

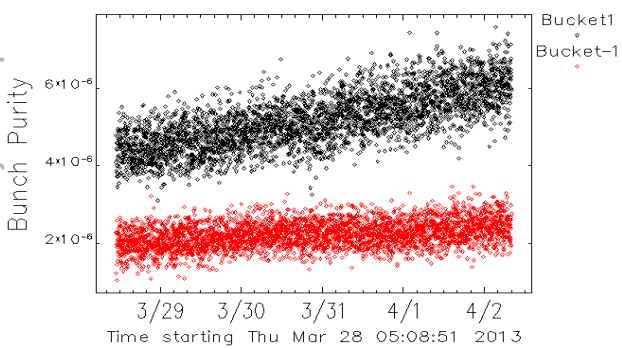

Figure 1: Normal accumulation of the +1 satellite bucket during user operations.

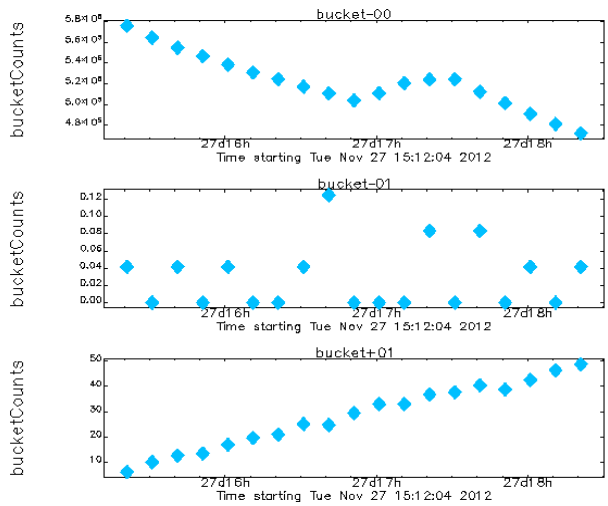

Figure 3: Average bucket count change during a test in which the injected beam is turned off while top-up injection systems were running. Top: main bucket. Middle: -1 bucket showing no growth. Bottom: +1 bucket showing steady growth.

LEAKAGE RATE FITTING

In order to find the relationship between the +1 bunch impurity and the change in storage ring chromaticity, we varied chromaticity in 0.5 steps and collected bunch purity data during Run-1 of 2013. We fit the resulting data with `sddsgenericfit` [1].

The +1 bucket relative counts can be expressed with the following differential equation:

$$dI = \frac{I_0}{T_0} C_{inj}\, dt - \frac{I}{T_b}\, dt + I_0\, R_{leak}\, dt \quad . \qquad (1)$$

The variables are defined as:
I_0 --- main bucket beam current

Copyright © 2013 CC-BY-3.0 and by the respective authors

I --- +1 satellite beam current
T_0 --- main bucket lifetime
R_{leak} --- defusing rate from main to +1 bucket
C_{inj} --- +1 bucket ratio of injected beam
T_b --- +1 bucket beam lifetime

The solution of this equation can be expressed as:

$$\frac{I(t)}{I_0}=\frac{I(0)}{I_0}e^{-\frac{t}{T_b}}+C_1[1-e^{-\frac{t}{T_b}}] \quad , \qquad (2)$$

where I(0) is the initial +1 satellite current, and C_1 is the expected final +1 bucket impurity defined as:

$$C_1=T_b\left(\frac{C_{inj}}{T_0}+R_{leak}\right) \quad . \qquad (3)$$

Injector +1 bunch impurity was estimated from bunch purity data taken immediately after a fill-from-zero. Average beam lifetime over the data collection time was used as T_0, mainly determined by the lifetime of the main bunches.

Table 1 lists fit results and other relevant parameters. The negative leakage rates in some cases are probably due to measurement error, which only indicates a very low or zero leakage rate. Figures 4 and 5 show plots of leakage rate and expected final +1 bunch purity versus chromaticity, respectively. The dependence of leakage rate on x-chromaticity is clear. The results also show that in order to avoid high +1 bucket counts we need to operate with a minimum x-chromaticity of ~4.0.

Table 1: Measured and Fit Parameters

Data date	x-chrom	+1 bucket asymptote impurity	+1 bucket lifetime (s)	Main bucket lifetime (s)	Leak rate (1/s)
03-13	3.122	$9.29e^{-04}$	$7.02e^{5}$	$4.04e^{4}$	$1.30e^{-9}$
03-20	3.625	$1.37e^{-04}$	$2.79e^{5}$	$3.90e^{4}$	$4.68e^{-10}$
03-27	5.638	$2.15e^{-06}$	$5.77e^{5}$	$3.49e^{4}$	$-2.0e^{-11}$
04-03	4.127	$1.82e^{-06}$	$5.47e^{5}$	$3.19e^{4}$	$-2.27e^{-11}$

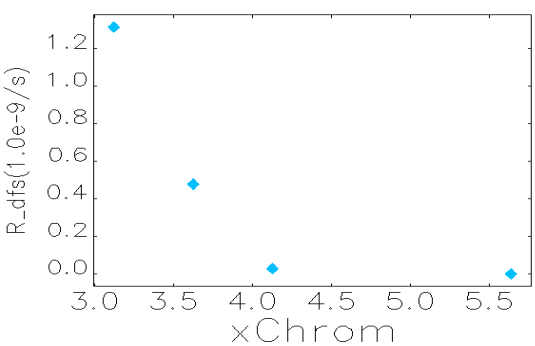

Figure 4: Fit leak rate versus x-chromaticity.

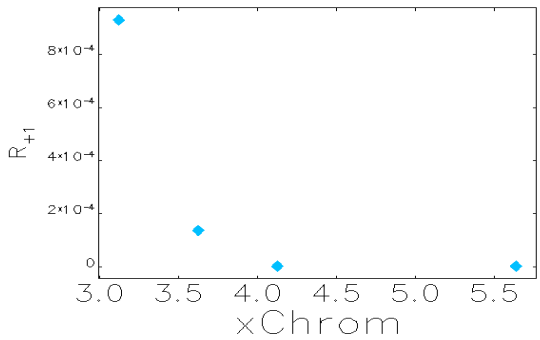

Figure 5: Expected final +1 impurity versus x-chromaticity.

ANALYSIS

The fact that +1 buckets gained electrons while -1 buckets did not implies occurrence of a longitudinal re-capture process.

Earlier studies of beam dynamic aperture and lifetime [2] found that decreasing chromaticity and subsequent reduction of non-linear tune shift extends the momentum acceptance of the APS storage ring beyond that of the normal-chromaticity lattice. We speculate that it is possible that "lost" electrons due to Touschek scattering or other processes stay longer around the longitudinal separatrix, as shown in Figure 6, and are recaptured in the following bucket due to another scattering event. However simulations we performed with `elegant` so far are unable to confirm this theory. One possible reason is that the required simulation time, on the order of 10^4 seconds scale, and total initial particle counts are too high for us to achieve in the limited time available. Further studies, such as varying gap voltage while observing change in the +1 bucket impurity and continued simulations with different parameters are planned.

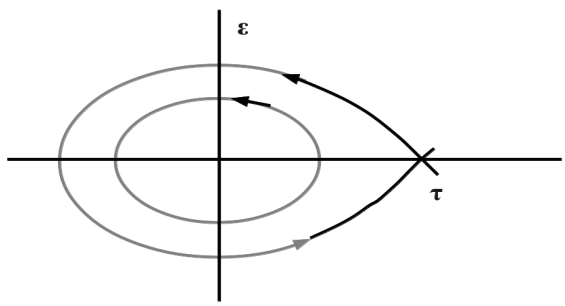

Figure 6: Longitudinal phase-space diagram of a storage ring bucket.

CONCLUSIONS

Recapture of electrons that are lost from the main bucket into the +1 satellite bucket has been observed during the most recent 24-singlet RHB lattice user run when x-chromaticity is +3.6 or lower. This is the first time we have observed this process in the APS storage ring. The leakage rate depends on the value of the x chromacity and

Copyright © 2013 CC-BY-3.0 and by the respective authors

is estimated to be around 10^{-9}/s. During a week-long top-up fill, the accumulated +1 bucket bunch impurity can be as high as a few times 10^{-4}. The recapture process stops completely when x-chromaticity is above 4.0. This observation may have implications for future APS storage ring lattice development.

ACKNOWLEDGEMENT

The authors acknowledge fruitful discussions with L. Emery, Y. Chae, K. Harkay, K. Schroeder and the assistance of APS operatons crew in collecting the data.

FUTURE NSLS-II INJECTOR UPGRADES*

T. Shaftan#, G. Wang, J. Rose, R. Fliller, R. Heese, F. Willeke, BNL, Upton, New York

Abstract

Last year we began commissioning of the NSLS-II injection system. In 2013 the NSLS-II injector, which consists of 200 MeV linac, 3 GeV booster, transport lines and storage ring injection straight section, will be entering operations. During injection system development we invested substantial efforts in preserving options for future injector upgrades and enhancements. In this paper we discuss our vision and plans of incremental evolution of the NSLS-II injector by implementing planned upgrades, such as the second gun, flexible bunch patterns, beam stacking in the booster, emittance compensation techniques in the transport lines, etc. These upgrades will expand the facility capabilities, improve the beam quality and increase operational reliability.

INTRODUCTION

The NSLS-II [1] is a state-of-the-art 3 GeV synchrotron light source under construction at Brookhaven National Laboratory. It will provide ultra-bright synchrotron radiation of 10^{21}·photons·s^{-1}·mm^{2}mrad^2·0.1%BW^{-1} at 2 keV and high photon flux of 10^{15}·photons·s^{-1}·0.1%BW^{-1}. The facility will support a minimum of 60 beamlines. Construction started in 2009 and commissioning is expected to be completed in 2014.

The NSLS-II injector [2] is now being commissioned to deliver beam performance sufficient for initial storage ring operations at low current. At a later stage the NSLS-II storage ring capabilities will continuously expand to include high intensity operations and top-off mode. This expansion will require the NSLS-II injector to reliably deliver electron beam at a high charge rate, with low losses and high stability in all six phase space coordinates. To meet the requirements of high-intensity ring operation we designed in a large scope of the injector upgrades. The upgrades, described in this paper, aimed to increase the NSLS-II facility capabilities, improve beam quality and reliability of the facility operations.

LINAC UPGRADES

Production of Short Pulses

The 200-MeV NSLS-II linac is a high-performance accelerator delivering up to 15 nC per shot with the emittance of 70 nm rad within trains of 20 ps (RMS) bunches. These excellent beam properties can find applications in generating bright flashes of radiation in THz-visible and hard X-ray wavelength range. Top-off time format (1 injection cycle per minute) permits using the injector linac for other purposes during at least 50 seconds every minute.

*This manuscript has been authored by Brookhaven Science Associates, LLC under Contract No. DE-AC02-98CH10886 with the U.S. Department of Energy.

#shaftan@bnl.gov

Some of these parameters (bunch length and beam emittance) can be greatly improved by addition of an RF gun that delivers an LCLS-like beam performance.

With an RF gun the NSLS-II injector linac will gain potential in generating short bursts of radiation via:

- Short pulses of THz/IR via CTR or in an undulator
- Coherent sources in IR – DUV range of wavelengths
- Short pulse X-rays via Compton Scattering

We designed the linac tunnel in such a way that there exist an ample space ahead of the linac for developing a user end station and upgrading the linac energy for building a short radiation pulse facility (Fig. 1).

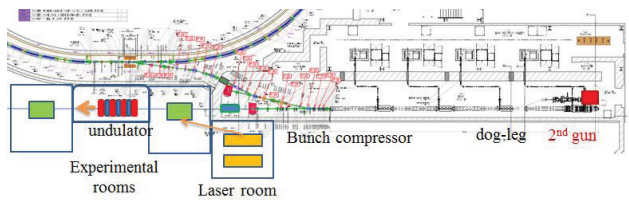

Figure 1: Potential layout of the short pulse facility.

Including the second gun [3] into the low-energy part of the linac will: a) increase reliability of the NSLS-II accelerator complex, b) enable more efficient operations in generating complex bunch patterns and, c) simplify switching between single-bunch and multi-bunch modes for the ring injection.

Generating Flexible Bunch Patterns

Specifications for the storage ring bunch pattern given by the NSLS-II users require sharp edges of the circulating bunch trains and uniform distribution of charge per bunch within a single train. This translates into challenging requirements on the gun pulser since its electronics defines the quality of the generated trains.

In order to enable generation of flat-top (relative bunch-to-bunch charge noise below 1%) trains with sharp edges (~2 ns) we proposed to include a short kicker (chopper) just upstream of the 100-keV gun (Fig. 2, [4]).

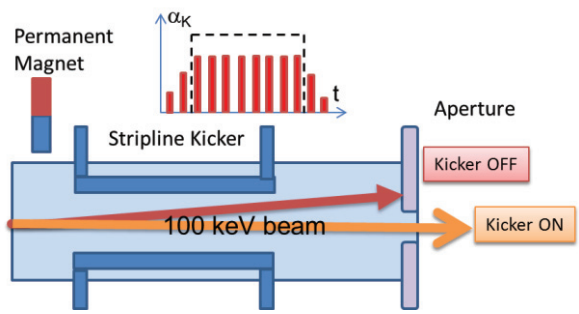

Figure 2: Schematics of the beam chopper.

This kicker will permit passing beam only inside the desired macropulse deflecting bunches outside to the

Copyright © 2013 CC-BY-3.0 and by the respective authors

chamber wall. The gun pulser performance is therefore simplified since the gun will be emitting long bunch trains with loose requirements on the train edges. The kicker will select the most uniform part of the bunch train and cleanly chop off the edges.

Another advantage of this compact device is in limiting the useless and harmful charge outside of the bunch train thus minimizing it from being accelerated and reducing beam loss at high energy.

During the design stage we allocated sufficient space for the chopper system in the linac front-end.

Beam Loading Compensation

The linac is designed to deliver charge 15 nC per shot with up to 150 bunches. The beam loading induces voltage in the sub-harmonic pre-buncher (SPB) and acceleration sections, which results in a large energy spread at the nominal beam current.

We designed an alternative way of beam loading compensation via using a BPM and a screen in the large dispersion region of the transport line upstream of the linac. BPM button signal is split into two paths: one follows to the regular BPM system and the other to the bunch-by-bunch system. The bunch-by-bunch energy slew along the train can be measured from the fast BPM system, while the bunch train energy spread is measured at the beam screen. We use the train average energy spread and bunch-by-bunch energy slew as the RF feed-forward signal to compensate the beam loading effect in the RF system. Then the bunch train beam quality will be optimized and the energy spread, induced by the beam loading, can be minimized.

Linac Digital RF Controller Upgrade

The linac will be upgraded to use the digital cavity controller developed for the NSLS-II booster and storage ring RF systems. Specialized firmware will provide double clocking of the output DAC to improve waveform ramp smoothness, add feed-forward capability to keep TW structure field constant in the presence of beam loading and fix a Master Oscillator reference ambiguity upon reset that we have with the original system.

BOOSTER UPGRADES

2-Hz Repetition Rate

While the NSLS-II booster will soon be commissioned at 1 Hz repetition rate, which is adequate for the initial phase of facility operations, we designed all of the injector subsystems to operate at the double frequency. Expanding the injector operations to 2 Hz will halve the demand of the injected charge per shot, increasing beam quality and reducing beam loss. It will also help to reduce the top-off injection cycle thus shortening perturbations on the stored beam orbit in the storage ring.

Beam Stacking

To further reduce requirements on the linac charge per shot we studied and then implemented beam stacking system in the booster [5]. The beam stacking is realized via closed bump with four booster injection kickers (Fig. 3) accommodating two consecutive bunch trains from the linac separated by 100 ms. Accumulated beam is accelerated and extracted from the booster as a single high-current train.

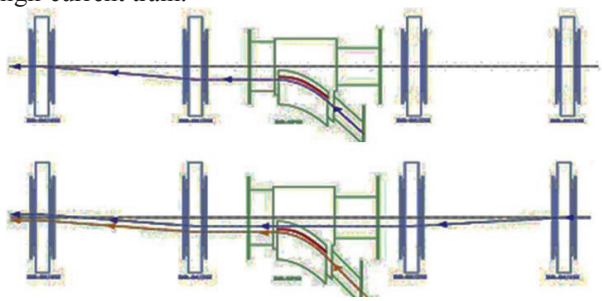

Figure 3: Concept of the beam stacking: upper and lower layouts show injection of the 1st and 2nd bunch trains.

Bunch Train Merging System

Another way of reducing linac output charge per bunch is in adding a high-frequency (i.e. 3 GHz) RF system and modifying the linac front-end to produce trains with 2ns/6=333ps bunch separation. After injection in the booster the 500 MHz RF system takes over and every six microbunches damp down into a single 500 MHz rf bucket. Decreasing charge per bunch should help increase capture efficiency in the linac front-end and reduce beam transverse emittance at 200 MeV for low-loss injection into the booster.

Bunch-by-Bunch Transverse Feedback System

High current circulating in the NSLS-II booster throughout the energy ramp may lead to development of instabilities, which will limit the injector output and create radiation losses in the injector complex. Sources of the potential instabilities include HOMs in the booster RF cavity, resistive wall, impedance of the vacuum chamber transitions and ion-related effects. In addition, bunch-by-bunch oscillations may lead to detrimental effects on the extracted beam quality. As such, the phase space area of the extracted beam may increase thereby increasing the beam emittance and creating losses in the storage ring.

Among the methods of battling the instabilities in the booster we assessed a concept of bunch-by-bunch feedback system, whose implementation for the booster may be similar to that in the storage ring. The diagnostics straight of the booster ring is long enough to accommodate a long stripline kicker fed by a broadband RF generator. The feedback will rely on measurements of bunch-by-bunch orbit deviations in the booster BPMs and adapt the waveform in accordance to the amplitudes of oscillations of consecutive bunches in the circulating train.

Emittance Correction System

Quality of the injector beam can be compromised by collective effects or through errors in the extraction line (i.e. ripples in the pulsed magnets). Consequently, bunches in the train may exit the booster with modulation

Copyright © 2013 CC-BY-3.0 and by the respective authors

in angle or position inflating the resulted projected beam emittance.

This parasitic bunch-by-bunch modulation can be corrected using a stripline installed at the exit of the booster, i.e. at the beginning of BSR transport line.

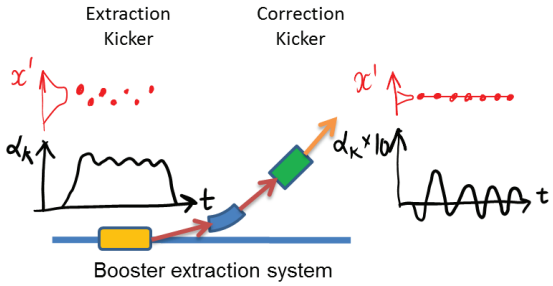

Figure 4: Concept of the horizontal emittance compensation.

The stripline will produce a modulated field waveform, so that bunches passing the stripline will receive negative angular kicks to minimize the angular spread along the extracted bunch train (Fig. 4, [6]).

STORAGE RING INJECTION SYSTEM UPGRADES

Slow Bump in the Injection Straight Section

Performance of the storage ring kickers will significantly contribute to the overall reliability of the NSLS-II accelerator complex. It is prudent therefore to reduce the maximum voltage on the kicker pulsers. We considered and analysed a solution of adding a 3 DC/Slow correctors [7] in the injection straight section, which will produce a closed bump helping the pulsed kickers. For sufficiently fast correctors the closed bump can be turn on during every injection cycle reducing the kicker maximum voltage by 30%. The storage ring injection straight section contains space sufficient for adding these three correctors.

Pulsed Sextupole

During the injection straight design we assessed injection via a pulsed multipole pioneered at SPring-8 [8]. In [9] and [10] we analysed the sextupole injection in details and concluded that integration of a strong pulsed sextupole into the storage ring injection straight will require substantial revisions of the BSR transport line optics. However we considered testing this alternative injection scheme at a later time.

Storage Ring and Booster Bunch Cleaning Systems

As demonstrated by experience of several synchrotron light sources the bunch cleaning systems are necessary to satisfy user requirements on quality of storage ring bunch pattern. Primarily for these experiments that deal with precise timing of their detectors it is required to maintain sharp edges of the storage ring bunch trains with the stray charge in the RF buckets between the trains below 0.01%.

There exist two sources of the stray electrons in the storage ring buckets: a) charge outside of the injected bunch trains and, b) electrons scattered out of full SR RF buckets via Touschek effect (multiple scattering). The latter is inherent property of a high-current storage ring and requires implementation of the SR bunch cleaning system. Estimates on the rates of accumulation of the Touschek-scattered electrons in the SR RF buckets are available in (Fig. 5, [11]).

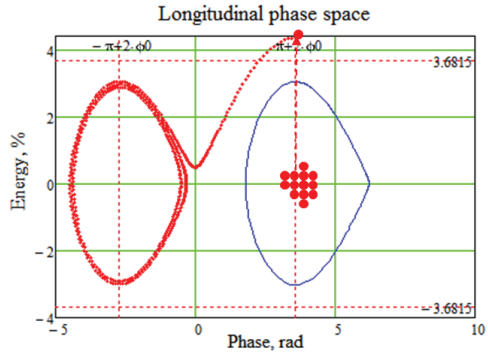

Figure 5: Accumulation of Touschek-scattered particles in an empty bucket.

Modern bunch cleaning system consists of a stripline driven by an RF generator, an aperture for constraining the vertical betatron amplitude of these electrons that are excited by the stripline, and a high-sensitivity bunch pattern monitor [12]. Motion of the unwanted bunches is driven by the stripline field until their vertical oscillation moves them outside the aperture. The bunch pattern monitor controls the purity of the circulating bunch train. We designed in provisions for integrating the required hardware for the bunch cleaners in both booster and storage ring.

Abstract

An effective method of introducing an energy modulation in an electron bunch by passing it through a dielectric-lined waveguide was recently demonstrated [1]. In the follow up experiment we successfully converted this energy modulation into a density modulation by means of a chicane beamline. The density modulated beam was sent through a foil target, producing THz transition radiation which was characterized using interferometric techniques. By changing the initial energy chirp of the beam we tuned the center frequency of the generated THz radiation in the range 0.68 – 0.9 THz. A table top high power narrowband tunable THz source based on this technique is proposed.

INTRODUCTION

In recent years there has been a large interest in the production of sub-picosecond bunch trains consisting of series of equally spaced electron micro bunches [2-6]. These bunch trains can be used for production of high power THz radiation [4–6, and references therein] and to drive resonant wakefields in plasma and dielectric wakefield accelerators [2, 3].

Sub-picosecond bunch trains can be generated directly from a photocathode of an electron gun using a series of uniformly spaced laser pulses [6-8]. Alternatively, a transverse-to-longitudinal phase space exchange in combination with a multi-slit mask [9-12] can be used. Another approach is to use difference frequency generation by double energy modulation of electrons in an undulator via interaction with optical lasers having slightly different carrier frequencies [13, 14]. In this paper we present an approach using energy modulation by means of the self-excited wake fields in a dielectric-lined [1] or corrugated waveguide [15] with subsequent conversion into a sub-picosecond period density modulation.

A strong energy modulation in an electron bunch passing through a dielectric-lined waveguide was recently demonstrated in reference [1]. Here, we report the successful conversion of this energy modulation into a density modulation and production of a picosecond bunch train. This result provides a foundation for a compact, tunable source of intense THz radiation [RSI].

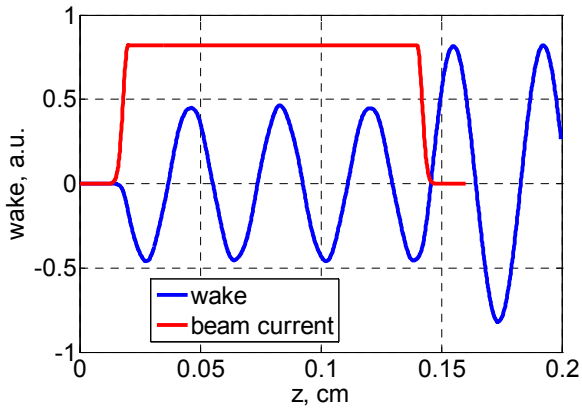

Figure 1: Periodic self-wakefield inside a long quasi-rectangular electron beam.

The principle of introducing an energy modulation in the beam is the following: when the bunch length is comparable or much longer than the wavelength of the fundamental mode of the wakefield, the wakefield inside the bunch will show an amplitude modulation, particularly for a triangular or rectangular shaped bunch (Fig. 1). If the beam has an energy chirp (linear correlation between energy and longitudinal coordinate) then the periodic self-wakefield (Fig. 1) produces an energy modulation (Fig. 2). This energy modulation can be converted into density modulation by means of chicane, a set of four dipoles arranged in a "+ - - +" fashion. Inside the chicane high energy particles travel a shorter distance than those at low energies, hence sections of the beam in which low energy particles are ahead of the high energy ones will be compressed (Fig. 2). If the beam has a positive chirp (head having a lower energy than the tail) initially, the whole beam is compresed as well. Hence the current is modulated at a higher frequency than the frequency of the wakefield mode that created the energy modulation in the first place!

Changing the energy chirp of the beam therefore allows us to tune the frequency of the current modulation. In the case of negative chirp the resulting modulation will be at a frequency lower than the energy-modulating frequency of the wakefield. This property allows us to tune the frequency over a wide range.

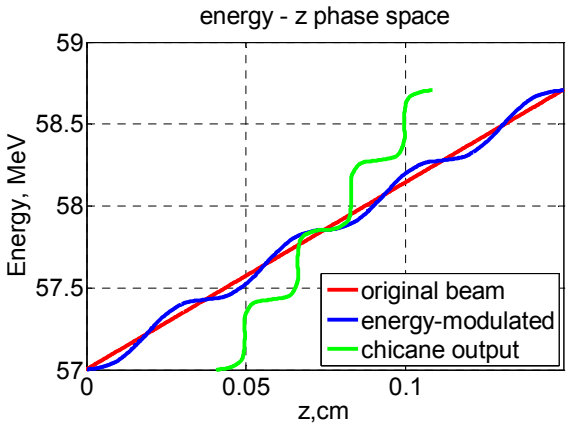

Figure 2: Illustration of the process of bunching and compression. Longitudinal phase space portraits for the incoming electron bunch (red), energy modulated bunch (blue) and density modulated bunch after the chicane (green).

If the original beam does not have an energy chirp (Fig. 3) then the current modulation after chicane is of the same frequency as the mode that created the energy modulation.

Chicanes are typically characterized by a so-called time-of-flight parameter, R_{56} (the transfer matrix element describing chicane's longitudinal dispersion). It relates the path length difference to the fractional energy offset [19] and has the units of cm.

$$\Delta\ell = R_{56}\left(\Delta E / E\right) \quad (1)$$

The time of flight parameter has to match the energy-longitudinal coordinate phase space to provide optimal compression. It is illustrated in Figure 3, where we plot the bunching factor b of an electron beam for various values of the chicane R_{56}.

$$b = \frac{1}{N}\sum_{i=1}^{N} e^{ikz} \quad (2)$$

While a time-of-flight parameter of 4.9 cm (Fig. 3) provides a density modulation of the beam, the corresponding bunching factor is on the order of 0.3. In contrast, R_{56} = 11 cm yields a maximum bunching factor of 0.5. These numbers, however, are rather large for practical realization. In the experiment we used a compact permanent magnet chicane with R_{56} = 1 cm. Even with a small time-of-flight parameter it is possible to have large bunching factors provided that initial beam is strongly modulated in energy prior entering the chicane [16].

EXPERIMENT

The experiment based on this concept was performed at the Accelerator Test Facility (ATF) at Brookhaven National Laboratory [16]. The electron bunches provided by the ATF beam line at 57 MeV had a rectangular peak current profile with a length of ~ 5 ps (1.5 mm) and amplitude of ~ 100 A. The current distribution is produced by passing the beam through two dispersive dipole magnets with a mask in between that cuts off the tails [10]. We can control the linear energy chirp along the electron bunch by changing the phase of the accelerating field in the linac. The head-to-tail energy variation was as large as 850 keV in the experiment, similar to the theoretical examples given previously. For a 1.5 mm long beam this would correspond to a chirp of 567 keV/mm.

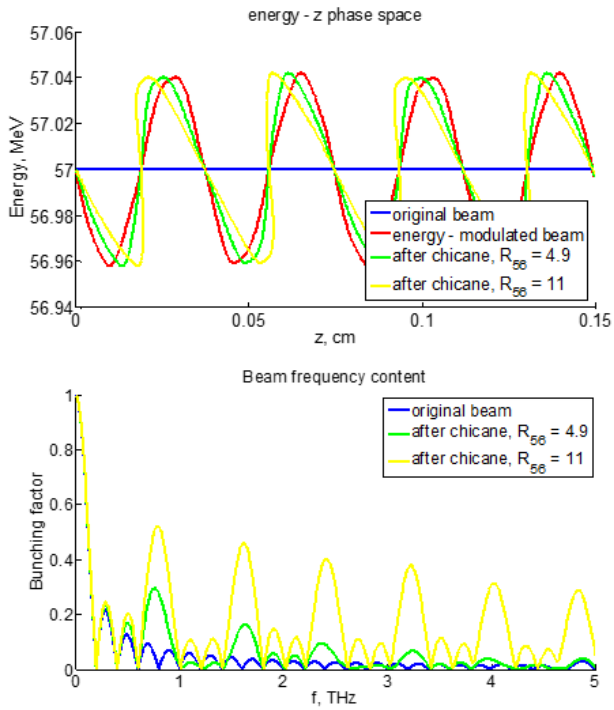

Figure 3: Bunching without compression. Top: Longitudinal phase space portraits for the incoming non-chirped electron bunch (blue), energy modulated bunch (red) and density modulated bunch after chicanes of different strengths (green and yellow). Bottom: frequency content of the beam. Initial beam (blue) and beam after chicanes of different strengths (green and yellow).

After acceleration, bunches were focused to a small transverse size (~ 100 μm rms) and transported through a 800 GHz, 2" long kapton (polyimide) tube, metallized on the outside and with a 300 micron inner radius and 28 micron wall thickness. The kapton has nearly constant permittivity ε in the range of frequencies between 0.5 THz and 1.5 THz. The chicane was made out of four identical permanent dipole magnets. Each magnet has 5 cm magnetic length and ~ 9.4 kG maximum magnetic field for a 5 mm magnetic gap. The distance between the first and the second magnet and the third and the fourth was 5 cm. This chicane had the matrix element value R_{56} =1 cm. We were able to move the chicane in and out of the beam line so that it was possible to measure the electron bunch properties both with and without the presence of the chicane. After the bunch passes through energy modulating structure and then through the chicane it becomes density modulated and this modulation can be measured by passing the bunch through a foil, producing coherent transition radiation (CTR).

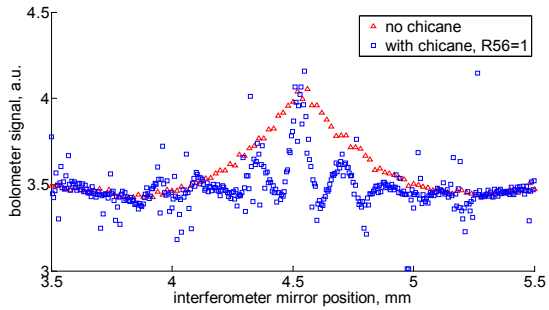

Figure 4: Measured THz CTR signal. Beam passing through chicane (blue rectangles) and chicane retracted (red triangles).

The time structure of the CTR signal is analyzed with a Michelson interferometer using a bolometer as the detector [9, 10]. The result of the interferometric measurement is the autocorrelation function (intensity as a function of the path length difference in the interferometer) of the CTR signal that has a periodicity related to the periodicity of electron bunch. The resulting bunching can be clearly observed through the periodicity of the autocorrelation function. Fig. 4 compares interferometric measurements of the original bunch (chicane retracted) and the density modulated bunch. The autocorrelation function is periodic for a signal produced by the density modulated beam, while the original long rectangular bunch does not produce periodicity over the distance spanned by interferometer mirror motion. We can also conclude that there are 4 beamlets in the density modulated beam (bunch train) because we have 7 pronounced peaks on the autocorrelation function plot. This determines that the bandwidth of the signal is about 25%. By changing the chirp of the beam we were able to tune the density modulation [16] over a range estimated at 0.68 to 0.9 THz.

Based on these encouraging results we have developed a concept for a beam based high peak power tunable THz source. All components are similar to those used in this experiment but adjusted to the specific needs of a dedicated THz radiation source. An electron bunch is produced in the gun and accelerated to a few MeV off-crest forming an energy chirp along the electron bunch. After that it passes through a dogleg (two dipole magnets of equal strength and opposite sign, Fig. 1) where a collimator is used to cut the bunch tails and to provide a uniform density distribution with a relatively sharp leading edge [10]. Next, similar to the experiment above this bunch traverses an energy modulating structure. The energy modulation acquired is converted into a density modulation in a chicane. The resulting bunch train is injected into the power extractor, which is essentially another wakefield producing structure, a dielectric loaded or corrugated metal waveguide equipped with a horn type antenna. Additional electron focusing optics may be needed to control the beam size as it loses energy in the extractor. For the 800 pC, 100 A, 57 MeV ATF beam we propose to use a 3 cm long quartz tube with ID = 0.3 mm and OD = 0.4 mm to produce a 0.7 THz, 170 ps long pulse with a peak power of 6 MW and 1 mJ energy per pulse.

ANALYSIS AND OPTIMIZATION OF COUPLER KICK IN APEX*

H. Qian#, S.Kwiatkowski, C.F. Papadopoulos, Z. Paret, F. Sannibale, J. Staples, R. Wells, LBNL, Berkeley, CA 94720, USA

Abstract

A high repetition rate (~MHz) and high brightness photoinjector, based on VHF band CW normal conducting (NC) RF gun, is being developed under Advanced Photoinjector EXperiment (APEX) at Lawrence Berkeley Lab. A NC 30 MeV L-band linac system will be added after the gun to demonstrate beam brightness with lower repetition rate (~10 Hz). In this paper, coupler kicks from APEX buncher and acceleration cavities are evaluated by 3D RF simulation, analytical model and beam tracking, and coupler cells are optimized to minimize emittance dilution due to coupler kicks.

INTRODUCTION

The Advanced Photo-injector Experiment (APEX) is for demonstration of MHz repetition rate high brightness electron beam (~300 pC, ~0.6 mm mrad) injection for the next generation high repetition rate X-ray free electron lasers [1]. APEX is staged in 3 phases. In phase 0, the VHF-band normal conducting RF gun was successfully conditioned to achieve CW operation at nominal beam energy (750 keV) with low vacuum pressure performance (10^{-11} – 10^{-9} Torr). In phase I, a 6D beam phase space characterization will be conducted at 750 keV in CW mode. In phase II, a NC 30 MeV linac will compress and accelerate the beam to reduce space charge effects, so that beam brightness will be more reliably characterized. The APEX beamline is shown in Fig. 1.

The designs of buncher cavity and booster cavity are based on the ALS harmonic cavity and the ANL-AWA acceleration cavity respectively [2, 3], as shown in Fig. 2, both of which are not optimized for low energy and low emittance photoinjectors in terms of coupler kick. The RF input coupler breaks cylindrical symmetry of acceleration field and induces RF multipoles, which may perturb beam alignment and emittance compensation. Such effects can be even worse for beam near the gun due to relatively lower beam energy and thus bigger beam sizes, and has been taken care of in previous low emittance photoinjectors [4-9].

In the following, the RF coupler kicks will be evaluated for the APEX buncher and acceleration cavities through both simulations and simplified analytical models, and geometry modifications are suggested and evaluated.

ANALYTICAL EVALUATION OF COUPLER KICK EFFECT

RF coupler induced emittance growth has been well investigated during the development of low emittance photoinjectors [4-9]. Here a simplified analytical model is used to summarize the coupler kick effects when beam travels through a coupler cell (Fig. 2). Inside the model, only RF force is considered and beam size inside the cell is assumed to be relatively constant. The longitudinal paraxial electric field is expressed as follows:

$$E_z(x,y,z,t) = E_z(x,y,z)e^{i(\omega_0 t+\varphi_0+\Delta(x,y,z))}. \quad (1)$$

where amplitude asymmetry is included in $E_z(x,y,z)$,and phase asymmetry is included in $\Delta(x,y,z)$. $\varphi_0 = 0$ is defined as maximum acceleration phase.

Considering first order phase asymmetry and amplitude asymmetries induced by dipole and quadrupole, RF phase and amplitude can be expressed as,

$$\Delta(x,y,z) = k_y y \, . \quad (2)$$

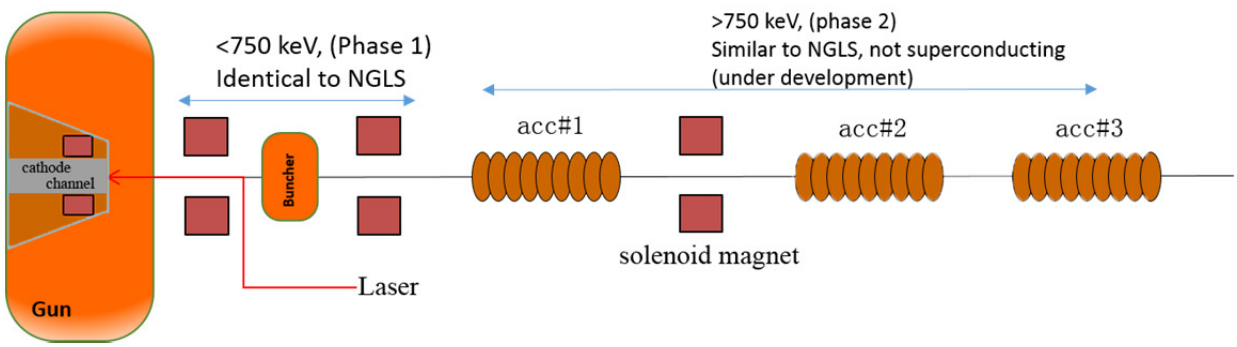

Figure 1: Schematic of the APEX injector beamline. Phase 1 is currently under operation. Phase 2 under development.

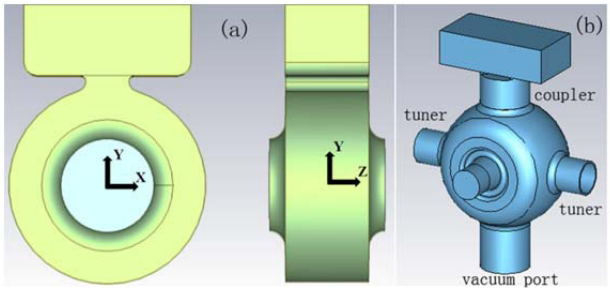

Figure 2: (a) Coupler cell of ANL-AWA cavity, (b) APEX buncher scaled from ALS harmonic cavity.

$$E_z(x,y,z) = E_0\cos(kz)(1-a_0(x^2+y^2) + a_1\,\mathrm{y} - a_2(x^2-y^2)) \quad (3)$$

where E_0 is the peak axial acceleration field, a_0, a_1 and a_2 are monopole, dipole and quadrupole coefficients, k_y is first order phase gradient.

RMS normalized projected emittance growth can be formulated as,

$$\Delta\varepsilon_{n,x}^{monopole} = \Delta\varepsilon_{n,y}^{monopole} = a_0\alpha\lambda\sigma_x^2\sigma_\varphi\cos\varphi_0\,. \quad (4)$$

$$\Delta\varepsilon_{n,y}^{dipole} = \frac{1}{2}a_1\alpha\lambda\sigma_y\sigma_\varphi\cos\varphi_0,\ \ \Delta\varepsilon_{n,x}^{dipole} = 0\,. \quad (5)$$

$$\Delta\varepsilon_{n,x}^{quadrupole} = \Delta\varepsilon_{n,y}^{quadrupole} = a_2\alpha\lambda\sigma_x^2\sigma_\varphi\cos\varphi_0\,. \quad (6)$$

$$\Delta\varepsilon_{n,y}^{phase} = \frac{1}{2}k_y\alpha\lambda\sigma_y\sigma_\varphi\sin\varphi_0\ \ \Delta\varepsilon_{n,x}^{phase} = 0\,. \quad (7)$$

where $\alpha = \dfrac{eE_0}{2mc^2k}$, λ is RF wavelength (twice coupler cell length), k is RF wave number, σ_x and σ_y are transverse RMS beam sizes, σ_φ is longitudinal RMS bunch length measured by RF phase. The total emittance growth is,

$$\Delta\varepsilon_{n,x} = \Delta\varepsilon_{n,x}^{monopole} + \Delta\varepsilon_{n,x}^{quadrupole}\,. \quad (8)$$

$$\Delta\varepsilon_{n,y} = \sqrt{\begin{matrix}(\Delta\varepsilon_{n,y}^{monopole} - \Delta\varepsilon_{n,y}^{quadrupole})^2 \\ +(\Delta\varepsilon_{n,y}^{dipole} - \Delta\varepsilon_{n,y}^{phase})^2\end{matrix}}\,. \quad (9)$$

RF SIMULATIONS

The preliminary APEX buncher cavity design (1.3 GHz) is scaled from ALS harmonic cavity (1.5 GHz), as shown in Fig. 2, and has a single waveguide coupler, a symmetric vacuum port and two RF tuner ports. The ANL-AWA cavity is a 1.3 GHz 7-cell standing wave cavity, and the RF power is fed into the cavity by a single waveguide coupler (Fig. 2). In order to feed the 7 cells, the coupling slot is big, which is expected to greatly distort the cylindrical field symmetry in coupler cell.

Coupler Kick Evaluation

CST Microwave studio is used to simulate 3D RF field map, and RF field in the middle plane of coupler cell is used to extract amplitude and phase asymmetry coefficients, as shown in Table 1. Eq. (5) to (7) are used to do a quick emittance growth evaluation based on Table 1 and one specific beamline optimization solution for 300 pC operation from ASTRA simulation [10, 11], as shown in Table 2.

Table 1: Amplitude and phase asymmetry coefficients

	Buncher	**AWA cavity**
a_1 (m^{-1})	0.007	0.9
a_2 (m^{-2})	8.7	1.4
k_y (mrad/m)	3.0	17

Table 2: Emittance growth (in mm mrad) evaluations for one APEX solution with 300 pC beam charge

	Buncher	**ACC #1**	**ACC #2**	**ACC #3**
$\Delta\varepsilon_{n,y}^{dipole}$	0.02	4.9	1.4	1.2
$\Delta\varepsilon_{n,x\ or\ y}^{quadruple}$	0.28	0.02	0.003	0.002
$\Delta\varepsilon_{n,y}^{phase}$	0.03	0.005	0.06	0.03

Table 2 shows coupler kick gives significant emittance growth in both buncher and acceleration cavities. Buncher cavity is dominated by quadrupole, and AWA cavity is dominated by dipole.

Coupler Cell Optimization

To minimize quadrupole in buncher cavity, tuner ports are made to be the same size as coupler port and vacuum port, and tuners are removed or retracted. To minimize dipole and phase asymmetry in AWA cavity, symmetric dual RF coupler is added (Fig. 3), and coupler size is tuned to restore the original power coupling factor. CST simulations show though dipole is minimized, quadruple is enhanced by an order of magnitude, so two dummy ports are added at 90 degree relative to coupler port to suppress quadrupole. Comparison between original and modified AWA coupler cell is displayed in Fig. 3.

After coupler cell optimization, with the same beamline settings as in Table 2, Eq. (5) to (7) predict coupler induced emittance growth are well below 0.05 mm mrad for both buncher and acceleration cavity.

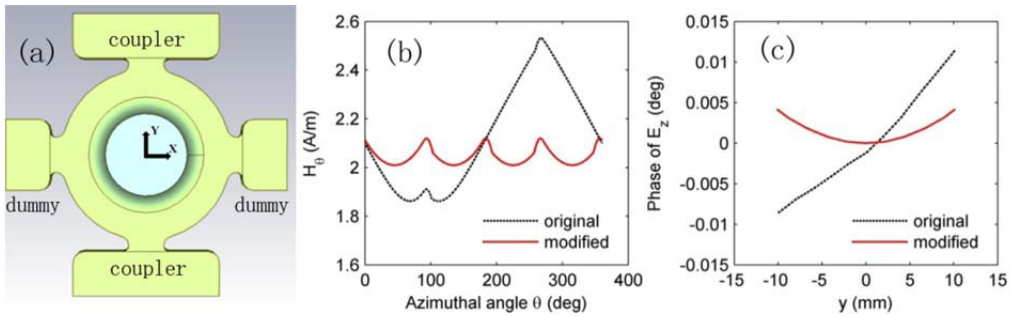

Figure 3: (a) 4-port optimization of AWA coupler cell, (b) azimuthal magnetic field amplitude at radius of 10 mm in central plane of coupler cell (z=0), (b) RF phase of E_z along line x=0 in plane z=0.

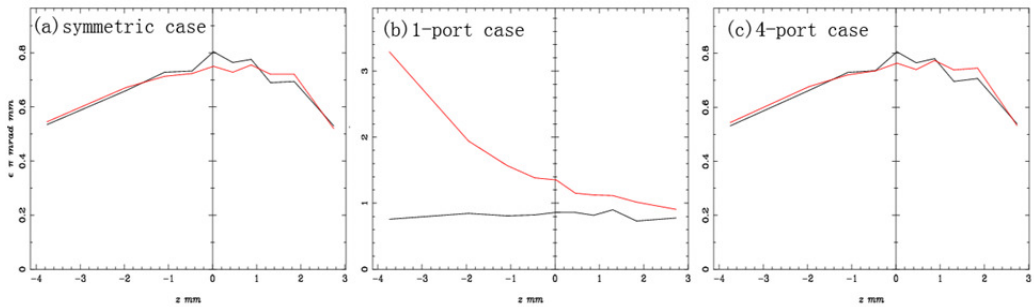

Figure 4: Slice emittance (x: blac, y: red) at ACC #3 exit (~14 MeV) for (a) symmetric map, (b) 1-port map, (c) 4-port map

BEAM TRACKING SIMULATIONS

To include both RF and other forces (space charge, solenoid focusing et al.), the 3D RF field maps from CST can be used in ASTRA simulations of the APEX beamline. In the following, three field maps of AWA cavity are used for one solution of the ongoing optimization process for the APEX beamline, as shown in Fig. 4. The "symmetric" case is based on input of the on-axis E_z field in ASTRA. In this case, ASTRA expands the fields E_r and B_φ around the axis up to 3rd order. This is by construction azimuthally symmetric and no emittance growth due to multipole field is possible. The "1-port" and "4-port" cases refer to 3D field maps based on the optimization described previously. Fig. 4 confirms the original AWA cavity (1-port) will cause huge emittance growth and the optimized AWA cavity (4-port) almost removes all coupler kicks.

CONCLUSION

Coupler kicks in the APEX injector are studied by RF simulation, analytical model and beam tracking, and huge emittance growth is found due to improper coupler cell designs of buncher and acceleration cavities. After symmetry optimization of coupler cell, coupler kicks are minimized and confirmed by ASTRA simulations.

LLNL X-BAND TEST STATION STATUS*

R.A. Marsh†, F. Albert, G. Anderson, S.G. Anderson, E.T. Dayton,
S.E. Fisher, D.J. Gibson, S.S. Wu, F.V. Hartemann, C.P.J. Barty
Lawrence Livermore National Laboratory, Livermore, CA 94550, USA

Abstract

An X-band test station is being built at LLNL to support inverse Compton-scattering x-ray and gamma-ray source development. The major components for the X-band test station have been designed, fabricated, installed, and aligned. The XL-4 klystron has been delivered, dressed and installed in the ScandiNova modulator, and tested to full peak power. Final assembly and bakeout of RF transport, test station supports, and accelerator components is complete, and the current status of commissioning and first beam will be presented and discussed. Future upgrade paths and configuration for a variety of x-ray and gamma-ray applications will be discussed along with schedule for planned experiments.

INTRODUCTION

Extremely bright narrow bandwidth gamma-ray sources are expanding the application of accelerator technology and light sources in new directions. LLNL has a successful history utilizing gamma-rays generated by a linac-driven, laser-based Compton scattering gamma-ray source [1, 2, 3, 4]. Next generation advancements in linac-based x-ray and gamma-ray production require increasing the average flux of gamma-rays at a specific energy (that is, $N/eV/sec$ at the energy of interest). One way to accomplish this is to increase the effective repetition rate by operating the RF photoinjector in a multi-bunch mode, accelerating multiple electron bunches per RF pulse. This multi-bunch mode will have stringent requirements for the electron bunch properties including low emittance and energy spread, but across multiple bunches. An X-band test station is under construction at LLNL to develop multi-bunch electron beams and generate x-rays. This paper summarizes progress and describes the current status of the project.

The RF gun is described in detail in [5]. Test station parameters are summarized in Table 1. Beam dynamics are summarized in Fig. 1 for a 250 pC bunch generated in the Mark 1 X-band RF gun and accelerated by a single T53 traveling wave accelerating section. Beam steering will use X-Y windowpane dipole magnets, and two quadrupole triplets will focus the beam for transport and quad-scan emittance measurement. A dump dipole magnet will double as a spectrometer once it has been calibrated.

Table 1: Test Station Parameters

Charge	25–250 pC
Normalized Emittance	<1 mm mrad
Gun Energy	7 MeV
Cathode Field	200 MV/m
Coupling β	1.7
Section Gradient	~70 MV/m
Final Energy	30 MeV

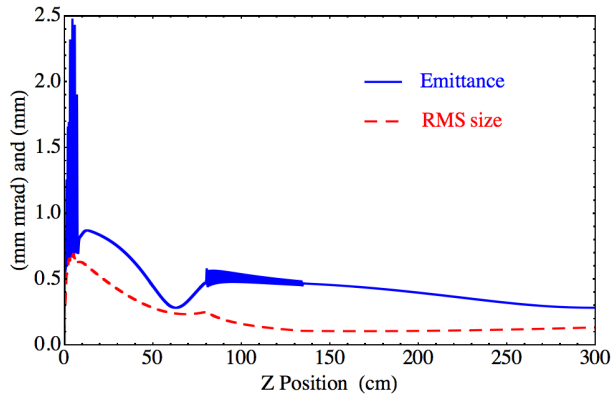

Figure 1: PARMELA beam dynamics simulation for a bunch charge of 250 pC.

TEST STATION

The test station layout is shown in Fig. 2. The high voltage modulator and X-band tube reside in a separate area with RF distribution fed through a hole in the wall to the linear accelerator. A manifold divides the power between the RF gun and the accelerating sections [6]. Testing of the klystron to full power is complete [7], and the RF load tree that was used for this testing is currently being disassembled to provide components for dressing the accelerating sections and provide components for the power division manifold. Support structures made from 80/20 mount to the laser tables and provide multi-dimensional adjustment for alignment of supported components to the beamline. The emittance compensation solenoid for the RF gun is mounted on precision ground rails so that it can be moved back to provide access to the gun. The gun support structure holds the RF gun, WR-90 pumpouts and pumps, as well as an RF gate valve on the beamline. The T53 accelerating structure is mounted on a SLAC designed strongback with end-to-end adjustment, which is then mounted on 80/20 supports that provide additional adjustment as well as support for RF distribution, loads, and vacuum pumps.

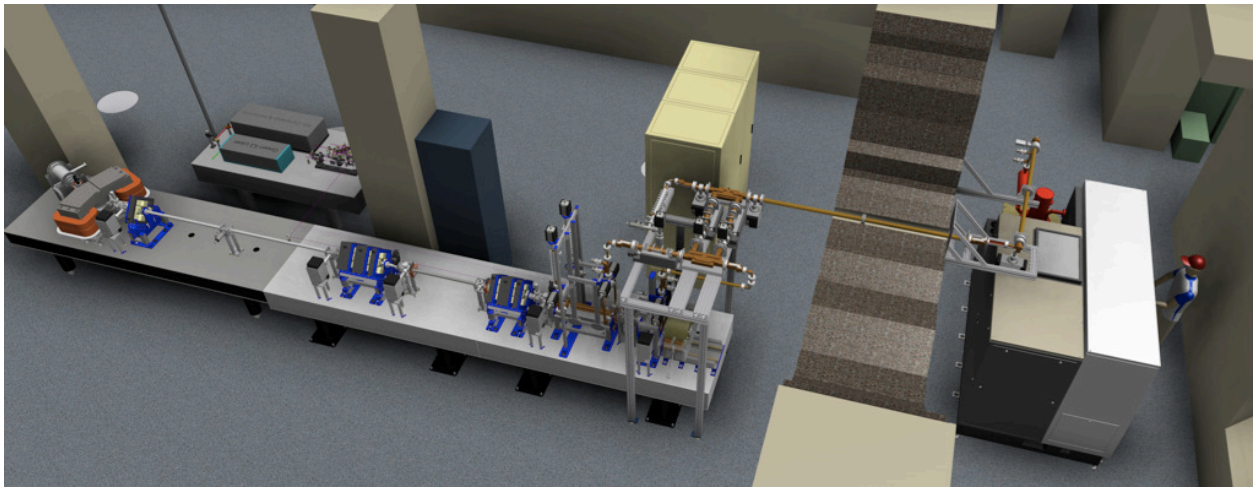

Figure 2: CAD rendering of the X-band test station. Test station position has been changed to optimize the RF distribution for minimal loss and permit for the expansion of the beamline for future experiments.

The quadrupole magnets are mounted together in triplets, with each stand having adjustability. The magnet alignment within their supports has been measured as reported in [8]. The steering magnets are mounted onto beamline vacuum flanges.

Alignment

The alignment specification on most components, driven by the desire to limit emittance growth, is ± 100 μm. As shown in [9], tolerances can become even tighter if emittance growth in low charge bunches is to be limited. An initial alignment procedure was developed for a 250 MeV X-band linac at LLNL [10], which has been adapted to the X-band test station. The general approach for alignment uses a precision CMM arm from Romer, with a quoted specification of ± 75 μm repeatability and volumetric accuracy over the full envelope reachable by the arm. The Romer arm and operating technician can be seen in Fig. 3. Physical contact with a probe tip allows encoders in the arm to map the exact position of each point input into the CMM software. The coordinate system of the arm is based on geometric features of individual components such as the cross-section of magnet pole pieces, or the outer radii of pillbox cell cups, combined with tooling ball fiducials that have been placed on magnets and accelerating structures. Initial measurement of the geometric features allows the external fiducials to be used in the future when features may be less accessible.

The emittance compensation solenoid is the heaviest component, and has the least adjustment (its height from the table is fixed). Magnet metrology measurements at SLAC confirmed that the magnetic and physical axes of the solenoid were aligned to within 25 μm. The solenoid was adjusted so that is was parallel with the laser table, and pointing along the table edge. Solenoid alignment set the coordinate system for subsequent components, with the beamline axis zero set by the mid plane of the Helmholtz pair outer pole faces: this will be the center for the RF gun so that there is no field on the cathode surface. Subsequent components are all aligned onto the beamline centerline, at an offset from the cathode driven by beam dynamics and mechanical design.

Figure 3: Photograph of X-band test station alignment. Romer CMM arm in use to precisely measure the 3D position of the T53 cells for proper alignment of the accelerating structure with respect to the beamline axis and cathode position.

The RF gun body was aligned on axis with the cathode cell backplane offset so that the internal cathode surface resides at the mid-plane of the solenoid. The RF gun beam-

line gate valve was also used for alignment of the RF gun support structure given that it is the furthest component downstream of the gun. The T53 section was measured with respect to pillbox cells and fiducials on each WR-90 RF port. The beamline position of the T53 accelerator section has been fixed from beam dynamics modeling and was set with respect to the outer face of the accelerator coupling cell. The quadrupole triplet alignment in their 80/20 support has been confirmed with magnetic measurement [8] so that the physical pole positions were used to position them in space. Fiducials on the quadrupole triplets were also mapped so that they can be used in the future to align the magnets or other beamline components when beamline pipe is in place and the pole faces are not accessible to the arm probe. The critical test station components were realigned following final assembly of the RF distribution components to insure the accelerator section and gun retain their precise location. It was necessary to measure the accelerator structure and quadruple magnet fiducially because the bore of the magnets and surface of the section were no longer accessible.

Bakeout

The RF gun vacuum system is comprised of: an RF input window; a WR-90 pumpout; the Mark 1 RF gun; a custom weldment cross; an all-metal RF gate valve; a hot cathode vacuum gauge; two 10 L/s ion pumps; two 40 L/s ion pumps; and additional vacuum nipples, T's, blanks, and an all-metal angle valve to connect the major components. After final assembly and alignment of this unit, the entirety of the system excluding the pump magnet housings has been wrapped with heater tape and aluminum foil, and baked to 120°C for over a week. A base pressure of 2 10^{-9} Torr has been achieved.

Baking the completed vacuum system of the beamline and RF distribution will provide the best possible starting point for RF processing and commissioning. The T53 accelerator section, gun diagnostic pop-in and photocathode laser mirror box, as well as the full RF distribution up to the klystron output window form a single vacuum system. The complete system bake was planned using 13 independent heater tape and PID control channels. The system was baked to 100°C for over a week and base pressures of 1–4 10^{-9} Torr was achieved once the system cooled to room temperature.

Conditioning

RF processing of the T53 accelerator section is underway. The control system for critical accelerator diagnostics is in place and tied into the arc detection system that was used for RF commissioning of the XL-4 klystron [7]. The arc detection chassis is active on the klystron forward and reverse, the RF gun forward and reverse, and the accelerator section forward and reverse. In addition the same NI chassis that does the real time monitoring acts as a digitizer for the modulator voltage and current. In order to condition most safely, the accelerator section is being brought to full power first, so that the transport waveguide can be processed and the control system can be debugged.

CONCLUSION

The major components for the X-band test station have been designed, fabricated, installed, and aligned. The XL-4 klystron has been delivered, dressed and installed in the ScandiNova modulator, and tested to full peak power [7, 11]. Assembly of RF transport, test station supports, and accelerator components, final assembly and bakeout have been completed. RF conditioning of the vacuum RF transport, accelerator section, and RF gun is underway. Laser transport for the photocathode drive laser is complete, and the laser system will be brought into operation once the laser safety interlock system installation is complete.

Conditioning is focusing on processing the RF gun to full operating power, which corresponds to 200 MV/m peak electric field on the cathode surface. Single bunch commissioning of the Mark 1 design will provide confidence that this first structure operates as designed, and will serve as a solid starting point for subsequent changes, such as a removable photocathode, and the use of various cathode materials for enhanced quantum efficiency. Charge scaling experiments will follow, partly to confirm predictions, as well as to identify important causes of emittance growth, and their scaling with charge. Multi-bunch operation will conclude testing of the Mark 1 RF gun, and allow verification of code predictions, direct measurement of bunch-to-bunch effects, and initial implementation compensation mechanisms.

SHAPING ELECTRON BUNCHES FOR ULTRA-BRIGHT ELECTRON BEAM ACCELERATION IN DIELECTRIC LOADED WAVEGUIDES*

Evgenya I. Simakov#, Dmitry Yu. Shchegolkov, C. Huang, and T.J. Kwan,
Los Alamos National Laboratory, Los Alamos, NM 87545, U.S.A.

Abstract

We describe a possible design of an Emittance Exchanger (EEX) which may be employed to generate a pair of a double-triangular drive bunch and a trapezoidal witness bunch for a Dielectric Wakefield Accelerator (DWA). We consider the concept of a high-brightness DWA with the gradient of above 100 MV/m and less than 0.1% induced energy spread in the accelerated beam as a possible afterburner for the proposed Los Alamos Matter-Radiation Interactions in Extremes (MaRIE) signature facility. We present the results of simulations with Elegant which take into account non-linear effects of the EEX beamline. Possibilities for producing ideal beam shapes to demonstrate low induced energy spread in a DWA are discussed.

INTRODUCTION

The modern discovery science has an emerging need for a very hard X-ray source, with high-peak fluxes of coherent 42-keV photons (~ 0.3 angstrom wavelength). High energy photons will allow resolving grain boundaries in materials in extreme states such as experiencing shock waves and being able to penetrate μm-to-mm sized samples. High photon energies are also required to prevent samples from disintegrating from a single X-ray pulse, allowing multiple images of transient effects. High-resolution imaging of these effects will optimally require up to 10^{12} photons per X-ray pulse, well above the ability of current technology. Los Alamos National Laboratory (LANL) has identified this discovery science frontier as an important part of its future mission and has proposed the Matter-Radiation Interactions in Extremes (MaRIE) facility [1], which includes an X-ray free electron laser (XFEL) as described in [2].

The number and the energy of photons produced by the XFEL is strongly dependent on the energy of the electron beam produced by the linear accelerator with the more energetic beam delivering more high energy photons to the user. Although generally the baseline design needs to be conservative and rely on existing technology, any future upgrade would immediately call for looking into the advanced accelerator concepts capable of boosting the electron beam energy up by a few GeV in a very short distance without degrading the beam quality. Typical electron beam quality parameters for XFEL applications are electron bunch charges of 0.1 to 1 nC, normalized rms emittances of 0.1 to 1 μm, and rms energy spreads of < 0.1%. By decreasing the bunch energy spread and emittance, it is possible to increase the total X-ray flux by orders of magnitude [2]. Dielectric Wakefield Accelerator (DWA) [3,4] has a potential to satisfy the required constraints of the afterburner and produce acceleration gradients above 100 MV/m and less than 0.1% spread in the gained beam energy [5].

We have initiated a project at LANL to demonstrate the proof-of-principle operation of a DWA with shaped drive and witness bunches at high gradient, and with enhanced transformer ratio and reduced energy spread.

REDUCING WITNESS BUNCH ENERGY SPREADS IN DWAs

DWAs are formed by one or several dielectric layers surrounded by metal cladding (Figure 1). The dielectric constant and the inner and outer radii of the dielectric tubes (or single tube in the simplest case) are chosen so that the phase velocity of the fundamental monopole mode (TM_{01}) is approximately equal to the speed of light and the mode is effectively excited by the beam passing in the central vacuum channel. In a collinear DWA the field generated by a leading, high-charge drive bunch is used to accelerate a trailing, low-charge main bunch which contains a relatively small amount of charge. The wakefields excited by a leading bunch have the remarkable property that the axial electric field and the transverse electric field are transversely uniform and linear, respectively. If one can make the wakefield to be axially constant along the bunch it will result in no induced energy spread within the bunch, leading to an extraordinary condition of preserving the main beam brightness while providing high gradient acceleration. We have realized that it is possible that an accelerated beam in a DWA can achieve the needed small energy spread if the longitudinal witness bunch profile is properly customized [5].

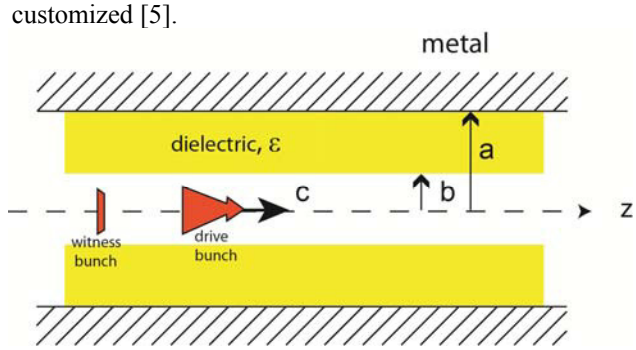

Figure 1: The schematic of a dielectric loaded waveguide with shaped electron beams traveling on axis.

Figure 2 shows the current profiles of the driving double triangular bunch and a trapezoidal witness bunch and their corresponding longitudinal wakefield generated

in a single mode wakefield accelerator. The wakefield is computed using the Green function method for the DWA geometry with parameters summarized in Table 1. It can be seen from the figure that the wakefield excited by the witness bunch interferes with the wake excited by the drive bunch which results in a uniform gradient experienced by the witness bunch. As a result, the induced energy spread in the witness bunch is below 10^{-5}.

In addition, Figure 2 illustrates the high transformer ratio generated by the double triangular drive bunch. The enhanced transformer ratios which result from generating the wake with the shaped drive bunches are important for achieving high gradients in DWAs.

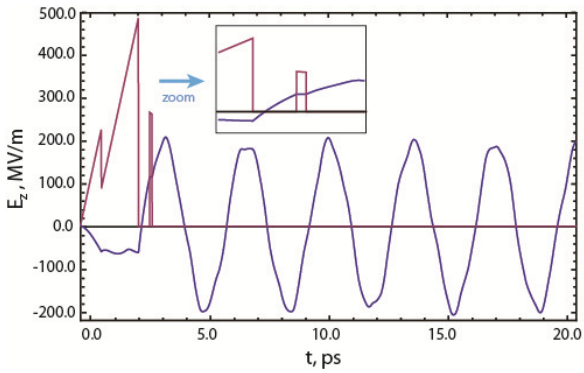

Figure 2: The current profiles of the drive and the witness bunches (red line) and the wakefield (blue line) excited by the pair of bunches in a proposed DWA configuration.

Table 1: Parameters of the 300 GHz Dielectric Wakefield Accelerator Configuration

Beam pipe ID, *2b*	1.14 mm
Dielectric tube ID, *2a*	1.24 mm
Waveguide cutoff	298 GHz
Charge of the drive bunch	5 nC
Length of the drive bunch	2.350 ps
Charge of the witness bunch	250 pC
Length of the witness bunch	100 fs
Time between the bunches	2.8017 ps
Transformer ratio	3.38
ΔG/G	$9*10^{-6}$

PRODUCING SHAPED BEAMS WITH EEX

In order to simultaneously generate the double triangular drive bunch and a trapezoidal witness bunch for a proof-of-principle demonstration, the recently proposed Emittance Exchanger (EEX) [6,7] can be employed. The schematic of a possible beamline is shown in Figure 3. The beamline starts with a mask which has two shaped slots. The slots have special shapes and are optimized to cut out the correct double triangular and trapezoidal beam profiles out of the Gaussian bunch (Figure 4). The mask is followed by an Emittance Exchanger which consists of two identical doglegs, a deflecting cavity in between them, and a number of corrective elements, such as a fundamental mode cavity, quadrupoles and possibly sextupoles. We conducted the extensive tuning of the EEX optics to convert the distribution of particles shaped in x direction into a distribution of particles similarly shaped in z direction.

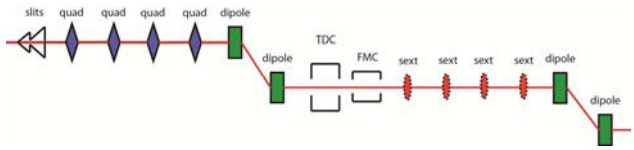

Figure 3: The schematic of a beamline for producing shaped electron bunches.

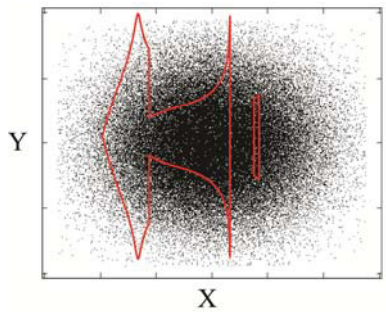

Figure 4: The shape of the mask plotted on top of the Gaussian bunch.

The beamline was modeled with Elegant [8], which is a matrix code. Without accounting for the space charge effect and coherent synchrotron radiation (CSR), the final 6-dimensional phase space coordinates of each particle in Elegant can be obtained from the initial phase space coordinates using different orders of transfer matrices of the beamline:

$$X_i^F = R_{ij}X_j + T_{ijk}X_jX_k + Q_{ijkl}X_jX_kX_l;\ \ i,j,k,l = 1,2,\dots 6.$$

In order to have the perfect transformation of the beam in the first (linear) order described by R-matrix, we want to have R_{5j}=0 except for R_{51}, which determines the stretch factor. The conditions R_{53}=R_{54}=0 are satisfied automatically in this configuration as the y-space remains uncoupled to both x and z spaces. In order to make R_{55}=R_{56}=0 the dispersion of the doglegs has to be matched to the deflecting cavity. Since the deflecting cavity of a finite length produces a time-correlated energy variation in the beam, it is necessary to include a fundamental mode cavity to compensate this effect.

Matrix elements R_{51} and R_{52} can be adjusted with the quadrupole magnets in front of the emittance exchanger. Using just two quadrupoles is sufficient to make R_{52}=0 and R_{51} equal to whatever required stretch factor. However, with only two quadrupoles we do not have any control over the width of the bunch (beta functions) along the beamline. The beta-functions may become quite large and the second order aberrations then become significant.

Copyright © 2013 CC-BY-3.0 and by the respective authors

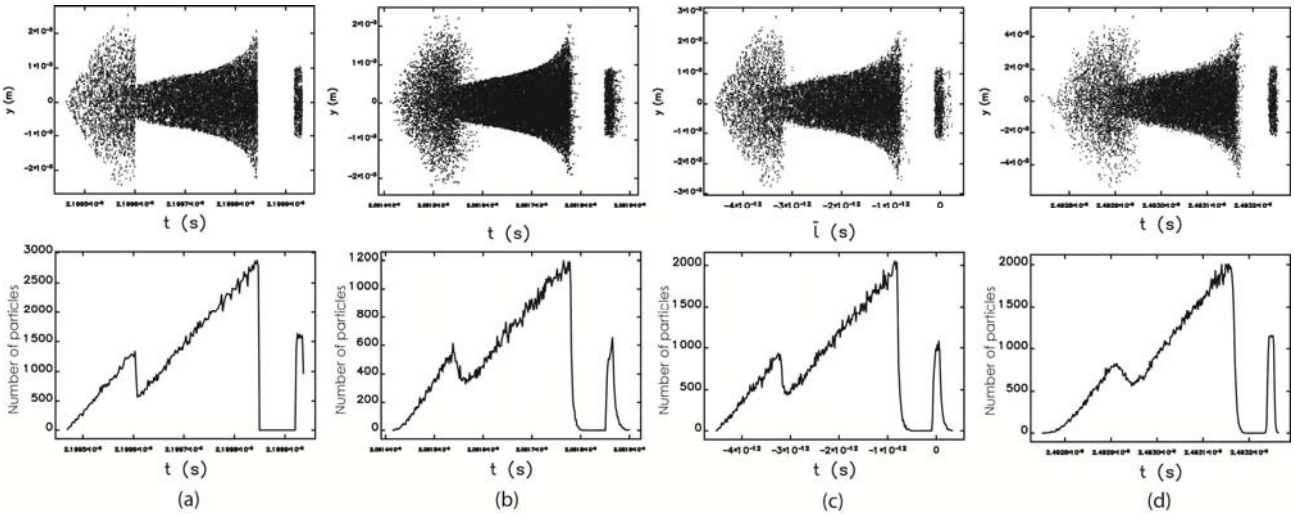

Figure 5: Distributions of the electrons (2D and integrated over y-axis) in the drive and witness bunches after the mask and the EEX as computed by Elegant: (a) in the first order of matrix elements, (b) in the third order of matrix elements, (c) in the first order with the second order matrix element T_{555} artificially included, and (d) in the third order with correcting sextupoles turned on.

With four quadrupole magnets before the EEX we have the control over R_{51}, R_{52}, beta functions and also over R_{61}, which we would like to keep small to avoid a longitudinal momentum chirp in the shaped bunch. Figure 5(a) shows the final distribution of particles and current in the shaped drive and witness bunches as computed with Elegant with only the first order of the transfer matrix.

The phase space exchange looks perfect in the first order simulations. However, when computations were performed to take into account the higher order matrices, aberrations were discovered (Figure 5(b)). We analysed the effects caused by different second and third order matrix elements and concluded that the observed changes in the shape of the witness bunch were mostly due to the effects of the second order matrix elements T_{555} and T_{551}. Figure 5(c) shows the distribution of electrons computed with the first order matrix and the T_{555} element artificially added. The aberrations due to the second order elements could be mitigated by placing a number of sextupole magnets in between the cavities and the second dogleg. Figure 5(d) shows the distribution of electrons with the sextupole corrections.

CONCLUSION

We have designed and optimized a beam shaping beamline to produce a double triangular drive and a trapezoidal witness bunches for a high transformer ratio low induced energy spread dielectric wakefield accelerator experiment. The beamline consisted of a mask followed by a tuned Emittance Exchanger. The EEX provides a unique tool for shaping beam currents in a small time scale. We realized that the EEX method is not perfect, as the higher order nonlinear effects in the beamline distort the desired pulse shape. Suppression of nonlinearities by inserting new elements into the beamline like quadrupoles, sextupoles or even octupoles can help reducing higher order nonlinearities, but will also increase complexity of the system that will eventually make tuning and aligning more difficult. The tighter focused beam may also become more prone to the space charge related effects. An experiment is planned in the near future to fully evaluate the nonlinearities and the space charge effects. We plan to conduct a beam shaping experiment with an EEX to evaluate the effects which are difficult to account for in simulations. This work may eventually evolve into a conceptual design of an afterburner for the proposed LANL future signature facility MaRIE. It also has the potential to advance the DWA technology to a level to make it suitable for a number of national security applications, including compact accelerators for warfighter support and active interrogation.

MONTE CARLO SIMULATIONS OF CHARGE TRANSPORT AND ELECTRON EMISSION FROM GaAs PHOTOCATHODES*

Yongjun Choi†, Dimitre A. Dimitrov, Chet Nieter, Tech-X Corp., Boulder, CO, USA
Siddharth Karkare, and Ivan Bazarov, CLASSE, Cornell University, Ithaca, New York, USA

Abstract

The need for a bright electron beam is increasing in the fields of x-ray science, electron diffraction and electron microscopy which are required for colliders. GaAs-based photocathodes have the potential to produce high-brightness, unpolarized and polarized, electron beams with performance that meets modern collider requirements. Even after decades of investigation, however, the exact mechanism of electron emission from GaAs is not well understood. Therefore, we investigate photoemission from a GaAs photocathode using detailed Monte Carlo electron transport simulations. Instead of a simple stepwise potential, we consider a triangular barrier including the effect of the image charge to take into account the effect of the applied field on the emission probability. The simulation results are compared with the experimental results for quantum efficiency and energy distributions of emitted electrons without the assumption of any ad hoc parameters.

INTRODUCTION

The successful operation of X-ray light sources, free electron laser (FEL), and linear accelerator facilities depends on providing reliable photocathodes [1] for generation of low emittance, high-brightness electron beams using conventional lasers.

An ideal photocathode must have a high quantum efficiency (QE), low mean transverse energy (MTE), a quick response time and a good operational lifetime. GaAs-based photocathodes have been experimentally tested and shown [2] to have the potential to produce high-brightness unpolarized and polarized, electron beams with performance (e.g., high QE and low emittance) that meets FEL and modern collider requirements. A better understanding of the physics of photoemission in GaAs will open new possibilities for creating very low emittance high efficiency photoemitters.

However, there are still a number of issues [3] to solve in order to develop an optimized photocathode design. It is of interest to better understand the quantum efficiency and energy distribution of generated beams as a function of temperature, laser frequency, cathode material, doping concentration, electron affinity, and surface properties (e.g., roughness, band bending, charge trapping).

† yjchoi@txcorp.com

Accurate simulation capabilities help to optimize the design of a semiconductor photocathode. Three dimensional, particle-in-cell (PIC) codes can accurately simulate the evolution of electron beams for these purposes.

The VSim simulation and modeling framework [4] includes a variety of physical models that make it useful for a broad range of research in plasma physics and computational electrodynamics. It can model a plasma as particles, a fluid, or a particle-fluid hybrid; it can treat electromagnetic fields either self-consistently or in the electrostatic limit; and it provides both explicit and implicit time updates.

In a previous work [5], we investigated effects of charge transport and surface properties on electron emission from GaAs with a specific surface potential. However, it did not include the image charge effect, zero applied field was assumed, and the space-charge field was not included in the models. Here, we have started to consider electron emission properties when the space-charge field is included and the applied field is non-zero. We have done simulations with a surface potential that is often used to investigate electron emission and includes the image charge effect. Finally, we have used a reduced model for the calculation of the electron emission probability that is fast to evaluate but potentially less accurate than the model in Ref. [5].

MODEL

The simulation is based on the three-step model initially proposed by Spicer [6]. The three valley model is used to describe the band structure of GaAs. Here, we briefly describe these models. More detailed explanation can be found in Ref. [5].

Three Step Model

The three-step model takes into account the dependence on photon energy and (implicitly) on temperature. Fig. 1 shows a schematic representation of the three-step model for *p*-doped GaAs photocathode. The creation of electron-hole pairs due to absorption of photons is treated in the first step. A photon with sufficient energy is absorbed by a valence band electron leading to its transition to the conduction band and the formation of a hole in the valence band. The difference between the photon energy and the energy gap of the semiconductor material is transferred into kinetic energy of the created free charge carriers. In the second step, created conduction band electrons undergo different scattering processes and propagate diffusively. Some of these electrons will reach the photocathode surface and be

Copyright © 2013 CC-BY-3.0 and by the respective authors

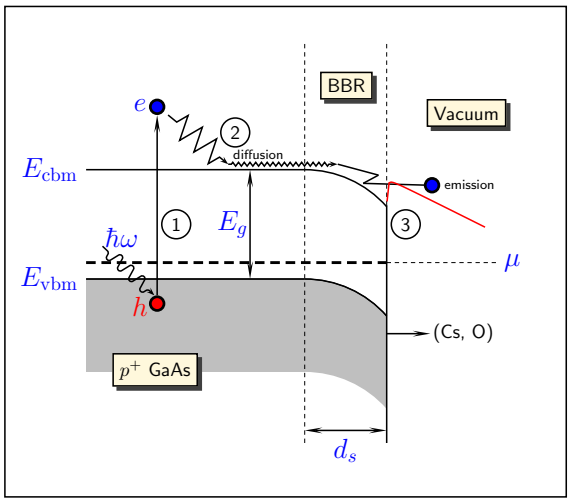

Figure 1: Schematic representation of the three-step model. First, a photon is absorbed causing the generation of an electron-hole pair. Next, the free electron undergoes phonon scattering and diffuses towards the GaAs cesiated electron affinity surface. In the final, third step, a conduction band electron undergoes emission (over barrier or tunneling) or reflection when impinging on the GaAs-vacuum interface.

emitted, during the third step as schematically shown in Figure 1.

Three Valley Model

In our simulation, we use the three valley model of GaAs, which assumes the top 3 valence bands (heave hole, light hole and the split-off) to be spherical and parabolic near the Γ point. The first conduction band is modelled as a combination of three valleys (Γ, L, and X valleys).

Electron-Hole Generation

As light propagates to a distance x in a photocathode (measured from its surface), its intensity decrease is given by the expression

$$I = I_o exp\left(-x/a\left(\hbar\omega\right)\right),$$

where $a\left(\hbar\omega\right)$ is the photon's energy-dependent absorption length. We assume that excitation of electrons from the valence band to the conduction band is the only dominant light absorption process. Doping dependent absorption length is calculated using the model developed by Lao *et al.* [7] The energy w.r.t. the conduction band minimum (CBM) of the electron excited into the Γ valley by a photon is calculated by equating the energy difference between the initial and final state of the electron to the energy of the photon [8].

Conduction Band Electron Transport

The charge transport of free carriers in the presence of applied electric field represents a drift-diffusion process. The simulation tracks electrons excited into the conduction band in both real space and k-space using semi-classical equation of motion. The main problem in modeling charge transport in GaAs is to determine the relevant scattering processes involved, how to calculate their rates as a function of electron energy, and how to determine final wave vectors in each type of scattering process. In this study, we considered impurity, phonon, and carrier-carrier scattering. For impurity scattering, we only consider scattering with charged impurities, because most impurities in GaAs are ionized at room temperatures. For phonon scattering, we consider acoustic, optical, and polar optical phonon scattering processes. Piezoelectric scattering is ignored. Here, we consider only electron-hole scattering (and neglect electron-electron and electron-plasmon processes) since it is the dominant carrier-carrier process for electrons in heavily *p*-doped GaAs. The density of free electrons is very small and plasma oscillations of the holes are heavily damped, therefore, electron-electron and electron-plasmon processes can be neglected.

Modeling Electron Emission

The simulation results we have reported here use the electron emission model developed by K. Jensen [9] with the image charge effect included in the surface potential. The potential energy of an electron in this surface potential is given by

$$V\left(x\right) = \chi - Fx - \frac{Q}{x}, \qquad (1)$$

where χ is the electron affinity (measured relative to the conduction band minimum at the surface), $Q = Q_0\left(K_s - 1\right)/\left(K_s + 1\right)$, $K_s \approx 13$ is the (static) dielectric constant for a GaAs cathode, and $Q_0 = q^2/\left(16\pi\varepsilon_0\right)$ with q the fundamental charge and ε_0 the permittivity of vacuum. The probability of emission is then given by Eq. (18) in Ref. [9] as a function of the electron's effective energy along the direction perpendicular to the emission surface. This approximate model for calculation of the emission probability, due to reducing the problem to one spatial dimension, requires us to extend our algorithm in VSim to explicitly preserve conservation of transverse momentum during emission. In the MATLAB code developed for the study by S. Karkare *et al.* [5], a transfer matrix (TM) approach was used to calculate the emission probability that explicitly takes into account conservation of transverse momentum. The TM method is currently being implemented in VSim and results with it will be presented elsewhere.

COMPARISON TO PHOTOEMISSION EXPERIMENTS

We use VSim with an electromagnetic pusher and include space charge effects. Band bending field and image charge effects are considered too. We also include the effect of an external applied field which was set to 1 MV/m. The values of GaAs parameters used in the simulations are given in Ref. [5]. The band bending region energy was 0.461 eV and its length was 8.4 nm calculated via the approach in Ref. [5]. Three-dimensional simulations are performed with

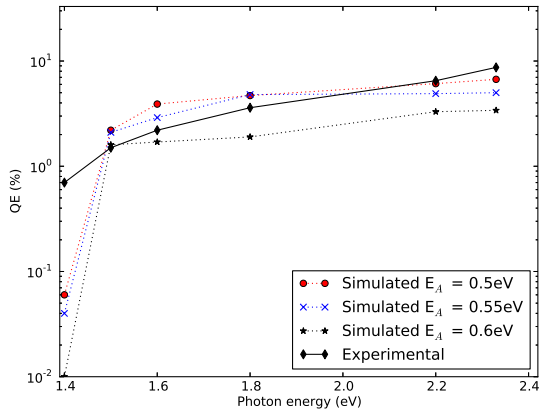

Figure 2: Comparison of measured and simulated spectral response. The electron affinity is an input parameter in the simulations. Results close to the experimental data are obtained for $\chi = 0.55$ eV.

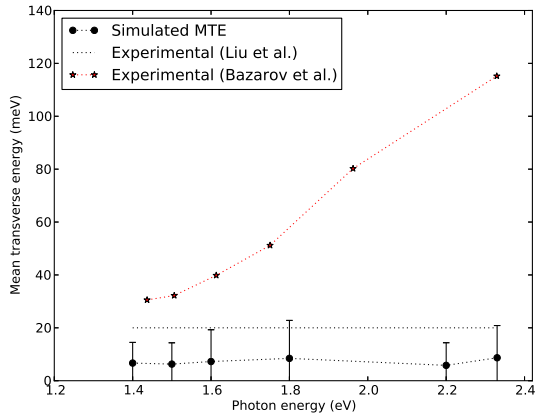

Figure 3: Comparison of measured (Liu *et al.* [10] and Bazarov *et al.* [11]) and simulated MTE using $\chi = 0.55$ eV in our simulations.

$30 \times 30 \times 30$ cells and 1000 electrons except for the lowest photon energy 1.4 eV in which case 10000 electrons were considered. We run simulations to 100 ps to collect data. The electron affinity is measured from the CBM at the GaAs surface (note that some authors consider χ relative to the CBM in bulk).

Spectral Response

Figure 2 shows the spectral response measurement along with the results obtained from the simulation for various values of electron affinity. The simulation results with electron affinity of 0.55 eV are overall closest to the experimental data. It is worth to mention that the simulation results are obtained entirely from the band structure and transport properties of GaAs and no ad-hoc parameters have been used. The only uncertain variable is the electron affinity which is deduced to be 0.55 eV (for the surface potential, Eq. (1), we considered) by comparing the simulated results to the experiment. In order to calculate the quantum efficiency, the reflectivity value of GaAs was taken from Ref. [5].

Mean Transverse Energy

We show MTE results from our simulations in Figure 3 together with data from two experimental measurements [10, 11]. The electron affinity was set to 0.55 eV in the simulations. Our results do not include scattering during emission process, and show very small MTE due to the narrow cone effect similar to the results from the MATLAB code [5]. The MTE deduced from the angular and energy distribution obtained by Liu *et al.* [10], using white light for excitation, is close to the simulation results. However, data from other experiments, including Bazarov *et al.* [11], give larger values outside of the narrow cone prediction. The reason for this discrepancy is still to be understood. Additional scattering during emission through the Cs layer was considered [5] leading to higher MTE values. However, emission dependence on surface roughness, orientation, surface cleanliness, and external electric field effects are still to be investigated in detail.

CONCLUSION

We presented simulation result on charge transport and electron emission from GaAs cathodes. Our model includes effects of applied field and image charge in the surface potential, space-charge fields and band bending. This model can achieve agreement with experimental data on QE with electron affinity the only free parameter varied. However, different surface potentials have been proposed and investigated in other studies [5] (and references therein). Further work is needed to determine the most relevant surface potential and related surface physics models (e.g. roughness and space-charge region in non-equilibrium) that could best describe observed experimental data.

HIGH CAPTURE LOW ENERGY SPREAD INVERSE FREE ELECTRON LASER ACCELERATOR

J. P. Duris, R. K. Li, P. Musumeci, E. Threlkeld
Department of Physics and Astronomy, UCLA, Los Angeles, CA 90095, USA

Abstract

We present the design and construction of a strongly period-, field-, and gap-tapered helical undulator for use in a high-gradient, high-efficiency helical IFEL experiment at Brookhaven ATF. The undulator design achieves efficient acceleration without prebunching by matching the ponderomotive and resonant energy gradients along the length of the interaction for the measured laser parameters. Simulations based on the measured undulator fields and experimental parameters suggest that as much as 43% of a 50 MeV beam will be accelerated to 94 MeV with 2.3% rms energy spread.

INTRODUCTION

Recent progress in inverse free electron laser acceleration (IFEL) has led to unprecedented acceleration gradients and energy gain for this class of accelerator. The STELLA experiment at ATF demonstrated efficient IFEL acceleration with gradients similar to conventional RF-accelerating cavities and captured up to 80% of the beam with the use of a prebunched beam [1]. The UCLA Neptune IFEL experiment first achieved accelerating gradients surpassing that of conventional rf-accelerators [2]. More recently, the UCLA-BNL helical IFEL collaboration at the Brookhaven Accelerator Test Facility (ATF) accelerated electrons from 52 MeV up to 106 MeV with a TW class CO_2 laser, averaging a 100 MeV/m accelerating gradient in the 54 cm long helical undulator [3]. The LLNL-UCLA IFEL effort currently underway at Lawrence Livermore National Lab aims to surpass these achievements by utilizing a multi-TW Ti:Sa laser [4] and has produced some significant initial results [5].

While IFEL accelerating gradients now outpace that of their rf counterparts, the higher gradients often come at the price of significant energy spread and low capture. One approach to improving capture is to match the longitudinal phase space of the beam to the longitudinal acceptance of the accelerator through microbunching as demonstrated by [1], and novel optical scale harmonic and adiabatic bunchers hold the promise of improved microbunching [6]. However, the efficiency of IFEL accelerators is often limited by spatiotemporal overlap of electron and laser beams as well as resonant energy and ponderomotive gradient mismatch. We aim to address these issues to allow monoenergetic acceleration with gradients larger than that of conventional accelerators without the use of prebunching.

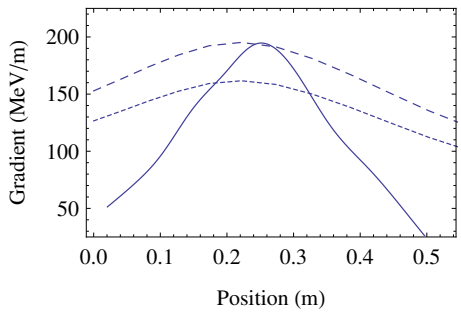

Figure 1: Resonant energy gradient set by the undulator tapering (solid) and ponderomotive gradients for the highest laser focal intensity of 23 TW/cm^2 (dashed) as well as for the median intensity of 18 TW/cm^2 (dotted).

GRADIENT MISMATCH

The UCLA-BNL helical IFEL collaboration at ATF was conceived to improve accelerating gradient through the use of the first strongly period- and field-tapered helical undulator. Whereas electrons propagating through a linear undulator undergo sinusoidal motion thereby reducing to zero twice per period their transverse velocity, the helical trajectories of the electrons propagating through the undulator provide continuous transverse velocity which in turn enables continuous energy transfer. This, coupled with a TW-class CO_2 laser, allowed for the acceleration of 52 MeV electrons up to 106 MeV [3].

The undulator was originally designed for use with a 9.6 cm Rayleigh range CO_2 laser. Unfortunately after construction, it was discovered that beam line space constraints and a restricting dipole aperture just upstream of the undulator necessitated a laser Rayleigh range of 30 cm. While the increased Rayleigh range had the positive benefit of easing transverse overlap tolerances by increasing the laser spot size, the on-axis intensity was reduced 3-fold, thereby significantly limiting the fraction captured and challenging the success of the experiment.

The problem can be better visualized by comparing the gradients set by the tapering of the undulator and that supplied by the ponderomotive interaction of the electrons in the combined undulator- and laser-fields. Figure 1 shows the resonant energy gradient set by the undulator and the ponderomotive gradient for various focal laser intensities (right plot). The resonant energy gradient usually exceeded the ponderomotive gradient, thereby significantly increasing the number of particles lost by reducing the ponderomotive bucket depth.

HELICAL UNDULATOR

In order to improve the efficiency of the interaction, either the laser focusing must be changed to match the undulator design or the undulator tapering must be modified to match the laser. The former proved to be expensive as the dipole gap would have to be increased and impractical since due to the experimental hall layout, the focusing optics would have to be placed in the middle of a walkway, blocking access to vacuum equipment and interlock systems. The chosen solution was to redesign and rebuild the undulator to accommodate the more relaxed laser focusing.

The helical undulator is the superposition of two Halbach permanent magnet undulators rotated 90 degrees about their common axis and shifted in phase by a quarter wavelength [7]. Each of the four opposing pairs of NdFeB magnets per period determines the period and on-axis field of each undulator for a fixed gap of 15 mm. In order to relax the tapering, we tapered the gap of the undulator. This extra degree of freedom enabled us to change the undulator strength K while the period remained fixed.

Undulator Design

The undulator design follows closely the methods described in [8]. Equations 1 and 2 describe the approximate longitudinal dynamics of a particle undergoing helical IFEL interaction. Here, $K_l = \frac{eE_0\lambda}{m_0c^2 2\pi}$ and $K = \frac{eB\lambda_w}{m_0c2\pi}$ are the laser and undulator normalized vector potentials respectively.

$$\frac{d\gamma}{dz} = \frac{kK_lK}{\gamma}\sin\psi \tag{1}$$

$$\frac{d\psi}{dz} = k_w - k\frac{1+K^2}{2\gamma^2} \tag{2}$$

Equation 1 describes the ponderomotive gradient due to the combined interaction of undulator- and laser-fields as evident by the presence of K and K_l in the equation. For a stationary resonant phase, a resonant particle's energy is determined completely by setting the phase advance to zero in Equation 2, thereby yielding the energy of the resonant particle: $\gamma_r = \sqrt{\frac{\lambda_w}{2\lambda}(1+K^2)}$. This resonant energy depends only on the undulator field strength K and wavelength λ_w; therefore, the gradient in the resonant energy is determined completely by the undulator.

The undulator tapering is then determined by Equation 3 which is found by equating the ponderomotive gradient from Equation 1 with the gradient in the resonant energy set by the undulator tapering. When the undulator period and laser parameters are specified along with the initial condition that K at the entrance be such that the resonant energy is equal to the input beam's 50 MeV, the differential equation yields K which in turn determines the on-axis field strength along the undulator. The undulator builder equation can then be used to estimate the gap along the undulator needed to create the designed on-axis field. The measured laser and e-beam parameters used in the tapering

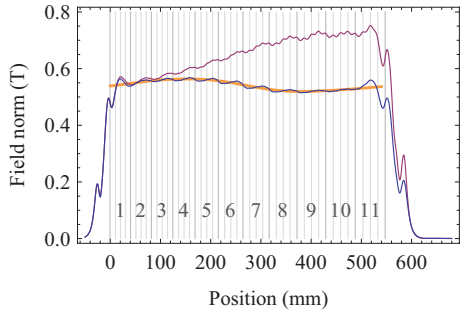

Figure 2: Design magnetic field amplitude along the undulator (orange) along with Radia simulation (blue) and the previous constant-gap undulator field (purple).

design are specified in Table 1. The design laser focal intensity dictates the threshold for full acceleration and was set to be 4 TW/cm^2 in order to be well within the capabilities of the laser in order to achieve full acceleration for most shots; furthermore, simulations show that this choice of design intensity maximizes capture for the more typical intensity of 18 TW/cm^2 observed previously. The resonant phase was chosen to be a constant $\pi/4$ as a compromise between bucket depth and ponderomotive gradient.

$$\frac{dK}{dz} = \frac{8\pi K K_l \sin\psi_r - \frac{d\lambda_w}{dz}\left(1+K^2\right)}{2\lambda_w K} \tag{3}$$

Table 1: Design Parameters

E-beam energy	50 MeV
Laser focal intensity	4 TW/cm^2
Laser wavelength	10.3 μm
Rayleigh range	30 cm
$1/e^2$ spot size	0.99 mm
M^2	1.07
Resonant phase	$\pi/4$
Laser waist	undulator midpoint

The 3D magnetostatic field solver Radia [9] was used to determine the placement of each magnet. Figure 2 shows the design field determined by the differential equation for K discussed above along with the field simulated by Radia with the design magnet gap configuration. The ripple in the Radia simulated field was introduced to minimize trajectory deflections for particles propagating on axis through the undulator. The trajectory is determined by the second integral of the field; however as the field increases towards the end of each period, the integral over one period is non-zero and the net effect is a kick to the particles. The ripple minimizes this deflection by canceling the second integral over each period.

Construction and Measurement

The undulator magnets are held in place by bolts which provide fine tuning of the gap over a range of a couple mm;

Copyright © 2013 CC-BY-3.0 and by the respective authors

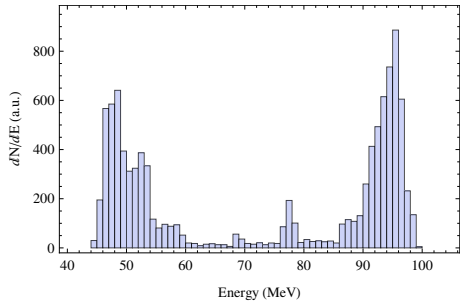

Figure 3: TREDI simulation utilizing the measured fields.

however since the half gap needed to be increased by about 2.5 mm towards the undulator's exit, aluminum shims were introduced to increase it by 3 mm. Measurements of the height of each magnet, width of the rails for each period, and the overall shim distance allowed for an estimate of the initial half gap with magnets retracted fully. The difference between design and measured half gap was calculated, and each magnet was driven into place. Since thread tolerances cause up to 200 μm play as each bolt was turned, a hall sensor was positioned on axis near each magnet before moving to detect movement as its corresponding bolt was turned.

After the initial magnet placement, the on-axis fields were measured and found to be systematically low by a couple percent. Magnets were then tuned slightly in pairs to increase the field to that of the Radia simulations. Finally, the fields were finely tuned to reduce the transverse kick and offset estimated by the first and second integrals of the field for a beam with energy 50 MeV. The final measured fields were found to agree to within 0.5% rms of the Radia simulations.

SIMULATIONS

Simulations were performed with the 3D IFEL code TREDI and are shown in Figure 3 for a 50 MeV input e-beam, laser focusing parameters listed in Table 1, and 18 TW/cm^2 laser focal intensity. TREDI solves the Lorentz force equations rather than averaging the motion of the electrons over an undulator period [10] and was previously bench-marked against IFEL experimental results in planar undulators [2]. The simulation includes time dependent effects, and the 1 ps long e-beam and 4.5 ps laser pulse are synchronized at the entrance to the undulator. The simulations show that for the expected experimental parameters, up to 43% of the beam is captured and transported to greater than 90 MeV. The accelerated beam has a mean energy of 94 MeV, energy spread of 2.3%, and is microbunched at 10.3 μm.

One of the benefits of the relaxed tapering is the relatively modest requirements on the laser performance. Figure 4 shows how the maximum particle energy varies as the input laser focal intensity is increased. While the laser focal intensity was previously seen to usually exceed 15 TW/m^2, the threshold for acceleration to 90 MeV for the measured undulator is just 5 TW/cm^2. This suggests that

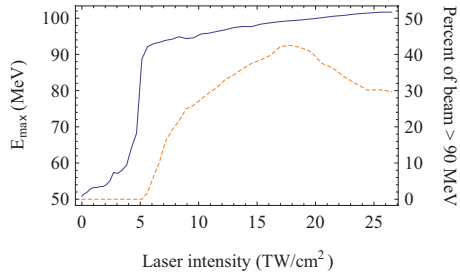

Figure 4: Maximum particle energy (solid) and fraction of beam with energy greater than 90 MeV (dashed) as a function of input laser focal intensity.

full energy acceleration should be obtained for most shots. Furthermore, a quarter of the beam is accelerated to greater than 90 MeV when the intensity is doubled to 10 TW/cm^2. These modest requirements on laser intensity for full acceleration open the door to studies of the accelerated beam.

CONCLUSIONS

While recent achievements in IFEL acceleration have focused on either high gradient or high efficiency acceleration, the UCLA-BNL helical IFEL collaboration aims to achieve both without the need for prebunching. The undulator tapering design achieves this by matching the resonant energy and ponderomotive accelerating gradients using the measured laser parameters through the novel strongly period-, field-, and gap-tapered helical undulator. The laser focal intensity threshold for full acceleration is well within the laser's observed limits leading to the possibility of studies of the accelerated beam. For moderate laser intensities, up to 43% of the e-beam should be transported to full energy, and production of a monoenergetic beam with few percent energy spread is expected.

Abstract

The University of Wisconsin-Madison has completed installation of a superconducting electron gun. Its concept was optimized to be the source for a CW free electron laser facility with multiple megahertz repetition rate end stations. This VHF superconducting configuration holds the promise of the highest performance for CW injectors. Initial commissioning efforts show that the cavity can achieve gradients of 35 MV/m at the cathode position. With the cathode inserted CW operation has been achieved at 20 MV/m with good control of microphonics, negligible dark current, and $Q_0 > 3\times10^9$ at 4 K. Bunch charges of ~100 pC have been delivered, and first simple beam measurements made. These preliminary results are very encouraging for production of 100s pC bunches with millimeter-milliradian or smaller normalized emittances.

MOTIVATION

An FEL complex operating at high repetition rates and delivering intense, ultra-short, fully-coherent, variably-polarized beams to multiple experiments enables transformational research in diverse science disciplines. The Wisconsin SRF electron gun program is a response to the demand for a very bright electron source that can be used for these next generation light sources. SRF guns hold the promise to produce very bright, CW beams because of the correlation between high electric field on the cathode and brightness [1].

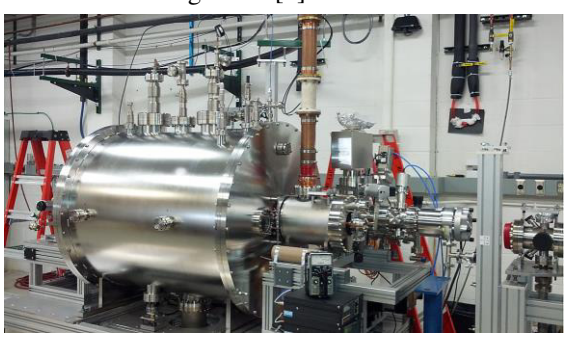

Figure 1: Electron gun installed in vault.

FACILITY OVERVIEW

The design uses a 199.6 MHz, quarter wave resonator geometry at a peak gradient up to 45 MV/m. Details of the superconducting cavity design, fabrication, and modeling have been presented in earlier publications [2]. The lower frequency design allows operation at 4 K and close to spatially constant electric field while the electron transits the accelerating gap. Thus, beam properties are expected to be superior to CW L-band guns, and relative to DC electron guns, should offer better performance with higher cathode fields. A copper photocathode was installed for initial testing with repetition rates limited to 1 kilohertz by the drive laser. Figure 1 shows the overall installation, and Table 1 contains key parameters for the gun.

Table 1: SRF Electron Gun Design Parameters

Max beam kinetic energy	4.0 MeV
Bunch charge	10–200 pC
Normalized trans. emittance	0.2–1 μm
Ultimate average beam current	1.0 mA
Peak current	50 A
Driving laser wavelength	266 nm

SUBSYSTEMS

RF System

The RF system utilizes a commercial, 30 kW, solid state transmitter driving coaxial waveguide through a circulator to the RF coupler. The low level RF controller (LLRF) [3] allows self-excited cavity operation and incorporates cavity fault and tuner control. It is based on the JLab upgrade design.

Magnets

The emittance compensation solenoid is of high temperature superconductor design. Nominal operating parameters are an integrated field of 3.1 T^2-mm at 38.45 A excitation at about 25-30 K (i.e., intermediate between LHe and LN_2 temperatures). An 18 bit AD7608 ADC is used to measure voltages at both ends and at the center of the solenoid for quench protection. The voltage difference between the two halves of the coil are compared and differences as small as 1 millivolt can be used to trigger a quench trip. There are two octupoles in the beamline. On each octupole the poles are independently powered with excitations mixed in software to produce normal and skew dipole and quadrupole correctors.

Cryostat

The cryostat consists of the helium vessel, internal tuner mechanism, cathode stalk, beam pipe, LN_2 cooled thermal radiation shield, magnetic shield, cryogenic plumbing and external vacuum vessel. The cavity is

*Work supported by DOE Award DE-SC0005264

+Current address: APS ANL

Copyright © 2013 CC-BY-3.0 and by the respective authors

immersed in 100 liters of batch fed LHe within the helium vessel. Minimizing static heat loss is critical since the LHe bath is not a closed loop system and the cryostat consumes LHe all the time that the cavity is held at 4.2 K. Calorimetric measurements using a heater in the helium vessel resulted in a static loss measurement of 6 W which agrees favorably with earlier calculated predictions of 7.5 W. Future plans include the addition of a LHe refrigerator, and the existing cryostat can be configured to run closed loop. The required modifications will most likely result in an increase in static thermal loss of approximately 2 W.

Photocathode Laser

The drive laser system consists of a Spectra Physics Tsunami titanium-sapphire oscillator seeding a Spitfire Pro Ultrafast Amplifier. It operates at 1 kHz and is synchronized to an external 80 MHz signal which is phase locked to the RF master oscillator. A Minioptic TPH tripler provides the frequency doubled and tripled beams at 400 nm and 266 nm respectively. The 800 nm light is used for laser diagnostics while the 266 nm light passes through an adjustable aperture optical transport system before being directed onto the photocathode.

The laser transport optical system consists of two nested Schiefspiegler telescopes with a 0.4 net magnification. A laser pulse length of 120 fs has been achieved.

Controls

The control system is based on EPICS utilizing several soft-IOCs running on a Scientific Linux server. Koyo DL205 PLCs are used to interface most of the beamline hardware. Additional soft-IOCs were written for cryogenic thermocouples, Faraday cup picoammeters, and motorized laser mirror mounts. Cameras are used to capture the YAG:Ce screen images. New capture software was written based on existing diagnostic cameras that implemented Gaussian fitting and automatic exposure control.

COMMISSIONING

Cooldown

Without a helium refrigerator, a two-step cool-down procedure has been utilized with vendor delivered LN_2 and LHe. The procedure takes two consecutive days. The first step, cooling down by LN_2, is performed on the first day followed by filling the cavity cryostat with liquid helium to complete the cool-down procedure on the second day. The first cool-down step also includes pre-cooling of the cavity cryostat by liquid nitrogen in a manual mode. Right before the liquid helium filling step (on the next day of the cool-down procedure) the cavity cryostat is purged by dry (boil-off) nitrogen until there is complete evaporation of the liquid nitrogen. Then, the gaseous nitrogen in the cryostat is purged by helium gas. Cooldown is about 29 hours to the most poorly cooled points. However, RF input can begin after about 10 hours.

Cathode Positioning

The cathode longitudinal position can be adjusted to ensure it is flush with the cavity surface. Although the cathode can be viewed axially through the cavity, the longitudinal positioning of the cathode face is complicated by the cryogenic contraction and flexure of the structure under vacuum load. Dead reckoning from warm measurements results in a ±2 mm error, which exceeds tolerances.

Our technique for positioning involves measurements of cavity resonant frequency versus cathode insertion. Comparable geometry runs were made in SuperFish [4]. The technique begins with frequency computations and measurements with the cathode withdrawn. From SuperFish one has the frequency shift expected with the cathode flush with the cavity's cathode snout; in this case it is nearly -3000 Hz. The cathode is then physically adjusted to achieve this frequency shift.

Microphonics

Generator Driven Resonator mode is an operating mode where the RF frequency is fixed and the cavity's mechanical tuner is used to keep the cavity frequency within a few hertz of the reference frequency. The field control chassis has the capability to send data on the phase difference between forward and transmitted power to a DAC output. The rms value of the frequency shift was 0.35 Hz and the peak-to-peak value was 2.7 Hz. The largest frequency component was a cavity frequency excursion of 0.14 Hz rms at a vibrational mode of 1.8 Hz The loaded Q of the cavity is 10^7. The microphonics are within the cavity bandwidth, and are well controlled by the LLRF system.

Plasma Processing and Q_0 Improvement

During the initial cold tests at Niowave, the cavity showed a low field Q_0 of 3×10^9 at 4 K. However, the cavity exhibited relatively severe field emission which limited operation to approximately 5 MV/m peak field at the cathode. To improve the anticipated initial performance, a novel surface preparation technique, plasma processing [5, 6], was used [7].

Figure 2 shows the Q_0 data plotted with the data from cold test at Niowave. Data show the cavity has a Q_0 of 3×10^9 at 4 K at a peak cathode gradient of 26 MV/m.

Performance Summary

Conditioning of the cavity and especially the cathode stalk has not been completed. The RF circulator failed at higher average powers and is currently under repair at the vendor, and further conditioning has been postponed. Following are performance limits achieved to date, but further improvements can be expected:

Highest CW gradient: 29 MV/m, cathode out
Highest CW gradient: 20 MV/m, cathode in
Highest pulsed gradient: 35 MV/m, cathode out
Highest pulsed gradient: 29 MV/m, cathode in
Dark current: < 1 pA at 20 MV/m CW

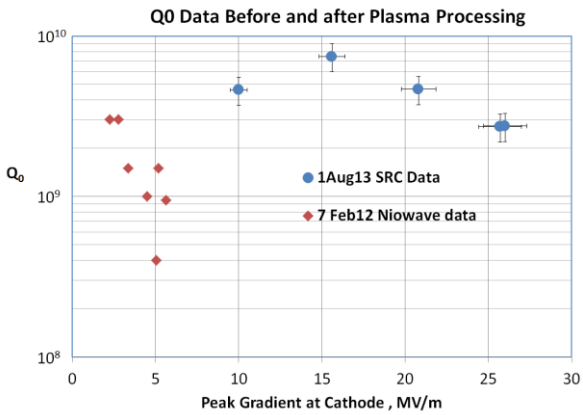

Figure 2: Calorimetric Q_0 data for cavity.

BEAM MEASUREMENTS

The gun and diagnostic beamline are shown in Figure 3. The transverse profile of the beam can be measured at three locations using 0.1 mm thick YAG:Ce screens. Two of the viewers, the first of which also contains a slit array, are located on the straight-ahead beamline, for use in

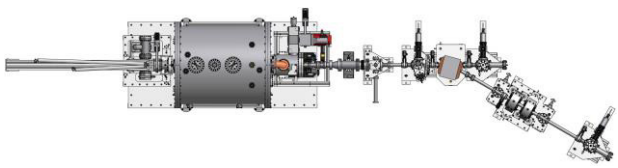

Figure 3: Layout of the gun and diagnostic beamline.

transverse emittance measurements. The third viewer is located on the 30° branch line, and is used to measure beam energy and energy spread. The beam is deflected down the branch line by an H-frame dipole. Both the straight-ahead line and the branch line are terminated with a Faraday cup/beam dump read by a picoammeter.

First beam measurements were made in mid-2013 although multipactor conditioning of the cathode stalk to higher gradients was still moving forward. To minimize cryogenic load during debugging of the diagnostics, first data were taken at 12 MV/m.

Initially there was 60 Hz motion of the beam that was traced to an AC solenoid on a vacuum valve. Additionally, it was found that the synchronization of the drive laser and the RF system was not stable. In particular, the 1 kHz repetition frequency from the drive laser is not well phase locked to the 200 MHz cavity fundamental, which results in an erratic bunch repetition rate and possible phase wandering. A laser upgrade is being provided by the vendor to correct this problem.

The electron energy was measured by centering the beam on the first beam viewer and the viewer on the 30° branch line. Based on the dipole calibration, the energy at 12 MV/m was 1.1 MeV. This is consistent what would be expected based on the accelerating gradient. The width of the beam spot on the 30° line viewer gave a projected energy spread of 2 % full width. The average bunch charge was measured to be roughly 100 pC.

Only one shift was devoted to transverse beam measurements before the RF circulator failure and only very limited data were acquired. We have initially used the quad-scan technique [8] for emittance measurement. To take space charge into account, ASTRA [9] simulations were compared to the measurements, and plausible emittances extracted. The estimated value for the normalized projected emittance is 1.5 mm-mrad. Given that laser/RF synchronization problem was present and that no systematic optimization was possible before the circulator failure, this result is surprisingly good and already near baseline goals. Since higher gradients can be obtained and optimization of phase tuning, cathode positioning, laser spot size, and emittance compensation has yet to be performed, considerable performance improvements can be expected.

FUTURE PLANS

A plan for a three year Phase II program is in place. We will work to fully characterize gun operation including exploration of tuning configurations (charge, peak current, RF phase, laser pulse length and spot size, emittance compensation, cavity gradient, etc.). The self-expanding blowout mode [10] and lower charge configurations for reduced emittance will be thoroughly investigated. A high repetition photocathode laser will be added together with a cathode preparation chamber for high quantum efficiency photocathode materials. Ultimately, exotic cathode materials for lowest emittance will be introduced. These improvements will allow operation at an average current of 1 mA at repetition rates up to 40 MHz.

SUMMARY

All together, the preliminary results are very encouraging for production of 100s pC bunches with millimeter-milliradian or smaller normalized emittances.

ACKNOWLEDGMENTS

We wish to thank Professor John Pfotenhauer and his cryogenics team for their help in the design of the cryostat and advice on cooldown procedures.

EFFECT OF RF GRADIENT UPON THE PERFORMANCE OF THE WISCONSIN SRF ELECTRON GUN*

R. A. Bosch#, Synchrotron Radiation Center, University of Wisconsin-Madison,
3731 Schneider Dr., Stoughton, WI 53589, USA
R. A. Legg, Jefferson Lab, 12000 Jefferson Avenue, Newport News, VA 23606, USA

Abstract

The performance of the Wisconsin 200-MHz SRF electron gun is simulated for several values of the RF gradient. Bunches with charge of 200 pC are modeled for the case where emittance compensation is completed during post-acceleration to 85 MeV in a TESLA module. We first perform simulations in which the initial bunch radius is optimal for the design gradient of 41 MV/m. We then optimize the radius as a function of RF gradient to improve the performance for low gradients.

INTRODUCTION

A superconducting radiofrequency (SRF) electron gun has been designed and constructed to produce 200-pC bunches that are suitable for a high-repetition-rate (5 MHz) soft-xray free electron laser (FEL) [1–5]. Bunches are created by laser illumination of a photocathode and then accelerated to an energy of 4 MeV by a 200-MHz SRF cavity with peak electric field of 41 MV/m on the cathode. The electron gun utilizes a Cu photocathode, which can be replaced with a Cs_2Te photocathode whose higher quantum efficiency allows operation with lower laser power.

When a bunch is accelerated and compressed to achieve a peak current of ~1 kA for an FEL, current and energy modulations can cause microbunching that spoils the FEL process [1]. To minimize modulations in longitudinal phase space at the expense of slightly increased transverse emittance, "blowout" mode is employed, in which the initial bunch length is small compared to that of the accelerated bunch [6]. Simulations of blowout mode show that longitudinal and transverse modulations of the initial bunch distribution emitted from the photocathode are smoothed out by the self field space charge force [3].

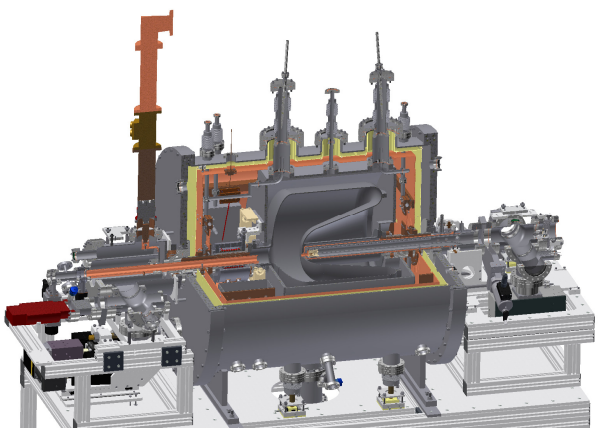

Figure 1: The photocathode, SRF cavity and high-temperature superconducting solenoid in the liquid-helium cryostat. Courtesy of G. C. Rogers.

We study the gun performance with simulations that include emittance compensation [7] from focusing the bunches in a high-temperature superconducting (HTS) solenoid [8] that is immediately downstream of the SRF cavity, and then accelerating them to 85 MeV in a cryomodule containing eight TESLA 1.3-GHz SRF cavities. The first TESLA cavity is used as a buncher, with the phase and gradient adjusted to control transverse focusing. The bunches become longitudinally frozen after travelling 3 m and reaching an energy of 6 MeV. For the design gradient of 41 MV/m, simulations indicate that bunches with normalized emittance of ~1 mm-mrad emerge from the cryomodule [5]. Figure 1 shows the photocathode, SRF cavity, and solenoid in the liquid-He-cooled cryostat.

In this article, we evaluate the production of 200-pC bunches when the peak electric field on the cathode of the 200-MHz cavity differs from the design gradient of 41 MV/m. The ASTRA [9] code is used to perform 100,000-particle simulations of a realistic bunch that initially has truncated Gaussian radial and longitudinal profiles, truncated at 0.8σ. (Note that for a Gaussian profile truncated at 0.8σ, σ is not the rms value.) For the Wisconsin electron gun, previous studies [5] have shown agreement between ASTRA simulations and simulations performed with the GPT code [10].

An initial longitudinal σ of 187.5 fs is studied; nearly identical results have been obtained with smaller values of the longitudinal σ, consistent with blowout mode. Since the electron velocity depends upon the RF gradient, we use the AUTOPHASE feature of the ASTRA code to set the RF phase when a bunch enters a TESLA cavity to equal the optimized phase for the design RF gradient of 41 MV/m.

A bunch is emitted from a Cu or Cs_2Te photocathode with initial transverse normalized slice emittances ε_x and ε_y that are related to the rms laser spot dimensions by $\varepsilon_{x,y}$ [mm-mrad] ≈ $\sigma_{x,y}$ [mm], and initial kinetic energy of ~0.5 eV [11, 12]. For a Gaussian radial profile truncated at $0.8\sigma_r$, the rms dimensions are given by $\sigma_{x,y} = 0.4\sigma_r$.

FIXED BUNCH RADIUS

We first considered the initial bunch radius that gives the lowest output emittance for the design gradient of 41 MV/m. For a truncated Gaussian radial profile truncated at $0.8\sigma_r$, this initial radius σ_r is 1.75 mm [5]. The rms

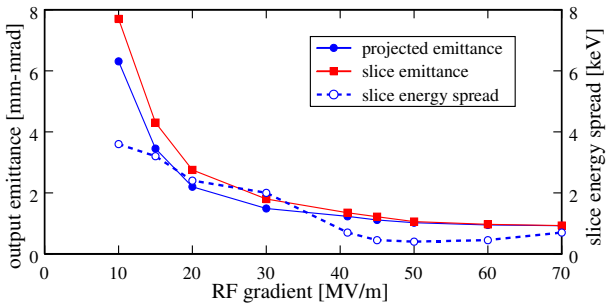

Figure 2: Bunch properties versus peak RF gradient, for a truncated Gaussian bunch distribution emitted from a Cu or Cs_2Te photocathode, with initial radial σ_r of 1.75 mm, initial longitudinal σ of 187.5 fs, and initial emittance of 0.7 mm-mrad. The focusing strength of the solenoid was optimized for each value of the RF gradient, in order to minimize the projected emittance. The normalized projected and slice emittances, and the slice energy spread, are evaluated at the exit of the TESLA module where the beam energy is 85 MeV.

bunch dimensions are $\sigma_{x,y}$ = 0.7 mm, so for a Cu or Cs_2Te photocathode, we assume that the initial normalized slice emittances are $\varepsilon_{x,y}$ = 0.7 mm-mrad. For the design gradient, the lowest projected emittance at the exit of the TESLA module is obtained when the longitudinal integral of the square of the solenoidal magnetic field, $\int B^2 dz$, equals 31.1 kG^2-cm. For this case, the normalized projected and slice emittances are 1.3 mm-mrad, the slice energy spread is 0.7 keV, and the peak current is 35 A.

For each value of the peak RF gradient that we studied, the solenoid field strength was optimized to obtain the lowest projected emittance at the exit of the TESLA module. Figure 2 shows the projected emittance of the bunch, and the slice emittance and slice energy spread in the longitudinal center of the bunch. To evaluate the slice properties, 200 slices—each containing 500 particles—were considered. Since the slice emittance is largest near the bunch center, it is possible for the projected emittance to be smaller than the slice emittance of the center slice. While the output emittances decrease with increasing RF gradient, the slice energy spread reaches a minimum value of 0.4 keV when the RF gradient is 50 MV/m.

OPTIMIZED BUNCH RADIUS

When the RF gradient is lower than the design value of 41 MV/m, the space-charge-induced emittance growth is increased for a given bunch radius. Consequently, the initial bunch radius that produces the smallest output emittance depends upon the RF gradient. We performed simulations in which the initial bunch radius and solenoid field strength were both optimized to obtain the smallest projected emittance for each value of the RF gradient, for a Cu or Cs_2Te photocathode with initial $\varepsilon_{x,y}$ [mm-mrad] = $\sigma_{x,y}$ [mm]. The results in Fig. 3(a) show that optimizing the initial bunch radius significantly improves the performance for RF gradients lower than the design value. The output emittances decrease with increasing RF

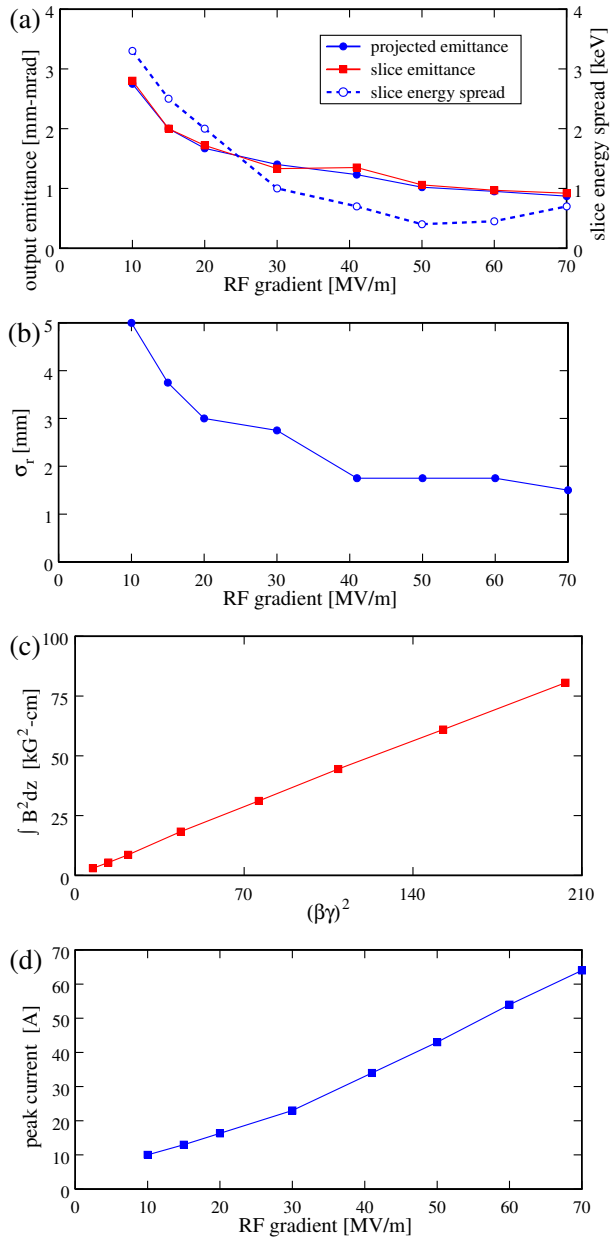

Figure 3: Bunch properties vs. peak RF gradient. The initial bunch radius and the solenoidal field are optimized for each value of the gradient to minimize the projected emittance for a Cu or Cs_2Te photocathode. (a) The normalized projected and slice emittances and slice energy spread at the exit of the TESLA module. (b) The optimal value of σ_r vs. RF gradient, for a Gaussian radial distribution truncated at $0.8\sigma_r$. (c) The integral of the square of the optimized solenoidal field, $\int B_z^2 dz$, vs. the bunch's $(\beta\gamma)^2$ in the solenoid. (d) Peak current at the exit of the TESLA module.

gradient, while the energy spread is minimized at 0.4 keV for a peak gradient of ~50 MV/m.

Figure 3(b) shows the optimal value of σ_r as a function of the RF gradient. For lower RF gradients, it is advantageous to have a larger initial radius, even though the initial emittance from the photocathode is increased.

Copyright © 2013 CC-BY-3.0 and by the respective authors

For the RF gradients studied, Fig. 3(c) shows that the longitudinal integral of the square of the solenoidal magnetic field, $\int B^2 dz$, is proportional to the bunch's $(\beta\gamma)^2$ in the solenoid, where β is the electron velocity divided by the speed of light, and γ is the relativistic factor. This indicates that the optimized focal length of the solenoid is independent of the RF gradient.

Neglecting space charge effects, the focal length of the solenoid, f, in the thin-lens approximation, obeys [13]

$$\frac{1}{f} = \left(\frac{e^2}{4m^2c^2} \right) \frac{\int B^2 dz}{(\beta\gamma)^2} , \quad (1)$$

where e is the electron charge, m is the electron mass, and c is the speed of light.

For the optimal solenoidal field strength, the calculated focal length is 0.29 m for all values of the RF gradient. The image of the cathode is located near to the entrance of the second RF cavity in the 8-cavity TESLA module, whose first RF cavity has phase and gradient adjusted for use as a buncher. The location of the cathode's image is consistent with the emittance compensation process, in which a beam waist is formed near to the entrance of the first RF cavity that is used for acceleration of the beam [1, 7].

Figure 3(d) shows the bunch's peak current at the exit of the TESLA module. The peak current increases with RF gradient because of decreasing longitudinal expansion due to space charge.

For simulations in which the initial bunch has a truncated Gaussian profile, a gradient of 15 MV/m is sufficient to produce a high-quality bunch with normalized transverse emittance of 2 mm-mrad, slice energy spread of 2.5 keV, and peak current of 13 A. For the design value of the gradient, 41 MV/m, a bunch is produced with normalized transverse emittance of 1.3 mm-mrad, slice energy spread of 0.7 keV, and peak current of 35 A. With a slightly larger gradient of 50 MV/m, the slice energy spread decreases to 0.4 keV, while the normalized emittance is 1 mm-mrad and the peak current is 43 A. For gradients exceeding 55 MV/m, the peak current exceeds 50 A.

SUMMARY

For the Wisconsin SRF electron gun, simulations have been performed to study the dependence of the output bunch properties upon the peak RF gradient on the cathode of the 200-MHz cavity. To model realistic bunches from laser illumination of a photocathode, we simulated bunches whose initial radial and longitudinal profiles are truncated Gaussian distributions, truncated at 0.8σ. To minimize the output emittance, we optimized the initial bunch radius and field strength of the emittance-compensation solenoid for each value of the RF gradient. For gradients of 10–70 MV/m, the output emittance decreases and the peak current increases with increasing gradient, while the slice energy spread is minimized at 0.4 keV for a gradient of 50 MV/m. For gradients exceeding 50 MV/m, the normalized output emittance is smaller than 1 mm-mrad, and for gradients exceeding 55 MV/m, the peak current exceeds 50 A.

For gradients exceeding 15 MV/m, the 200-pC bunches have normalized slice and projected emittances smaller than 2 mm-mrad, slice energy spreads smaller than 2.5 keV, and peak currents exceeding 13 A. These bunches are suitable for a soft xray FEL.

STUDY ON 2 CELL RF-DEFLECTOR CAVITY FOR ULTRA-SHORT ELECTRON BUNCH MEASUREMENT*

T. Takahashi†, Y. Nishimura, M. Nishiyama, K. Sakaue, M. Washio
Waseda University, Tokyo, Japan

T. Takatomi, J. Urakawa, KEK, Ibaraki, Japan

Abstract

We have been studying on an rf-deflector system to measure ultra-short electron beam bunch length at Waseda University. By using HFSS, we optimized the design of the 2 cell rf-deflector which is operating on π-mode, standing wave, dipole (TM_{110}-like) mode at 2856 MHz. We have finished manufacturing under the collaboration with High Energy Accelerator Research Organization (KEK) and installing the rf-deflector in the accelerator system of Waseda University. It is estimated that this rf-deflector has sufficient performance for measuring the ultra-short electron bunch. Now the experiment has just begun and confirmed electron beam is swept by this rf-deflector. Bunch length measurement will be soon carried out accurately. In this paper, the design of rf-deflector, the estimation for rf-deflector performance, the present progress and the future plan will be described.

INTRODUCTION

At Waseda University, a compact linear accelerator system based on photo-cathode rf electron gun is applied for the various researches and we have two kinds of rf electron guns as beam sources, 1.6 cell S-band Cs-Te photo-cathode rf gun (1.6 cell gun) for the pulse radiolysis [1] and the laser Compton scattering [2], Energy chirping cell attached rf gun (ECC gun) for the generation of coherent THz radiation [3]. It is necessary to measure time structure of electron beam on several picoseconds region on 1.6 cell gun and bunch length of several hundreds femtoseconds on ECC gun in the future. Therefore, we have been developing an rf-deflector system in order to achieve the bunch length measurement with high temporal resolution.

PRINCIPLE OF BUNCH LENGTH MEASUREMENT BY RF-DEFLECTOR

When rf electromagnetic wave is supplied into an rf-deflector, a proper resonant mode is excited. The resonant electromagnetic field in the beam line produces force on the beam. The magnitude of the force which influences on each part of the electron bunch is different in association with temporal change. When this force has vertical direction to the beam line, the beam after the passage of an rf-deflector is tilted as it drifts. This means the longitudinal distribution of the beam is converted to the transverse. The bunch length can be calculated by observing the transverse distribution. The outline of bunch length measurement by an rf-deflector is below (Fig.1).

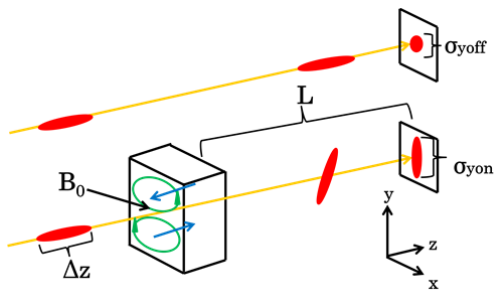

Figure 1: Outline of bunch length measurement.

In Waseda University, we have designed the rf-deflector which produces only Lorentz force to the beam by a magnetic field, using a TM110-like mode. By solving the equation of motion to electron, bunch length Δz is expressed by (assuming the Gaussian profile):

$$\Delta z = \frac{E\sqrt{{\sigma_{yon}}^2 - {\sigma_{yoff}}^2}}{2cB_0L\{\cos(\omega t_0 + \phi) - \cos\phi\}} \qquad (1)$$

where σ_{yon} and σ_{yoff} are the vertical beam size at the profile monitor when the rf-deflector is on and off, respectively, B_0 the peak magnetic field in the rf-deflector, L drift distance between the outlet of the rf-deflector and the profile monitor, φ the rf phase when the bunch enters the rf-deflector, ω the angular frequency of the rf-deflector, E the beam energy, t_0 the traveling time of the bunch in the rf-deflector, c the velocity of light. Then the number of 2 in the denominator represents the 2 cell structure of the rf-deflector. When σ_{yon} is measured, it is supposed that the time resolution becomes higher if the space covered by σ_{yoff} is smaller. So it is important to get large σ_{yon} and small σ_{yoff}. According to Eq. (1), the large magnitude of B_0 or L brings about the progress of time resolution, and ultra-short bunch length measurement could be possible. Because L has the limitation considering the size of the accelerator facility, we have designed the form of the rf-deflector with the larger

magnitude of B_0 and adopted the rectangular-based 2 cell rf-deflector as a result.

DESIGN AND MANUFACTURING OF RF-DEFLECTOR

We have used HFSS simulating 3D full-wave electromagnetic fields for the design of the rf-deflector [4]. An rf-deflector is a kind of cavity, and proper resonant modes related to the form of a cavity are conducted by solving Maxwell equation. We have determined the cavity parameters to make TM110-like mode on 2856 MHz. The largest magnitude of B_0 has been obtained, adjusting the sizes of x and y directions.

We have improved the structure from 1 cell to 2 cell for the further progress of temporal resolution. The π-mode operation of 2 cell cavity provides larger tilt for electron bunch. The structure of the 2 cell rf-deflector is shown in Fig. 2. The magnetic field in 2 cell rf-deflector (Fig. 3) and the coupling with the waveguide have been optimized on HFSS.

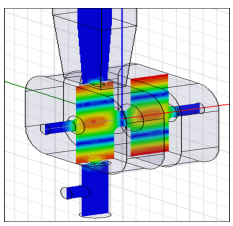

Figure 2: Structure of 2 cell rf-deflector (HFSS).

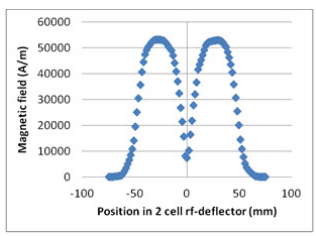

Figure 3: Magnetic field in 2 cell rf-deflector with 750 kW supply (HFSS).

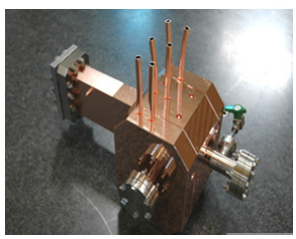

Figure 4: Structure of 2 cell rf-deflector.

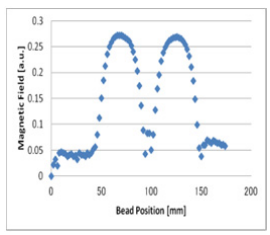

Figure 5: Magnetic field in 2 cell rf-deflector.

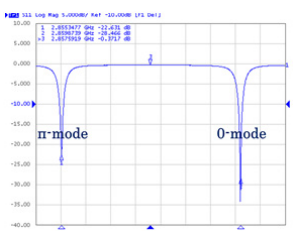

Figure 6: Reflecting method result.

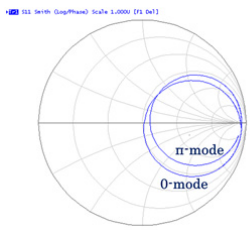

Figure 7: Smith chart.

On the basis of this design by HFSS we have manufactured the 2 cell rf-deflector under the collaboration with High Energy Accelerator Research Organization (KEK). The cavity was processed the fabrication-coordination of rf frequency iteration 4 times. After achieving the desired frequency, the each part was brazed. The finished 2 cell rf-deflector is shown in Fig. 4. Some tuners and water pipes are attached to each cell.

For the purpose of the installation in the accelerator system at Wasede University, we have tuned the rf-deflector by the tuners and temperature of the rf-deflector. The results after the tuning are shown in Fig. 5, Fig. 6, and Fig. 7. Figure 5 shows that the magnetic field strength in each cell is almost the same by the beads method. Figures 6 and 7 show the results of measurement by reflecting method and the smith chart on network analyzer. These indicate the coupling with the waveguide is suitable. The comparison of the cavity parameters after tuning and the desired value is shown on Table 1. The desired value has been set under air condition. The fabrication and tuning of the rf-deflector have successfully processed, as shown in Table 1.

Table 1: Target Parameters of RF-deflector Design

Parameters	Result	Desired value
π mode	2855.348MHz	2855.372MHz
0 mode	2859.874MHz	2859.922MHz
Δf	4.526MHz	4.55MHz(HFSS)
Q value on π mode	16298	17282(HFSS)
Ratio of magnetic field	1:0.9875	1:1
Coupling constant β	0.839	1.000

SETUP AND EXPERIMENT

After establishing the rf-deflector, we have installed in the accelerator system. The outline of the setup is shown in Fig.8 and the accelerator system after installation shown in Fig. 9. We can measure the beam energy by the bending magnet and the charge by the FCT in the downstream of the rf-deflector. Because of our systematic condition, we have installed the rf-deflector falling sideways. This means the beam is tilted in x direction, so we think of the beam size in x direction as σ_{yon} and σ_{yoff}. The rf-power for the rf-deflector is variable in the range of 0~750kW through the attenuator.

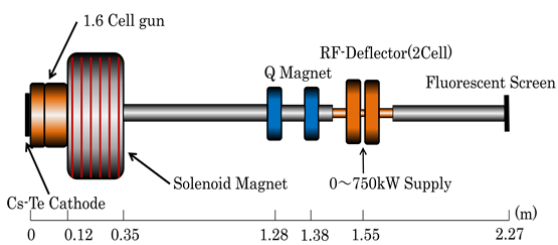

Figure 8: Setup of rf-deflector system.

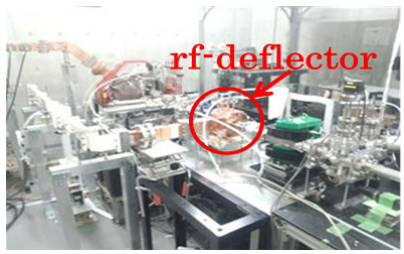
Copyright © 2013 CC-BY-3.0 and by the respective authors



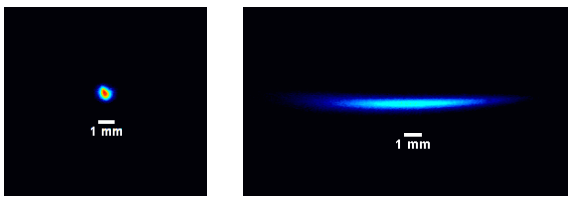


Figure 9: RF-deflector system.

Now the experiment has just begun. First of all, we had to confirm the rf-deflector is operating properly. We have observed the focused beam on the screen with the rf-deflector off to optimize the currents in the solenoid magnet and Q magnets. The deflected beam has been observed at the zero-crossing phase with the rf-deflector when 175kW rf-power was supplied. These profiles are shown in Fig. 10. The peak position of the beam doesn't move compared with Fig 10 (A) at the zero-crossing phase. The beam parameters were about 4.8MeV and 3pC. In Fig. 10, σ_{yoff} is about 220μm and σ_{yon} is about 3.26mm. This result indicates that the rf-deflector is operating properly.

(A) (B)

Figure 10: Observed beam profiles. (A): deflector is off, (B): deflected bunch at the zero-crossing phase.

Because B_0 is 320G with 175kW supply on HFSS simulation, the bunch length can be estimated to be 2.07ps from Eq. (1). The temporal resolution of the rf-deflector means the limitation of measurable bunch length and is derived as the bunch length in the case that σ_{yon} equals σ_{yoff}. Therefore, the temporal resolution is approximately 140fs from σ_{yoff}, σ_{yon}, and the bunch length.

The B_0 that we discussed above is not correct value. The actual B_0 in the rf-deflector is now under calibration, otherwise the accurate bunch length and temporal resolution can not be calculated. The B_0 calibration is accomplished by fitting the displacement about the peak of the beam, Δy, to the rf-deflector phase, φ_0. The displacement Δy is expressed by:

$$\Delta y = \frac{c^2 B_0 L}{E\omega}\{\sin(\omega t_0 + \phi_0) - \sin\phi_0\} \qquad (2)$$

These parameters are the same as described in Eq. (1). Since the actual B_0 is probably smaller than the value on HFSS due to the loss of the rf-power, the accurate bunch length and temporal resolution will come to be larger. However, the simulation result may not have much difference, thus we can estimate that this rf-deflector system has a capability of measuring ultra-short bunch. Concerning the short bunch beam, which has the several picoseconds length, the temporal structure of the electron bunch can be observed. The precise bunch length measurement will be soon carried out.

CONCLUSIONS AND PROSPECTS

In this paper, we introduced the rf-deflector system for the bunch length measurement with high temporal resolution and described the procedure for 2 cell rf-deflector. We have achieved 2 cell rf-deflector which will be able to measure several hundreds of femtoseconds bunch. Now we have finished installation in our accelerator system and confirmed the rf-deflector operating properly. The precise bunch length measurement and dynamics studies of rf-gun will be soon carried out.

10S FEMTOSECOND BUNCH LENGTH MEASUREMENT BASED ON COHERENT TRANSITION RADIATION*

Xianhai Lu†, Wenhui Huang, Chuanxiang Tang, Tsinghua University, Beijing 100084, P. R. China‡
K.G. Roberts, R.K. Li, P. Musumeci, H.S. To, UCLA, Los Angeles, CA 90095, USA

Abstract

In this paper, we discuss bunch length measurement based on coherent transition radiation for 10s femtosecond electron bunches with of several MeV energy and several pC charge. The ultrashort bunch length is obtained by velocity bunching using a compact dual slot resonantly coupled linac located after an RF photoinjector. Strong focusing with a solenoid is required to enhance the radiation generation. Filters are used to reconstruct coherent transition radiation spectrum. The transverse and longitudinal form factors are also studied with simulation.

INTRODUCTION

Bunch length measurement is a basic issue in beam diagnostic. Traditional methods for bunch length measurements includes using deflecting cavity[1], using radiation based spectrum methods[2] and electro-optic detection methods[3]. By using velocity bunching method, sub picosecond or 10s femtosecond bunch can be generated in several MeV energy and several pC charge regime, for applications such as ultrafast electron diffraction and Thomson scattering. To measure the bunch length at the maximum compression plain, coherent transition radiation (CTR) method is more appropriate than direct methods using deflecting cavity, since the latter measurements are extended in z and can only give an estimate for the average bunch length over the measurement distance. Another advantage of using CTR method for measuring ultrashort bunch is the energy of coherent transition radiation increases significantly as the bunch length decrease, which is favorable to detection.

In this paper, we discuss a bunch length measurement method based on coherent transition radiation, for 10s femtosecond electron bunch length obtained by velocity bunching using a linac. The method and setup are described in the following section. In the end, preliminary experimental results are also presented.

METHOD

For transition radiation generated by electron crossing metal boundary, the process can be viewed as collision process of electron with its image charge. The spectrum and angular distribution of energy generated in the collision can be obtained by calculating the Lienard-Wiechert potential as [4]:

$$\frac{\mathrm{d}E_s}{\mathrm{d}\omega\cdot\mathrm{d}\Omega}=\frac{e^2}{4\pi^2c^3}\left(\frac{\vec{v}\times\vec{n}}{1-\vec{n}\cdot\vec{v}/c}-\frac{\vec{v'}\times\vec{n}}{1-\vec{n}\cdot\vec{v'}/c}\right)^2, \quad (1)$$

where E_s is the radiation energy of single electron,ω is the angular frequency of radiation, Ω is the solid angle, e is the charge of electron, c is the speed of light in vacuum, $\vec{n}$ is the direction of radiation, $\vec{v}$ and $\vec{v'}$ are the velocities of electron and its image charge. It is noted that the angular distribution does not depend on frequency. For a 45 degree collision, the velocity $\vec{v}$ and $\vec{v'}$ are determined by the setup, then we can calculate the energy distribution by integrating over the solid angle collected by an off axis parabolic (OAP).

The total radiation energy of a bunch E_b is the sum of single electrons, taking consideration of phase effect into account. The expression can be written as:

$$\frac{\mathrm{d}E_b}{\mathrm{d}\omega\cdot\mathrm{d}\Omega}=|N\cdot f(\omega)|^2E_s(\omega) \quad (2)$$

$$=\frac{e^2|N\cdot f(\omega)|^2}{4\pi^2c^3}\left(\frac{\vec{v}\times\vec{n}}{1-\vec{n}\cdot\vec{v}/c}-\frac{\vec{v'}\times\vec{n}}{1-\vec{n}\cdot\vec{v'}/c}\right)^2, \quad (3)$$

where $f(\omega)$ is the coherent factor. When the longitudinal size of bunch is much longer than the transverse size and the radiation are concentrated in small angle around beam axis, transverse coherent effect can be neglect and the coherent factor can be written as:

$$f(\omega)=f_L(\omega)=\frac{1}{N}\sum_{j=1}^{N}e^{i\omega t_j}\cong\int_{-\infty}^{+\infty}\rho(t)e^{i\omega t}\mathrm{d}t, \quad (4)$$

where $\rho(t)$ is the normalized distribution function. For wavelength longer than bunch length, the field created by electrons are coherent and the total energy is proportional to the square of number of electrons. In the case of low energy bunch and comparable transverse bunch size and longitudinal size multiplied by γ ($\sigma_x \backsimeq \gamma\sigma_z$), the effect of transverse size of bunch should not be neglected. For a numerical example, the wavelength of CTR corresponding to 40 fs bunch ranges around 12 μm, assuming the transverse spot size is 100 μm, when viewed at the angle larger than 7 degree from the axis, the maximum phase difference of radiation emitting from different transverse position can be larger than one period. Then the coherent factor should be written as:

$$f(\omega)=f_L(\omega)f_T(\omega), \quad (5)$$

with the transverse coherent factor as:

$$f_T(\omega) \cong \int_{-\infty}^{+\infty} \tilde{\rho}(r) e^{i\omega(\vec{r}\cdot\vec{n}/c)} \mathrm{d}t, \qquad (6)$$

where $\vec{r}$ and $\tilde{\rho}(r)$ are the transverse position and transverse normalized distribution function respectively. To consider the exact coherent effect, we calculate both the longitudinal and transverse coherent factor at given wavelength and angle, for different spot size and different bunch length (assuming Gaussian profiles). Then we integrate the total energy over the solid angle (within 30 degrees from beam axis) and 10 % frequency (FWHM) using numerical method. The result of integration is displayed in Fig. 1.

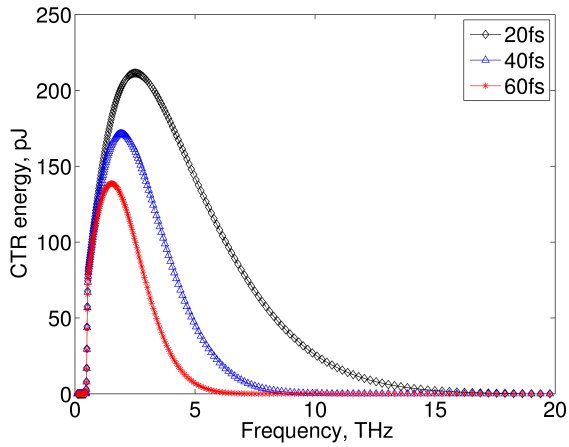

Figure 1: CTR spectrum for rms bunch length of 20 fs, 40 fs, 60fs of energy of 5 MeV, charge of 3 pC and rms spot size of 50 μm.

Figure 1 shows the CTR energy at 3∼5 THz is sensitive to the length of bunch, while the energy at low frequency (1 THz) is relatively insensitive. This characteristic implies we can use the ratio of high frequency CTR energy over low frequency one as a measurement of bunch length.

SETUP

Ultrashort Bunch Generation

The schematic of beam line is shown in Fig. 2. The first solenoid (soleA) right after RF gun is used to match the beam into a standing wave linac, which is operated at compressing phase. After the linac, the bunch drifts and compresses at the CTR target about 1.6 m downstream. The phase of linac determines the compressed point, which should be set coincident with the plain of CTR target. A second solenoid(soleB) is placed about 0.4 m upstream the CTR target to focus the beam to a minimal spot size on CTR target to enhance the transverse coherent effect. The CTR target is a 1/10 wavelength gold mirror of 1cm × 1cm, which can be treated as an infinity perfect boundary for electron of several MeV energy. The distance of CTR target from the cathode of RF gun is 3.78 m.

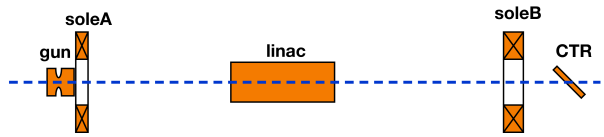

Figure 2: Schematic of beam line.

The energy and energy spread of the linac is calculated with GPT[5], shown in Fig.3. It shows the bunch is compressed to the minimal length at linac phase about 77 degree off crest. The minimal rms bunch length that can be achieved is as low as 21 fs. At the same time the second solenoid can be tuned to achieve spot size of rms 30 μm. It should be noted that there is a tradeoff between the smallest spot size and shortest bunch length, since it is easier to compress or focus in one dimension with a low charge density of the other dimension.

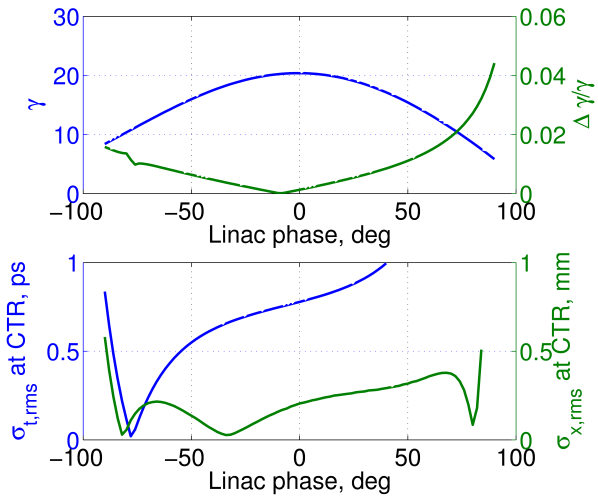

Figure 3: Energy, energy spread, spot size and bunch length with respect to linac phase.

CTR Collection and Spot Size Measurement

The whole setup of CTR collection is placed in a vacuum chamber. A moveable stage can insert the CTR target or a YAG screen onto the beamline. The thickness of YAG is 30 μm with spatial resolution smaller than 5 μm [6]. The measurement of spot size is important for deriving the bunch length. A 90 degree, 1 inch diameter OAP with parent focal length of 1 inch is well aligned and mounted near the CTR target. Two 1.5 inch diameter THz mirrors are used to guide the parallel radiation to a 3 inch diameter OAP with parent focal length of 6 inches. The focused radiation after second OAP passes through a 3 mm thick TPX window[7] on the wall of vacuum chamber and collected by a pyroelectric detector. Filters of different wavelength can be inserted before the detector.

RESULT AND DISCUSSION

In the first round experiment, the energy of signal is sufficient to be detected with a pyroelectric detector with sensitivity of 0.3 mV/nJ. A solenoid scanning is performed and the total CTR energy is measured under 20 pC charge. The result is shown in Fig. 4.

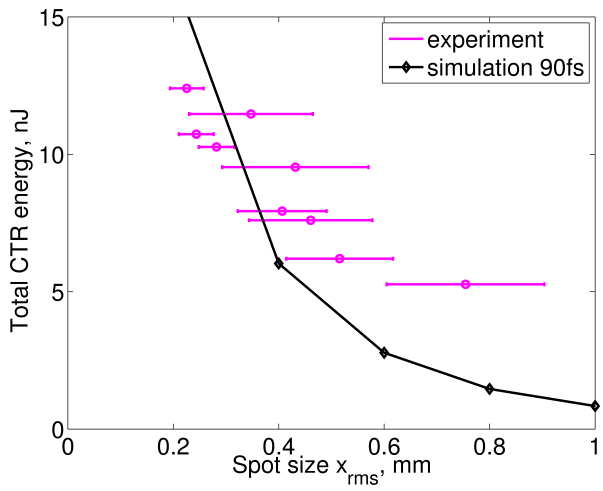

Figure 4: Total CTR energy detected with respect to rms spot size at CTR target under 20 pC charge.

Figure 4 show the total energy decreases as spot size increase, which is in consistent with the degraded transverse coherence of the bunch. However, since this total energy is not sensitive to bunch length, we can estimate a longitudinal bunch size larger than 10s fs order. With lower charge of 5 pC, linac phase scanning is also performed to study the effect of velocity compressing, shown in Fig. 5. Figure 5 shows the compressing point is important to generate CTR.

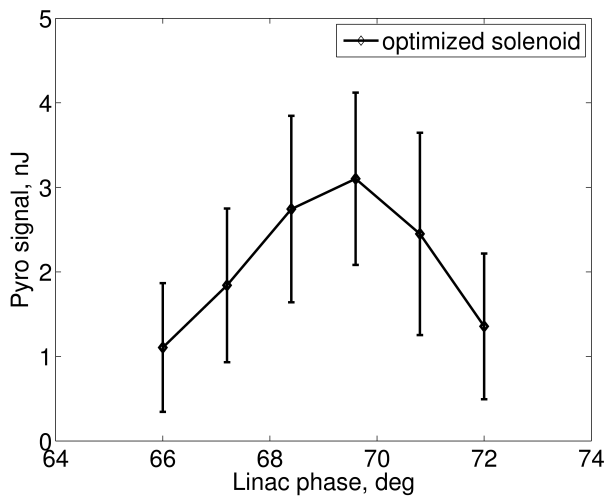

Figure 5: Total CTR energy detected with respect to phase of linac.

Large error bars in both Fig. 4 and Fig. 5 show instability of spot size and CTR energy. This is caused by the jitter of RF system, especially the jitter of gun phase, resulting in the mismatch of compressing point and CTR target. Another challenge is that the calibration of the transmission and detection efficiency for different wavelength. A second round experiment is planned to use more sensitive detectors for lower charge bunch, aiming at measuring the ratio of CTR energy at different frequency and deriving ultrashort bunch length.

CONCLUSION

In this paper, we discuss an CTR based bunch length measurement method for 10s fs bunch of several MeV energy and several pC charge. The CTR energy spectrum is precisely calculated using numerical integration method, considering transverse and longitudinal coherent effect. A relative CTR component ratio measurement is proposed to derive bunch length. Simulation is performed and predicts compressed bunch length of 20 fs (rms), with spot size of 30 μm (rms) at the CTR target. The preliminary experiment shows significant dependence of total CTR energy on spot size and linac phase.

HIGH-CHARGE FEMTOSECOND ELECTRON GENERATIONS FOR ULTRAFAST, HIGH-BRIGHTNESS ELECTRON BEAM APPLICATIONS*

Jangho Park#, Hans Bluem, John Rathke, Tom Schultheiss, and Alan M. M. Todd
Advanced Energy Systems, Inc., Medford, New York 11763, USA

Abstract

Generation and preservation of ultrafast, high-brightness electron beams is one of the major challenges in accelerator research and development (R&D) for beam applications such as free electron lasers (FEL) and ultrafast electron diffraction (UED). Transverse and longitudinal space charge forces play a key role in emittance dilution and bunch lengthening respectively, for all high-brightness beams. We present a newly-designed, X-band, photocathode, radio frequency (RF), electron gun that utilizes radial bunch compression to deliver a compact ultrafast, high-brightness source. By compensating for the path length difference in an extremely-high-acceleration-gradient cavity with a curved cathode, we numerically demonstrate the potential for achieving more than an order of magnitude increase in beam brightness over existing electron guns. The thermo-mechanical analysis and conceptual design that demonstrate the viability and reliability of the concept are also presented.

INTRODUCTION

Ultrafast high-brightness electron beams are desired as injectors for light sources, including FELs, energy recovery linacs (ERL) and medical devices, amongst other applications. Brightness is the holy grail of most light sources and brighter, short-pulse electron injectors are to be prized where there are no downstream transport consequences of the short bunches. An example is micro bunching instabilities that can result from transport interactions with the energy modulations induced by the longitudinal space charge (LSC) forces in the bunches. These sources may also find direct application in advanced accelerators like the plasma wake-field accelerator (PWFA) and ultrafast electron diffraction (UED) [1]. Plasma accelerators promise orders-of magnitude increases in accelerating gradient to greater than 100 GeV/m and could lead to very compact and economical systems for those many accelerator applications that require high particle energies. Ultrafast diffraction techniques, which provide information about atomic-scale molecular structure, are critical to chemists and material scientist in their research and development activities.

In the generation of ultrafast, high-brightness electron beams, space-charge forces play a fundamental role in emittance dilution and bunch lengthening within the gun and subsequent emittance compensation drift. In order to generate and preserve the beam brightness, transverse and longitudinal space charge effects have to be precisely managed. Several different approaches have been reported and are being actively pursued within the worldwide accelerator community. These include various velocity bunching and magnetic compression techniques. However, each option suffers drawbacks that must be overcome in order to deliver a compact and economic ultrafast, high-brightness source.

In order to develop an improved ultrafast high-brightness electron source, we have proposed a scheme that compensates for path length differences by using a curved cathode [2]. This introduces radial compression that compensates for geometric bunch lengthening effects when coupled with extremely-high-acceleration-gradient to minimize the impact of space-charge forces. The AES-patented rear-fed coaxial cathode coupling eliminates contributions to transverse emittance from non-axisymmetric modes [3]. We show that combining these effects is feasible and does indeed deliver a more compact, economic, ultrafast high-brightness electron beam for the identified applications.

CAVITY AND COUPLING DESIGN

For a high-aspect-ratio (short bunch length) electron bunch, the asymptotic bunch length due to the space charge forces of a uniformly accelerated bunch is expressed by:

$$\Delta t_{sc}(\infty) = \frac{mc^2}{e}\frac{Q}{\pi R^2 \varepsilon_0 c E^2}. \qquad (1)$$

This ignores the drive laser duration and assumes prompt response from a copper cathode with a constant laser spot radius (R). Here, bunch lengthening due to space charge is inversely proportion to the square of the bunch radius (R) and the square of the accelerating field (E). The bunch lengthens due to the longer trajectories of the outer particles, compared to electrons emitted closer to the axis, and is proportional to the square of the beam radius.

Our previous upstream, coaxial, waveguide-fed gun cavity design had the drawback that the radial space for electron beam emission and drive laser insertion was relatively small [4]. We have now completed the RF analysis for a coaxial RF feed from the rear of the gun. Standard codes like the SLAC-developed S3P code [5] and SUPERFISH have been used to complete the RF design used in the reported beam dynamics analysis. Following Ref. [3], we focused on the geometry of the coaxial coupler and the iris between the cells, in order to maximize shunt impedance and thus minimize losses for a given cathode voltage. The coaxial coupler and the iris

changes required adjustment of the thermal stress analysis and the location of the cooling channels. The RF design in the cathode area also affects the beam dynamics design. To allow for flexibility in cathode materials, the cathode has been designed as a detachable and adjustable structure. A completely axisymmetric gun delivers improved emittance and permits optimal placement of the emittance compensating solenoid.

The physics design of an X-band RF gun cavity with a curved cathode and a coaxial RF coupling scheme, embedded in an emittance compensating magnetic field has been optimized. Various curved and flat cathode geometric models have been studied using the SUPERFISH. We varied the radius of curvature to optimize the beam dynamics output. The resultant SUPERFISH output field files were translated into input files for the [6] beam dynamics code. Figure 1 shows a cavity cross-section with field lines from SUPERFISH. The radius of the coaxial coupler has been chosen to prevent the transmission of the lowest high-order TE01 mode through the coaxial waveguide.

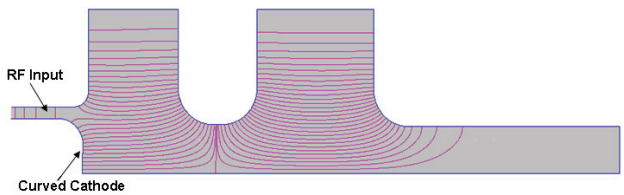

Figure 1: SUPERFISH model of the 1.6 cell, X-band, π-mode, RF gun cavity with rear-fed coaxial coupling.

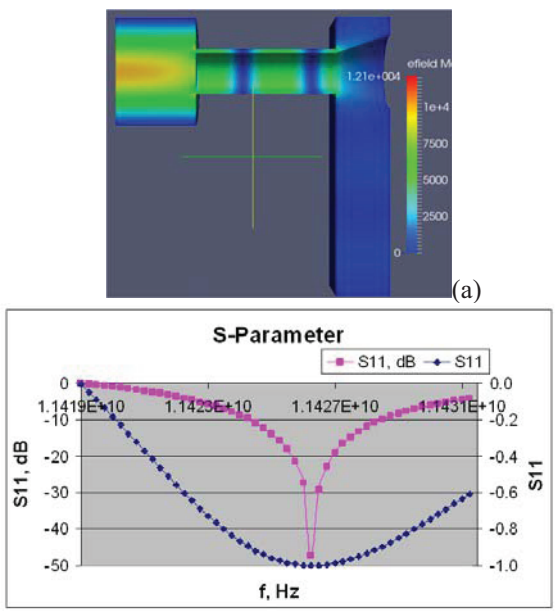

Figure 2: (a) Coupling structure electric fields in the rectangular to coaxial waveguide transition, and (b) the normalized S11 parameter for the coupling structure.

The waveguide to coaxial cavity coupling transition has been designed using by SLAC developed S3P code [5]. Figure 2(a) shows that WR-90 rectangular to coaxial waveguide transition. The coaxial waveguide and the cavity resonate as TEM and TM modes, respectively. Figure 2(b) shows the normalized S-parameter - the transmission/reflection coefficient for the coupling structure. The cavity resonant frequency is 11.426 GHz for the geometry shown.

BEAM DYNAMICS CACULATION

The beam dynamics analysis addressed several aspects of the gun design. Firstly, we anticipated that the higher accelerating field in the X-band cavity would reduce the longitudinal and transverse emittance growth produced by space charge forces, thereby delivering our goal of an ultrafast, high-brightness, electron bunch. Secondly, by utilizing a curved cathode, we expected that the focusing field near the cathode surface would lead to improved integrated transverse beam focusing and improved beam brightness. Finally, we predicted that the curved cathode would compensate for the bunch lengthening induced by path length variation across the cathode, due to the combined effect of the focusing elements and the RF in the cavity.

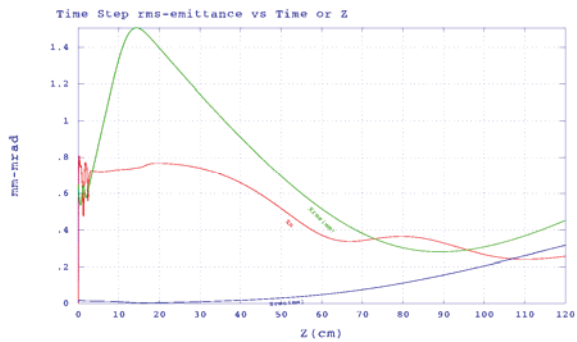

Figure 3: Evolution of the bunch length (blue), beam size (green) and emittance (red) along the beam axis.

Various simulations were performed using TStep [6], an evolved version of PARMELA, to investigate the effect of the bunch charge on the bunch length and beam brightness. Figure 3 shows the evolution of the bunch length, beam size and emittance along the beam axis. At the interaction point 45 cm from the cathode, we deliver a 2.5 MeV, 20 pC bunch with a transverse rms emittance of 0.81 π mm-mrad. The 82 fsec FWHM bunch has a transverse rms beam spot of 0.71 mm with an energy spread of 0.6 %. These results are very similar to those achieved with the upstream-fed coaxial RF design [4].

THERMAL DESIGN

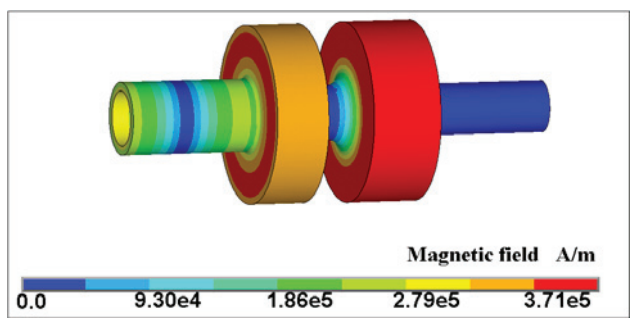

Figure 4: Magnetic field values during an RF pulse.

Copyright © 2013 CC-BY-3.0 and by the respective authors

SUPERFISH normalizes electric fields to a maximum of 1 MV/m. Our design maximum electric field is 250 MV/m in the gun. The wall losses thus scale from the indicated 467 watts to 4.23 MW, thus requiring pulsed RF power. Figure 4 shows the RF surface magnetic fields. The proposed RF pulse duration is 200 nsec and the repetition rate is 200 Hz, resulting in a duty factor of 4.0 x 10^{-5}. This low duty factor enables the adoption of a simplified cooling scheme for the design.

The magnetic fields in the waveguide and coaxial feed were determined from the geometry and the operating point power. The magnetic fields along with wall and the resistance were used to determine the local power loss on the walls, where the power loss is iterated to reflect the temperature dependent resistance of the walls. Figure 5 shows the resistive wall power densities.

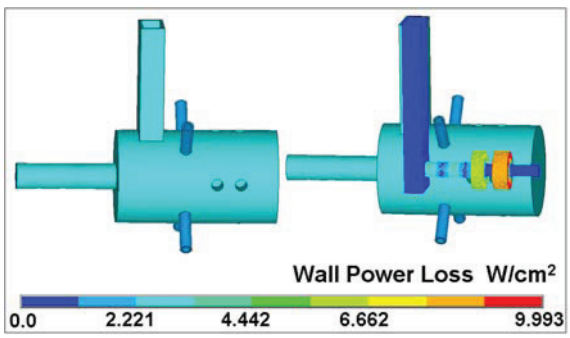

Figure 5: Average power loss on the cavity walls with a duty factor of 4.0 x 10^{-5}.

A cooling water flow rate of 2.3 gpm through the eight cooling channels is used to keep the temperatures within the acceptable range. Figure 6 shows the temperature distribution within the gun and on the cooling channel surfaces. The iris between the two cells is not cooled directly, but is cooled with thermal conduction through the copper walls. The temperature rise between the inlet cooling water and the maximum copper surface temperature is only 6.3ºC.

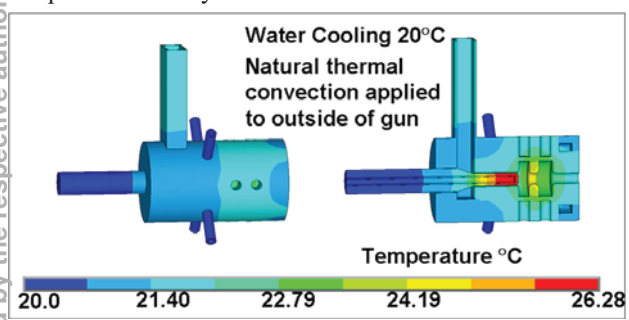

Figure 6: Temperature distribution in the gun body. The supplied water cooling temperature is 20ºC. Natural thermal convection is applied outside of the gun.

The displacements derived from the temperature variation were then applied to the RF model. The RF model was then rerun to determine a frequency comparison with the original geometry. This showed a shift of -644. kHz. This can easily be compensated by developing the geometry to be at the design frequency for an elevated design temperature. The inlet cooling temperature would then need to be about 3.4ºC below this design temperature to operate at the design frequency.

The waveguide and vacuum barrel were cooled by natural convection and conduction to the gun body. The rectangular waveguide was made of copper and the vacuum barrel and flanges were modelled as stainless steel. The ambient temperature was assumed to be 20ºC and the resulting temperature rising was only 1.2ºC. Thermal conduction in the waveguide was high enough and the field penetration of the perforations small enough, that the temperature rise was not significant. The thermo-structural and RF frequency shift analysis demonstrates that the design of this electron gun running at 4.0 x 10^{-5} duty factor is robust. The temperature rise of the gun body is small, less than 5ºC, the displacements are small, less than 0.8 x 10^{-4} inches, the Von Mises stresses are low, less than 1100 psi, and the frequency shift is manageable. Hence the design and thermal management of this gun have adequate head room for robust operation.

SUMMARY

AES has recently completed the design of an ultrafast, high-brightness, electron source for FEL, ERL and advanced accelerator injectors. The gun is particularly suited to UED analysis. The beam dynamics analysis of such an X-band, ultrafast, RF gun with a curved copper cathode has been demonstrated to deliver an order of magnitude increase in beam brightness over existing S-band electron guns. Thermo-structural analysis and mechanical design shows the achievement of robust operation at a duty factor of 4.0 x 10^{-5}. Proposals have been submitted to perform the experimental validation of the device at the BNL Accelerator Test Facility (ATF).

ACKNOWLEDGMENT

Abstract

A new high-charge RF gun is now operating at the Argonne Wakefield Accelerator (AWA) facility at Argonne National Laboratory (ANL). The 1.5 cell 1.3 GHz gun uses a Cesium telluride photocathode driven with a 248 nm laser to provide short-pulse, high charge electron beams for the new 75 MeV drive beamline. The high-gradient RF gun (peak field on the cathode $>$ 80MV/m) is a key piece of the facility upgrade. The large Cs_2Te photocathode (diameter $>$ 30 mm) is fabricated in-house. The photo-injector generates high-charge, short pulse, single bunches (Q $>$ 100 nC) or bunch-trains (Q$>$1000 nC) for wakefield experiments, typically involving dielectric-loaded accelerating structures. Field-emitted dark current from the Cs_2Te cathode was measured during RF conditioning. Fowler-Nordheim plots of the data are presented and compared to similar measurements made using a copper cathode in the initial phase of conditioning. Results of quantum efficiency (QE) studies are presented with the cathode operating in both single and bunch-train modes.

EMISSION STUDY PLAN AND GOALS

The 1.5 cell, 1.3 GHz, AWA drive-gun is now operating, using high Quantum Efficiency (QE) Cs_2Te photocathodes fabricated in-house [1]. The photocathode requirements are QE greater than 1% with a lifetime of weeks to months while experiencing a very high gradient (80 MV/m) peak RF field on the cathode. The primary function of the gun is to provide high-charge, short-pulse electron beams to drive wakefield structures [2]. As part of the turn-on process, we are conducting field emission and photoemission studies in the gun.

Photocathode Field Emission Study

We measured and characterized field emission from two different photocathodes used during the two phases of RF conditioning. Copper was used for the initial gun conditioning, followed by Cs_2Te thin film on Molybdenum for planned high-charge operation. We hope to use the data to better understand the relative impact of different factors influencing the level of field emission and its possible mitigation.

Photoemission Study

We characterized photoemission from the Cs_2Te photocathode under various conditions. Using 2-10 ps, 248 nm wavelength laser pulses, we are studying photoemission at high gradient to optimize the performance of the photocathode and the gun. At the time of the writing of this paper, QE measurements of the photocathode in the gun have been made over a period of about 6 weeks.

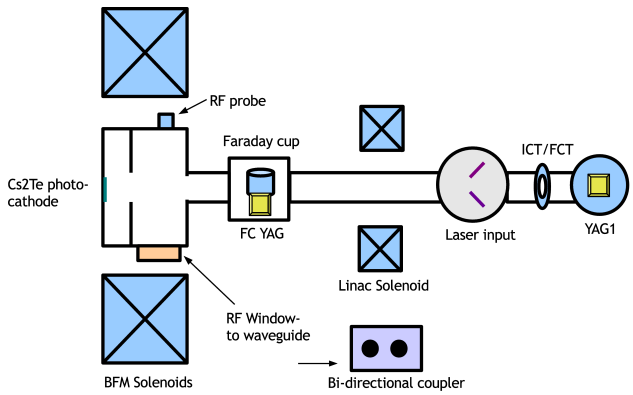

Figure 1: The L-band 1.5 cell photocathode gun with the relative positions of diagnostics to be used (cartoon - not to scale). The RF power input is measured near the RF window using a bi-directional coupler. The dark current is measured with a Faraday cup 58 cm from the cathode. The beam charge is measured using an Integrating Current Transformer (ICT). YAG(Ce) scintillating screens to image the beam and the dark current are available at two locations. In addition, an in-vacuum mirror at the Faraday cup location may be used to observe the photocathode and help to identify emission sites (not to scale).

EXPERIMENTAL SETUP

The beamline with the relative positions of diagnostics used for the experiments is depicted in a schematic shown in Fig. 1. RF power measurements were made using a dual-directional coupler connected in series in the waveguide just before the gun. The dark current was measured using a Faraday cup. The beam charge was measured using a Bergoz combination in-flange Integrating Current Transformer (ICT) and Fast Current Transformer (FCT).

Copyright © 2013 CC-BY-3.0 and by the respective authors

YAG(Ce) scintillator screens were used to image the beam at two locations.

RF CONDITIONING AND FIELD EMISSION

RF conditioning of the gun was begun in 2011 but was interrupted by AWA upgrade expansion construction. To protect the both the gun and the cesium telluride cathode from effects of RF damage, the first round of conditioning took about 160 hours to reach 88 MV/m. The RF pulse length was 8 microseconds and repetition rates varied from 1 to 10 Hz. Next, the first Cs_2Te photocathode was installed and conditioned to 25 MV/m. Both photocathodes were used to produce electron beams, but progress was halted due to upgrade activities. Drive gun operation and the studies discussed herein resumed in summer 2013 and are on-going.

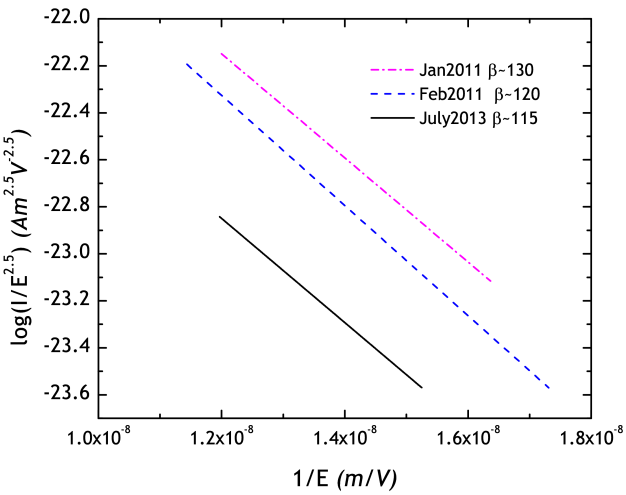

Figure 2: Initial RF conditioning was done with a copper photocathode. Linear fits of Fowler-Nordheim plots for the Cu cathode at several points in the conditioning process. The field enhancement factor (β) calculated from the slope of each fit indicate field enhancement in the gun with the Cu cathode is stable at about 120 after conditioning to 88 MV/m.

During conditioning, dark current data was taken with a Faraday cup located 58 cm from photocathode. The gun fields were measured using a diode at the bi-directional coupler in the waveguide near the RF window. Data from the copper cathode indicates a reasonable level of dark current and a field enhancement factor β=120.

Field emission from the cesium telluride photocathode was also measured with the Faraday cup during conditioning. Field emission from p-type semi-conductors has been shown to behave quite differently from metals and may result in non-linear Fowler-Nordheim plots [4]. As seen in Fig. 3 ,the preliminary results are suggestive of a field dependent, much lower β.

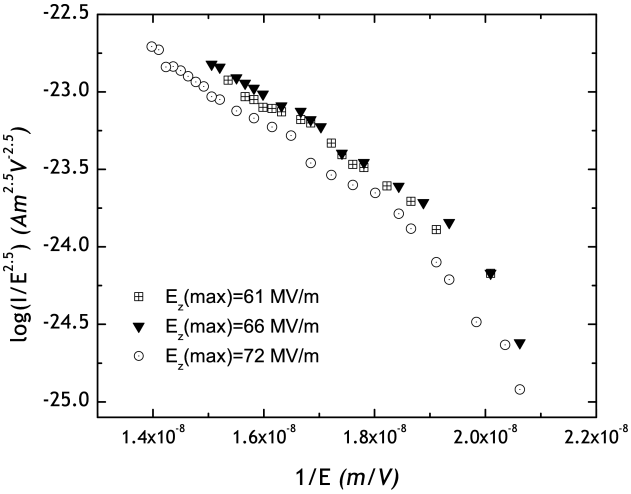

Figure 3: RF conditioning with Cs_2Te, a p-type semi-conductor thin-film photocathode. Three Fowler-Nordheim plots from data taken as conditioning proceeded appear non-linear, suggestive of β with a possible field dependence.

ONGOING PHOTOEMISSION STUDIES: PRELIMINARY RESULTS

Conditioning of the Cesium telluride cathode proceeded with some caution due to the vacuum requirement (low $10^{-}10$ torr). Arcing occurred fairly frequently as the field level was raised. The photocathode shows some small spots (about 0.5 mm in diameter), possibly indicating damage to the thin film from arcing during RF conditioning.

Once the photocathode was conditioned to about 30 MV/m, we began photoemission studies. Photoemission measurements were made using the experimental setup sketched in Figs. 1 and depend on laser power measurements concurrent with beam charge measurements in order to distinguish shot-to-shot variations in the laser or the QE. The diagnostics for the QE phase scan single bunch and bunch-train measurements [5] include the Bergoz in-flange ICT (to measure total charge) with FCT (to resolve individual bunches) described previously as well as a PD10-C OPHIR photodiode sensor with laser energy meter to measure laser power per pulse. We have been collecting data for QE lifetime studies on all the photocathodes we make for several years, but the data presented in this paper is from the first one operated for an extended period of time in the gun at high field. For a comparison, see Fig. 5

We performed QE-RF field dependence measurements by two methods: 1) by varying the peak RF power into the gun and 2) by varying the laser input phase with constant RF power. Plots of average QE values phase scans with 150 pC charge at several different RF field levels are plotted in Fig. 4. The QE remains relatively flat, showing little or no evidence of field enhancement. The laser photon energy at 5 eV is well above the photoemission threshold.

Copyright © 2013 CC-BY-3.0 and by the respective authors

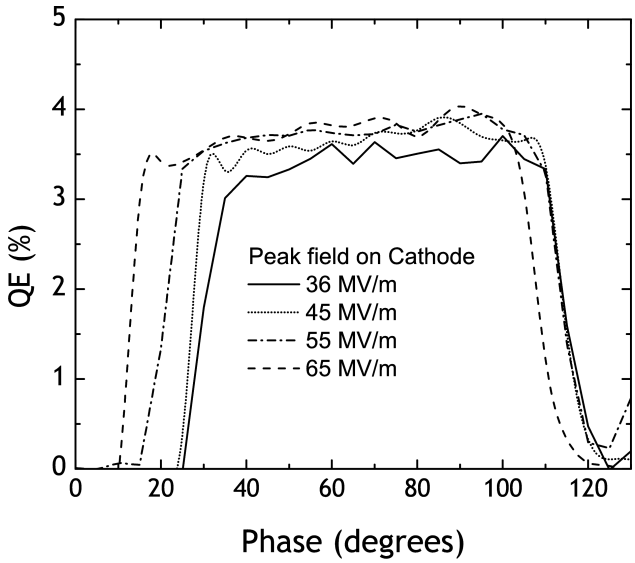

Figure 4: Averaged data from 4 phase scans at 36, 45, 55, and 65 MV/m. The scans are relatively flat showing little or no evidence of field enhancement.

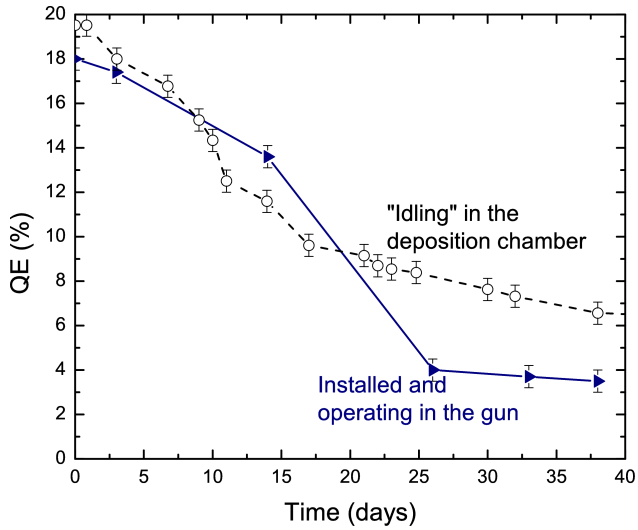

Figure 5: The QE for two photocathodes is plotted vs. time. The photocathode installed in the gun shows a promising QE lifetime, still near 4% in the gun after operating more than a month. Plotted for comparison is the QE lifetime of a photocathode "idling" in the deposition chamber.

Additional Studies and Analysis

The emission studies discussed here are broad in scope and continuing. For these reasons, only some of the highlights and preliminary results are presented. Additional work or data still to be analyzed includes: high charge phase scans, rastering the cathode with the laser to probe the spatial uniformity of QE, mapping the QE variations across the cathode and tracing them back to the deposition process or RF conditioning damage. Such a QE map may be of assistance in understanding variations in QE vs. laser spot size. Also planned are 1000 nC long bunch train QE measurements: generate from 4 to 32 bunches per train with 770 ps separation (1 RF period). The data will be analyzed for possible QE bunch-train position dependence.

SUMMARY

The first Cs_2Te photocathode is operating successfully at AWA in the new drive gun. In an effort to understand the performance limitations of the new gun and photocathode, photocathode emission studies will be conducted during conditioning and initial operation. RF conditioning of the Cesium telluride cathode has proceeded to 72 MV/m while maintaining QE at required levels. QE Phase scans using on-line laser energy and charge measurements indicate that the QE remains high after 1 month. Bunch train measurements have been performed, but the results are still being analyzed. The photocathode still in the gun shows a promising QE lifetime, plateauing near 4% in the gun after more than a month in the gun and over 6.6×10^{-10} RF pulses. Results from these studies will be analyzed and used to optimize the photocathode drive gun operation.

THE CATHODE PREPARATION CHAMBER FOR THE DC HIGH CURRENT HIGH POLARIZATION GUN*

O. Rahman†, I. Ben-Zvi, D. Gassner, A. Pikin, T. Rao, E. Riehn, B. Sheehy, J. Skartika, E. Wang, Q. Wu, BNL, Upton, NY 11973, USA.

Abstract

A compact cathode preparation chamber for the high current high polarization gun for the proposed eRHIC project has been designed and assembled at Brookhaven National Laboratory. This preparation chamber will be used to activate GaAs photocathodes to be used in the Gatling gun. The chamber is capable of achieving XHV on a consistent basis. Bulk GaAs samples were activated in this chamber with standard QE for the respective wavelength. In this paper, we discuss the design of this vacuum system, the heat cleaning and the activation procedure for the GaAs sample which will eventually be followed for the Gatling gun.

INTRODUCTION

The High Current High Polarization Electron Gun is one of the most important research projects for the proposed eRHIC project [1]. The average current is required to be 50 mA and the polarization requirement is more than 80%.For weekly exchange of cathodes, given that two guns are used, one cathode has to provide 50 mA of average current for 85 hours, which yields to 15300 C of charge. The maximum reported charge extracted is 1000 C, which is a order of magnitude lower than the requirement [2]. To solve this problem, 50 mA of current can be distributed over 20 photocathodes such that each cathode has to provide 2.5 mA of current for 85 hours, yielding 765 C of charge. This solution of combining 20 bunches to one common beam axis solves the problem of charge limitation without sacrificing the high average current requirement. The high polarization can be obtained using Superlattice GaAs which is able to provide polarization greater than 80% in a consistent basis [3]. For the R&D and "proof of principle" experiment, bulk GaAs will be used.

DESIGN OF THE CATHODE PREPARATION CHAMBER

The cathode preparation chamber is a compact design including 3 crosses, two of them are 6-way crosses and the other one is a standard 4 way cross. These three crosses are stacked on top of each other with the 4-way cross at the bottom. The cathode holder is moved up and down using a magnetic manipulator. One NEG pump and one turbo pump is attached to the bottom 4-way cross. The middle cross contains the tungsten filament, another NEG pump, one Ion pump and a view port. The top-most cross includes the Cs source, a pick up anode, a variable leak valve for Oxygen, an Extractor gauge to measure low pressure and a window through which laser shine the sample. A cross sectional view of the assembly is shown in Fig. 1 and the front view of the actual system is shown in Fig. 2. The vacuum and heat cleaning components are described in detail in the following sections.

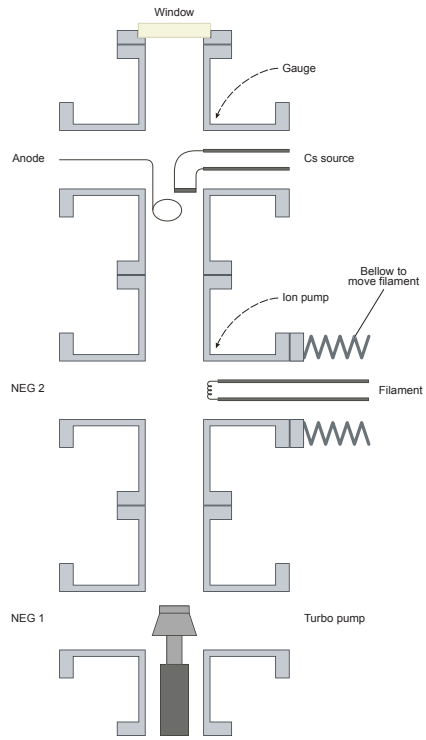

Figure 1: Cross sectional view of the cathode preparation chamber.

VACUUM COMPONENTS AND BAKE OUT PROCEDURE

The bake out procedure is extensive since activating GaAs requires XHV i.e low 10^{-11} Torr scale vacuum. The chamber at 200°C for approximately a week. Heater tapes are used to wrap the chamber and K-type thermocouples are used in 8 different locations of the chamber to make

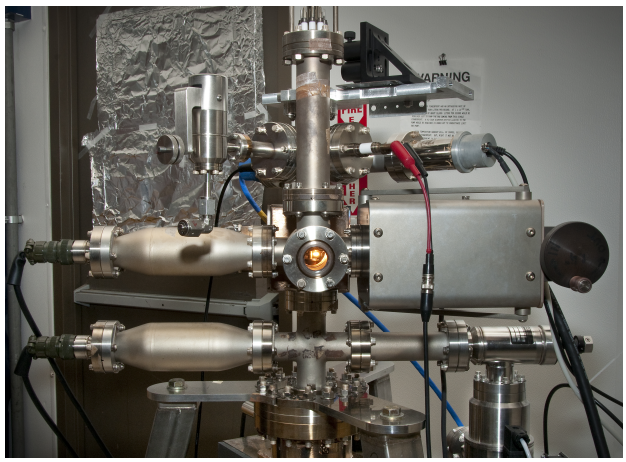

Figure 2: Front view of the cathode preparation chamber.

Table 1: Vacuum Pumps used in the Prep. Chamber

Pump	Pumping speed	location in the chamber
Ion pump	50 l/s	Middle cross
NEG 1	80 l/s	Bottom cross
NEG 2	80 l/s	Middle cross

sure that the temperature is uniform over the entire chamber.Different pumps that are installed in this system is described in Table 1.The NEG pumps are Capacitorr D400 units from SAES getters and the Ion pump is a standard Gamma Vacuum one.

Temperature data is saved to a computer using an Omega USB data acquisition module. The temperature of the chamber is increased gradually from room temperature to 200°C in 50°C increments over the course of two days.

One AxTRAN ISX2 gauge, a hot cathode extractor type gauge, is used to monitor pressure data. The NEG pumps are activated twice during the bakeout cycle, once the temperature of the system is 100°C and then right before the cooling of the system begins. Every other component of the system is also degassed during the heating cycle when the system is at 200°C including the filament, the Cs source, the cathode holder and the gauge.

A typical Pressure Vs Time graph is show in Fig. 3. While cooling down, the system is also brought down gradually from 200°C to 80°C to room temperature. While the system is at 80°C, the RGA is degassed.

HEAT CLEANING AND ACTIVATION

Before GaAs is activated, the surface of the sample needs to be cleaned either by conventional heat cleaning or atomic Hydrogen cleaning. We use a commercially available Tungsten filament from a 250W light bulb to heat up the sample by radiation to a desired temperature. The heat cleaning setup is shown in Fig. 4. The filament

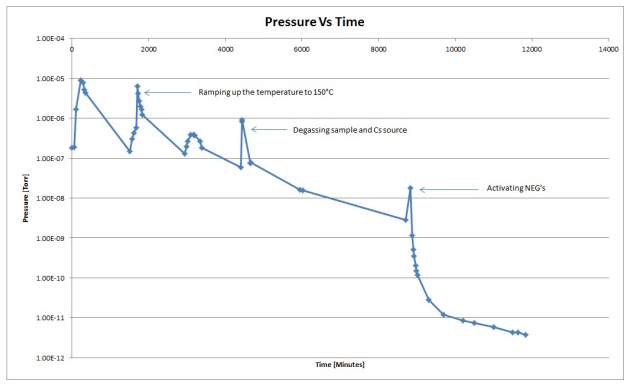

Figure 3: Pressure of the chamber during a bake-out procedure.

is inserted into the chamber using a feedthrough which is connected to a bellow that is compressible and the position of the filament can be adjusted.

It should be noted that the vertical position of the cathode

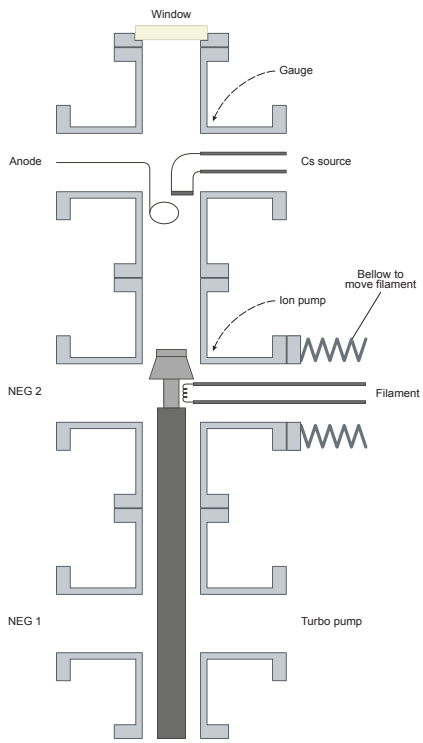

Figure 4: Schematic diagram of the heat cleaning procedure.

and the position of the filament has to be exact in order to have the right temperature on the surface of the sample. Meticulous calibration tests were performed to measure the surface temperature of the GaAs as a function of the driving current through the filament with a fixed vertical height and fixed filament position. For our heat cleaning procedure, we use the calibration curve to obtain

Copyright © 2013 CC-BY-3.0 and by the respective authors

a temperature of 580°C on the surface of the GaAs.

After the heat cleaning is done for 45 minutes, it takes approximately 2 hours for the sample to come back down to room temperature (also obtained from the calibration experiment). For activation, we use a standard evaporation Cs source from SAES getters. The laser is a 650 nm diode CW laser. A sample activation curve is shown in Fig. 5.

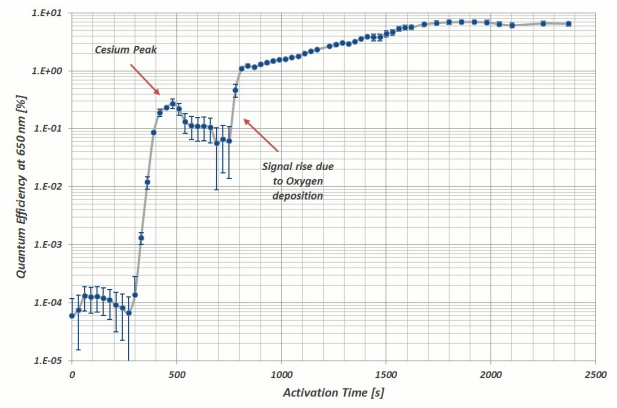

Figure 5: Typical activation curve.

Typically the first real signal is measured after 350 seconds and the Cs peak is seen after 500 seconds. This activation process is a co-deposition process where the Cs and Oxygen are applied to the surface simultaneously after the signal has reached the Cs peak. Multiple activations were performed using this technique and the QE ranges between 6% to 8% for 650 nm light.

CONCLUSION AND FUTURE PLAN

A compact prototype preparation chamber to activate GaAs photocathodes is assembled and tested. The chamber has shown to be XHV achievable and bulk GaAs samples were activated in the chamber with standard QE for 650 nm light. This chamber is scheduled to be installed on the storage chamber and a two cathode test is scheuled to be performed early next year. Eventually, this chamber prototype will be used to activate Superlattice GaAs photocathodes for the full operation of the High Current High Polarization Gun.

PARMELA SIMULATION FOR BNL 704MHZ SRF GUN IN LOW EMITTANCE OPERATION

E. Wang, J, Kewisch, I. Ben-zvi, BNL, Upton, NY 11973

Abstract

The BNL 704MHz 0.5 cell SRF gun is designed for an ERL prototype with high bunch charge and high average current, but may ultimately be used to generate a high brightness electron beam for a high power far infrared free electron laser (FEL) without energy recovery. In simulations with the space charge tracking code PARMELA we obtained a transverse normalized beam emittance of 0.22 mm-mrad for a bunch charge of 300 pC. The schematic layout of 704 MHz gun and its preliminary beam dynamics are presented in this paper. The emittance of electron beam was optimized for 300 pC bunch charge, 20 ps bunch length and 20 MeV operations.

INTRODUCTION

A high repetition rate FELs requires an electron beam with an extremely good emittance and operating in CW mode. The transverse normalized emittance of the electron bunch is matched to a FEL beam if

$$\gamma\varepsilon_{x,y} < \frac{1}{4\pi}\gamma\lambda_r$$

where γ is the electron energy and λr is the FEL wavelength. The reduction the transverse emittance from the RF gun and the optimization beam optics are the goals of this paper. To realize the high repetition rate and high average power FEL, the gun has to work in CW mode.

SRF gun combines the high gradients of normal conducting RF gun with the CW mode operation of superconducting RF technology. It is demonstrated to be capable of generating a low emittance beam in CW mode operation. The 704MHz superconducting gun for BNL ERL prototype is commissioned now[1]. As an ERL injector, this gun must accelerate electrons to 2-2.5MeV with bunch charge up to 5nC dependent on the operational parameters. In pervious simulations it was shown that this gun is capable of providing the beams with 1.4μm rms normalized emittance with a bunch charge of 1.4nC.

In our PARMELA simulation we reduced the bunch charge to 300 pC and obtained a normalized transverse emittance of 0.22 mm-mrad after acceleration to energy of 20MeV. The optimization code RTX was used in this work as a wrapper around the PARMELA program. The 2D electric field map of the gun and cavities was obtained with Superfish and passed into PARMELA. The average axial electric field in the gun is assuming 9.4MV/m.

BEAM OPTICS ARRANGEMENT

The layout of the accelerator is shown on Figure 1. The beam energy at half cell SRF gun exit is 2MeV. Then it will be boosted to 20MeV by a 5 cell cavity. Two solenoids are used to maintain the beam size and space charge compensation. A 3rd harmonic cavity is used to reduce the energy spread. A uniform spatial and temporal distributions laser shape was assumed to drive the beam from cathode. The 704MHz cavity shape is shown on Figure 2. The initial beam and accelerator parameters are listed as Table 1.

Multiple parameters including laser spot size, emission phase, beam length, solenoids' field, 3rd harmonic cavity parameters must be optimized.

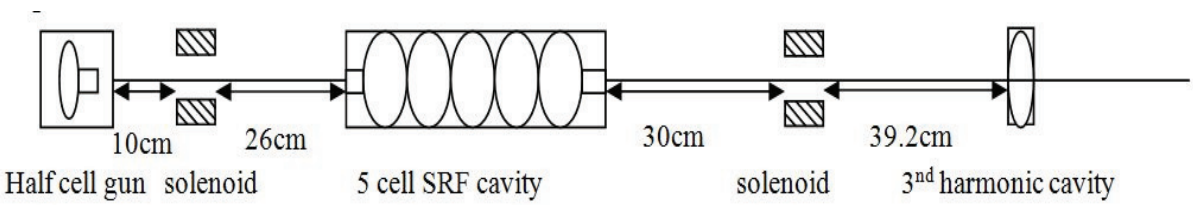

Figure 1: The layout of beam optics. The optimized distance is labelled.

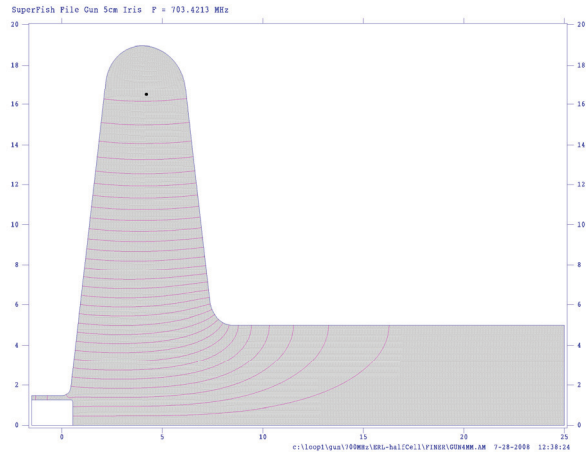

Figure 2: The fundamental mode in the 704Hz SRF gun. The cathode position can be adjusted.

The input parameters assumed for the PAMELA simulations are summarized in Table 1.

Table 1: The Optimized Parameter for Low Emittance Operation

Parameter	Value at 40MV/m
Bunch charge at cathode	300pC
Longitudinal charge distribution at cathode	Uniform
Transverse charge distribution at cathode	Uniform
Bunch length at cathode	20ps rms
Thermal emittance, $\varepsilon_{n,th}$	0.23μm
Gun gradient E_0	9.4MV/m
Injection phase	15.3 degrees
Boost gradient E_0	25MV/m

BEAM OPTICS OPTIMIZATION PROCEDURE

RTX code[2] is a beam optics optimization code which uses the Condor optimizer[3] and PARMELA for the calculation of the beam dynamics. The optimization is performed in several steps in order to limit the number of variables and reduce the optimization time:

- Define the gun geometry and calculate the EM fields using Superfish. The recess of the cathode was adjusted in 6 steps and the following optimization steps were executed for each position of the cathode.
- Single electron tracking to optimize the phase of RF gun and linac. The goal is to reach the maximum energy at the exit of the 5 cell cavity and the minimum energy at the exit of the 3rd harmonic cavity.
- With 5000 particles optimize the spot size on the cathode. The goal is to reach the minimum the normalized emittance at the gun exit.
- With 5000 particles find the strength of the solenoid strength and the distance between the solenoid and the 5 cell cavity, minimizing the normalized emittance at the end of the linac.
- With 5000 particles find the strength of the second solenoid, optimizing the emittance at the exit of 3rd harmonic cavity. The improvement in this step is small.
- Optimized the beam energy spread by varying the phase, gradient of 3rd harmonic cavity and the phase of the accelerating cavity.
- With 10000 particles perform a global optimization of spot size, emission phase, cavity phase, solenoids field and components distance.
- Confirm the final result with 100000 particles.

EMITTANCE OPTIMIZATION

The electron beam energy increases as the function of position is shown in Figure 3. The optimized beam injection phase is 15.3 degrees on the cathode.

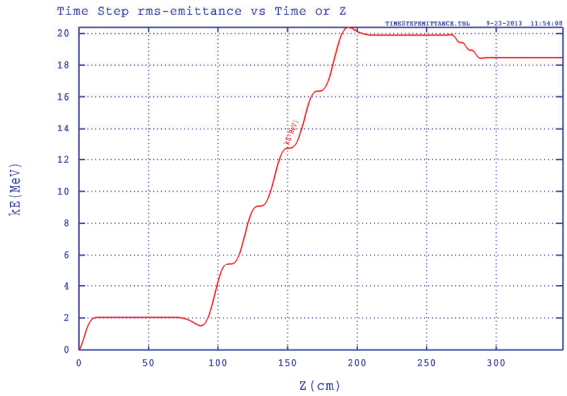

Figure 3: The electron energy as the function of longitudinal position.

The beam emittance from an RF gun is determined by the thermal emittance, the RF emittance and the space charge emittance. It can be written by

$$\varepsilon_n = \sqrt{\varepsilon_{\text{thermal}}^2 + \varepsilon_{\text{rf}}^2 + \varepsilon_{\text{sc}}^2}$$

where the thermal emittance refers to initial beam emittance at cathode emission surface, the RF emittance refers to time dependent focusing of the beam by RF field in the gun cavity and the space charge emittance refers to the repulsive force attributable to space charge cause the emittance to increase. To obtain optimized emittance result in a short time, 5000 particles were used in entire beam line simulation.

A larger laser beam size increases the thermal emittance while a smaller spot size increases the space charge emittance. Therefore varying the beam spot radius can be used to minimize the value of normalized emittance at the exit of gun. The optimized initial beam size is 0.67mm diameter. Here, we assume the beam has a beer can shape, i.e. a uniform transverse and longitudinal distribution.

In the gun the electrons in a bunch will experience different RF kicks depending on the longitudinal position along inside the. This will cause the projected emittance to increase[4]. The minimum RF emittance occurs when the bunch experiences the maximum field amplitude. To minimize the RF emittance, the initial emission phase and laser spot size are varied together.

Copyright © 2013 CC-BY-3.0 and by the respective authors

By recessing the cathode we obtain focusing of the beam by creating a radial electric field near the cathode. In a normal conducting gun this is accomplish using magnetic coils outside the copper cavity. This is not possible in a SRF gun. We found the best position of the cathode to be 5.4 mm behind the cavity wall at a peak RF field at the cathode of 40MV/m. Figure 4 shows the transverse normalized emittance as function of distance from cathode with the optimized parameter.

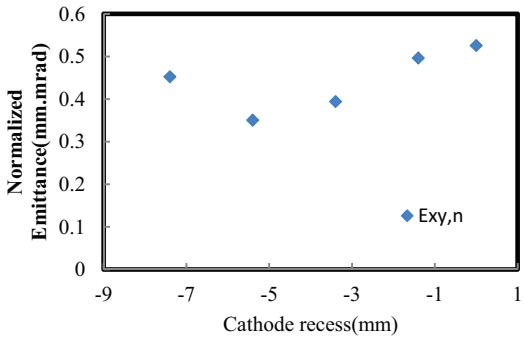

Figure 4: Transverse normalized emittance dependent on cathode insertion position.

The middle section of the bunch usually experiences higher defocusing from space charge forces then the head or tail of the bunch. This results in a bunch rotation in a phase space which is different for beam ends and middle section and increases the projected emittance. A focusing lens in combination with a drift is capable of compensating the overall emittance growth[5]. We place two solenoids to maintain the beam size and compensate emittance increase due to the linear space charge. The first solenoid is placed 10 cm from the gun exit to allow for the space needed for the cryostat. The RF focusing of the booster must match to the beam invariant envelope to damp the emittance oscillations. This matching requires the beam waist is at entrance to the booster linac. The optimized value of B_z is 891G. The optimized position of the booster entrance to the cathode was found to be 46.7 cm,

The beam energy is then boosted to 20 MeV by the 5 cell SRF cavity. A second solenoid is used to optimize the emittance at the end of beam line. A minimum emittance was found when the solenoid field is 197G and the location of the second solenoid entrance is 185.2 cm from the cathode.

As the electrons are accelerated in the 5 cell cavity the particles in the head and tail of the bunch gain less energy than the particles in the centre. This effect can be compensated by deceleration in a 3rd harmonic cavity with a frequency of 2111.1MHz. This cavity is placed downstream of booster cavity. By varying the phase of the 5 cell cavity together with the phase and voltage of the 3rd harmonic cavity we can eliminate the linear and quadratic components of the energy distribution.

At cavity exit, the beam energy spread is 960eV which corresponds to $5 \cdot 10^{-5}$ of full beam energy.

After the separate optimization of the parameters the laser spot size, the strength of both solenoids and the drift length are optimized together. Since the optimization starts close to the final values convergence is quickly reached. Finally, the complete beam line is calculated with 1 million particles to obtain final transverse emittance evolution in the beam line. (shown on Figure 5). A normalized transverse emittance of 0.22 mm-mrad was obtained.

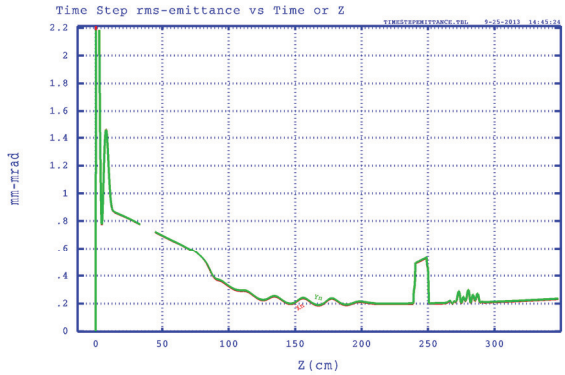

Figure 5: Transverse normalized emittance as function of longitudinal position.

CONCLUSION

We used PARMELA and RTX code to find the best beam optics arrangement for 300pC bunch charge operation of BNL 704MHz gun. 0.22 mm-mrad normalized transverse emittance was obtained. The beam energy spread is minimized to $5 \cdot 10^{-5}$.

Abstract

The future electron ion collider (eRHIC) at Brookhaven National Laboratory requires a polarized electron source with high average current, short bunch length, and small emittance. The-state-of-the-art single polarized electron photocathode is far from delivering the required 50mA current due to ion back-bombardment limiting the cathode's lifetime and surface charge limit. In our design of the funnelling gun, currently under construction, the electron bunches generated from 20 photocathodes in a 220 kV DC gun are funnelled into a single common beam-axis. This article details design of the optics of our high-average-current polarized electron gun, and presents our simulation of the beam's dynamics and the design of the combiner. We also report herein our progress in constructing the funnelling gun.

INTRODUCTION

A key technological demand in constructing a future heavy-ion collider lies in assuring a high average-current, high-bunch-charge polarized electron source. To meet the requirements for luminosity and electron energy for an electron- and heavy-ion-collider, we are developing a polarized electron source with an average current of 50mA, and a 2.3A peak current. The quantum efficiency (QE) lifetime due to ion back-bombardment limits the level of the achievable average current, and bunch charge with a single GaAs photocathode in a DC gun. One approach to extending charge lifetime is to funnel the electron bunches generated from several photocathodes to a single common axis. In our design, each photocathode generates an average current of 2.5 mA. We placed twenty GaAs photocathodes along the rim of a 32 cm-diameter cathode electrode at a potential of -220 kV. A series of fixed magnetic field dipoles first bend the off-axis electron bunches that then are merged into the main axis by a rotating magnetic field. Figure 1 is the schematic layout of the funnelling gun for transporting current from the cathodes to the depressed collector that acts as a beam dump. Each cathode produces an electron bunch with a 700 kHz of repetition rate. The timing of the radiating laser to the cathode is such that each cathode emits with delay of 70ns after the previous one. After funnelling, the bunches' repetition frequency is 14 MHz; the total average current reaches 50 mA.

#wange@bnl.gov

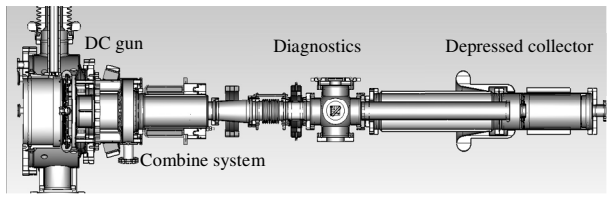

Figure 1: Schematic layout of funnelling gun.

GUN SETUP

The detailed design oft the gun was described earlier [1].We used a Pierce-like DC gun to accelerate the electrons. A focusing field near the cathode balances the effect of the strong space-charge from the bunch. The optimized angle between the cathode and the cathode's electrode is 157°; the gap voltage is 220V across 2.8mm. The maximum field on the cathode is 5.3MV/m. Solenoids placed after the anodes compensate for the defocusing of the space charge in the gun's DC gap. We designed compensated dogleg trajectories in the beam's funnelling system encompassing 20 fixed bending fields, one for each cathode, generated by 20 dipole-magnets, along with a single rotating bending-field generated by the magnetic combiner. Several components of the beam diagnostics are sited downstream, and finally, the beam will absorbed by a depressed collector. Two solenoids downstream of the combiner maintain the beam size.

SIMULATION OF THE COMBINER FIELD

We are using 20 dipole coils and 40 quadrupole ones with a sine AC current to generate rotational dipole- and quadrupole fields [2]. The OPERA AC steady-state solutions confirmed the degree of rotation of the fields, and also that the multicathode emitted beams are in phase. The effect on the beam of the rotating time-dependent field can be ignored. In simulating the gun , we used the static-field maps generated by Opera-3D/TOSCA for simulating the 3D beam in CST Particle Studio. We also generated a rotation dipole- and quadrupole-field from CST EM studio time-domain solver. The 20-sine excition signal is sent to the dipoles; each of them has an 18-degree phase shift. We obtained the animation of the rotating field in the time frame. We used the same setup for generating the rotational quadrupole field. Figure 2 shows the field distribution simulated by CST. The simulated rotated field was used in a PIC solver to assess the the funneling of the multiple bunches . However, the simulation consumed too much time and power due to the RAM limitation in the personal computer and its I/O speed.

Copyright © 2013 CC-BY-3.0 and by the respective authors

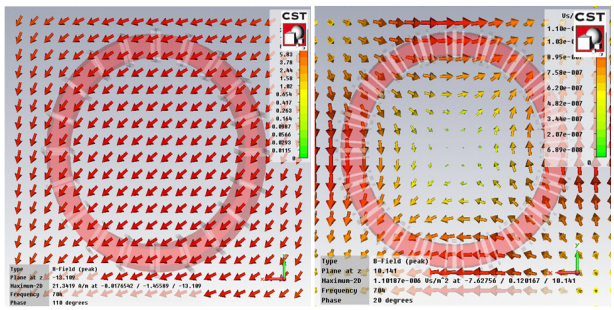

Figure 2: Dipole-field (left) and Quadrupole-field (right) of combiner simulated by CST.

BEAM DYNAMICS

The main problems in beam dynamics are the high bunch-charge, the three-dimensional geometry of the beam's path, and the non-axial symmetricity of the field at the DC gap and at the combiner's entrance about the beam's axis. Therefore, we studied the beam dynamics of the gun and the design of the beam line's optics using "Particle Studio", the 3D beam-tracking code and Particle In Cell (PIC) code developed by Computer Simulation Technology (CST). The following were the three goals of designing the beam line's optics for this gun : i) Prevent the beam from approaching the beam pipe; ii) minimize the beam's emittance at the place of diagnostic cross position, and, iii) focus the beam into the depressed collector. We started by simulating a single beam. The 3D CST Particle studio's tracking solver was used to obtain the beam's transverse parameters. Table I summarizes the optimized input parameters for the simulations.

Table I: Input parameters after optimization

Parameter	Value
Bunch charge	3.5nC
Longitudinal distribution	Gaussian distribution(σ=1.5ns)
Transverse distribution	Uniform
Bunch length at cathode	1.5ns
Bunch radius at cathode	4mm
Thermal emittance, ε_{th}	0.5 μm/mm(rms)
DC gap voltage	220kV
Combiner	Center field=24.5G; Physical length=20cm
First solenoid	Maximum field=560G; Physical length=5.4cm
Second solenoid	Maximum field=184G; Physical length=10.5cm
Third solenoid	Maximum field=366G; Physical length=6.3cm

The current density from the cathode is 4.6A/cm^2, i.e. lower than the limit of GaAs surface charge. Figure 3 shows that the beams' envelope and its transverse normalized RMS emittance as a function of distance with and without the combiner's quadrupole field.

The space-charge force at a 3.5nC bunch with 220keV energy dominates the growth of emittance. The combiner that generates a rotating dipole and a rotating quadrupole magnetic field is synchronized to the beam. Without the quadrupole, the beam lacks focusing in the direction of bending, but experiences excess focusing in the direction of the field. Changing the quadrupole current will equalize the focusing effect in two transverse directions; we obtained a diameter of 15 mm in the round beam's profile at the diagnostic cross when we apply a 7.5A current on the quadrupole coils wherein the divergence angle is x'/y'=23.6mrad/25.1mrad. The transverse normalized RMS emittance is $\varepsilon_{n,x}$/ $\varepsilon_{n,y}$=17.0mm mrad/14.9mm mrad when a quadrupole current is applied.

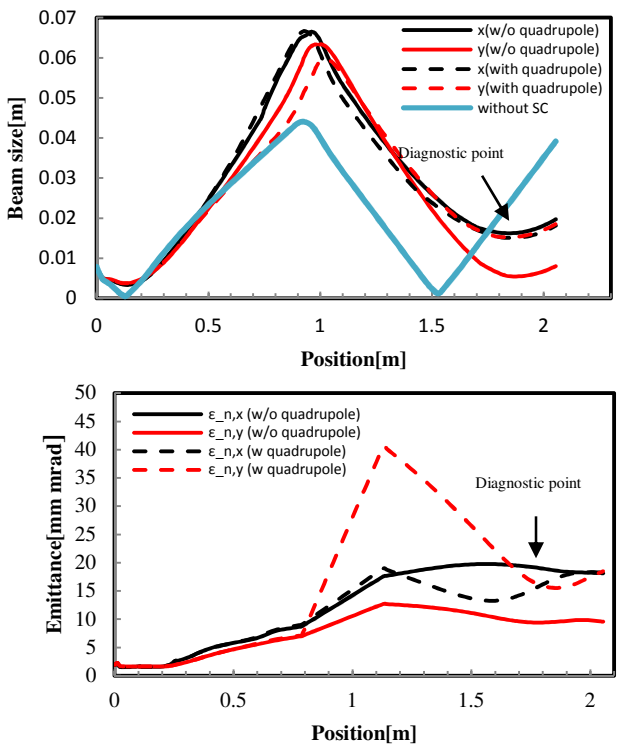

Figure 3 (top): The beam size as a function of distance with and without combiner quadrupole field. The blue curve shows the beam's size without space charge. (bottom) The normalized transverse RMS emittance as a function of distance with and without the combiner's quadrupole field.

Figure 4 illustrates the trajectory of the entire beam line based on the parameters given in Table 1. The beam expands downstream of the diagnostic cross. Therefore, we installed a third solenoid to focus the beam into the depressed collector. The diameter of the beam's waist at the entrance to the collector is 15mm, half that at the collector's entrance aperture. The beam's longitudinal character was simulated using the CST Particle Studio PIC code. The full-beam energy spread at the beam diagnostic cross is 22keV. The energy spread of 97% of the bunch particles is 8keV, viz., an acceptably small energy compared to its energy after the booster.

Copyright © 2013 CC-BY-3.0 and by the respective authors

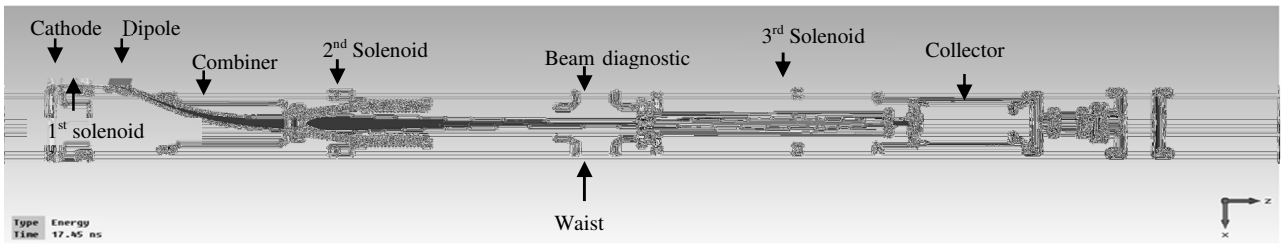

Figure 4: Tracking the entire beam-line. The black curve is the simulated bundle of beam trajectories using the CST particle-tracking solver.

ESTIMATION OF TOLERANCE

A single power-supply will drive the combiner coils' controlling stability to < 25 ppm. The machine's tolerance will be controlled to < 25μm. Based on current's vibration and assembly tolerance on the combiner, we estimate there is 1% non-uniformity transverse distribution on it. The multiple beam size will increase 9.8% and the normalized emittance will increase by 11.3% due to the field tolerance. To get the beam into the entrance aperture of the depressed collector, the tolerance of the timing of the combiner signal allows ±2 degree shift that corresponds to ±8ns.

BEAM-LOSS

Anywhere that a very small fraction of the electron beam strikes the gun's wall, oxidizing gas is desorbed, and the cathode can sustain damage. Several mechanisms contribute to beam loss, such as the formation of a halo round the beam, and the emission of electrons by scattering light or a dark current. We evaluated, in realistic geometry, the loss due to the beam halo by tracking test particles near the beam's edge while modelling the core beam as a slug of charge. The test particles have a different betatron oscillation period from that of the core beam due to defocusing by space charge; this mismatch contributes to the formation of the halo.

We first estimated the position from the cathode at which the beam halo was generated. e. Space-charge changes the force outside the beam, actually reducing the wavelength of betatron oscillation from its value without space charge. We expect the particles at the beam's edge to attain a maximum separation from the beam at one-quarter of that wavelength (λ+/4). The following calculation was based on reference [3].The generalized perveance of a single beam-let is 0.0002526 in combiner. For a constant beam radius, we must apply external focusing with the strength k_o^2, where k_o is the betatron wavenumber with no space charge.

$$K_0^2 = \frac{K}{a^2} + \frac{\varepsilon}{a^4}$$

Here, a is the 2*rms beam radius, and ε is the 4*rms non-normalized emittance. K is generalized perveance. We quantify the space-charge force by defining the intensity parameter χ.

$$\chi \equiv \frac{K}{K_0^2 a^2}$$

Using this notation, the reduction in betatron wavelength outside the beam is given by the factor sqrt(1+χ), so the surface particles separate position for the maximum excursion is

$$\frac{\lambda_+}{4} = \frac{2\pi}{4k_0\sqrt{1+\chi}}$$

Based on the beam parameters in Table 1, the calculation results in a distance of 62 cm where the halo beam is generated. It is further downstream of combiner exit.

We also studied the beam's halo by a particle-core model using the PIC code. Two annular-DC electron sources were placed at the cathode and the exit of the first solenoid. The cathode material was set as vacuum to avoid distorting the field. Fifty points uniformly distributed on the imaginary source generated the test particles. We set the average current at 1nA, allowing us to ignore the space-charge force from the test particles. These particles have the same energy and same divergence as the core beam at the site of the imaginary source. Once the beam reaches the annular source, the test particles surrounding the core beam feel its space charge. Tracking their position can identify the mechanism of halo formation and assess beam loss. The bunch approaches the beam pipe at two positions due to lack of focusing upstream of the combiner. One position is at the entrance to the combiner, and another is at the combiner's exit. Our simulation shows that the closest distance between the test particles and aperture at the first position is 11.2mm, and 19.2mm at the second position. Particles at surface of the bunch evidently cannot strike to the beam pipe and desorbs gases. Other mechanisms of beam loss remain to be determined experimentally.

ACKNOWLEDGMENT

The author thanks to Prof. R.A. Kishek for invaluable discussion on beam loss.

A TWO FREQUENCY GUN FOR HIGH CURRENT THERMIONIC CATHODE ELECTRON INJECTOR SYSTEMS

J. Edelen, S. Biedron, J. Harris, S.V. Milton, Colorado State University, Fort Collins, Colorado
J. Lewellen LANL, Los Alamos, NM

Abstract

This paper discusses work done at Colorado State University (CSU) on designing a radio frequency, thermionic cathode electron gun for high-current injection systems for free electron lasers. Some background and a brief overview of other facilities using this type of injector is provided followed by the basic theory of back-bombardment and why it is a problem for such high-current injectors. We then discuss the theory of how a second frequency in the gun could mitigate this back-bombardment effect. Scaling from a previous design to the relevant CSU frequencies and using beam simulations we show results comparable with previous work done in this field [1]. We found that for a 100-pC bunch charge operating at 10MV/m gradient the harmonic field produced a 63% reduction in the back-bombardment power.

INTRODUCTION

Production of 1) high-brightness, 2) low-emittance, and 3) high-average current beams is necessary for high average power free-electron lasers (FELs) and with regards to the first two the use of photocathode RF guns dominate. However, achieving high-average currents in the photocathode mode is complicated by the need of robust, high-quantum efficiency cathodes and complex laser systems. A simple thermionic cathode RF gun system can achieve quite high average currents and, properly designed, can achieve the high-brightness required for many FEL applications in the IR and longer wavelengths [2,3,4,5]; furthermore, the cathodes tend to be robust and long-lived (months to years).

While the use of thermionic cathodes can drastically increase the cathode lifetime, use of such cathodes presents two major complications. The first and foremost is how to prevent the potentially destructive electron back-bombardment, while of secondary concern is how to operate the accelerator in a pulsed mode, which is useful for characterizing the machine.

This paper does not address pulsed-power operation; however, previous work has analysed the possibility of both laser-gated thermionic emission or cathode grids to gate the emission [6]. Instead here we focus on a method to mitigate the electron back-bombardment heating effect.

BACK-BOMBARDMENT IN THERMIONIC RF GUNS

A thermionic cathode when held at a chosen elevated temperature will continuously emit electrons at a rate dependent on the cathode temperature. If the field on the cathode is positive there will be no emission because the field attracts the electrons back to the cathode. When the field is negative the emission from the cathode will be continuous. Some electrons, which are emitted late in the RF cycle, will not gain enough energy to exit the gun and will be accelerated back towards the cathode. These back-bombarded electrons transfer their energy to the cathode surface in the form of heat and subsequently can raise the cathode temperature. This effect is referred to as back-bombardment and is a negative feedback mechanism: higher temperatures produce more electrons, which in turn increase the back-bombardment. If left unchecked, cathode damage may occur.

Using a simple Newtonian model, we computed the trajectories of a single electron subjected to a time varying RF field. Figure 1 shows, as a function of injection phase, the resulting final position of these particles. A time domain overlay of the RF fields is also shown.

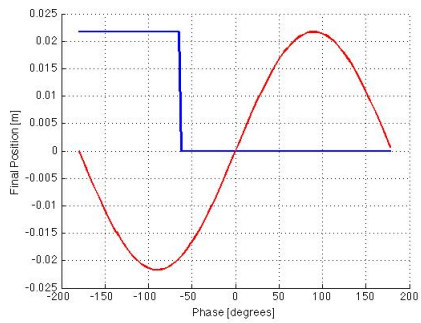

Figure 1: The resultant back-bombardment phase profile for a gap of 2cm and a RF frequency of 1.3GHz. Using a simple Newtonian model.

As stated previously, when the field is positive there is no emission so even though these particles have a final position of zero, they also never gain any energy. However for this model, there is a range of phases from roughly -63 to 0 degrees, where emission occurs but the particles ultimately are accelerated backwards by the rapidly changing field and strike the cathode. This corresponds to about 1/3rd of the region where emission is favourable and back-bombardment occurs.

THEORY OF BACK-BOMBARDMENT MITIGATION

In order to mitigate the back-bombardment effect we must consider what ideal waveform will completely eliminate this effect. A waveform that emits over some time, then holds zero long enough for the particles to

Copyright © 2013 CC-BY-3.0 and by the respective authors

leave the cavity before turning negative, should eliminate back-bombardment. This waveform and its resulting back-bombardment profile, similar to that of figure 1, are presented in figure 2.

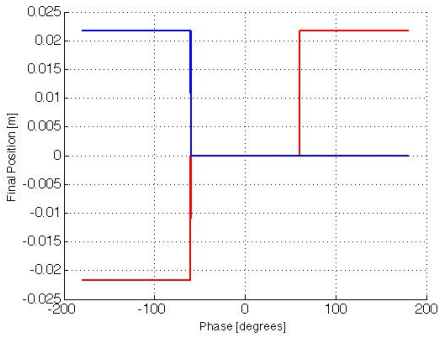

Figure 2: Ideal waveform (red) for complete back-bombardment mitigation with an overlay of its emission phase profile (blue).

This ideal waveform has practical limitations, so we must consider an approximation. We can express this periodic waveform through the use of a Fourier series. To eliminate possible adverse effects due to spurious overshoot caused by an incomplete set of harmonics we consider the first order approximation seen in equation 1.

$$E_z(t) = E_0 \sin(\omega t - \pi) + \frac{E_0}{2}\sin(2\omega t) \qquad (1)$$

The result of the back-bombardment phase profile, similar to those seen in figures 1 and 2, is presented in figure 3 with the overlay of our approximated ideal RF waveform.

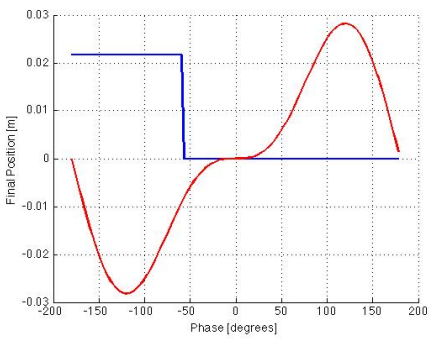

Figure 3: Phase profile for the two-frequency case using a simple Newtonian model (blue) with the temporal field envelope overlay (red).

Figure 4 compares the result of figure 1 and figure 3. This shows that we should see a decrease in the back-bombardment by the introduction of the first harmonic mode in the RF gun. This however was not optimized in relative field amplitude strength and relative phase or for other effects such as space charge. We need to consider a more general parameter space and do a proper scan over this space. Equation 2 represents a more general field profile where the harmonic phase and field ratio are given as variables.

$$E_z(t) = E_0(\sin(\omega t) + H\sin(2\omega t + \phi)) \qquad (2)$$

To better understand how the back-bombardment may vary, we performed a scan of these parameters on a 1D model for the back-bombardment.

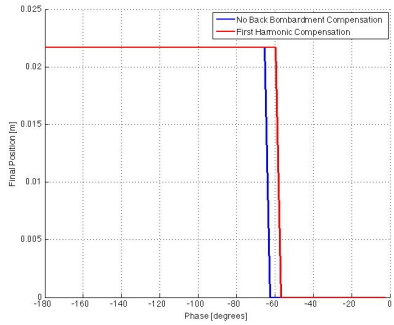

Figure 4: Comparison of the output phase profiles for the two-frequency case and the single frequency case.

Figure 5 shows the back-bombardment power in watts as a function of the harmonic field ratio and relative RF phase for the waveform defined by equation 2. The back-bombarded particle's energy is computed when it strikes the cathode, which is used to compute the energy deposited per RF cycle and consequently the back-bombardment power.

Our expected local minimum near 0.5 HFR and 180-degree phase offset is present, however the true local minimum occurs at 0.75 HFR and a 240-degree phase shift. This theoretical model predicts approximately a 40% reduction in the back-bombardment.

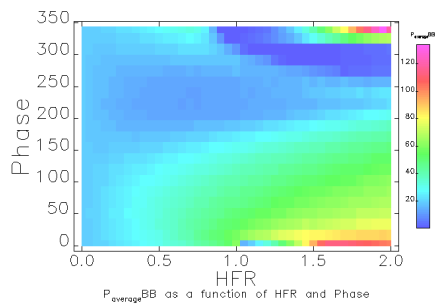

Figure 5: Theoretical result for the back-bombardment power as a function of the harmonic field ratio and the relative phase of the two RF powers.

There is also a minimum band in the upper right corner of the parameter space, since this does not appear in our simulations we believe this to be an artefact of the nonrelativistic approximation.

BEAM SIMULATIONS

The beam transport simulations were conducted using SPIFFE [7], a 2.5-D electromagnetic solver that includes space charge effects.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Without Space Charge

To compare our theoretical model with the more complete and realistic relativistic simulation we begin by running the same parameter scan as before with space charge calculations turned off. The gradient of the cavity was 10MV/m. What we see is a general trend that corresponds with the basic non-relativistic approximation, though with some specific variances due to these approximations.

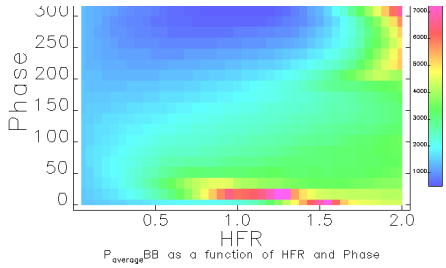

Figure 6: Back-bombardment simulation power as a function of harmonic field and the relative RF phase. The minimum is at 310 degrees and 1.1 HFR

With Space Charge

Having satisfied ourselves that the theoretical and non-space-charge simulations generally agree we turn on the space charge and execute a parameter scan over the same space as before. In this case we are assuming a modest amount of charge (100pC) emitted uniformly during a cycle. We see that the global minimum is roughly in the same location as in the non space charge region. This is indicative that in this modest charge case the space charge is not significantly affecting the ability of the harmonic mode to reduce the back-bombardment.

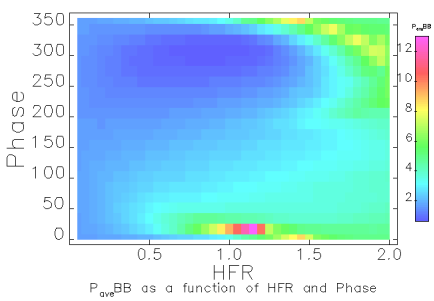

Figure 7: Back-bombardment as a function of the harmonic field ratio and the relative RF phase.

The back-bombardment power reaches a minimum at a relative phase of 310 degrees and a harmonic field ratio of 0.85. With no harmonic compensation the average back-bombardment power is 1.6kW. After introducing compensation the average back-bombardment power is reduced to 617W, about 37% of the baseline.

It should also be noted that while the harmonic field can mitigate the back-bombardment, improper tuning could increase it, which would greatly compound the cathode heating effects.

CONCLUSIONS

We have shown that the technique of using a harmonic field to reduce back-bombardment in thermionic guns can reduce the average back-bombardment power by about 63%.

THE CONCEPTUAL DESIGN OF PXIE VACUUM SYSTEM

A. Chen*, V. Lebedev, A. Shemyakin
Fermilab#, Batavia, IL 60510, USA

Abstract

The Project X Injector Experiment (PXIE) [1] will be a prototype of the Project X front end to validate the design concept and decrease technical risks. It consists of a 30 kV, 5mA DC H^- ion source (IS); Low Energy Beam Transport (LEBT); 2.1 MeV CW RFQ; Medium Energy Beam Transport (MEBT) that forms a desired bunch structure by removing ~80% of bunches; two SC cryomodules (CMs) accelerating the 1 mA beam to ~25 MeV; and High Energy Beam Transport with a dump (HEBT). Its vacuum system design will also establish the design guidance for the entire vacuum system of Project X, especially the requirement of low particulate vacuum that is sufficient in practise and at the same time is cost efficient to ensure the performance of CMs.

GAS LOADS AND LIMITATIONS

The PXIE vacuum system consists of four regions that can be separated by vacuum gate valves for commissioning or repairs: IS-LEBT-RFQ, MEBT, Cryomodules, and HEBT-DUMP. Different regions have different gas load sources and different limitations.

The main gas load in IS-LEBT-RFQ region is the gas flow from the IS, ~500 mTorr·l/s. Also, commissioning and machine tuning will be done in a pulse mode, when a chopper in the LEBT produces pulses of variable duration from 1 μs to 16 ms at 60 Hz repetition frequency. In this mode, almost all beam generated by the IS is absorbed in the chopper, and protons recombining inside the chopper's absorber into hydrogen, create an additional load ~1 mTorr·l/s. Vacuum limitations in this region are two-fold. First, the beam loss resulting from H^- stripping should be small, <5%. Second, the pressure in the RFQ and, consequently, gas flow from LEBT should be low to avoid discharges. From practical experience of other labs, pressure < 10^{-6} Torr should suffice.

The gas load in the MEBT region is a combination of outgassing of vacuum surfaces and gaskets; a hydrogen flux from the MEBT absorber irradiated by ~4 mA of the chopped-out beam; and a load from the MEBT scraping system. In the MEBT, vacuum restrictions are related to proximity to SRF. In addition to a gas and microparticles incoming to CMs, which is discussed in the next section, a flow of neutral hydrogen atoms created by stripping of H^- ions should be limited. Such atoms fly along the direction of the parent ions and can reach 2K surfaces of the cryomodules. To make irradiation of CMs by these atoms negligible (≤0.1 W of additional heat load), the vacuum integral over the MEBT length is limited to 1×10^{-6} Torr·m. Also, an aperture restriction after the MEBT absorber introduces differential pumping that dramatically improves pressure near the CM. Finally, scarpers installed at the end of MEBT additionally restrict the solid angle of penetration into the CMs.

Operating vacuum in the CMs is determined by the cryo-pumping and doesn't affect the beam directly. Vacuum limitations in the HEBT are determined mainly by the gas flow into SRF, and the main source of the gas is the beam dump.

Note that one of the vacuum-related effects considered in the course of PXIE design is a possibility of blistering. If hydrogen diffusion in a surface exposed to bombardment by the main beam or its tails is low, protons, implanted by an H^- ion impact, recombine in the bulk into hydrogen which is accumulated in dislocations until the built-up pressure breaks the overlaying material. Corresponding jump of local pressure can result in a beam loss. The issue is expected to be addressed by a system of collimation in LEBT and MEBT and preferential use of molybdenum for surfaces that are likely to be exposed to the beam irradiation.

THE SYSTEM DESIGN

A concept of beam line vacuum system derived from the limitations described above can be divided into three levels of vacuum environment (Figure 1):

1. Ultra High Vacuum and Low Particulate
2. High Vacuum areas (HV)
3. Transition areas

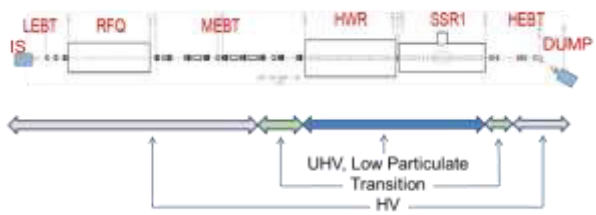

Figure 1: PXIE System Layout with classification of vacuum levels. HWR and SSR1 indicate location of two cryomodules.

UHV and Low Particulate Areas

These areas include two cryomodules, HWR and SSR1. With the cryomodules operating at 2K, cryo-pumping decreases the residual gas pressure below 10^{-10} Torr, mainly driven by the operation temperature. The challenge for this region is to achieve low enough pressure (10^{-7} Torr) at the room temperature before cooling down. Bypass vacuum pipe is designed to alleviate the conductance restriction due to the small aperture and large length of the cavity strings. To guarantee a low particulate environment for SRF operation, all necessary measures as proper handling,

clean rooms, gas flow control during pumping and venting etc. are applied. Cold cathode (CC) gauges are used to minimize the heat load from gauging.

HV Areas

The areas from the H- ion source up to the beam absorber at MEBT and downstream of the transition area in HEBT, where the residual gas pressure is 10^{-7} Torr or above, are classified as HV. Turbo pumps are chosen for locations with the highest gas load: the ion source, LEBT chopper, RFQ, MEBT absorber, and the beam dump. Otherwise, pumping is provided by ion pumps.

The DC ion source is continuously supplied with hydrogen gas. Inside the plasma chamber, the hydrogen pressure of $3 \cdot 10^{-2}$ Torr is to be maintained while the pressure downstream is 10^{-6} Torr in order to avoid large beam loss due to H^- stripping. The pressure gradient is achieved by a differential pumping scheme with two 1000 l/s turbo pumps.

Pressure ~10^{-6} Torr in LEBT is achieved by installing a 300 l/s turbo pump at the chopper, where the large gas load is expected when the chopper intercepts major fraction of the beam, and by a 100 l/s ion pump in the middle of the beam line.

In the RFQ, ~10^{-7} Torr vacuum required for reliable operation is provided by two 1000 l/s turbo pumps. Additional two vacuum ports can be used to increase the total pumping capacity if found necessary.

The HV portion of the MEBT is from the RFQ to downstream of the absorber. The absorber, the largest source of the gas load in the MEBT, is pumped by two 1000 l/s turbo pumps, while two upstream ion pumps compensate outgassing of vacuum surfaces. The beam optics downstream of the absorber is adjusted to decrease the beam size and allow placing a 10 mm ID, 200 mm length tube for differential pumping.

The HEBT line consists of magnets and beam instrumentations at room temperature. Its portion starting ~2m downstream of the SSR1 cryomodule is designated as HV. Pumping here is done with several ion pumps. Because a large amount of hydrogen is produced in the beam dump, 2000 l/s turbo pumping is applied. A differential pumping scheme is applied in the first 2m region in order to achieve UHV in the vicinity of SSR1.

Transition Areas

The optimum design of areas providing transitions between UHV and HV will be one of the study goals for the PXIE experiments. These areas, the downstream portion of MEBT and upstream portion of HEBT, are used to minimize the risk of degrading SRF cryomodules due to migration of gas and microparticles from HV components. The gas flow to the cryomodules causes a gas deposition on cryogenic surfaces. While there are no exhaustive experiments or a cohesive theory on the subject, there are indications in the literature that such accumulation at the surface of cryogenic cavities degrades their performance. On the other hand, the closest analogue, a HWR in the Argonne National lab, successfully operates at the pressure of 5×10^{-8} Torr immediately upstream of the cryomodule, though with the residual gas composed primarily by water [2]. To be on a safe side, the pressure in the transition areas is specified to be $\leq 1 \times 10^{-9}$ Torr (H_2). In addition, the optics was designed so that the CM element closest to the room-temperature elements is a solenoid, so that the cryo surfaces inside it could effectively shield the SRF cavities.

A low particulate vacuum practices are applied to ~2m of immediate vicinity of the cryomodules. The roughing/venting ports are arranged in the way minimizing the particle migration towards CM, and the flow rate of roughing/venting is regulated to reduce the risk of particle migration. Note that specific of the PXIE

is a CW beam, which space charge may assist in transport of microparticles between different location during operation. We believe that such effect would manifest itself as degradation of properties of SRF cavities closest to the warm elements, and, if found, may require lengthening of the transition areas in the design of the Project X.

The transition areas also include fast acting valves on both ends of the cryomodules to prevent catastrophic failures in a case of vacuum accidents in the room temperature parts.

Vacuum requirements for various locations of the PXIE vacuum chamber are summarized in Table 1, and calculated pressure profiles are shown in Figures 2-4.

Other Vacuum Systems

Besides the beam vacuum, there are two other vacuum systems in cryomodules.

The RF couplers in the HWR cryomodule have two ceramic windows which separate coupler vacuum from the beam vacuum and atmosphere. The power coupler vacuum systems are at $\leq 10^{-6}$ Torr. These small volumes of vacuum are maintained by ion pumps (one per coupler). This vacuum system has to be monitored in real time because the ceramic window isolate it from cryomodule beam vacuum is under high RF power and is very delicate. Classified as HV region.

Insulating Vacuum in HWR and SSR1 is required for cryo-isolation. The pressure shall be 10^{-5} Torr prior to cooldown. These systems will be pumped with turbo and roughing pumps. Pressure shall be maintained 10^{-6} Torr or better at cold. CC gauges shall be used. The pumps once used in this system shall not be used for UHV system because of contamination.

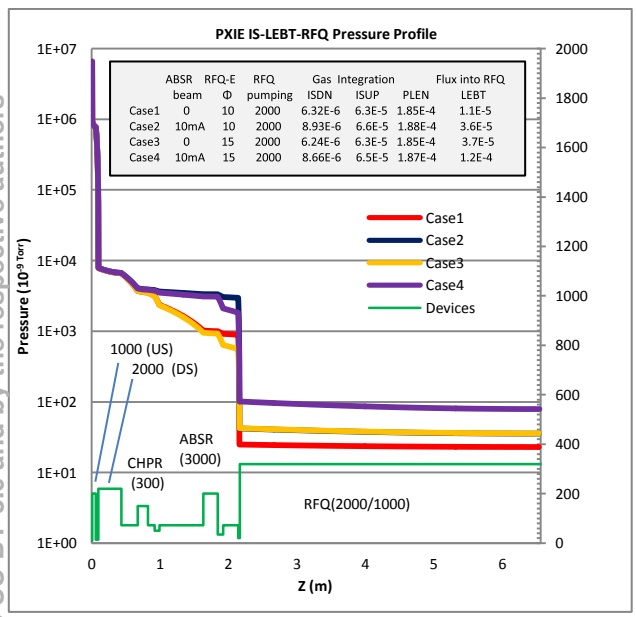

Figure 2: The pressure profile in IS-LEBT-RFQ. The number in parentheses is pumping speed in l/s. The IS has 1000 l/s turbo in its upstream chamber and 2000 l/s in down stream chamber. The flow rate of hydrogen is 0.5 torr·l/s. the gas integration is in Torr·m. the equivalent aperture of devices is in mm. there is no gas flow at the downstream end of RFQ.

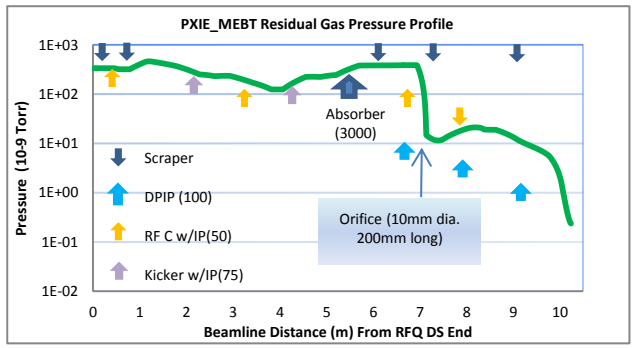

Figure 3: The pressure profile in MEBT. There is no gas flow at the both ends. The number in parentheses is pumping speed in l/s.

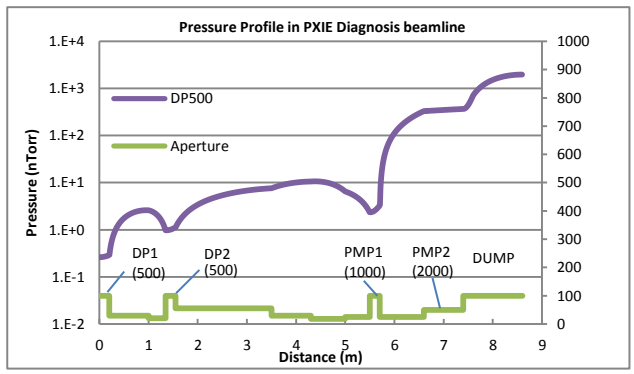

Figure 4: The pressure profile in HEBT-DUMP. The number in parentheses is pumping speed in l/s. there is no gas flow at the ends.

DEVELOPMENT OF A COMPACT PHOTO-INJECTOR WITH RF-FOCUSING LENS FOR SHORT PULSE ELECTRON SOURCE APPLICATION

[1]Alenxander Grabenhofer, [2]Douglas W. Eaton, and [1, 3]Young-Min Shin
[1]Department of Physics, Northern Illinois University, Dekalb, IL, 60115, USA

Abstract

For development of compact ultrafast electron source system, we are currently designing a short-pulse RF-gun with RF focusing structure by means of a series of comprehensive modeling analysis processes. EM design of a 2.5 cell resonant cavity with input coupler, acceleration dynamics of photo-emitted electron bunch, EM design of RF-lens with input coupler, and phase-space analysis of focused electron bunch are systematically examined with multi-physics simulators. All the features of the 2.856 GHz cavity geometry were precisely engineered for acceleration energies ranging from 100 keV to 500 keV (safety limited) to be powered by our 5 MW S-band klystron. The klystron (Thales TH2163) and modulator system (ScandiNova K1 turnkey system) were successfully installed and tested. Performance tests of the klystron system show peak output power > 5 MW, as per operation specifications. At the quasi-relativistic energies, the electron source is capable of generating 100fC – 1 pC electron bunch with pulse duration close to 30 fs – 1 ps and transverse size of a few hundred microns. PIC simulations have shown that the electron bunch undergoes fast RF acceleration, rapidly reaching the desired energies, which can be controlled by tuning RF injection phase and input driving power. It has been shown that it is possible to also focus/compress the bunch longitudinally using a RF-lens, which would allow us to control the temporal resolution of the system as well. While our primary analysis has been performed on a 2.5 cell design, we are also looking into half-cell (single cavity) design that is expected to provide the same range of beam energy with a simple configuration.

INTRODUCTION

The ultrafast electron diffraction (UED) source is one of the most powerful time-resolved spectroscopic/ microscopic tools capable of visualizing the sub-atomic world in a femto-second time frame. A successfully developed UED system will enable us to observe various ultrafast phenomena in chemical and biological substances of solid, gas and liquid phases. The instrument will be a useful tool for a wide range of scientific experiments in chemistry, biology, physics, radiolysis, and engineering on which accurate spatiotemporal analysis methodology is highly demanded. Ultrafast technology with sub-atomic resolution within the femto-second range, while still immature, far exceeds the current technical capacity of commercially available electron microscopes. This technology is not achievable from any single unit or commercial product, as integral parts and their systematic integration are still under development. For spectroscopic application, the main advantage of electron diffraction is that the electrons scatter off all atoms and atom-atom pairs in the molecular sample. Thus, unlike spectroscopy wherein the probe is turned to specific transitions, the electron probe is sensitive to all species in its path and can hence uncover structures that spectroscopy may be blind to. This type of spectroscopic imaging technique can offer spatiotemporal information of transitional dynamics and chemical reaction in liquid and solid states that are of main interest in NIU, as described in the next section, and the proposed UED system is expected to secure sufficient spatial and temporal resolution with good spatial coherence for those kinds of studies. The UED technique employs time-delayed ultrafast pulses – a laser pulse to initiate the reaction and an electron pulse to probe the ensuing structural change in the molecular sample. The resulting electron diffraction patterns are then recorded on a CCD camera. These processes can only produce femto-second electron diffraction when all the elements are properly orchestrated in harmony, which requires a sophisticated design process. In particular, as a key element of a UED system, a short pulse electron source must be capable of producing highly mono-energetic electron bunches of a few hundred keV to a few MeV to create dynamic scattering images with femto-second/sub-angstrom spatiotemporal resolution. Currently, we have a 5.5 MW S-band klystron driver for a photo-injector that has been designed with a 2.5 cell RF-gun to produce 100 ~ 500 keV electron bunches.

BACKGROUND AND OBJECTIVES

Most of UED systems have employed the photocathode-based DC gun with an energy in the range of 30 ~ 100keV（Max. DC field = 10 ~ 12 MV/m）and 400 ~ 600 fs at 10^3~10^4 e-/pulse. However, with the DC guns, bunch length and energy spread are increased during beam transport. The bunch length of a 30 keV e-beam is, for instance, increased from fs to a few ps and the energy spread ($\Delta E/E$) becomes ~ 3×10^{-3} to a distance of 40 cm. It is thus difficult to obtain a < 100 fs electron bunch with $\Delta E/E < 10^{-3}$ using DC guns. Also, to reduce the space charge effect in low energy DC gun system, the distance between sample and cathode should be minimized (4 ~ 5 cm) and/or the number of electrons in bunch should be decreased to 10^3 e-/bunch with 400 fs. It is difficult to observe the ultrafast dynamics with single-

Copyright © 2013 CC-BY-3.0 and by the respective authors

shot measurement and the studies of low-energy UED are limited to the reversible processes. Recently, photocathode RF-guns with higher accelerating gradients and electron density are therefore widely investigated for femto-second UED system application, which is also considered in our approach. We plan to pursue mechanical design and manufacturing of a RF-gun and high vacuum chambers, including a cooling system. The machined parts will be inspected by the Engineering Department and our HP8510C VNA will be available for spectrum analysis of the manufactured RF cavity.

SYSTEM CONFIGURATION

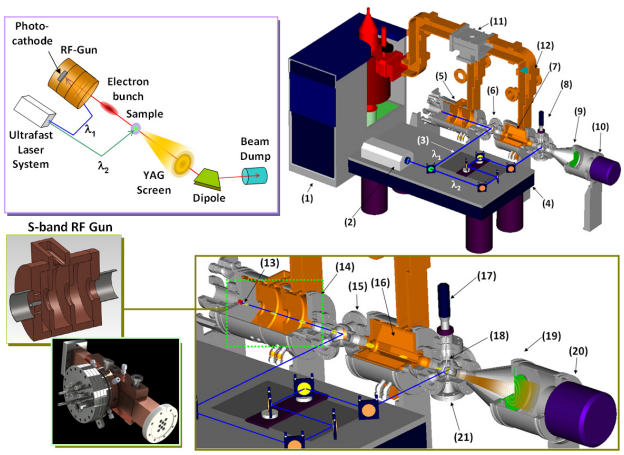

Figure 1: (a) Conceptual sketch of ultrafast electron diffraction system (b) engineering drawing of the designed NIU UED system. The RF power source (S-band klystron system) is already under installation with several other RF components (insets: designed 2.5 cell cavity and S-band photoinjector, courtesy of Radiabeam). See text for details.

Figure 1 is an engineering sketch of the proposed instrument that mainly consists of ultrafast laser system, a RF-gun, beam focusing devices, a 6-way cross sample chamber with a micrometer aligner, Yttrium aluminium garnet (YAG) screen with femto-second optoelectronic CCD camera, and electron beam dump with a bending section, if necessary. The electron bunch is photo-emitted by illuminating a photocathode with an ultra-short laser (that could eventually be spatiotemporally shaped). This pump-probe configuration, where the pump is a μJ laser pulse and the probe is the electron beam, could have enormous advantages in studying the dynamics of system in transient states with sub 100-fs (and eventually attosecond) time resolution. The short pulse electron source in the proposed UED unit mainly includes a femto-second laser system, a RF-gun, and a buncher for pulsed operation with femto-second electron packets. The system will employ a regeneratively mode-locked laser that produces ultra-short pulses of up to 10 ~ 100 nJ at 800 nm with variable pulse width (100 fs to 10 ps) and repetition rate (~ 80 MHz). The output pulses pass through two successive nonlinear crystals to be frequency tripled (267 nm). The harmonic is separated from the residual infrared radiation (IR) beam by dichroic mirrors, and the frequency-tripled pulses are introduced to the photocathode of the RF-gun for generating the electron pulse. The residual IR fundamental beam remains available to heat or excite samples and clock the time through a computer-controlled optical delay line for time-resolved applications. In order to pursue electron diffraction spectroscopy with sufficiently high signal-to-noise ratio, electron bunches need to contain > 10^6 electrons per a pulse. A photocathode with a quantum efficiency of 10^{-6} will require 10^{12} UV photons per a pulse to provide the 10^6 electrons/pulse. 10% efficiency in the two harmonic generation steps from the near IR to the UV implies 10^{14} IR photons/pulse. For the ~ 1eV IR photon energy, one then arrives at an IR laser pulse energy of ~ 10 μJ. A 10 μJ laser pulse energy is difficult to obtain from a fs laser oscillator directly as 0.1 – 1 μJ is about the limit with long cavity and/or cavity dumping techniques. A high QE (> ~ 10^{-4}) photocathode may thus be needed in order to create > 10^6 electrons/pulse with the laser energy. The first approach under our consideration is to use a Magnesium (Mg) photocathode (work function: 3.66 eV) at 267nm that has demonstrated relative high QE (10^{-3}) under modest vacuum condition [1].

SIMULATION MODELING ANALYSIS

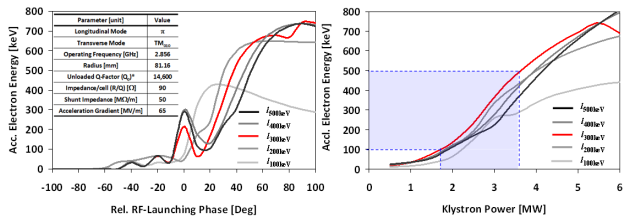

Figure 2: Optimally designed RF-gun parameters (table) and RF-launching phase and klystron power versus electron energy graphs obtained from tracking/PIC simulations with various cell-to-cell distances for beam-wave synchronization (1 pC bunch charge and 100 fs pulse).

As shown in Fig. 2, the acceleration performance of the design RF gun was examined with CST PIC solver. CST PIC code is the 3D particle-in-cell simulator based on finite-difference-time-domain (FDTD) algorithm that includes space charge effects of an electron bunch, represented by a collection of macro-particles, using real-time field profiles and ambient energy losses. The macro-particles are deposited on a grid and Poisson's equation is solved in the rest frame of the electron bunch and the electrostatic fields are Lorentz-transformed to compute the total force experienced by each macro-particle in laboratory frame. For the particle simulation, the electric and magnetic fields of 2.856 GHz, π, TM_{010}-mode, provided by CST Eigenmode solver, are imported into the cavity in particle-tracking and PIC simulation models. The initial laser distribution was taken to be an ultra-short

Copyright © 2013 CC-BY-3.0 and by the respective authors

laser pulse and a perfect three dimensional ellipsoidal distribution. At quasi-relativistic energies the electron source is capable of generating 100fC ~ 1 pC electron bunch with pulse

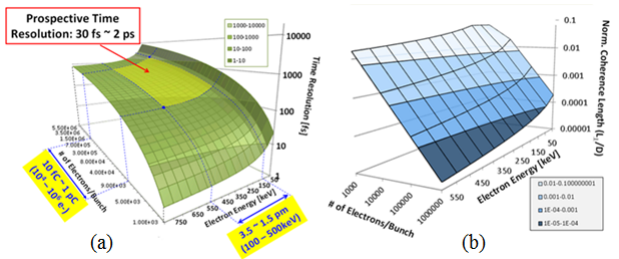

Figure 3: (a) spatiotemporal resolution and (b) coherence length versus # of electrons and electron energy.

duration close to 30 fs ~ 1 ps and transverse size of few hundred microns. At lower energies similar performances can be achieved with lower (100 fC) bunch charge. The space charge effect appears more dominant at the lower energies in that transverse and longitudinal emittances are diluted in the phase-space. A preliminary design is examined with the RF-gun by particle-tracking and PIC simulations. The electron bunch emitted from the cathode is slightly blown up for Columbic space charge force and then rapidly decreases toward the gun exit, but once entering in the focusing field region, it is rapidly squeezed in the axial directions. The simulations show that the bunch has improved momentum linearization in phase-space with spatial compression.

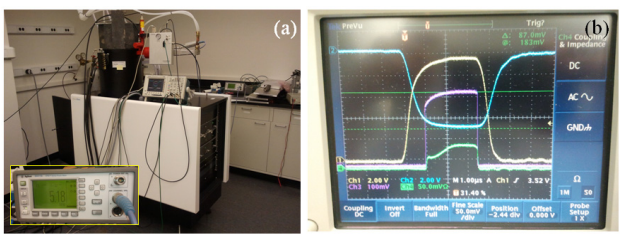

Figure 4: (a) Assembled S-band klystron (Thales TH2163) and modulator system (inset: output power measured by a power-meter) (b) waveforms of pulsed power measured by an oscilloscope.

A crucial component in the case of pump-probe experiment will be the precise measurement of the delay time between the laser pump and electron probe beams. Time stamping with 10 fs resolution will be achieved using an electro-optical modulator [2,3]. If the device does not offer fast enough response to distinct temporal evolution of diffracting patterns, it may be combined with streak camera to improve time resolution, which may also require a deflecting device. The time-resolution of the best optoelectronic streak cameras is around 100 femto-seconds. Measurement of pulses shorter than this duration requires other techniques such as optical autocorrelation and frequency-resolved optical gating (FROG) [4,5]. Figure 3 shows prospective specification of our designed UED system that is assessed by analytic calculations [6]. One can see in Fig. 3 that the 100 ~ 500 keV, corresponding to 1.5 ~ 3.5 pm spatial resolution, leads to 30 fs ~ 2 ps time resolution with ~ 10^4 ~ 10^6 electrons (~ 10 fC ~ 1 pC).

RF-TEST OF KLYSTRON SYSTEM

As a part of plan of a short pulse electron beam source construction, we installed and commissioned the S-band klystron (Thales TH2163) and modulator system (ScandiNova K1 turnkey system), as shown in Fig. 4. The high power RF-test ended up successfully demonstrating a ~ 5.2 MW peak power with 4 μs pulse width. The optical table and some waveguide components were added to the system, which will be used as a high power driver for the RF-gun once an accelerating mode cavity is added.

CONCLUSION

We have been developing a short pulse electron source for ultra-fast electron diffraction (UED) application at Northern Illinois University (NIU). The construction of the compact ultrafast electron source and associated detection equipment will be a great opportunity for the unique resource and technology in beam and laser physics, electrical engineering and other associated accelerator technologies, and support users from biology, chemistry, condensed matter physics, and medicine, among other fields.

Abstract

A 3.9 GHz deflecting mode (π, TM_{110}) cavity has been long used for six-dimensional phase-space beam manipulation tests [1-5] at the A0 Photo-Injector Lab (16 MeV) in Fermilab and their extended applications with vacuum cryomodules are currently planned at the Advanced Superconducting Test Accelerator (ASTA) user facility (> 50 MeV). Despite the successful test results, the cavity, however, demonstrated limited RF performance during liquid nitrogen (LN_2) ambient operation that was inferior to theoretical prediction. We have been performing full analysis of the designed cavity by analytic calculation and comprehensive system simulation analysis to solve complex thermodynamics and mechanical stresses. The re-assembled cryomodule is currently under the test with a 50 kW klystron at the Fermilab A0 beamline, which will benchmark the modeling analysis. The test result will be used to design vacuum cryomodules for the 3.9 GHz deflecting mode cavity that will be employed at the ASTA facility for beam diagnostics and phase-space control.

INTRODUCTION

Over the past decade, a multi-cell deflecting (TM_{110}) mode cavity has been employed for phase-space manipulation tests of high brightness beams [1-6] at the Fermilab A0 photoinjector (A0PI), and extended applications are currently scheduled at the ASTA user facility (> 50 MeV). Despite the past successful experimental results, the cavity demonstrated a limited RF performance during liquid nitrogen (LN_2) operation, which did not reach the theoretically predicted gradient. The designed cavity has been fully examined with theoretical calculations, based on the Panofsky-Wenzel theorem, using an integrated modeling tool with a comprehensive system analysis capacity to solve complex thermodynamics and the mechanical stress of the multi-cell. This paper discusses the cryogenic RF performance of the 5-cell deflecting mode cavity with numerical modeling analysis. It also presents up-to-date test simulation results of an integrated thermo-stress analysis modeling tool on the deflecting cavity vacuum-cryomodule and low power RF-test results of warm (room-temp, 297 K) and cold (LN_2-temp, 80K) cavities.

SYSTEM DESCRIPTION

At the Fermilab A0PI, the deflecting mode cavity has been used for various beam optics experiments. The cavity was designed with 5 cells to maximize kick strength and powered with a 50 kW (peak), S-band (3.9 GHz) klystron. The RF power was coupled into the cavity through the high power TEM-mode coaxial coupler that was built in the liquid nitrogen (LN_2) vessel. The coupler design includes a temperature gradient from cryogenic temperature (80K) of a LN_2-ambient cavity to room temperature of an input waveguide. As the emittance exchange only requires modest fields and short pulse lengths, the TM_{110} mode cavity was constructed out of oxygen-free, high conductivity (OFHC) copper [7]. A higher Q_0 was required than what was achievable at room temperature with the OFHC copper. We see that Q_0 is proportional to the square root of the copper's bulk conductivity. A Q_0 2.4 times greater was achieved by simply incorporating a LN_2 cryogenic jacket into the design.

The system is designed with the LN_2 vessel because the conductivity of normal conducting copper is increased 6 times from $5.8 \times 10^7\ \Omega^{-1}m^{-1}$ at room temperature to $3.5 \times 10^8\ \Omega^{-1}m^{-1}$ at 80 K, which doubles the cavity Q. The cryo-vessel was designed with three frequency tuning screws, attached to the chamber-outside body at one end and the flange, brazed with the beam pipe at the other end, across the flexible bellows. The tuners push the flange against the body and the mechanical pressure is transferred to the cavity through the beam pipe so the structural distortion by the tuner induces frequency change. As this simple design did not include vacuum insulation, the LN_2-temperature (~ 80 K) was maintained by shielding the outer body with foam insulation. The coaxial input coupler was designed with the critical matching condition, $\beta = Q_0/Q_e \sim 1$, for maximum RF power coupling into the cavity. The original design includes many practical considerations in various technical aspects. However, a high-Q cavity sensitively responds to dimensional deviations and external perturbations, which could significantly limit the deflecting performance in a cryostat. In particular, structural variation of the input coupler can significantly influence RF coupling characteristics producing an unevenly distributed field profile. It is thus highly probable that the limited deflecting performance of the 5 cell can be attributed to an off-resonance RF coupling presumably owing to design error, fabrication error, and/or cryo-cooling contraction. In order to completely identify the operational constraints, we thus investigated the cavity design and estimated its performance with a theoretical assessment incorporated with numerical data of RF simulation modeling analysis.

We conclude that the off-resonance coupling leads to a reduction in the kick strength because it more likely perturbs the field distribution, decreasing cell-to-cell field uniformity, rather than directly weakening the field

Copyright © 2013 CC-BY-3.0 and by the respective authors

strength. The accelerating potential vs. radial position and the deflecting force versus the field deviation. Note that the increasing rate of the deflecting field amplitude along the radial distance is noticeably reduced with loss of field uniformity, which is reflected in the deflecting force: kick strength drops down to 2.9 from 3.95 with 40 % non-uniformity (35.6 % reduction). Eventually, one can see that poorly coupled RF power, accompanying perturbation of the field distribution, possibly causes a 30 ~ 40 % deficiency of the deflecting strength.

SIMULATION MODELING

The frequency shift ($TM_{110,\pi}$ mode) due to the effective temperature declination from room temperature (300 K) to LN_2 (80 K) is explained by the uniform change of the cavity volume. The frequency is increased from 3.8725 GHz at 300 K to 3.8870 GHz at 80 K, which corresponds to 68 kHz/K. The simulation analysis estimates that cryo-cooling causes roughly a 24 MHz frequency deviation to the design cavity that would need to be considered in the process of determining cavity dimensions. This approximate analytic assessment is effective for quantifying an average deviation with the assumption that the entire cavity uniformly contracts with a decrease in temperature. However, it does not accurately predict local displacements due to RF-loading impacts over the structure, in particular on the system with fixed points. Moreover, it is limited in accurately implementing localized effects of critical heat sources such as RF loading and beam loading in the cryomodule analysis. Therefore, we extensively investigated RF-thermal characteristics of this 5-cell cryomodule with full 3D thermal and mechanical simulation modeling analysis. More details are discussed in the next section.

Figure 1 depicts the recently designed vacuum-cryomodule containing the 3.9 GHz 5-cell deflecting mode cavity that could be installed at the Fermilab ASTA user's facility. It is designed with the vacuum insulator, instead of the foam insulator. Volumetric contraction and thermal fluctuation resulting from LN_2 cooling is no longer a critical factor since the vacuum insulator tank is an excellent heat reservoir for the LN_2 vessel, which linearly cools the ambient temperature down to 77 – 80 K and maintains it consistently. Instead, it is more critical to consider RF loading and beam loading for CW or high duty operation of high intensity or high power machines. The frequency tuner is similar to the original design except that it is mounted on the vacuum tank with an additional flexible bellows. In this design, the amount of liquid nitrogen is controlled by the N_2 inlet and vent/relief and its level is monitored by the LN_2 level probe. The temperature of the LN_2 vessel remains constant by means of the vacuum insulation tank. However, even in the thermally insulated vacuum system energy of long pulse duration deposits a considerable amount of power on the cavity surfaces that can increase the ambient temperature so highly as to exceed the temperature threshold of bubble formation in the N_2 fluid.

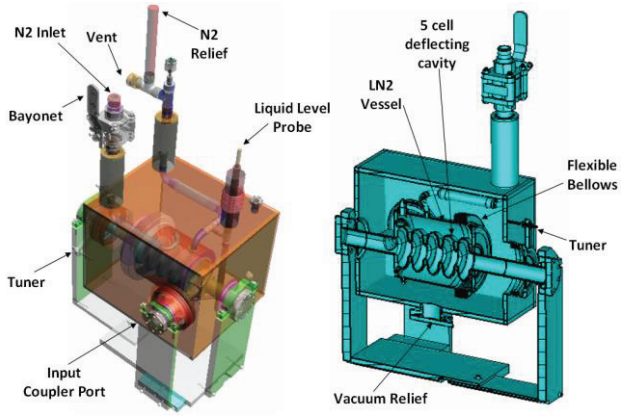

Figure 1: Designed vacuum-cryostat with a 5 cell deflecting mode cavity (a) x-ray image and (b) cross-sectional view

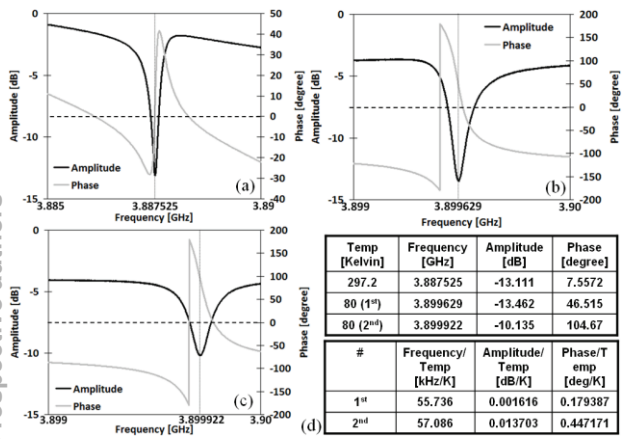
If a deposited power density on the cavity surface exceeds 1 W/cm^2 on average, it is highly probable that the ambient temperature exceeds the LN_2 boiling point (~ 77 – 80 K) so as to rapidly increase gap pressure and create N_2 bubbles that may change the ambient pressure around the cavity in the LN_2 vessel. The excessive fluctuation of vessel pressure could substantially impact cavity performance via frequency change, structural distortion, and even quench on the cavity. Therefore, we simply calculated average power densities deposited on the cavity surface with respect to pulse width and pulse repetition rate (PRR). For the calculation, it is assumed that the cavity receives 70 kW from the klystron and the surface area of the 5 cell is 97.96 cm^2 outside and 89.36 cm^2 inside, respectively. A pulse condition is with less than 1 W/cm^2 RF deposition on the outside and inside cavity surface. Although the calculation is based on the assumption that total RF power is deposited on the cavity surface, it appears that the RF pulse condition (1 ms/5 Hz) of 3.9 GHz deflecting mode cavity planned for the ASTA test facility surely exceeds 1 W/cm^2, which is about 4 W/cm^2 inside and 3.5 W/cm^2 outside. We examined the RF-loading characteristics with a full 3D simulation modeling analysis using an integrated multi-physics computational platform.



Simulations show S_{11} spectra of the original and deformed 5 cell structures, obtained from frequency domain solvers before and after RF-loading of 1 ms pulse to the cavity. The displacement of thermal energy deposition causes 7.32 MHz frequency shift, accompanied with 2.82 dB amplitude change and 59 degree phase deviation, on the $TM_{110,\pi}$ mode, which is beyond the FWHM (full-width-half-maximum) bandwidth of the input signal. The designed system has a thermal sensitivity of 1.32 MHz/K, corresponding to 0.51 dB/K and 10.7 degree/K.

HIGH POWER RF-TEST

The 5 cell cavity in the cryo-vessel, after completely shielded by thermal insulation foams, was tested at room-

(297 K) and LN_2-temperature (80 K). The cold cavity parameters were measured twice after 0 day and 20 days long cooling operations to observe temporal variation of thermal stability. Figure 2 shows S_{11} spectra (amplitude and phase) of the warm and cold cavities and thermal variations of a TM_{110}-mode. It appears that the resonant frequency is up-shifted with ~ 12.1 MHz by the thermal transition from T = 297.2 K to T = 80 K, corresponding to 55.74 kHz/K, under the condition that cavity frequency varies linearly with temperature. The resonant frequency further rose to 3.899922 GHz after 20 days cooling, corresponding to converged thermal frequency variation of ~ 57 kHz/K, which is close to the simulation result, 64 kHz/K. The return loss remains steady at the initial cooling, while it is gradually increased to ~ - 10 dB, corresponding to 0.0137 dB/K. Even the reduction of coupling level will leave the system fairly operational as 90 % of driving power is still coupled in the system. The instantaneous phase deviation is ~ 0.18 degree/K, but it is also gradually increased up to 0.447 degree/K after 20 days cryo-operation. Therefore, the measurement implies that in the early stage of LN_2-operating mode the system can operate with temporal change of < 5 K in terms of amplitude/phase deviation. However, as the vessel loses cooling efficiency with increasing time, acceptable temperature range for the system drops down to < 2 K, which might exceed ambient thermal fluctuation beyond controllable range of the foam-insulated system. For a better thermal management, a cryo-vessel should thus be designed with a vacuum-insulation, which is currently planned with the ASTA 5-cell deflecting mode cavities.

Temp [Kelvin]	Frequency [GHz]	Amplitude [dB]	Phase [degree]

Figure 2: Experimental S_{11}-spectal data of the 5 cell test cavity measured at (a) room temperature (T = 297.2 K), and LN_2-cooled temperature (T = 80 K) (b) 0-day and (c) 20 days after cooling started.

BEAM TEST

A deflecting force of the LN_2-cooled transverse deflecting cavity (TDC) is tested with a beam of p ~ 3.5 MeV/c and bunch length (σ_z) ~ 5 ps. We scanned RF launching phases to extrapolate transverse kick strength, $k = eV_\perp/E\rho$. Figure 3 is the phase-scanned beam position and envelope graphs. The drift distance of the beam monitor measuring a peak-to-peak deflection ~ 17 mm is ~ 1.22 m from the TDC, which corresponds to the deflection voltage of ~ 24.4 kV. The kick strength, k, from the data is calculated to be ~ 0.41 m^{-1}. We will continuously test the cavity to characterize a R_{65} term.

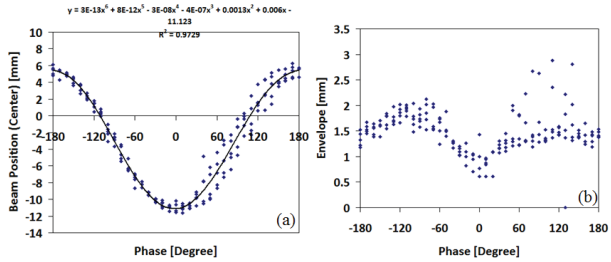

Figure 3: Beam Test result (p ~ 3.5 MeV/c): phase scans of (a) beam center position and (b) envelope.

CONCLUSION

A normal conducting multi-cell deflecting mode cavity has been used for various beam control applications in an LN_2-vessel at the Fermilab A0PI and currently it is planned to accommodate vacuum-cryomodules of either normal conducting or superconducting deflecting mode cavities in the ASTA beam line for higher energy beam tests. Despite successful test results of the previous experiments on 6D phase-space manipulation, the 5-cell cavity demonstrated limited performance. The preliminary high power RF-test and beam test were done and currently systematic optimization of the sensitivity modeling analysis on the deflecting mode vacuum-cryomodule is under consideration in comparison with experimental data.

ACKNOWLEDGMENT

We would like to acknowledge Philippe R. G. Piot for the support of the experiment. We also thank James Santucci, Jerry M. Makara, and Christopher Prokop for the technical support of the system setup for the experiment.

RF GUN WATER TEMPERATURE CONTROL SYSTEM AT ASTA *

P. Stabile#, M. Ball, J. Czajkowski, J. Firebaugh, P. Kasley, P.S. Prieto, T. Zuchnik,
Fermilab, Batavia, IL, 60510, USA

Abstract

A linear electron accelerator is in the late stage of construction at the Advanced Superconducting Test Accelerator (ASTA) facility at Fermilab. The purpose of this accelerator is to operate, study and develop the superconducting cavities and associated systems to be used in future superconducting accelerators. ASTA incorporates an L-band radiofrequency (RF) gun with a coaxial RF input operation at 1.3GHz, based on 1+1/2 cell DESY-type gun, followed by two superconducting cavities. A temperature control system regulates the RF power transmission between 5MW Klystron and the RF Gun. Its role is to maintain the resonant frequency by exploiting the 16.5ppm/ºC thermal expansion of the copper. Temperature is regulated by mixing chilled low conductivity water (LCW) with circulating water between the cavity and gun skid located outside the radiation cave. A fine pneumatic actuated valve controls the chilled water flow and in turn is controlled by a feedforward/feedback regulation algorithm. This paper will describe the water temperature control system used to stabilize the tuning frequency of the RF Gun.

INTRODUCTION

Fermilab is constructing ASTA at the existing New Muon Lab (NML) building. ASTA is part of Fermilab new state-of-the-art superconducting radio frequency (SRF) test facility complex. ASTA facility [1] consists of a shielding cave which houses the accelerator, as well as areas for support equipment and systems required for operation. The accelerator consists of three distinct sections: the injector, SRF accelerator, and the test beam lines including space for a small storage ring. The injector is a 1.3GHz photocathode electron RF gun which generates electron bunches repeated at 3MHz within a macro pulse of nominal duration of 1ms [2, 3].

The RF power to the gun is supplied by a 5MW, 1.3GHz klystron. The temperature control loop stabilizes the temperature of the RF Gun when RF power is applied and also during no RF power cycles.

The temperature control loop regulates the water temperature to ±0.18 ºC which, at a centre frequency of 1.3GHz, keeps the frequency shift of the Gun, within 5KHz (23KHz/ ºC). A 5KHz shift corresponds to a reflected power less than –22dB.

SYSTEM DESCRIPTION

The task of the cooling system is to mix the outgoing warm water with the supply LCW water regulating the desired temperature of the circulating water. Figure 1 shows the piping schematic of the RF gun cooling system. The cooling skid is located outside the radiation shielding and water is pumped through approximately 80 feet of piping. A PLC is integrated into the cooling skid to read back the temperature and flow measured by the different sensors and to control the flow rate of the LCW. The temperature of the LCW supply is stabilized to 90±1ºF (~32.22 ±0.5ºC) by an external control system running on an independent PLC. The amount of the incoming supply LCW is controlled by a fine pneumatic valve that allows a flow rate between 0 and 15GPM. The position of the valve is controlled by a dedicated PID loop build into the valve controller.

A heater is used to mix the LCW cold water and the warm water from the RF Gun and can supply between 0 and 12KW of power. The mixed water flows to the gun at a fixed rate of 15 GPM through nine cooling channels, seven with 10mm ID and two with 6mm ID tubing connections, cooling down the cavity. The return water from the gun is split between the heater and a return connection to the main chiller system.

SYSTEM MODELING

An appropriate model of the system was first made. The RF Gun cooling can be divided into a combination of two subsystems:

- Heater
- RF Gun

Heater

The heater has a fixed volume tank completely filled with almost 1.5 gallons of water. The LCW (m_1) is mixed with the return water from the gun (m_3). The output water (m_2) from the heater flows at constant rate to the gun and removes the necessary amount heat from the cavity.

The water temperature from the heater to the Gun has to be stable; avoiding fluctuations in temperature reduces power reflections from the gun.

The heater can be modeled as a mixing tank with two inputs and one output. The differential equations describing it are:

$$M_\sigma \frac{dT_{02}}{dt} c_p + m_3 T_{02} c_p = m_1 T_{01} c_p + m_2 T_{06} c_p + HPWR\,, \quad (1)$$

$$\frac{dV}{dt} = m_1 + m_2 - m_3\,, \quad (2)$$

where:

- M_σ = volume of water of the heater (US GALLONS)
- m_1 = LCW water flow rate (GPM)
- m_2 = Return flow rate from the gun (GPM)
- m_3 = Output flow rate from the heater (GPM)
- HPWR = Heater power (KW)
- c_p = Specific heat capacity of the water at constant pressure(J/g* ºC)
- T_{02} = water temperature at the output of the heater (ºC)
- T_{06} = return water temperature from the gun (ºC)
- T_{02} = supply water temperature (ºC)
- V = heater water volume (US GALLONS).

The total water flow in the Gun is constant and the time constant of the system is:

$$\tau = M_\sigma / m_3\,, \quad (3)$$

which is equal to 5.96 sec. The steady state point can be calculated using:

$$T_{02} = T_{01}\frac{m_1}{m_3} + T_{06}\frac{m_2}{m_3} + \frac{HPWR}{c_p m_3} \quad (4)$$

RF Gun

A cavity constructed of a single metal has as percent change in wavelength equals the percent change in linear dimension which is proportional to temperature. Frequency de-tuning of the cavity caused by expansion and deformation of the copper causes an increase of the reflected power and RF phase instability. If the frequency deviates from the drive frequency, the power reflected from the cavity will cause standing waves within the waveguide.

The thermal expansion of the copper is about 17.68ppm/ºC (1ppm/ºC more from the one expected) resulting in a 23KHz frequency shift per degree Celsius.

As a first approximation the cavity can be considered as a tank with water flowing through it that maintains a constant volume [4]. Assuming that the inlet water instantaneously and completely mixes into the volume, the thermal mass C will be at the outlet temperature T_{OUT}. The change in outlet temperature will be equal to the net power flowing into the volume divided by its thermal capacitance.

The following differential equation describes the system:

$$\frac{dTout}{dt} = \frac{P_{r\,f}}{C} + \frac{F}{AC}(Tin - Tout)\,. \quad (5)$$

The time constant is:

$$\tau = F / AC\,, \quad (6)$$

which depends on the set flow rate of the chilled water. The steady state point can be calculated:

$$Tout = \frac{A P_{r\,f}}{F} + Tin\,, \quad (7)$$

where:

- P_{rf} = Average RF power injected to the gun (KW)
- F = Flow rate of the chilled water (GPM)
- C = Heat capacity of the water(KJ/ ºC)
- A = Heat factor (ºC*GPM/KW)

IMPLEMENTATION

A combined feedforward/feedback control system has been implemented to improve performance over a simple feedback control (Figure 2).

When a step in the RF power or in the temperature set-point occurs, the feedforward algorithm calculates and sets the new LCW flow rate as a function of temperature variation of the cavity per unit of flow (ºC/GPM) and per unit of power (ºC/KW). The algorithm uses the initial conditions of the system (T_{CAV}, T_{SET}, T_{LCW}, T_{IN}, RF_{Power}) and the final steady state point calculates the new flow set-point. The controller take into consideration the effects of pure time delay due to pipe lengths and also the changes taking place in the return water flow temperature.

Copyright © 2013 CC-BY-3.0 and by the respective authors

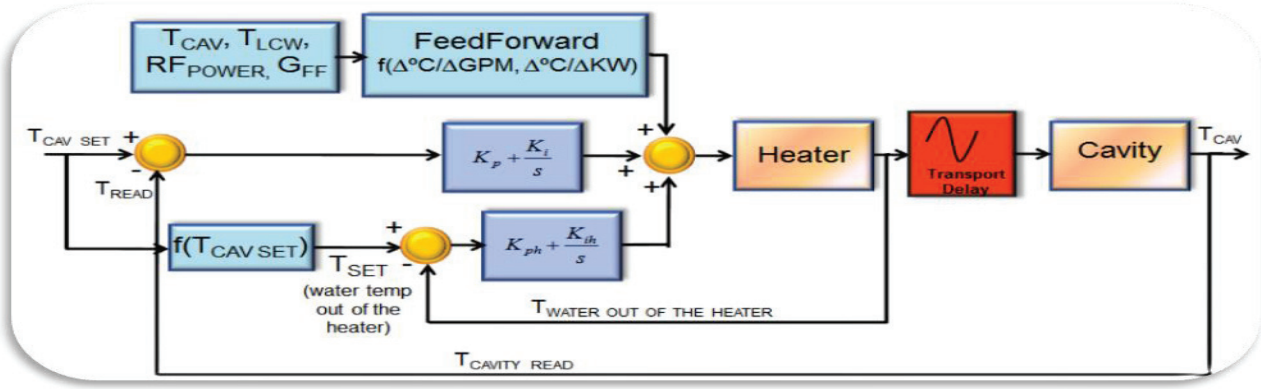

Figure 2: Feedforward/feedback block diagram.

The chilled water takes almost 40 sec. to reach the cavity enclosure, then an additional 20 sec. is required to reach the cavity.

The feedforward is an open loop response, therefore the controller needs to observe the effect of the feedforward loop on the gun temperature before closing the loop with the feedback loop. Once the steady state has been reached within ±0.24 ºC, the feedback suppresses the steady state error.

The cavity feedback was implemented as a proportional and an integral controller with a closed loop bandwidth of ω_{CL}=Kp(Tin- Tout)/AC ~0.005Hz. This makes the feedforward critical for improving the bandwidth of the controller. A conservative design has 45º phase margin.

The Ki/Kp gain ratios in the cavity feedback loop were chosen in order to minimize the overshoot of the system and meet the target phase margin. The water travel time is a "pure delay" that adds 100º to the total phase shift and can be overcame by the feedforward.

An inner feedback control loop has been added to the controller to stabilize the water temperature coming from the heater and it is still in the first stages of development.

This inner feedback loop doesn't have the pipe transport delay therefore its bandwidth is higher than the cavity loop.

RESULTS

The RF Gun is in final stages of conditioning and first electron beam has been produced.

Figure 3 shows the temperature control obtained with a constant power applied to the RF Gun. The temperature set-point is 42.1ºC and the peak RF Power is 1.7MW with a pulse rate of 1Hz and a pulse width of 800µsec. The orange trace is the cavity temperature. The data collected shows that the cavity temperature can be stabilized in a range of 42.1 ±0.18 ºC.

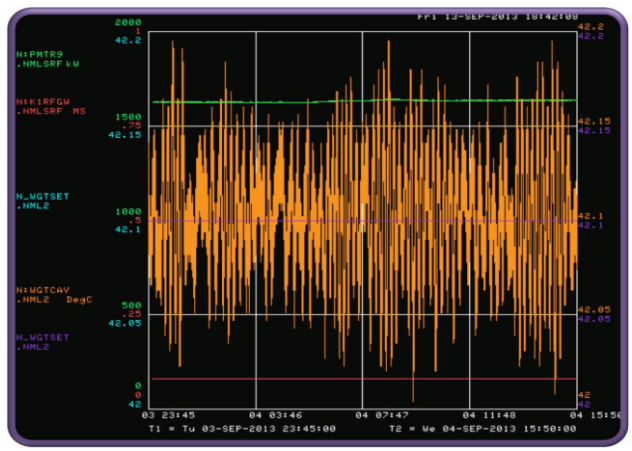

Figure 3: Cavity Temperature control with no RF power.

Abstract

The Idaho Accelerator Center (IAC) of Idaho State University has been operating a 44 MeV L-band linac for high average power THz generation, various nuclear physic related applications, medical isotope generation, and Laser Compton Scattering (LCS) based X-ray generation [1]. As of August 2012, the IAC has been upgrading the 44 MeV linac with a new computer based EPICS accelerator control system to replace the old analog control system. So far, this upgrade includes control of two GigE CCD cameras, and several magnet power supplies with embedded IEEE controllers [2]. However, the 44 MeV linac also has some magnet power supplies which are controlled with external RSTL controllers. This paper describes the development of the EPICS accelerator control system to control Lambda EMS and TCR magnet power supplies with these external RSTL controllers.

INTRODUCTION

To improve the reproducibility and stability of the 44 MeV linac, the previous analog control system was upgraded to a computer based control system. The control system chosen for this upgrade was the Experimental Physics and Industrial Control System (EPICS). As of August 2012, this upgrade included a control system for 2 Prosilica GigE CCD cameras, 32 TDK-Lambda ZUP power supplies, and 15 Lambda EMS power supplies with embedded controllers [2]. However, the 44 MeV linac also contains 3 Lambda EMS power supplies and one Lambda TCR power supply with external RSTL controllers. Figure 1 shows half of the control system for the magnet power supplies including Lambda EMS power supplies with embedded controllers, Lambda EMS with the external RSTL controllers, and a solitary Lambda TCR power supply with an external RSTL controller [3,4][1]. This paper describes how the control of these magnet power supplies with external RSTL controllers was accomplished. The full description of the EPICS accelerator control system for the 44 MeV linac will be published at another conference [5]. As shown in Fig. 1, the EMS power supplies and TCR power supplies were connected to their own dedicated MOXA terminal server with RS485-RS232 conversion interfaces [6]. Then, the terminal server was connected to the EPICS server via an isolated network using an Ethernet cable and a 3Com network switching hub. After that, a means to communicate with the power supplies was developed by using two EPICS modules (ASYN and StreamDevice) supplied with the synApps package [2]. Then, device support applications were manually programmed for the power supplies, and the current was controlled by manipulating process variables (PVs) using MEDM Operator Interface (OPI) panels.

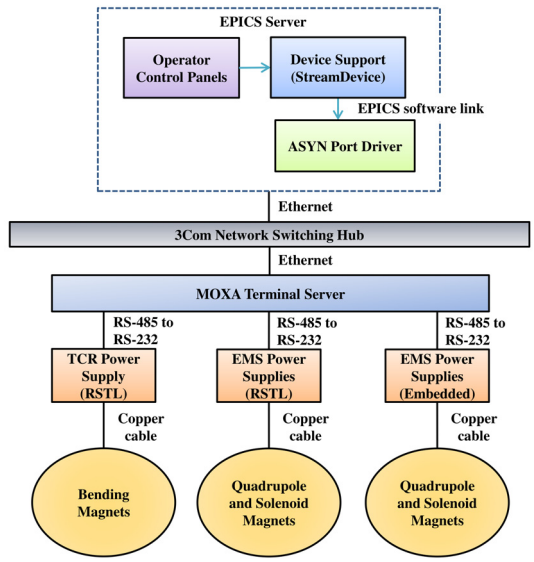

Figure 1: Experimental setup of EPICS server and hardware for the IAC 44 MeV linac.

HARDWARE CONFIGURATION

Before creating the PVs, the RSTL controllers had to be configured to work with the Lambda EMS and Lambda TCR power supplies. For the Lambda EMS power supplies, it was just a matter of following the connection diagram for the RSTL to TB1 connector in the manual [7]. However, the interface from the RSTL to the Lambda TCR power supply took some additional configuration for the RSTL. Since the RSTL was rated for a 40 V power supply and the Lambda TCR was a 160 V power supply, the first configuration detail was to add a couple resistors to the RSTL board. This was done to create a voltage divider and reduce the high voltage from the Lambda TCR to a level

* Mail: andranth@isu.edu

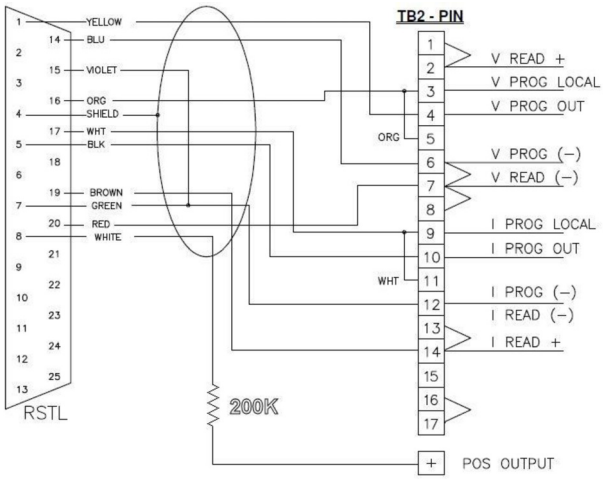

Figure 2: Connection diagram for cable going from RSTL to TB2 connector on Lambda TCR power supply [8].

that would not damage the analog to digital converter chip in the RSTL. After this, a 25 pin cable, which came with the RSTL, had to be connected from the RSTL to the TB2 connector as shown in Fig. 2 [8]. There was a 200 kΩ resistor added in series from the positive output busbar on the Lambda TCR to pin 8 on the RSTL 25 pin connector. This was done to reduce the voltage load on the 25 pin connector to within it's specifications. To complete the hardware configuration, the Lambda TCR power supply had to be calibrated to ensure that the current readback would follow the EPICS programmed current value as close as possible [7].

DEVICE SUPPORT APPLICATIONS

After the hardware configuration and calibration, the next step was to turn off the "echo" setting of the external RSTL controller. Then make a device support application containing the files to create PVs. The device communication was accomplished by installing the synApps software package including ASYN and StreamDevice [2].

Application Creation for Power Supplies

The creation of PVs for both types of power supplies was almost the same because they both use external RSTL controllers. To create the application, the following commands were used [2]:

- makeSupport.pl -t streamSCPI TCR_
- makeSupport.pl -t streamSCPI EMS_
- makeBaseApp.pl -t ioc EMS_and_TCR
- makeBaseApp.pl -t ioc -i EMS_and_TCR

The first two commands create support directories for the Lambda EMS and Lambda TCR power supplies. These support directories contain the files to create PVs. The third command creates a configure and an application directory. The fourth command creates an iocBoot directory, which contains the *st.cmd* file [2]. The "EMS_and_TCR" are arbitrary names for the application directory and the directory under iocBoot containing the *st.cmd* file.

Protocol Files

The module StreamDevice uses protocol files to translate commands that follow the SCPI (Standard Commands for Programmable Instruments) standard into a format that EPICS records can use [2]. For example, the SCPI command to measure the current (MC) from the RSTL manual looks like this [7]:

- getC{out "MC"; in "%6f"; in "";}

In this case, getC is a protocol, which sends the command MC "out" to the device and gets a response "in" from the device. The RSTL sends back two "in" responses, the first is a number with six floating digits, and the second is just a blank line that follows a command sent to and from the RSTL. The blank line serves as a form of confirmation that the RSTL received a command from the user. The other key component for making a PV is a record in a database file. [2]

Database File

The database files are where the records are located. The PVs are made by putting the protocol name (i.e. getC) into the input or output fields in the record [2]. Here is an example of a record to read the current:

```
record( ai, "$(P):90A_BENDS:curr_r") {
  field( DESC, "Readback Current")
  field( DTYP, "stream")
  field( INP, "@TCR.proto getC $(PORT19) $(A)")
  field( PREC, "3")
  field( EGU, "Amps")
  field( HOPR, "65")
  field( LOPR, "0")}
```

In this case, the only difference between the Lambda EMS and the Lambda TCR is the definition of the High Operational Range (HOPR) of the current. For the Lambda EMS this is 30 A and for the Lambda TCR it's 65 A. In the record above, a field of particular interest is the INP field. This field sends the command defined as the protocol "getC" located in the protocol file "TCR.proto" to the port and address of the device. The $(PORT19), $(A), and $(P) are all defined in the *st.cmd* file.

st.cmd File

This is an executable file that creates a channel between the RSTL and EPICS by using an IP address, a portName, and an address. This file also loads all of the records that are in the database files. An IP address is specified by entering the following line in the *st.cmd* file:

[2]For more protocol file information and more on SCPI commands, see reference [2].

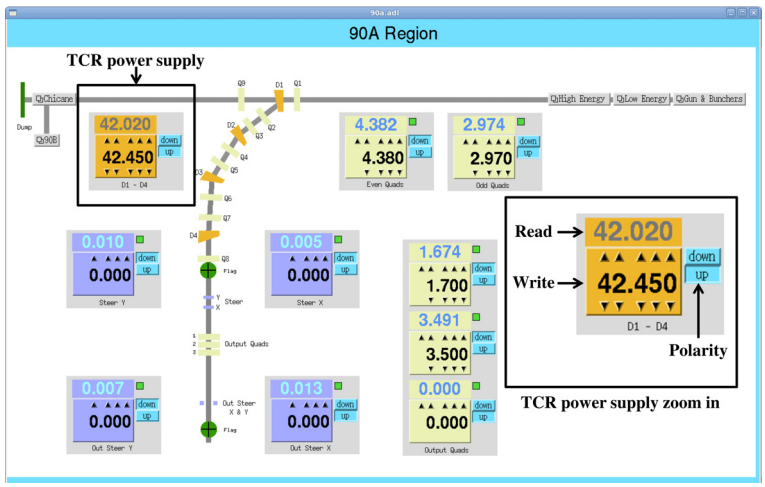

Figure 3: An MEDM OPI pannel to control and read the current of the magnet power supplies for the 44 MeV linac.

drvAsynIPPortConfigure("P19","134.50.x.y:4019",0,0,0)

Here P19 is a portName, which is an arbitrary identifier used to define $(PORT19) from records as an IP address (134.50.x.y) and a port (4019) on the MOXA terminal server [2]. In this case, P19 was used because this particular power supply was connected to the nineteenth port of the MOXA terminal server. The rest (0,0,0) specifies *priority, noAutoConnect,* and *noProcessEos* [2]. To specify a database in the *st.cmd* file, a line similar to the following was used:

dbLoadRecords("db/A.db","P=$(P),PORT19=P19,A=19")

Here the A.db is the database file that contains all of the needed records to control the power supply. The macro P is used as a linac identifier, in this case P is 44MeV. The PORT19 is the same as the portName. The address (A=19) for this set-up ran from 1 - 32, because there were 32 ports on each MOXA terminal server [2].

MEDM DISPLAY

Motif Editor and Display Manager (MEDM) is an EPICS extension which provides a way to create simple OPI's like the one shown in Fig. 3. This display contains a representation of the linac with the magnets being controlled. The circled box controls the TCR power supply, which controls all dipole magnets in this region of the linac. The operator changes the set (Write) current PV by clicking the black arrows or by typing a value manually. The actual readback value from the power supply is displayed in the box above write. Since all the power supplies are unipolar, the direction of the current has to be changed with external circuitry. The "Polarity" on the display gives the operator an indication of the direction of the current.[3]

[3]The other control widgets on this display are for embedded controlled power supplies, see reference [2].

CONCLUSION

The goal of this part of the 44 MeV control system upgrade was to control old Lambda EMS and TCR magnet power supplies with external RSTL controllers using EPICS. This was accomplished by using ASYN and StreamDevice to create a communication channel between EPICS and the power supplies, and then convert SCPI commands into PVs. Afterwards, MEDM OPIs were developed to control and monitor those PVs. The addition of the control system for these older magnet power supplies almost completes the EPICS upgrade for the 44 MeV linac, the rest of the control system with save/restore functionality will be described in the next conference paper [5].

ACKNOWLEDGMENTS

I would like to thank Jeff Bush, the technical group leader at TDK-Lambda Inc., for all of his help and advice in configuring the RSTL through email correspondence. I would also like to thank Dr. Kukhee Kim, Dr. Debbie Rogind, and Dr. Ernest Williams for teaching me a lot about developing EPICS device support applications through summer internships at SLAC national lab from 2011 to 2013.

PROGRESS REPORT OF H⁻ ION BEAM PRODUCTION AT THE LANL ION SOURCE TEST STAND*

I.N. Draganić#, Y.K. Batygin, C.M. Fortgang, R. W. Garnett, J. Gioia, S. S. Kurennoy, R. C. McCrady, J. F. O'Hara, G. Rouleau, L. Rybarcyk, LANL, Los Alamos, NM 87545, USA

Abstract

As part of the Los Alamos Neutron Science Center (LANSCE) the Ion Source Test Stand (ISTS) is a flexible, stand-alone facility used for H⁻ ion beam source development and studies of low energy beam transport. It consists of a surface converter ion source with a multi-cusp permanent-magnet plasma confinement structure, an 80-kV high-voltage electrostatic extraction column, a low-energy ion beam transport line, and beam phase-space diagnostics. After resolving several technical issues, the ISTS was successfully restarted during the summer of 2012. Since then we have performed several long duration experiments. A development program is ongoing with the goals of improving source performance (e.g. reliability, availability, increased current, etc.) and beam transport efficiency (beam neutralization at low energy, beam dynamics with/without noble gas injection, etc.). Several enhancements to performance are being investigated in order to achieve a forthcoming upgrade requirement of LANSCE operations in 2014: beam current of 16-18 mA, 120-Hz operation at a duty factor of 10% and a source lifetime of greater than 28 days. We present a short description of the ISTS apparatus, obtained results and forthcoming experiments.

H⁻ ION SOURCE TEST STAND

The ion source test stand (ISTS) (Figure 1) was developed to perform H⁻ beam research in support of operation of H⁻ source of LANSCE user facility [1, 2]. It is a replica of the 80 keV injector in the H⁻ dome of LANSCE which is used to accelerate beam to 750 keV using a Cockcroft-Walton high-voltage generator. The ion beam optics consists of a four electrode electrostatic accelerating column (Pierce electrode -80 kV, extraction electrode -67 kV, column electrode -27 kV and grounded electrode), two focusing solenoid magnets separated by a distance of 1.9 m, two emittance measurement stations (IDEM02 and IDEM03), an electrostatic beam deflector, and a 4° bending magnet to separate H⁻ beam from electrons (see Fig 1). Beam current is measured by a calibrated current monitor and Faraday cup. The beam line is equipped with a residual gas analyzer (RGA) to characterize outgassing processes and a noble gas injection subsystem (Ar, Xe, etc.).

The first long ISTS run (over four weeks) was successfully performed during August and September 2012. The H⁻ ion beam was extracted in the range of 10 to 14 mA using a pulsed source gate of 835μs with repetition rate of 120 Hz (or ion source duty factor of 0.102).

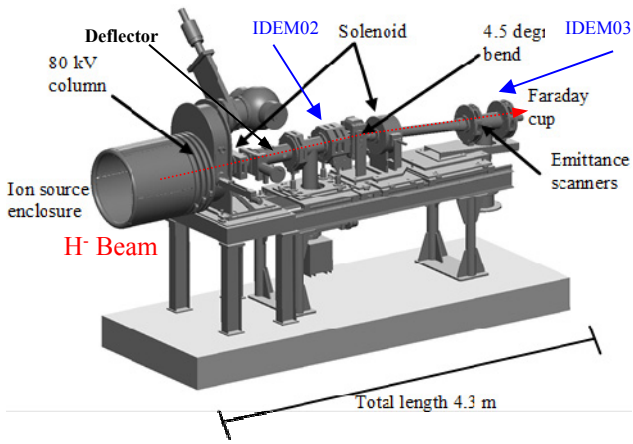

Figure 1: Schematic layout of the H⁻ ion source test stand.

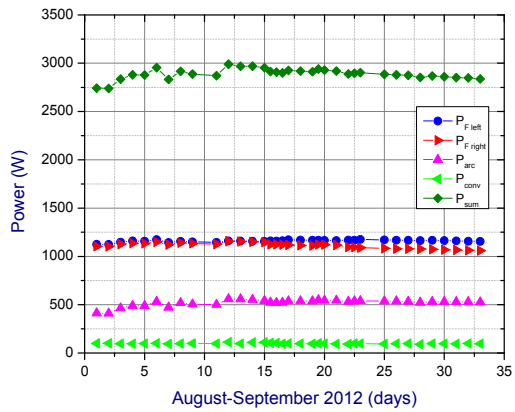

Figure 2: Source of power losses in the H⁻ ion source includes thermal dissipation of the two filaments, arc discharge and converter electrode loses at 120 Hz.

A set of standard operational parameters for the ISTS set were applied to achieve a nominal working regime for the ion source and beam transport at low energy of 80 KeV. The thermal power distribution is shown in Fig. 2. The total source power was less than 3 kW. The tungsten filament relative differential resistances were recorded during the entire run cycle as a diagnostic tool for the source lifetime. First preliminary data of the filament differential resistance of ~8.0% presented in Fig. 3 indicates that the a typical LANSCE H^- ion source will be able to last over 28 days at a high duty factor (0.102). In fact, the differential resistances of both filaments after 33 days did not exceed an empirical criterion for catastrophic failure of 12 % total increase in filaments resistance for this type of H^- surface converter ion source. Comprehensive tests of ion source reliability in "production like" operation conditions are underway. Detailed analysis of the source lifetime and filament differential resistance is described in Ref. [3]. The ISTS was used to produce a lower H^- ion beam at 35 keV in order to study H^- beam neutralization effects for the first time. Some recent results are described below.

SPACE-CHARGE NEUTRALIZATION STUDY

Beam emittance scans were performed using the IDEM02 and IDEM03 beam emittance stations. A typical emitance scan using the standard slit-and-collector emittance-measurement system is presented in Fig. 4. During beam measurements, the electrostatic deflector pulse was kept constant at a repetition rate of 4 Hz and pulse length of 625 μs, while emittance measurements were sampled within a 50 μs gate with variable delay of τ = 10 - 580 μs with respect to the beginning of the deflector pulse, reproducing different values of beam pulse at both stations. All measurements were performed at standard working vacuum pressure of $1.6 \cdot 10^{-6}$ Torr. The H^- beam intensity was 9.3 mA for beam energy of 80 keV. The purpose of this experiment was to determine the level of beam space charge neutralization as a fuction of tme in the beam pelse. Figures 5 and 6 show the variation of beam parameters versus beam pulse. The beam parameter values of are stabilized after 100 - 150 μs.

Determination of the level of compensated space charge was done through comparison of results of measurements and simulation. These results indicate that 100% neutralization is achieved after 120 μs for a beam energy of 80 keV, while the same level of neutralization is achieved after 200 μs with a beam energy of 35 keV achieves. The beam neutralization results are described in detail in Ref. [4].

HIGH CONVERTER VOLTAGE EXPERIMENTS

The extracted H^- beam current was tuned by adjusting converter voltage in the range from 220 to 500 V for a discharge current of 26 A. For each point a corresponding cesium oven temperature (200 to 240 C) was allowed to stabilize over several hours (3-4 hours per point) to get

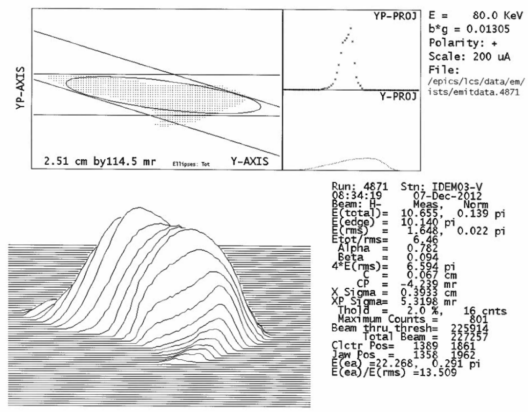

Figure 4: Characteristic transverse phase space data (H^- beam vertical emittance scan recorded using IDM03).

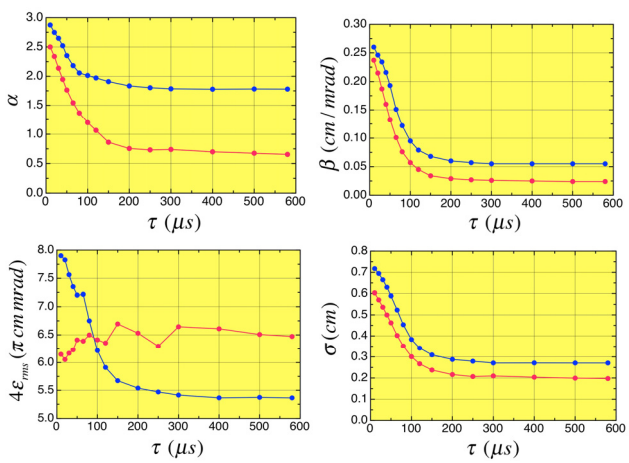

Figure 6: Parameters of 80 keV beam parameters at IDEM03: (blue) horizontal, (red) vertical.

the maximum output current. Optimal converter voltage increases with increasing cesium oven temperature (see Fig. 7A). Similar temperature dependence was measured and discussed in the previous ISTS work described in Ref.

Copyright © 2013 CC-BY-3.0 and by the respective authors

[5]. We have observed H- beam current increases up to 30 % with elevated converter voltage (Fig. 7B). The new results are in agreement with theoretical models, but different from results recorded before at the ISTS [5]. Previous beam intensity measurements were independent of high converter voltage and emittance measurements were not taken. In our set of measurements we were able to record emittance scans using both EM stations. Transverse emittance dependence on elevated converter voltage is shown in Fig 8A. Total emittance values are constant over the converter voltage range of 250 to 450 V, except for IDEM02 scans in vertical direction. 7 to 11 π-cm-mrad, 4-rms emittance increase in the vertical direction was measured on the second station. Beam brightness was constant for the whole range of high voltage (see Fig 8. B). We plan to repeat the same measurements with extracted beam over the beam current range of 16 -18 mA (production level for LANSCE) and converter voltages up to 600 V. We expect to see an increase of H- beam currents up to 21 - 23 mA. We hope that the new experiments will resolve disagreements between different experimental results and theoretical models for the formation of H- ions on the surface of negatively biased electrode (converter).

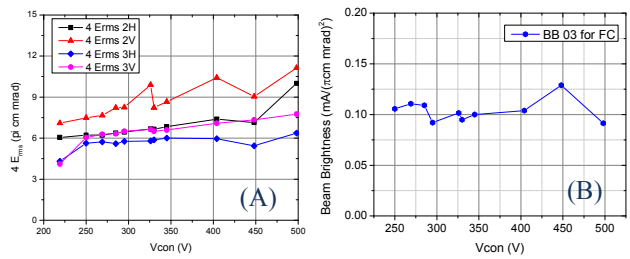

Figure 8: (A) Emittance measurements performed at IDEM02 and IDEM03 stations as a function of elevated converter voltage. (B) H- beam brightness as a function of converter voltage.

ISTS DEVELOPMENTS PLAN

The H- ion beam development plan for better performance consists of 28 different proposals. They are compatible with a previously described development plan for the ISTS [6]. The plan includes some of the following proposals:

- Improvement by elevating source body temperature by reduction the water flow in the source body/ side plates cooling loops or increasing input water temperature.
- Optimizing converter geometry and position.
- Modification of the converter electrode water cooling channels for more uniform current density production over the electrode surface.
- Addition of an inner hot liner (screen) for better control over Cs coverage of the converter and reduction in Cs dissipation.
- Installation of a third filament for higher discharge currents, plasma density and enhanced production of H- beam.
- Investigation of thicker filament diameters for increased electron emission area, higher discharge current and higher extraction of negative ion beams.
- AC versus DC voltage driven filament heating for prolongation of source lifetime and higher extracted beam currents.
- Continued space charge neutralization experiments: 80 keV/35 keV H- beam transport at different values of beam pulse length, different vacuum pressures, and different residual gases (by injection of heavy noble gases Ar, Kr, Xe into transport beam line).

These development efforts are expected to enhance performance of the LANSCE surface converter ion source in the long term. Upcoming, near-term ISTS experiments will focus on demonstrating reliable 120 HZ source operations for >28 days in support of 2014 LANSCE operation requirements.

ACKNOWLEDGEMENT

The authors are thankful to James Stelzer, Nathan Okamoto, and Jerry Paul for help in processing and preparation of the ion sources used for this study.

A SPECIALIZED MEBT DESIGN FOR THE LANSCE H+ RFQ UPGRADE PROJECT*

C. Fortgang#, Y. Batygin, R. Garnett, S. Kurennoy, L. Rybarcyk, LANL, Los Alamos, NM USA

Abstract

The LANSCE accelerator operates with both H^+ and H^- ions. Presently, each species has its own 750-keV Cockcroft-Walton (CW) and an initial transport line. The two transport lines merge into a common transport after which both species are injected into the 201.25-MHz DTL. The H^+ CW will be replaced with a 4-rod RFQ that is now in final design. Because of the complication of accommodating two beam species, the MEBT for the RFQ beam is much longer than usual. The length of the MEBT for the H+ beam, and a requirement to merge it with the existing common transport, present new and unique challenges for the MEBT design. In particular, multiple ¼-wave bunchers in addition to the existing final buncher upstream of the DTL are necessary to minimize phase spread of the RFQ output beam for DTL injection. Estimates of emittance growth, matching into the DTL over a range of H^+ beam currents, and simulations through the first two DTL tanks are presented.

INTRODUCTION

The LANSCE accelerator presently has 2 CWs for H^+ and H^- operation. The plan is to replace the H^+ CW with a 750-keV 4-rod RFQ being designed by IAP (Frankfurt) and Kress GmbH (with LANL input) and fabricated by Kress. The design of the RFQ transport line is complicated by the fact that it has to merge with the H^- transport line. The RFQ specifications that are relevant to the MEBT design are: RF frequency = 201.25 MHz, beam energy = 750 keV, RFQ maximum output emittance (rms, norm.) = 0.023 π cm-mrad, and maximum input current = 35 mA. The goals for the MEBT physics design are to minimize beam loss and emittance growth while maintaining the longitudinal bunching produced by the RFQ, under the constraint that the common transport for the 2 species not be modified. A discussion of the overall LANSCE RFQ project is given in [1].

PHYSICS DESIGN

Figure 1 shows the beam envelope and phase spread for the $5\varepsilon_{rms}$ beam from a TRACE-3D [2] simulation.

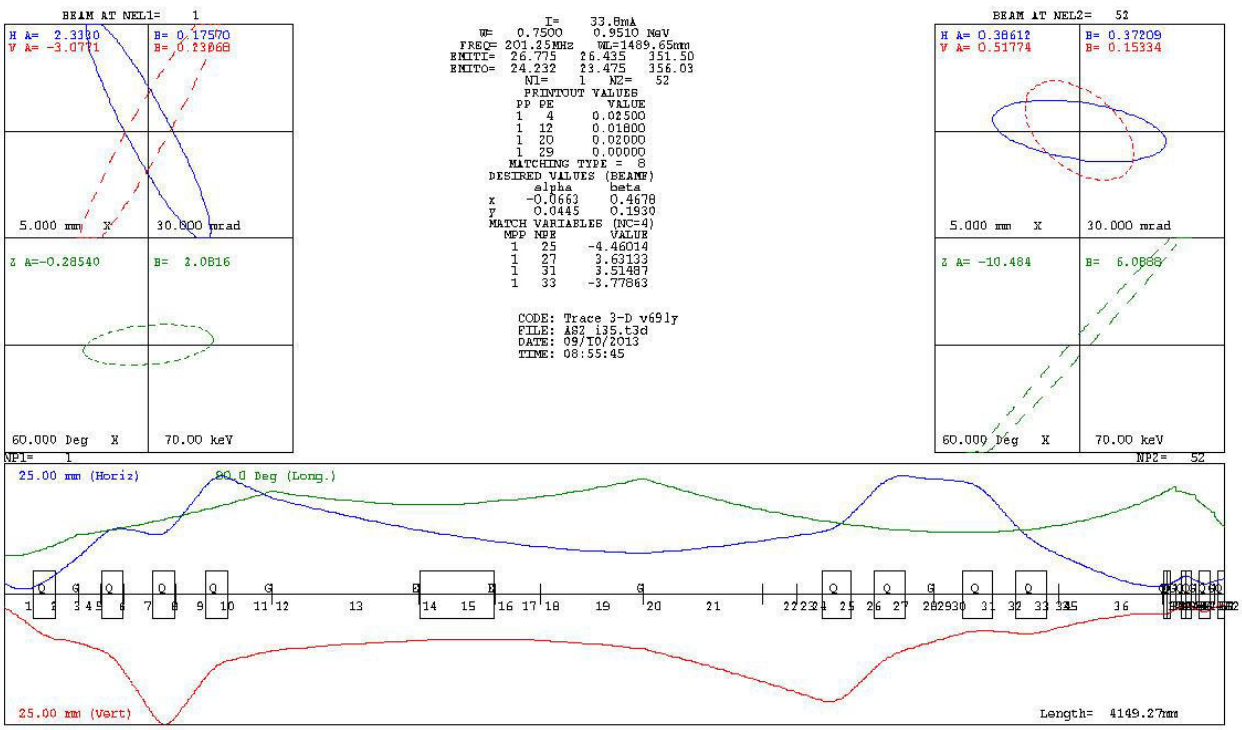

Figure 1: TRACE3D beam envelope for the $5\varepsilon_{rms}$ beam in the MEBT for ~34 mA.

*Work Supported by USDOE DE-AC52-06NA25396
cfortgang@lanl.gov

The total length of the MEBT, 4.15 m, is much longer than would normally be desired. Figure 2 shows the present layout of the 2 transport lines and their merger before injection into the DTL.

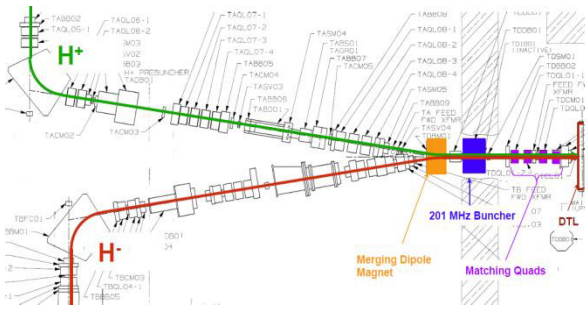

Figure 2: Present H^+/H^- CW injector layout.

The input beam for the TRACE simulation uses the output beam Twiss parameters from a PARMTEQM [3] RFQ simulation. The beam current is 33.8 mA at 750 keV. The rms normalized transverse emittance is 0.021 π cm-mrad and longitudinal rms emittance is 0.07 π MeV-deg. The RFQ beam is transported to the existing 9° bending magnet (element 15 in Fig. 1) using 4 quads and 2 quarter-wave bunching cavities [4]. We chose these cavities because they are compact. They require about 3 kW of RF peak power for 25 kV of cavity voltage. The 9° bending magnet is where the 2 species merge. Everything downstream of the bending magnet currently exists and will not be physically modified. Part of the design process is to have the beam small in the main buncher (MB) cavity (element 20) to manage the emittance growth due to non-linear RF fields. However, we found that if we insist on a waist in both transverse planes at the MB then there is too much beam loss due to scraping elsewhere in the MEBT. The asymmetric position of the waists allows us to have an acceptable beam size in the MB and at the same time minimizes the maximum beam size elsewhere. The first 4 quadrupole magnets are used to position the waists and the last 4 quadrupole magnets match the beam transversely into the DTL. Careful inspection of Fig. 1 shows that there is room for a 4th buncher in the middle of the last 4 quads but it has been decided not to use that space for a buncher because of our constraint to leave the existing common transport unmodified. The design as shown does not have a deflector for beam gating. In order to save on space we decided to put the deflector in the LEBT, upstream of the RFQ. The drift space just upstream of the bending magnet is not available for hardware because that is where the 2 merging beam lines come so close together that there is no available room transversely.

Longitudinal matching of the RFQ beam into the DTL is more challenging than the transverse match. The reasons are the long distant required to transport the beam and the limited allocation of beam line space for bunchers. Without space charge the longitudinal envelope equation for a drift can be integrated twice for the beam size. The result is,

$$\varphi(z) = z_o \left[(1+ z_o' \, z/z_o)^2 + (\varepsilon_z \; z / z_o^2)^2 \right]^{0.5} \; 360/(\beta\lambda) \quad (1)$$

where φ(z) is the beam size in degrees, z_o and z_o' are the initial longitudinal beam size and divergence, ε_z is 5 times the rms longitudinal emittance, β=v/c, and λ is the RF wavelength. If we consider the drift following a buncher, then z_o is the longitudinal beam size at the buncher and $z_o' < 0$ is proportional to the buncher cavity voltage. If we differentiate (1) and solve for the position of the waist following a buncher we obtain,

$$z_{waist} = |z_o'| \, z_o / (z_o'^2 + \varepsilon_z^2/z_o^2) \quad (2)$$

Examination of (2) shows that for a given z_o and ε_z there is a maximum value for z_{waist} with z_o' being an independent parameter. This can also be seen in Figure 3 where (1) is plotted for 6 different buncher focusing strengths. The black line connects the waist positions (circles) for each case. For this example the farthest distance from the buncher where the beam is at a longitudinal focus is ~550 mm (magenta waist).

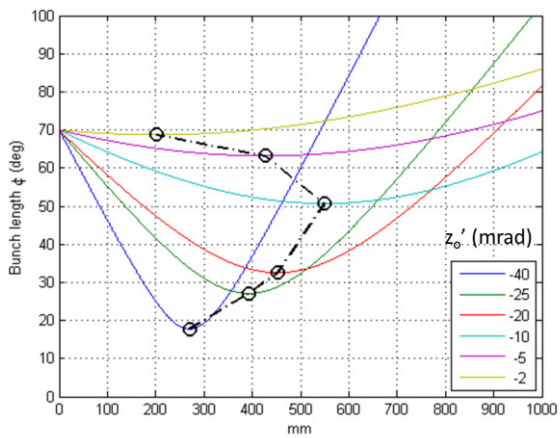

Figure 3: Bunch length downstream of a buncher cavity for 6 different focusing strengths. There is a limit to how far downstream the waist can be positioned.

The drift between the MB and the DTL entrance is larger than the farthest possible waist position downstream from the MB. Therefore, the beam cannot be focused to the proper size longitudinally at the DTL entrance using the MB and so the longitudinal match is less than ideal. However, our design gets the best possible match under the constraints and still results in a better capture by the DTL than is achieved presently with the DC beam produced by the CW.

Fig. 1 represents a point design for one particular current and emittance. We have checked that for lower currents and higher emittances we can still transversely match the beam into the DTL. However, a complication exists for dual species matching due to the common transport downstream of the 9° bending magnet where a

Copyright © 2013 CC-BY-3.0 and by the respective authors

compromise must be found to match both beams using the final 4 quads. Ideally, one can set the quads nearest the DTL for matching the H^+ beam and then use H^- quads (upstream of the merge point) to match the H^- beam into the DTL.

PARTICLE SIMULATION RESULTS

After doing a preliminary design with TRACE 3D we check and optimize the design with the multi-particle beam dynamics code PARMILA [5]. The PARMILA simulations start at the entrance to the MEBT and end after the 2nd DTL tank where the beam energy is 40 MeV. Table 1 shows the results of the particle simulations for 2 different RFQ input beam currents and an input emittance of $\varepsilon_{n,rms}$ = 0.02 π-cm-mrad.

Table 1: PARMILA simulation results for 2 different beam currents. The quantities in the last row are the transmission through the RFQ, MEBT, and DTL respectively.

RFQ I input	35 mA	24 mA
RFQ I output	33.8 mA	23.5 mA
εx, εy (π-cm-mrad)	0.021, 0.021	0.022, 0.022
εz (MeV-deg)	0.070	0.064
MEBT I output	33.0 mA	23 mA
εx, εy (π cm-mrad)	0 .036, 0.029	0.029, .028
εz (MeV-deg)	0.25	0.146
DTL Tanks2- I output	26.6 mA	21.05 mA
εx, εy (π-cm-mrad)	0.079, 0.041	0.059, 0.034
εz (MeV-deg)	0.345	0.295
Vgap Bunchers (kV)	20, 15, 22	22, 13, 24
Iout / Iin : RFQ,MEBT,DTL	.966, .976, .806	.979, .979, .915

The estimated beam loss, emittance growth, and transmission shown in Table 1 meets our requirements. In particular, the capture of 91.5% by the DTL for the 24-mA case is better than the ~80% capture presently achieved during routine LANSCE operation with lower beam current (~10.5 mA).

The PARMILA phase space plots at the exit of the MEBT for the case of 33.8 mA out of the RFQ (1st column of Table 1) are shown in Figure 4. Note the large longitudinal phase spread due to the long drifts without buncher cavities.

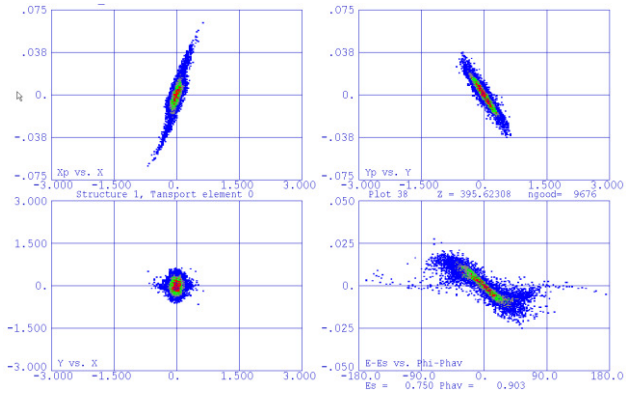

Figure 4: Beam phase space and x-y plots at the end of the MEBT for the case of 33.8 mA beam out of the RFQ.

SUMMARY

Design of a MEBT for the LANSCE H^+ RFQ project has been presented. Complications of the MEBT design because of the need to transport 2 species to the DTL has been discussed and addressed. A design using TRACE3D has been verified with particle simulations. The simulations predict good capture and transmission through the first 2 tanks of the DTL up to 40 MeV.

DESIGN OF A DUOPLASMATRON EXTRACTION GEOMETRY AND LEBT FOR THE LANSCE H^+ RFQ PROJECT *

C. Fortgang#, Y. Batygin, I. Draganic, R. Garnett, R. McCrady, L. Rybarcyk, LANL, Los Alamos, NM USA

Abstract

The 750-keV H^+ Cockcroft-Walton at LANSCE will be replaced with a 4-rod RFQ with injection energy of 35 keV. The existing duoplasmatron source extraction optics need to be modified to produce up to 35 mA of H^+ current with an emittance <0.02 pi-cm-mrad (rms,norm) for injection into the RFQ. In addition to source modifications we need a new LEBT for transport and matching into the RFQ. The LEBT uses 2 magnetic solenoids with enough drift space between them to accommodate diagnostics and a beam deflector. The LEBT is designed to work over a range of space-charge neutralized currents and emittances. The LEBT is optimized in the sense that it minimizes the beam size in both solenoids for a point design of a given neutralized current and emittance. Special attention has been given to estimating emittance growth due to solenoid aberrations. Examples of source-to-RFQ matching and emittance growth (due to both non-linear space charge and solenoid aberrations) are presented over a range of currents and emittances about the design point. A preliminary mechanical layout drawing will also be presented.

INTRODUCTION

The LANSCE accelerator presently has 2 CWs for H^+ and H^- operation. The plan is to replace the H^+ CW with a 750-keV 4-rod RFQ being designed by IAP (Frankfurt) and Kress GmbH (with LANL input) and fabricated by Kress. The input energy of the RFQ is 35 keV at a maximum beam current of 35 mA. The design emittance for the RFQ input beam is 0.02 π-cm-mrad, rms-normalized. Presently the LANSCE users of H^+ require about 18 mA of extracted beam. The current H^+ duoplasmatron source is very reliable and has been used for decades at LANSCE. We will use the existing duoplasmatron source with a newly designed extraction system and LEBT for beam injection into the RFQ. For the LEBT a magnetic focusing system was chosen. Careful attention has been paid to the solenoid design so that emittance growth due to non-linear focusing terms is made negligible.

SOURCE EXTRACTION DESIGN

Figure 1 shows the extraction geometry for the 35 keV source. The source design was done using the finite element code TRAK [1]. The relevant parameters are: Pierce, extractor, electron suppressor and ground electrode apertures equal 5 mm, 6 mm, 8 mm and 16 mm, respectively. The gap between the Pierce aperture and the extractor is 12 mm. The Pierce and electron suppressor electrodes are held at 35 kV and -2 kV. The extractor voltage is varied to minimize the emittance for each extracted beam current, mainly determined by the source plasma density and T_e (proportional to source arc current). In Fig. 1 the extractor gap voltage (ΔV) is 22.6 kV and the extracted current is 18 mA. The maximum electric field is 3.44 kV/cm. For 35 mA of extracted current the extractor gap voltage is 35 kV and the maximum electric field is 5.3 kV/cm which is still below our goal of Epeak < 7 kV/cm. A cutaway view of the source design is shown in Fig. 2.

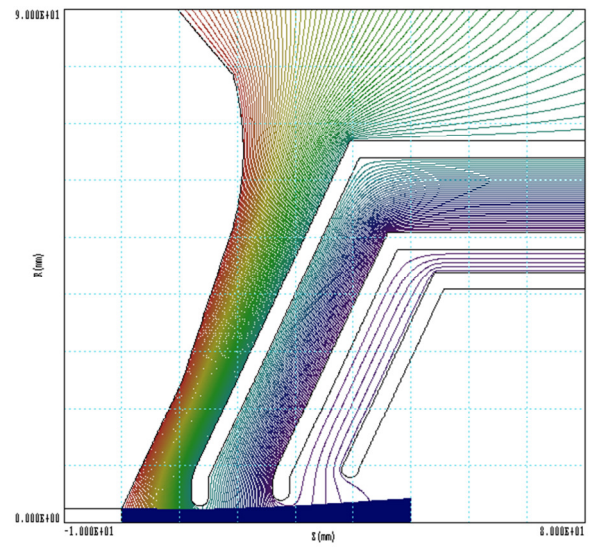

Figure 1: Electrode geometry and beam extraction for a 35 keV, 18 mA H^+ beam. Grid spacing is 10 mm/div.

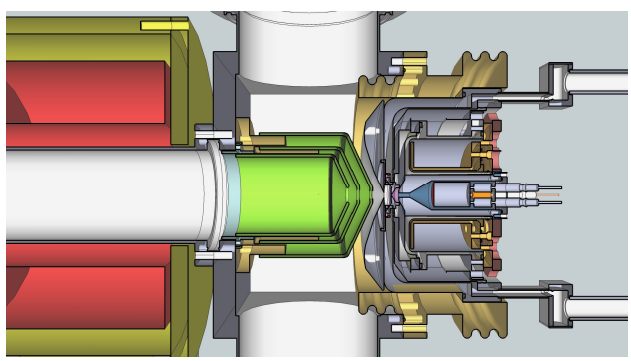

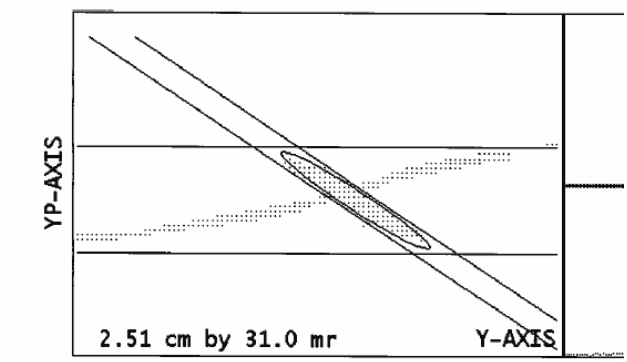

Figure 2: Duoplasmatron source is on the right. Extraction electrodes are in the center and the 1st LEBT solenoid is on the left. Pumps are above and below electrodes.

The TRAK code was used to adjust the electrode shapes to produce a uniform and laminar beam to minimize emittance growth due to nonlinear space charge fields and geometric optic aberrations in the first few centimeters downstream of the source aperture. Presently at LANSCE, with ≈15 mA of H^+ current at 750 keV the measured beam emittance is ≈ 0.004 π-cm-mrad, rms-normalized (Fig. 3). The second beam seen in the figure is H_2^+. The measured ratio $\varepsilon_{total}/\varepsilon_{rms}$ = 5.6 is indicative of a waterbag distribution ($\varepsilon_{total}/\varepsilon_{rms}$ = 6.0). For our LEBT design with 35 mA of extracted current we assume an emittance of 0.0075 π-cm-mrad.

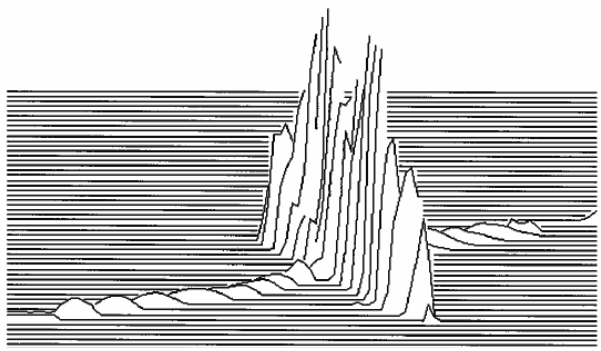

Figure 3: Measured H^+ transverse phase space at 750 keV for the LANSCE duoplasmatron source. H_2^+ beam is also observed.

LEBT DESIGN

A TRACE2D envelope simulation of the $4\varepsilon_{rms}$ beam is shown in Fig. 4.

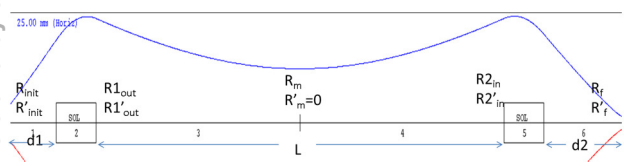

Figure 4: TRACE 2D envelope simulation with LEBT design variables defined. The source aperture is 50 mm upstream of the simulation starting point on the left.

A magnetic LEBT was selected instead of an electrostatic design so as to have a high degree of space charge neutralization via ionization of the background neutral gas. With less effective current, emittance growth due to the nonlinear space-charge force is reduced to a tolerable level. In addition, for the same focal length magnetostatic lenses have smaller aberrations than electrostatic lenses [2]. An electrostatic deflector (for beam gating), emittance diagnostic, steering magnet and valve (not shown) will be located in the drift between the 2 solenoids. Our design is an optimized point design [3] in the following sense: for a given drift distance L between solenoids, a beam waist at the center (R'_m=0), a given effective (partially neutralized) beam current, and a given beam emittance, there is one value for the beam size at the waist (R_m) that minimizes the beam size ($R1_{out}$ = $R2_{in}$) in both solenoids. This is desirable to minimize emittance growth due to nonlinear solenoid focusing. Once the beam size at the waist, R_m, is determined then $R1_{out}$, $R1'_{out}$, $R2_{in}$ and $R2'_{in}$ are determined. With that information the beam is matched backwards to the source with d1 and the strength of the 1st solenoid (B1) as matching variables. Similarly, the beam is matched to the RFQ input with d2 and B2 as matching variables. If the beam current or emittance are different from the optimized point design parameters, the beam can still be matched to the RFQ using different solenoid strengths but the symmetry of the design is broken. The beam size in the solenoids will grow if either the emittance or current is larger than the point design. Table 1 gives the LEBT parameters.

Table 1: LEBT Parameters

ε initial rms- normalized	0.0075 π cm-mrad
Source to d1	50 mm
d1	204 mm
L	1800 mm
d2	346 mm
Solenoids effective length	176 mm
R max in solenoids	24.5 mm
R waist between solenoids	11 mm
R final	1.38 mm
R' final	- 31.4 mrad
B1 max	2758 Gauss
B2 max	2536 Gauss

SOLENOID DESIGN

An important aspect of the LEBT design is to minimize emittance growth. If the beam size in the solenoids is not small compared to the solenoid aperture then there will be emittance growth due to non-linear effects. To second order the deflection of an ion after traversing a solenoid is,

$$\Delta r' = - e^2 / (4 (m \gamma v_z)^2) \quad x \int [Bz^2(0,z)\, r - \tfrac{1}{2}\, r^3\, Bz(0,z)\, \partial^2/\partial z^2 (Bz(0,z))]\, dz .$$

The first term in brackets is the usual linear focusing. The second term in brackets is non-linear. Smaller beams have less aberration because of the r^3 dependence.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Longer solenoids that result in the same deflection as shorter solenoids will also have less aberration. This comes from the $\partial^2/\partial z^2$ (Bz(0,z)) factor which makes less of a contribution to the line integral if the magnetic field profile is flat and sharp (long solenoids) as opposed to peaked and rounded (short solenoids). The integrated second derivative term is <0 so the overall effect of the second term is >0 and thus larger radii particles are over focused. It is more practical to make a solenoid longer than it is to make the aperture larger. After iterating on solenoid designs and particle simulations, we settled on an iron yoke design with the following specifications: solenoid physical length = 250 mm, effective length = 176.3 mm, aperture = 54 mm, and coil current density ≈ 4.1 Amps/mm^2. A solenoid of these dimensions causes a small but acceptable amount of emittance growth.

PARTICLE SIMULATIONS

To simulate the effects of both solenoid aberrations and nonlinear space charge on emittance growth in the LEBT we use the particle tracking code BEAMPATH [4]. Figure 5 shows particle tracks through the LEBT for a waterbag distribution. This distribution was selected based on the emittance measurement results previously discussed. Based upon measurement and calculations we expect the level of space charge neutralization to be ~ 90%. Therefore, the effective beam current is 3.5 mA. Qualitatively the beam is mostly laminar though some ray crossing is observed.

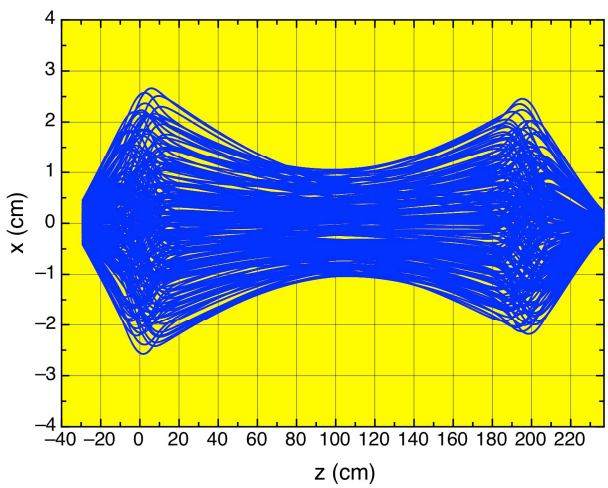

Figure 5: BEAMPATH simulation of matched beam in the LEBT. A waterbag distribution is assumed.

Figure 6 shows the emittance growth along the LEBT, again starting with a waterbag distribution and an effective current of 3.5 mA. The dashed line is the emittance growth with nonlinear space charge included but with the nonlinear solenoid focusing term turned off. The solid line includes the solenoid nonlinear focusing. The emittance growth due to solenoid aberrations is relatively small for the reasons given above. The simulated normalized rms emittance at the RFQ match point is comfortably below our requirement of 0.02 π cm-mrad.

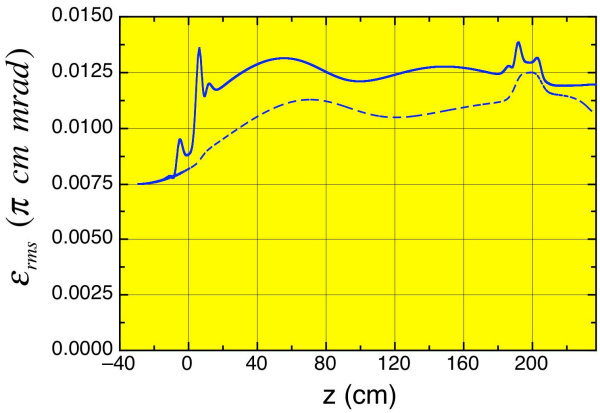

Figure 6: Emittance growth along the LEBT with (solid line) and without (dashed line) nonlinear solenoid focusing included.

SUMMARY

A new 35-keV extraction system for the H^+ duoplasmatron source and an optimized point design of a LEBT for matching into the H^+ RFQ has been presented. The physics design of the extraction system has been incorporated into a solid model. The LEBT design is optimized to minimize the beam size in the solenoids for the expected emittance, neutralized beam current, and desired drift space between the solenoids. Careful attention has been given to the solenoid design so that emittance growth due to nonlinear focusing is at an acceptable level. The physics design of the source extraction system and LEBT is complete and mechanical design will start this coming year.

APPLICATION AND CALIBRATION ASPECTS OF A NEW HIGH-PERFORMANCE BEAM-DYNAMICS SIMULATOR FOR THE LANSCE LINAC *

L. J. Rybarcyk# and X. Pang, Los Alamos National Laboratory, Los Alamos, NM, 87545, USA

Abstract

The Los Alamos Neutron Science Center utilizes a linear accelerator (linac) consisting of two 750-keV injectors, a 100-MeV drift tube linac and an 800-MeV coupled cavity linac to provide both H^- and H^+ beams to several user facilities. We are presently developing a graphics processing unit (GPU)-based high-performance multiparticle beam-dynamics simulator to aid in tune-up and operation of the linac. Our primary goal is to create an on-line tool that will act as a virtual beam diagnostic and in pseudo real-time provide accelerator operators and physicists with insight into the evolution of the beam throughout the linac. This paper will discuss potential applications of this tool and aspects of the various calibrations that are a prerequisite to using the model.

INTRODUCTION

High power linacs, such as the Los Alamos Neutron Science Center (LANSCE) 800-MeV accelerator, use a combination of well defined physics-model based tune-up procedures and empirical optimization to establish low-loss operation under high-power beam conditions. Although the low beam power tune-up is typically performed with an array of beam diagnostics, the subsequent adjustments under high beam power conditions are performed with little or no direct beam information and focus mainly on reducing beam spill as measured with radiation monitors located along the linac and beam lines. A better situation would be one where tuning activities are guided by more detailed information about the beam properties along the linac. Although one possible option would be to install numerous beam diagnostic devices all along the accelerator, this is rather impractical due to cost considerations and the interceptive nature of many of the desired devices. Another possible option is to utilize a beam dynamics model along with a *realistic* beam distribution to predict the beam characteristics along the linac. The beam dynamics model would need to contain enough physics to predict with reasonable accuracy the properties of the beam along the linac, but also be fast enough to provide near real-time feedback, as an actual beam diagnostics device would. At LANSCE we are pursuing the latter approach as a means to provide additional information and insight into the evolution of the beam along the linac. Besides serving as a virtual beam diagnostic during tune-up and operation, this model can also serve other functions as will be discussed.

*Work supported by US DOE under contract DE-AC52-06NA25396.
#lrybarcyk@lanl.gov

THE SIMULATOR

The new high-performance, multi-particle, beam-dynamics simulator is based upon the widely used ion linac design and simulation code PARMILA [1], but rewritten in C++ and NVIDIA's CUDA C [2] to enable a modern code architecture that can utilize the power of the Graphics Processing Unit (GPU) technology for tremendous performance improvements [3]. PARMILA was chosen as it incorporates essential physics required to simulate a realistic beam distribution in various ion linac structures and beam line components, algorithms that have been tested and benchmarked and approximations that enable faster execution without sacrificing significant accuracy.

The physics model for the linac is based upon design and as-built information regarding the linac geometry and accelerating fields and is stored in an SQL database. When the simulator is used in an "on-line" mode, a *data server* reads in real-time the linac parameters from the EPICS control system and pipes the data into the SQL database, where they are converted into physics model quantities. Alternatively, in the "off-line" mode, the user may chose to modify the stored values of linac parameters, which are subsequently converted to physics model quantities. In either case, the simulator reads the database at the beginning of the simulation. This SQL database also contains the conversions and calibration constants that relate the data system set points to the corresponding physics model quantities. Specific procedures are performed to establish the correct value for each of the calibration constant required by the model.

APPLICATIONS

Although originally developed to serve as an online model for tune-up and operation of the linac, it has become clear that the high-performance, multi-particle, beam-dynamics simulator can also be used in other valuable ways. Many of the following activities could be performed with a standard off-line, "slow", beam dynamics code. However, the benefit for many of these applications is that the simulator response is rapid, i.e. pseudo real-time, and the connection to the accelerator control system conveys the sense of operating a real machine, not just a model, which facilitates these activities.

Virtual Beam Diagnostic

The main goal of the simulator development is to provide operations personnel with pseudo real-time information about the beam evolution along the linac to

Copyright © 2013 CC-BY-3.0 and by the respective authors

aid in the tune-up and subsequent empirical fine-tuning of machine parameters. In this case the simulator is configured to run in an online mode, continuously updating the model with the latest operational set points and then looping through the beam dynamics simulation before updating the graphical output of various quantities along the linac. An example of the simulator running H^- beam through the LANSCE drift tube linac (DTL) is shown in Figure 1. As various DTL parameters are adjusted via EPICS controls the simulator continually updates the display in pseudo real-time with beam information, such as profiles, emittances, losses and phase-space distributions.

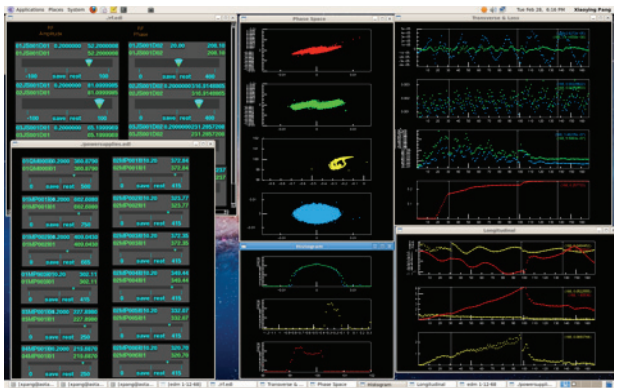

Figure 1: EPICS control sliders (left) and simulation output that includes profile, phase space, centroid, size, emittance and loss plots.

Training

In an off-line mode the simulator can be used to help train operators and physicists regarding the nuances of operating a high-power linac. Along this vein it can be used to develop better insight and understanding into the effect that various accelerator parameter changes have upon the beam along the linac.

Troubleshooting

Troubleshooting linac performance often occurs during the start-up phase when measurements do not meet expectation. The simulator can be invaluable here to help diagnosis and debug particular problems with the linac.

During the most recent start-up of the LANSCE linac, we observed characteristically different phase scans in the last tank of our DTL. About the same time we observed unexpected changes in the cavity field phase in the first DTL tank. Using the simulator we were able to reproduce similar phase scan results when a significant phase shift was introduced into the first tank. This led us to find and fix a problem with the signal path from the RF reference line to DTL tank 1 LLRF controls.

Test Bed

Another valuable use for the simulator is as a development and test facility for various feedback and control schemes. These are schemes that would normally require access to the linac control parameters via the EPICS control system. Recently, this was done using the simulator and was aimed at testing a model-independent optimization approach for establishing control set points in the linac. [4]

Optimization

Since the simulator is meant to provide detailed information about the beam along the linac, it can also be used to find a more optimal way to operate the accelerator. Over many years of high power beam operation at LANSCE, the operations staff has found lower beam loss solutions that require operating the machine away from design values. This can also be explored with the simulator. Evolutionary optimization approaches such as the multi-objective genetic algorithm (MOGA) and multi-objective particle swarm optimization (MOPSO) are being investigated as a way to help find stable, low beam-loss solutions that better define and quantify the beam conditions along the linac [5].

CALIBRATIONS

Before using the simulator to provide meaningful information about the beam evolution along the linac it must be calibrated. That is, the transformations associated with the control system set points to physics model parameters must be established. These calibrations include focusing magnet strengths, RF field phase and amplitude for the bunching and accelerating structures, and space-charge compensation in the low-energy beam transports. Some of the calibrations are done offline and some are beam-based.

The magnet calibrations relate power supply current to field. These are done offline and based upon fitting excitation curve data of field vs. current.

Depending upon the type of cavity, the RF bunchers and accelerating tanks utilize both offline and beam based approaches. The single-gap buncher cavities that are used in the 750-keV beam transports utilize an offline calibration. An EM-field calculation of the cavity was performed using SUPERFISH [6] to extract the theoretical E_oTL, Q_u and P_{cav}. In addition, measurements were made of the cavity Q along with each buncher cavity amplifiers output power vs. amplitude set point. These results were combined to produce the effective gap voltage vs. amplitude set point. The phase set point is calibrated with a beam-based measurement known as a phase scan and is described below.

The accelerating sections of the linac require beam-based measurements to establish the RF calibrations. For each section driven by one RF amplifier there is a separate phase offset and amplitude scale factor that must be determined to properly tie the control setting to the physics model. For the DTL these are calibrated using a standard phase scan method. The phase scan measures the beam current above an energy threshold as a function of the phase setting of the tank being scanned. The size and location of the current distribution is related to the

Copyright © 2013 CC-BY-3.0 and by the respective authors

amplitude and phase of the accelerating field in the tank. Figure 2 shows two measured phase scans of DTL tank 1 along with the fits produced by the simulator. The phase scans represent the cases with the first of two LEBT bunchers off and on, respectively. Tank 1 amplitude scale factor and the two buncher cavity phase offsets were extracted from the fits to these data.

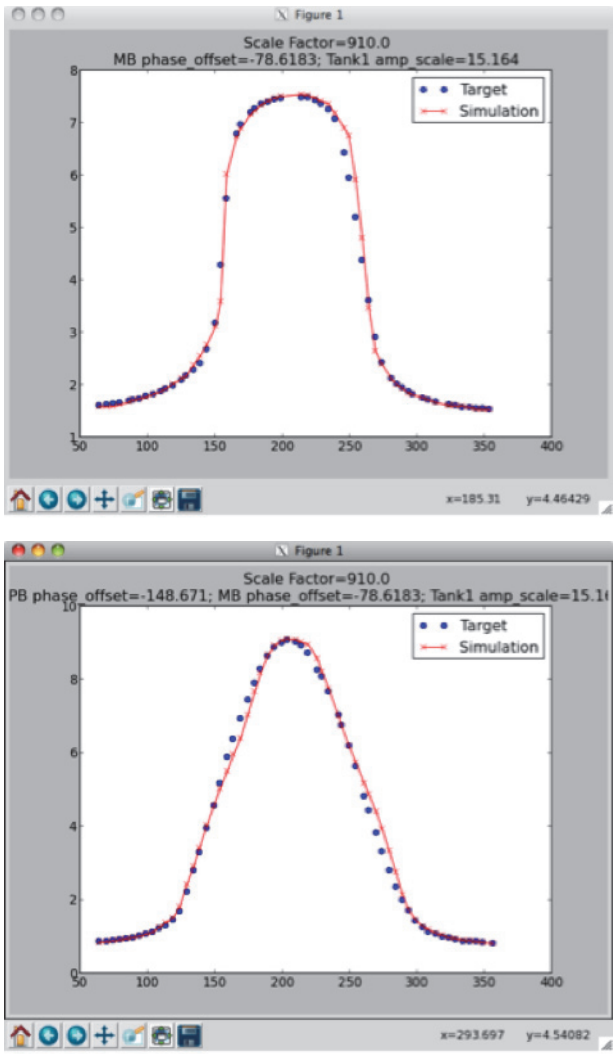

Figure 2: Measured (blue dots) and simulated (red line) phase scan data for Tank 1 of the DTL. Upper (lower) panel is for the case when the first of two LEBT buncher cavities is off (on).

The coupled cavity linac (CCL) is just now being incorporated into the simulator and therefore has not yet been include in LANSCE linac model. However, the calibration of the phase offset and amplitude scale factor for each CCL accelerating module will be performed by fitting measured phase scans similar to what has been done elsewhere [7].

An additional factor that we have chosen to include in the model is the space-charge compensation of the beam, which is the result of interactions with residual gas in the nominally evacuated beam line. Measurements in the low-energy beam transports (LEBT) where space-charge forces are significant showed different degrees of compensation present [8]. This space charge compensation factor is derived from a comparison of measured beam emittances and model predictions.

SUMMARY

A high-performance, multi-particle beam dynamics simulator is being developed for the LANSCE linac and will serve as a virtual beam diagnostic by providing staff with additional information about the beam along the linac during tune-up and operation of the facility. In addition it can also function as a tool for training linac operations personnel, troubleshooting issues associated with beam operations, as a test-bed for new control schemes and for optimization of the linac operation. The simulator requires the calibration of various constants that relate linac control system parameters to various physics model values. These are done using a combination of offline and beam-based procedures. The beam-based approach extracts calibration constants from fits to various tune-up measurements.

ACKNOWLEDGMENT

The authors want to thank Scott Bailey for his efforts in setting up the EPICS system on the GPU workstation that helped enable the development and testing of this simulator.

INTEGRATION BETWEEN THE FRIB LINAC MECHANICAL CAD MODEL GEOMETRY AND THE ACCELERATOR PHYSICS LATTICE DATABASE*

M. Johnson#, N. Bultman, I. Grender, M. Leitner, G. Morgan, O. Yair, Q. Zhao
Facility for Rare Isotope Beams (FRIB), Michigan State University, E. Lansing, MI 48824, USA

Abstract

This paper will summarize the systems engineering techniques utilized to translate the FRIB accelerator physics lattice file to actual three-dimensional CAD geometry for linac components. An automated approach of using the accelerator physics lattice database used for optics and particle simulation has been implemented to generate data points used to position the technical 3-dimensional CAD geometry. This coordinated method ensures consistency between the technical and scientific design domains throughout the project design phases. The FRIB configuration management used to control lattice and CAD model revisions is also discussed. In addition, the paper discusses fiducialization plans and tolerance stack up analysis to meet positional requirements for FRIB cryomodules, diagnostics, and the beam delivery magnet systems.

DATA MANAGEMENT

The layout of the FRIB accelerator physics lattice file is composed of the basic element layouts of the driver linac. This layout is accomplished using spreadsheet file to define the undeveloped geometry of ion sources, focusing and steering magnets, accelerating cryomodules, radio frequency quadrupole (RFQ), The alignment placement requirements of the accelerator components are summarized in [1,2]. An automated script imports the lattice points into our mechanical CAD software generating local coordinates for the centers of each component, called a skeleton file. The three-dimensional design geometry is then located to each coordinate in the skeleton file making up the complete linac geometry. The Survey and Alignment Group will develop and maintain a proprietal data handling system composed of a relational database and a workable simplified wireframe graphics model [3]. This system will be integrated with the FRIB project database currently under development within the Controls and Computing Group. All components requiring alignment will have associated fiducials. The fiducials are placed on the wireframe component model and these in turn are placed at the correct location in the design lattice based upon the data gathered during the fiducialization process. The wireframe graphical model is a single graphical representation of every point that the Survey and Alignment Group is given as a design location. The relational database provides functionality for archiving and retrieving data from various epochs of the project's evolution in order to keep abreast of revisions and network re-observation campaigns. In addition to coordinate data and associated uncertainties the database will hold information regarding nomenclature, instrumentation, tooling, fiducialization, and ideal component design lattice positions.

General Layout

As shown in Figure 1, the driver accelerator consists of Electron Cyclotron Resonance (ECR) ion sources, a low energy beam transport containing a pre-buncher and electrostatic deflectors for machine protection, a Radiofrequency Quadrupole (RFQ) linac, linac segment 1 (with Quarter-wave Resonators (QWR) of β=0.041 and 0.085) accelerating the beam up to 20 MeV/u where the beam is stripped to higher charge states, linac segments 2 and 3 (with Half-wave Resonators (HWR) of β=0.29 and 0.53) accelerating the beam above 200 MeV/u, folding segments to confine the footprint and facilitate beam collimation, and a beam delivery system to transport to the target a tightly focused beam.

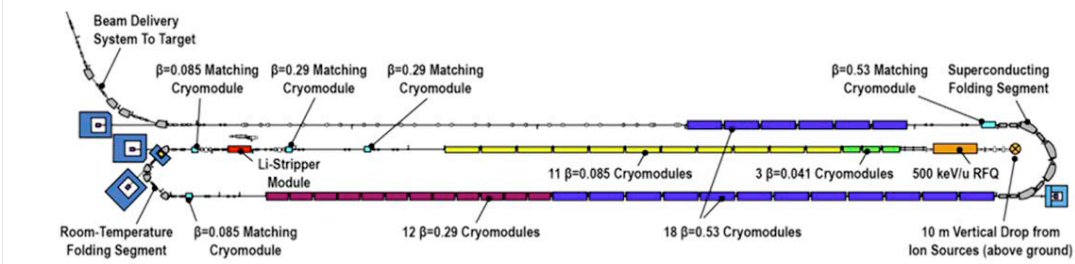

Figure 1: The FRIB accelerator layout at the tunnel level.

ALIGNMENT NETWORK

At present the core processes are in the project-specific refinement phase. The FRIB global coordinate system (GCS) is the single cartesian site-wide reference system used by the Survey and Alignment Group to integrate the spatial information and placement requirements of the Accelerator Systems Division (ASD), the Experimental Facilities Division (ESD), the Conventional Facilities Division (CFD), and the civil construction effort. The network is an array of monuments permanently affixed in the floor and to walls to realize coordinate system. The Z-axis of the coordinate system is oriented to gravity at all locations, as the effect of earth curvature is to be regarded as insignificant with regard to project requirements. The floor monuments holes will be drilled and the monument bodies grouted in place when the concrete substrate is sufficiently cured, allowing the maximum time to elapse before the first network campaign begins. The monument body accepts a 1-1/2" spherically mounted retroreflector (SMR) the center of which is considered a geometric point and conceptually defines the monument location. The Spallation Neutron Source (SNS) floor monument design is to be adopted for FRIB. The SNS design requires no intermediate fixture for placing the SMR into the monument body. The wall monument design has yet to be chosen but several designs are under consideration with the main criteria being the method by which they are affixed and cost. Measurements are made to the SMR primarily by laser trackers and total station instruments. Digital level measurements are also made, but in that case the SMR is replaced by a solid sphere of the same dimension and measurements made to the sphere's uppermost point utilizing a bar-coded invar rod that are reduced to the sphere's center by its nominal radius.

Network observations are made to the monuments from a series of instrument stations. The series of instrument stations and observations through the front end, linac tunnel, target area and existing NSCL constitutes a network observation campaign. The objective of a network observation campaign will be the production of a triad of X, Y and Z coordinate values with the GCS.

The uncertainties associated with the monument locations represent an upper limit on the achievable global precision of alignment. The component-to-component tolerances are found in the FRIB Driver Linac Element Placement Requirements document and the Experimental Systems Alignment Requirements document.

The network path begins at the ECR ion source in the front end the beam transitions to the linac floor through a 13 m vertical drop. Monuments affixed to the walls through the vertical drop provide for the placement of instruments near the 6 m mark as well as above and below. In similar fashion, the nearby equipment hatch will also be utilized. Employing differential leveling techniques through narrow vertical passages is particularly difficult and special fixtures and aids will be needed. The linac is a folded design so there is no single corridor from which instruments may have lines of sight to all components within any particular cross section of the tunnel. Two corridors of linac floor allow for the necessary lines of sight. Along the length of the tunnel there will be monuments placed in 4 rows spaced 5 meters apart. Where available wall space will be utilized for monument placements. The rows will be spaced at 5 meter intervals along the beam path, resulting in an approximate total of 150 monuments.

COMPONENT ALIGNMENT SCHEMES

Vertical Drop Alignment

FRIB will write individual fiducialization procedure documents for each species of component in which unique or special considerations are addressed. The adjustment process should be fairly straighforward for many components, especially those spanning the linac floor. The vertical drop from the ECR to the linac floor offer significant challenges for the alignment process. The design makes use of two spaceframes, shown in figure 2, to which the individual components are affixed. In this region, the beamline components consists of 2 sets of 3 electrostatic quadrupoles residing in a common vacuum housing, vacuum pumps, profile monitor diagnostics. The individual components are mounted and aligned within the space frame in a horizontal orientation. Subsequently the individual component fiducial locations are verified and transferred to spaceframe fiducials. Alignment mounts are then placed in the drop and the spaceframe is installed and aligned. Using this method reduces alignment in the vertical drop to just two components.

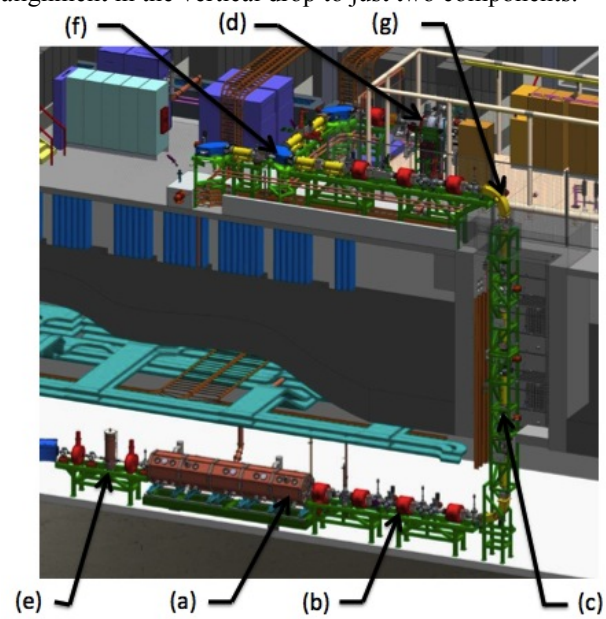

Figure 2: Vertical beamline transport section. (a) Radio Frequency Quadrupole, (b) RT solenoid, (c) vertical spaceframe, (d) SC ion source, (e) bunching resonator, (f and g) RT dipole magnet.

Cryomodule Alignment

Resonator and solenoid alignment of the cryomodule is accomplished using a mechanical axis line established from the entrance and exit 3-3/8" gate valves. The gate valves are part of weldments that are assembled with dowel pins to the vacuum vessel bottom plate which doubles as a strong back with external fuducials visible for tunnel placement. The bottom plate also supports the superconducting resonators attached to cold rail structures via G-10 thermal insulating support posts.

During assembly the inside of the resonator's niobium beam tubes are fuducialized to temporary SMR nests on the helium vessel. Once assembled to the bottom plate the vessels locations are logged with respect to the bottom plate fuducials in order to transform the local fiducialization coordinates into design lattice coordinates to be used for alignment in the GCS. The bottom plate fuducials are then used to place the mechanical beam axis orientation into the design lattice.

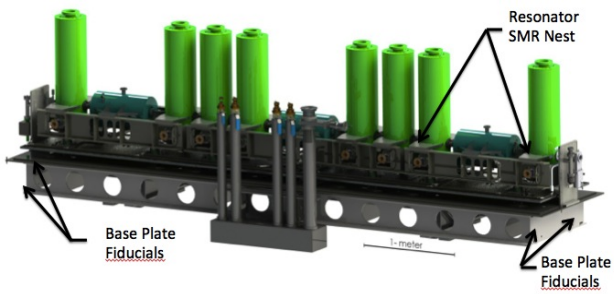

Figure 3: Cryomodule cold mass alignment setup.

Diagnostics Alignment

Beamline diagnostics located between cryomodules are integrated into the linac vacuum system boxes, shown in figure 4. These vacuum boxes and diagnostics assemblies consist of beam profile, beam current, beam position and the ability to house beam loss monitors.

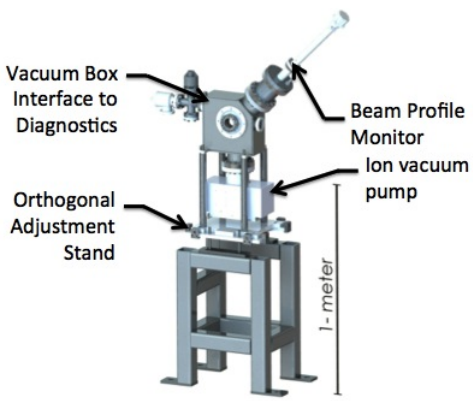

Figure 4: Integrated beam diagnostics, orthogonal adjustment and vacuum system.

Fidulization is performed during assembly and recorded into the alignment database. The diagnostic components are aligned via the vacuum box's external SMR nests. To do this efficiently the use of a coordinate measuring machine (CMM) arm may be used. The vacuum box is positioned to the tunnel network via the external SMR nests.

Magnet Alignment

The driver linac portion of the accelerator consist of room temperature (RT) X-Y correcting magnets, RT quadrupoles, super conducting (SC) dipole magnets, RT dipole magnets.

Magnetic field mapping is done with respect to 6.35 mm [.250"] holes in the pole tip steel, which are then fuducialed to SMR nests visible at tunnel installation. The SC dipole is shown in figure 5.

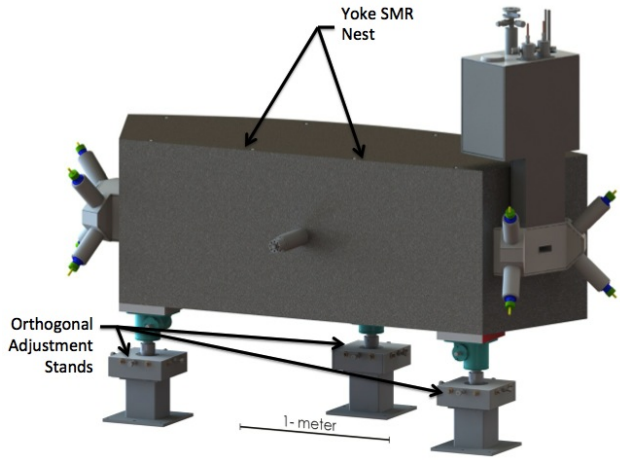

Figure 5: Folding segment 2 superconducting dipole magnet.

SYSTEMS ENGINEERING

The lattice file and corresponding 3D mechanical CAD geometry is stored in a read-only database after drafting checking and stakeholder approvals. The database is controlled using a commercial engineering software package [4]. Subsequent changes follow a formal engineering change order process that records the design history, requirements and subsequent specifications.

IMPROVING EFFICIENCY OF IONS PRODUCTION IN ION SOURCE WITH SADDLE ANTENNA*

V. Dudnikov#, R. Johnson, Muons, Inc., Batavia, IL 60510, USA, S. Murrey, T. Pinnisi, C. Piller, M. Santana, M. Stockli, R. Welton, ORNL, Oak Ridge, TN 37831, USA

Abstract

Extraction of positive and negative ions from a saddle antenna radio-frequency surface plasma source (SA RF SPS) is considered. Several versions of new plasma generators with different antennas and magnetic field configurations were tested in the small Test Stand. The efficiency of positive ion generation in plasma has been improved up to 80 times from 2.5 mA/cm^2 kW to ~0.2 A/cm^2 per 1 kW. For cesiation was used a heating of the cesium chromate cartridges. A small oven for cesium compounds and alloys decomposition by heating was developed and tested. After cesiation a current of negative ions to the collector was increased from ~1 mA to 10 mA with RF power ~ 1.5 kW in the plasma and longitudinal magnetic field B_l~250 Gauss. A specific efficiency of H$^-$ production was increased up to ~ 20 mA/ cm^2 kW from previous ~2.5 mA/ cm^2 kW.

INTRODUCTION

Development of the saddle antenna RF surface plasma source (SA RF SPS) was proposed for improve efficiency of H$^-$ ion production and improve SPS reliability and availability [1-4]. Now RF SPS for accelerators with emission aperture 7 mm have the efficiency of H$^-$ ion generation ~1 mA/kW and RF power ~ 50 kW is needed for 50 mA beam current production [5]. With this efficiency delivered current is enough for 1 MW proton beam production but the high RF power required for the sources can create problems for very long term operation at higher beam power. This efficiency is too low for CW operation with current ~10 mA necessary for Project X and for cyclotrons injection.

In tested version of SA RF SPS the specific efficiency of positive ion generation was increased to ~0.2 A/ cm^2 kW and a specific efficiency of H- production was increased up to ~ 20 mA/cm^2 kW from previous ~2.5 mA/ cm^2 kW.

The total efficiency of the surface plasma produced fraction of the H$^-$ beam is a product of the probability of secondary emission of H$^-$ caused by plasma bombardment of the collar surface around the emission aperture, the probability of extraction of emitted H$^-$, and the rate of bombarding plasma flux [6,7].

The coefficient of secondary emission of H- is determined by surface properties (proper cesiation) and the spectrum of the plasma particles bombarding the collar/emitter surface around the emission aperture. The cesiation was improved recently [5] and appears to be nearly optimal. The probability of extraction of H$^-$ emitted from the collar surface is dependent on the surface collar shape [4-7], which was optimized recently to improve H$^-$ emission. The problem of efficient plasma generation is being addressed by the development of new RF plasma generators with higher plasma generation efficiency and better concentration of useful plasma flux onto the internal surfaces of the collar around the emission aperture for lower RF power [1-4]. In this project, we use the saddle antenna, which has its RF magnetic field transverse to the source axis, combined with an axial DC magnetic field, to concentrate the plasma on the collar where the negative ions are formed by secondary emission [1-4,6,7].

SA SPS DESIGN

The schematic of a large RF SA SPS with the AlN ceramic discharge chamber, saddle antenna, and DC solenoid is shown in Fig. 1. The chamber has an ID=68 mm. The saddle antenna in this SPS with inductance L=3.5 μH is made from water cooled copper tube. RF assisted triggering plasma gun (TPG) is attached to discharge chamber from left. An extraction system is attached from right side.

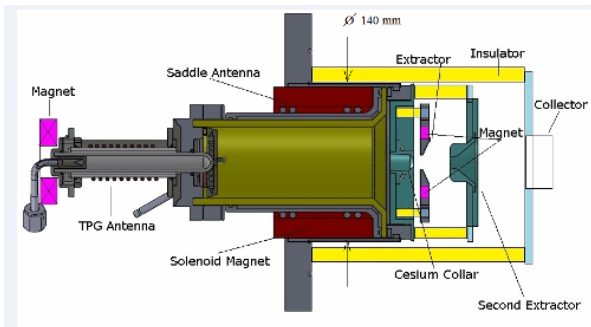

Figure 1: A schematic of the SA SPS with an extraction system and a collector.

Design of the extraction system is shown in Fig. 2. The strong transverse magnetic field (up to 1 kG) is created in the collar (4) by permanent magnets (7) inserted into water cooled extractor (6) attached to the plasma plate (1) through ceramic insulators (5). SA SPS was tested with emission and extractor's apertures of 6 mm diameters.
A Cesium vapor can be delivered to the emitter cone (2)

from Cs chromate cartridges (4) heated by plasma or from a resistive heated Cs oven (3).

Schematic of ion beam formation is shown in Fig. 3. Ions are extracted from the cone by extraction voltage Uex between the cone and the extractor and accelerated by voltage in the second gape. Co-extracted electrons are well collected to the extractor along magnetic field lines without drift in crossed ExB field.

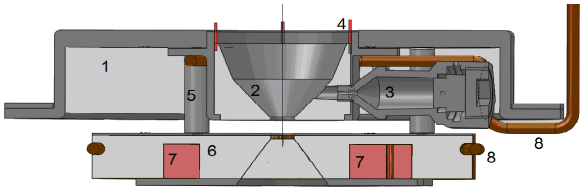

Figure 2: Extraction system of the RF SA SPS. 1- plasma electrode; 2-emitter/converter cone; 3-Cesium oven; 4-Cs cartridges; 5-ceramic insulators; 6- extraction electrode; 7- permanent magnet; 8-cooling tubes.

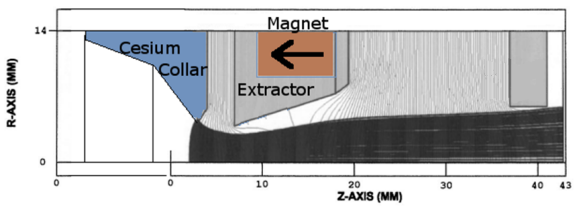

Figure 3: A schematic of ion beam formation (emission aperture is 6 mm diameter).

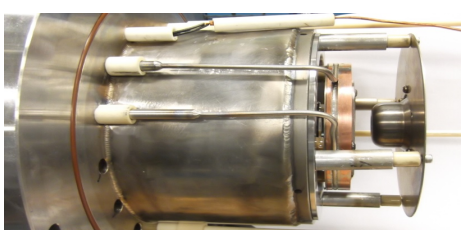
The strong transverse magnetic field B_t suppress electron collection by collector and the secondary emission is suppressed by magnet attached to the collector.

The RF discharge in the TPG was excited by RF (13.56 MHz) generator with power up to 0.6 kW. For the SA discharge excitation was used RF (13.56 MHz) generator with power up to 2.5 kW. The RF power loss in SA and matching network was ~1 kW and up to ~1.5 kW can be used for plasma generation.

The plasma electrode with Cs collar/cone was grounded. Extractor, accelerator electrode and collector were biased by high voltages Uex up to 15 kV and Uc up to 15 kV. Pulsed currents to these electrodes were registered by Pearson transformers with sensitivity 1 V/A.



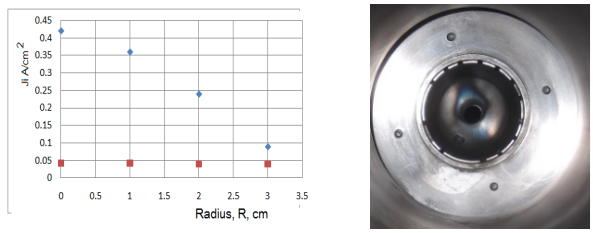


Figure 4: SA SPS with extractor and collector.

A photo of assembled SA SPS with extractor is shown in Fig. 4.

The magnetic field B_l up to 250 G is created by solenoid exited by current Im up to 70 A with voltage Um up to 8 V. A hydrogen gas flow was controlled by MKS mass flow controller.

EXPERIMENTAL RESULTS

Several versions of plasma generators with different antennas and magnetic field configurations were fabricated and tested in the test stand. A pulsed RF (13.56 MHz) discharges with duration 1-2 ms, up to 60Hz and power up to 1.5 kW in the plasma were tested. Produced positive ion emission current density distribution along the radius R is shown in Fig. 5.

a b

Figure 5: a) Ion emission current density Ji (A/cm^2) (plasma density) along the radius R (cm) at high magnetic field (blue) and at low magnetic field (brown) with RF power 1.5 kW in the plasma (observed by small collectors) without transverse magnetic field Bt. b) Trace of plasma flux on the collar converter wall with transverse magnetic field Bt~1 kG concentrated up to 8 mm of diameter.

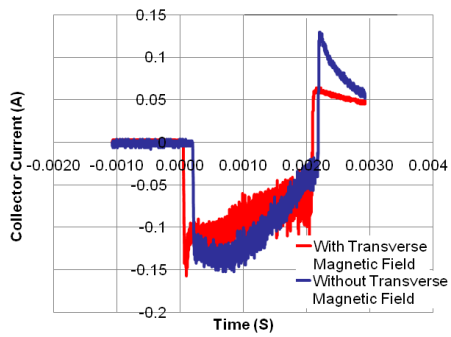

Figure 6: Traces of positive ion current to the collector with and without transverse magnetic field.

Up to 100 mA of positive ion was extracted with emission aperture 6 mm at RF power ~1.5 kW in plasma as shown in Fig. 6.

After cesiaion the negative ion current to the collector Ic was increased from 1 mA to 10 mA and electron current to the extractor Iex was reduced from 0.15 A to 0.1 A.

Examples of Ic and Iex signals are shown in Fig. 7.

Dependences of Ic on RF power in the plasma Prf is shown in Fig. 8 (upper scale). Dependences of Ic on the solenoid voltage Um is shown in Fig. 9. Dependences of Ic on the extraction voltage is shown in Fig. 10. The collector current I_c increases by a factor of 7 as the longitudinal magnetic field Bl increases from 0 to 250 G. and increases with the extraction voltage. The extraction

electrode was biased up to Uex~15 kV and collector was biased up to Uc~15 kV. SA SPS can operate at the gas flow decreased down to Q=8.3 sccm (standard cm^3/minute), while the H^- current increased up to 10 mA at P_{rf}=1.5 kW (H^- generation efficiency was up to I_c/P_{rf} = 6 mA/kW with cesiation).

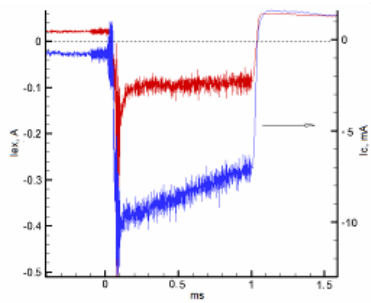

Figure 7: Signals from extractor Iex=0.1A (electron current, red) left scale and signal from collector Ic=10mA (negative ion current, blue) right scale. Signal slope connected with a low inductance of the Pearson transformer.

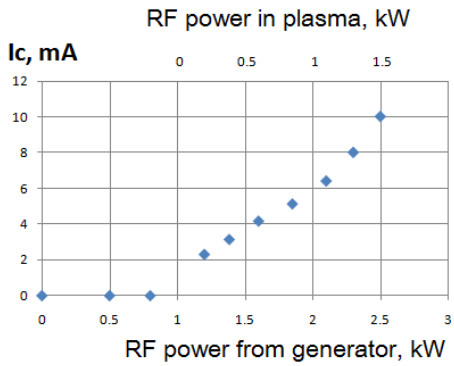

Figure 8: Dependence of Ic on RF power in the plasma Prf (upper scale) and from generator (bottom scale).

The longitudinal magnetic field from the solenoid at the emission aperture is below 50 G and does not change the suppression and deflection of co-extracted electrons by the transverse magnetic field Bt~1 kG.. However, the optimal cesiation was not reached because the extractor current Iex is high. Most efficient and stable cesiation was produced with a dark (carbon) film deposition on the emitter cone (2) in Fig.2.

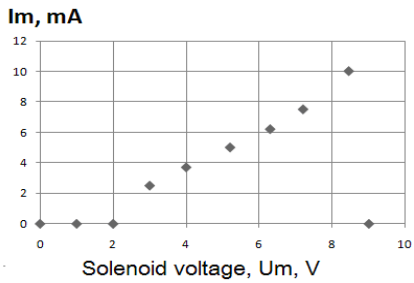

Figure 9: Dependence of Ic on the solenoid voltage Um.

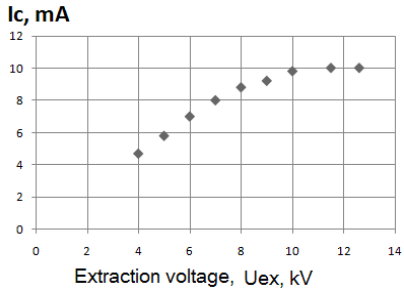

Figure 10: Dependence of the collector current Ic on the extraction voltage Uex. RF power in the plasma Prf=1.5 kW, the solenoid voltage Um=8.3 V. Gas flow Q=8.6 sccm.

Extraction current has a significant level of noise with frequencies fn~1-2 MHz. Ion beam shape is indicated by sputtering traces on the Molybdenum plate of the extractor electrode, on the accelerating electrode and on the collector as shown in Fig. 11.

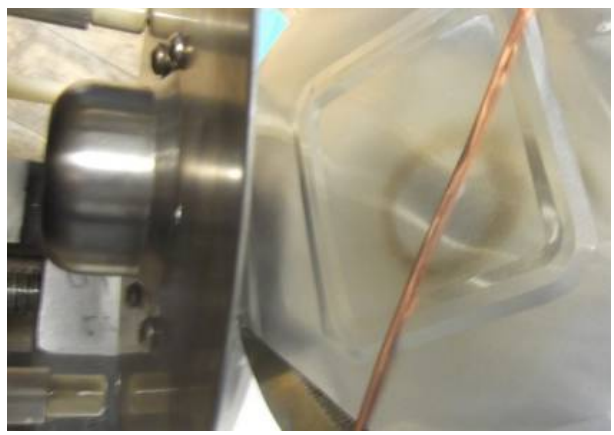

Figure 11: Accelerating electrode and a collector with a trace of sputtering by negative ion beams.

With demonstrated efficiency ~20 mA/cm2 kW it is enough ~10 kW of RF power for 60 mA of H- production, necessary for SNS operation with beam power 1.4 MW. RF SPS for CW operation with beam current ~10-15 mA can be developed with manageable RF power ~ 2 kW.

Abstract

We report on the operation of a field-emission diamond cathode in a L-band RF-gun (1.3 GHz) at Fermilab's HBESL facility. The diamond cathode consists of an array of a million sub-micrometric pyramidal diamond tips.Beam currents in excess of 10 mA were observed and the cathode did not show appreciable signs of degradation after days of operation. Measured Fowler-Nordheim characteristics and transverse beam densities are also reported.

INTRODUCTION

Over the past years, field-emission (FE) electron sources have been the subject of intense researches due to several advantages they offer over photoemission and thermionic sources. The main advantages of FE sources stem from their ability to produce very low-emittance bunched beams, their capability to generate high-average current beams, and the absence of requirement for an auxiliary laser system. A single-tip FE emits electrons from a very small transverse area and can therefore produce beams with extremely small, quantum-degenerate, transverse emittances [1, 2]. When arranged as large arrays, field-emission-array (FEA) cathodes can provide substantial average currents [3] to the detriment of emittance which then scales linearly with the FEA macroscopic radius [4, 5].

Pulsed field-emission occurs when a FE cathode experiences a time-dependent field, e.g., when located in a resonant radiofrequency (RF) cavity and the root-mean-square (rms) duration of the bunch is $\sigma_t \simeq \omega^{-1}[\beta_e E_0/B(\phi)]^{-1/2}$ where $\omega \equiv 2\pi f$ where E_0 and f refer to the field amplitude and frequency. The latter pulse duration is obtained by taking the current density, $B(\phi)$ is a function of the workfunction ϕ associated to the cathode material and β_e is a field-enhancement factor [6, 7]. Nominally, the bunch rms duration is a significant fraction of the RF field period typically resulting in beams with large energy spread. This limitation can however be circumvented by exposing the FE cathode to superimposed electromagnetic fields [8].

In this paper we report on the first operation of a diamond FEA (DFEA) cathode in a conventional L-band RF gun nominally operated with a Cesium Telluride (Cs_2Te) photocathode. The DFEA is composed of ungated diamond pyramids which have proven to be rugged. Depending on the size and pitch of the pyramids, tests under DC voltages have showed field emission to begin at macroscopic fields $E_0 \simeq 5$ MV/m, and current density as high as 30 A.m^{-2} has been obtained [9].

EXPERIMENTAL SETUP

The geometry of the DFEA cathode used for the experiment reported below appears in Fig. 1(a,b). It consists of an array of $\sim 1000 \times 1000$ pyramidal diamond tips with their extremities separated by ~ 10 μm. The typical pyramid base is ~ 4 μm and the radius of curvature of the tip is on the order of 10 nm. Electrostatic simulations performed with the finite-difference element program POISSON [10], indicate that local fields in excess of ~ 0.9 GV/m are achieved at the tip when subjected to a macroscopic field $E_0 = 30$ MV/m (corresponding to $\beta_e \sim 30$).

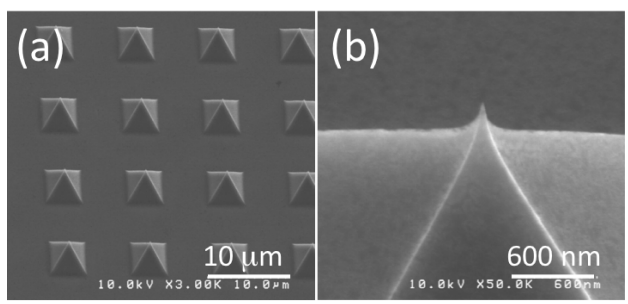

Figure 1: Electron-microscope photographs of the DFEA pattern (a) and close up of one pyramidal tip (b).

The cathode pattern was formed using a mold-transfer process whereby chemical vapor deposited (CVD) diamond is grown in sharpened silicon molds [11]. Using various techniques, DFEAs can be produced with single, double, or quadtip emitters. A variety of growth recipes

are used to achieve a desired combination of sp^2 and sp^3 carbon, dopant concentration, and nitrogen content. The DFEA are brazed on a Molybdenum substrate.

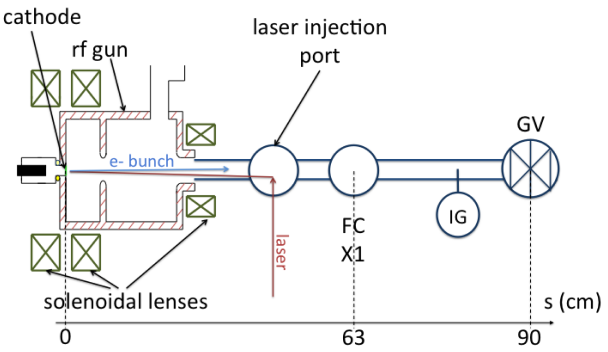

Figure 2: Experimental setup used to carry field-emission studies (a) . The legend is as follows: "FC": Faraday cup, "IG" ion gauge, "X1": scintillating screen for transverse beam density measurement.The insets are photograph of the DFEA cathode in its final position in the RF gun (b), and of the cathode holder with diamond coating on its font surface before insertion in the RF gun (c).

The DFEA cathode was located on the back plate of a 1.625-cell RF gun operating on the TM_{010} π mode at $f = 1.3$-GHz. The RF gun is powered by a $\leq$ 3-MW peak-power klystron pulsed at 1 Hz [12].

For the measurement presented below the RF macropulse width was set to 35 μs. The RF gun is surrounded by three solenoidal lenses that control the beam's transverse size. The charge and transverse distribution of the emitted electron beam can be measured with respectively a Faraday cup (FC) and scintillating screen (X1); see Fig. 2. Both diagnostics are located at $z = 0.63$ m from the cathode and are remotely insertable. The X1 screen is imaged on a charged-coupled-device (CCD) optical camera. A variable iris and neutral-density filters are used to attenuate the emitted optical radiation and mitigate saturation of the CCD. The optical resolution of the imaging system is $\sim$ 100 μm. A ion gauge (IG) located 0.5 m from the gun monitors the vacuum level in the section composed of the gun and diagnostics. Typical vacuum pressure levels in this beamline section are $\sim 1 \times 10^{-9}$ Torr. The forward RF power, P, injected in the RF gun cavity is measured using a calibrated RF diode detecting the low power from -30-dB directional coupler installed on the RF waveguide. The measured forward power can be used to infer the peak electric field at the cathode surface via $E_0[\mathrm{MV/m}] \simeq 2.234 \times 10^2 \sqrt{P[\mathrm{MW}]}$ where the RF-gun quality factor is taken to be $Q \simeq 2.3 \times 10^4$ and the cathode is assumed to be flushed with the RF-gun back plate.

The DFEA's substrate was brazed on a Molybdenum cathode holder compatible with the load-lock insertion mechanism used in the RF gun; see Fig. 3. The cathode holder was inserted in the RF gun and its position was adjusted to insure the gun resonant frequency remains at 1.3 GHz (as monitored with a spectrum analyzer). To insure electrical contact between the cathode holder and RF-gun-cavity walls, a Cu-Be spring is used. This spring is also found to be a source of spurious negligible field-emission current.

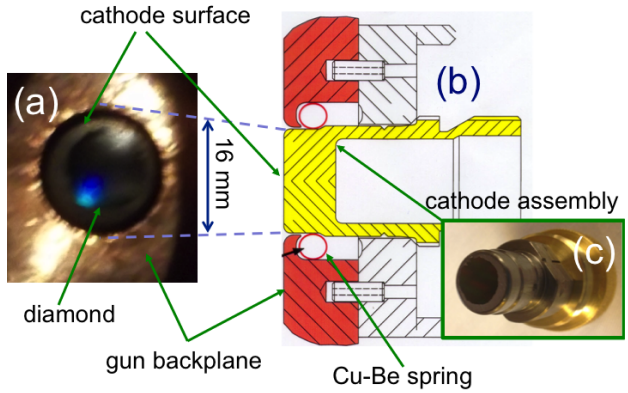

Figure 3: Photograph of the DFEA cathode (dark-blue area) inserted in the RF gun (copper back plate shown) (a). Cross-section sketch of the cathode insertion mechanism showing the RF gun back-plate (red) with cathode holder (yellow) (b). Photograph of the cathode holder (c).

MEASUREMENTS

A sample of F-N characteristics recorded over several days of operations appear in Fig. 4. The curves all have similar slopes at high fields [$\nu \equiv B(\phi)/\beta_e = 129.5 \pm 6.2$] for the cathode in its nominal position (with its emitting surface flushed with the RF gun backplate). A somewhat different slope is observed ($\nu' = 213.2 \pm 0.5$) when the cathode is retracted by a $\sim$ 2 mm. For these measurement the solenoids were turned off.

During the running period, the vacuum level was monitored and did not appreciably deteriorate ($\leq 1.2 \times 10^{-9}$ Torr). The current was also recorded for long period of time (typically up to one to two hours). An apparent current drift was observed by tracked back to klystron power drift over the time. Accounting for the E-field drift by computing an "instantaneous" F-N slope as $\mu \equiv E_0 \times \ln(I/E_0^2)$ indicates that the emission is stable with typical relative rms variation $\langle[(\delta\mu)/\mu]^2\rangle^{1/2} \simeq 0.37\%$. In practice correlated changes due to klystron-power drifts can easily be mitigated using a slow feedback loop.

The beam densities at X1 measured for a sample of operating conditions appear in Fig. 5. The beam sizes increase with field strength (due to larger emitting area) but can be

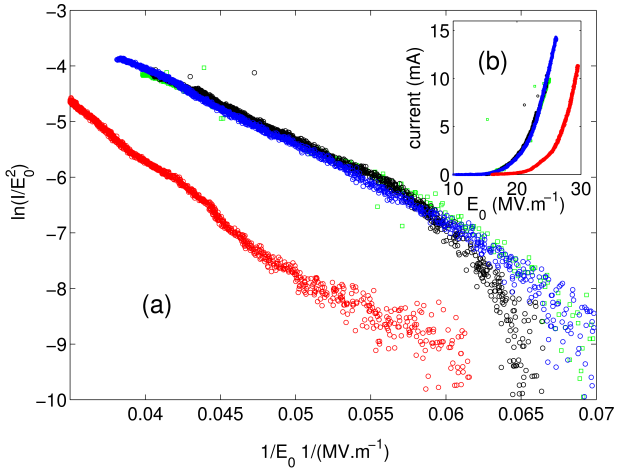

Figure 4: F-N plots (a) for the nominal (green, blue, black traces) and retracted (red) cathode position. For the nominal cases, the black and blue traces were respectively taken 10 and 59 days later than the black trace). The inset (b) displays the current evolution versus macroscopic field amplitude.

focused to a 1-mm (rms) spot size with the solenoids; see Fig. 5(d).

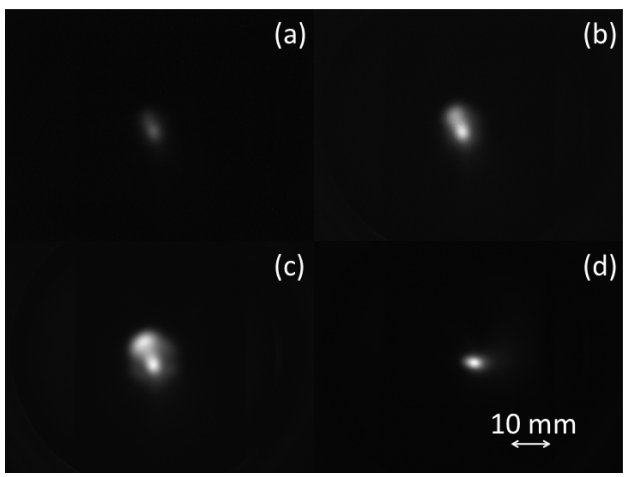

Figure 5: Transverse beam density measured at X1 for three cases of forward power $\hat{E}_0 \simeq 23.5$ (a), 25.5 (b) and 31 MV/m (c) with solenoids off and for a focused beam and $\hat{E}_0 = 31$ MV/m (d).

CONCLUSION

In summary we successfully demonstrated the operation of a DFEA cathode in a conventional L-band RF gun nominally design to operate using photocathodes. These results represent a significant step toward the realization of robust laser-free compact light sources for industrial, medical, and defense applications. Further tests will focus on characterizing the emittance of the beams generated from smaller-area FEA cathodes along with producing short bunch using gated DFEA cathodes currently under development [13].

MULTIPHOTON EMISSION FROM CESIUM TELLURIDE PHOTOCATHODES

H. Panuganti†, C. Prokop, Department of Physics, Northern Illinois University, DeKalb, IL, USA
P. Piot, Fermi National Accelerator Laboratory, Batavia, IL, USA

Abstract

The High-Brightness Electron Source Lab (HBESL) at Fermilab operates an L-band RF gun (1.3-GHz) that incorporates a Cesium Telluride (Cs_2Te) photocathode illuminated by an ultra-short (sub-100 fs) laser pulses. In this contribution we report recent studies on exploring the electron beam emission using 800 nm laser pulses (instead of the 266 nm nominal wavelength used for linear photoemission).

INTRODUCTION

Photocathodes are excellent sources for production of short electron bunches [1]. Production of short bunches is possible due to the advancements in the drive laser pulse times combined with availability of fast-response photocathodes. Photoemission allows generating higher charges compared to field- and thermionic emission, and also with small beam transverse emittance. One good parameter to characterize the performance of a photocathode is quantum efficiency (QE), which is defined as the number of electrons emitted for a unit photon. Cesium Telluride is considered to be an exceptionally high QE (up to 20 %) semiconductor photocathode [2]. The work function of Cs_2Te 4.6 eV corresponds to the laser wavelength of 266 nm falling in the ultraviolet (UV) region. Since most of the commercially available lasers include lasing media with high gain in the infrared (IR), frequency up-conversion to the UV is generally done for linear photoemission from metallic and some semiconductor cathodes. For titanium sapphire based laser systems (λ~800 nm), UV pulses for photoemission are obtained from frequency tripling of IR pulses using a two-stage process consisting of a second harmonic generation (SHG) stage followed by a sum frequency generation (SFG). In order to preserve the short pulse duration during the up-conversion process, both stages generally use thin BBO crystals which results in low IR-to-UV conversion efficiency typically < 10%. In this paper we present preliminary results toward attempting to generate electron bunches with commensurate charge directly using the amplifier IR pulse. We specifically report on the observation of two-photon emission from Cs_2Te.

PHOTOCATHODE THEORY

Spicer developed the first model in 1958 to explain photoemission in semiconductors, which is commonly referred to as the Three Step Model, which models the photoemission mechanism as a bulk effect [3]. In the first step, an electron absorbs a photon and gets excited from the valence band to the conduction band. In the second step, the excited electron transports to the surface. In the third step, the electron escapes to the vacuum level resulting in emission. The QE equation for a semi-infinite photocathode slab is given by [3]

$$QE = [1 - R]\frac{\frac{\alpha_{PE}}{\alpha}P_E}{1+\frac{1}{\alpha L}}$$

Where R is the reflectivity of the material; α is the intensity attenuation coefficient of the photocathode material; α_{PE} represents the coefficient of absorption for the vacuum level, or the number of electrons that are excited to the vacuum level that can possibly photoemit per unit laser intensity available; L is called the escape length which represents the strength of the electron scattering; P_E is the probability that an electron at the surface with sufficient energy to escape, escapes. Here all the parameters are functions of $h\upsilon$. Fowler-Dubridge model is derived for photoemission for metallic photocathodes based on similar approach. It is the first step (photo-absorption and excitation) that distinguishes between single-photon emission from multiphoton emission. Once the electrons get excited, the rest of the processes viz. electron transport to the surface and electron escape remain the same. In single photon emission the intensity dependence of QE goes away. But in multi-photon emission α_{PE} additionally depends on the intensity of the light (temporal) besides $h\upsilon$, as the non-linear "simultaneous" absorption of multiple photons (of lower energy) has to occur to excite an electron to the vacuum level. Hence shorter laser pulses are required for higher order photoemission.

EXPERIMENT

The experiment reported in this paper was carried at the high brightness electron source laboratory (HBESL). The HBESL facility consists of a 1.5 cell L-band 1.3 GHz RF gun powered by a 3 MW klystron. The photocathode drive laser consists of a broadband (200 nm) Octavius oscillator followed by a SpectraPhysics regenerative amplifier. The amplified IR pulse typically has 100 fs duration. The IR-to-UV SHG and SFG conversion processes incorporate respectively a 0.300 and 0.150 mm BBO crystals. The crystal thicknesses were optimized with SNLO and short UV pulse (130 fs), and were measured using a polarizing-gating UV FROG. The produced pulses were short enough to enable the production of uniformly charged ellipsoidal bunches using the blow-out regime [4]. A schematic of the experimental setup used for our experiment appears in Fig. 1. A 4 mJ amplified laser pulse is sent to the HBESL accelerator

† harsha.panuganti@gmail.com

vault where it is converted to UV. The laser energy can also be measured prior to the injection into the accelerator beamline using an energy meter and a calibrated diode. A virtual cathode – a one-to-one optical image of the photocathode, located outside of the vacuum – enables the measurement of the laser transverse distribution on the photocathode. The laser hits the Cs_2Te photocathode under normal incidence angle. The charge emitted from the photocathode can be collected by a Faraday cup (FC) located immediately downstream of the gun; see Fig. 1. The FC was calibrated with an integrated current transformer (ICT) at high charge (nC) values and is used to measure the low charge values associated with the bunches produced via multiphoton emission.

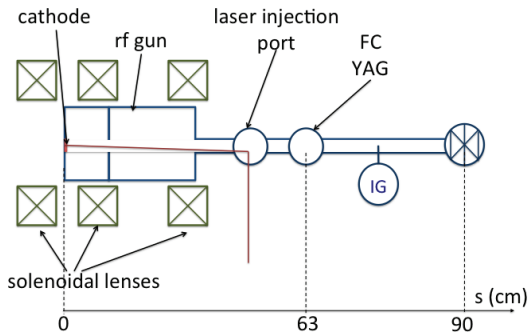

Figure 1: Overview of the HBESL electron source area. The IR pulse is injected through the laser injection port. The legend is *FC*: Faraday cup, *IG*: ion gauge, *YAG*: Yttrium Aluminum Garnet scintillating screen.

The produced bunch charge downstream of the RF gun strongly depends on the relative phase between the laser and the gun's RF field. Figure 2 shows the measured charge as a function of the launch phase referred with respect to the RF master oscillator. For this measurement the amplified IR laser pulse was directly sent to the cathode. The three traces correspond to three different laser transverse spot sizes of 3, 5 and 7 mm.

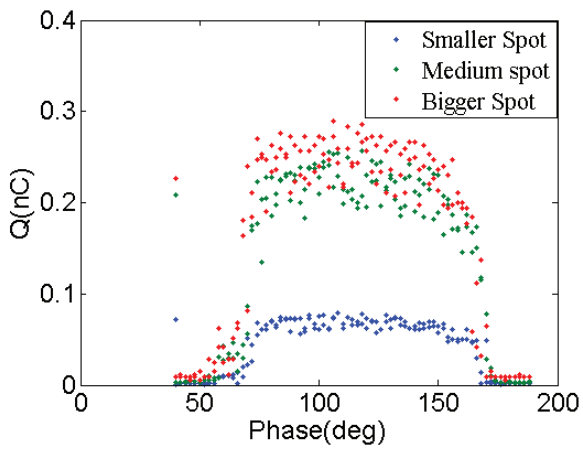

Figure 2: Charge dependence on laser phase relative to the gun (with an arbitrary phase offset). The blue, green, and red traces correspond respectively to laser spot diameter of 3, 5 and 7 mm on the photocathode.

The shape of the phase scan traces confirms that the charge emitted is from photoemission. Figure 3 shows the charge yield in the Faraday cup as a function of the laser energy for the same three different laser spot sizes.

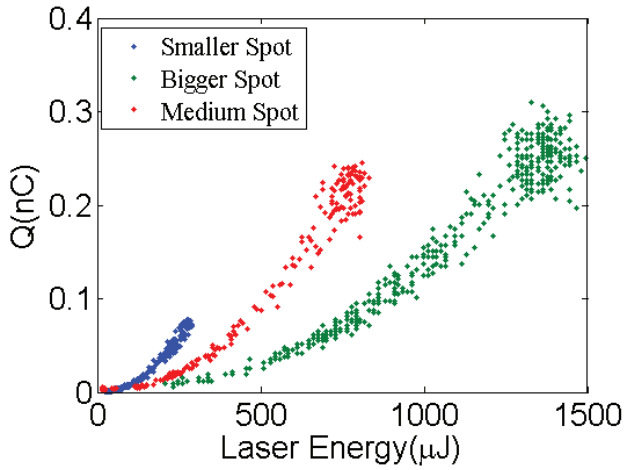

Figure 3: Charge variation as a function of laser energy for the three laser spot sizes considered in Fig. 2.

The stronger nonlinear dependence of the charge on the laser energy for the smaller spot size indicates that higher energy flux (J/m^2) produces higher charge in photoemission from the IR laser. Taking the laser's transverse density to follow a Gaussian distribution, smaller spot sizes obtained by clipping a larger spot impinges a higher laser flux for a given total laser energy and hence produces higher charge. The nonlinear signature of the charge–energy traces reported in Fig. 3 hint to a nonlinear photoemission process. To further quantify the dependence of the charge on the laser energy, we plot Fig. 3 on a log-log scale; see Fig. 4. The overall linear regression of the data confirms that the charge scales as $Q \propto I^2$ (where I is the laser intensity) suggesting that two-photon emission is the dominant process rather than the anticipated three-photon emission [5]. Some data points at lower charge/energy values with possible higher contribution from background noise (represented by '+') were omitted for linear curve fitting.

Photoemission is an independent process from charge acceleration, but the charge yield out of the RF gun which has a practical importance depends on the accelerating gradient in the gun due to the different electron beam dynamics. Figure 5 shows the log-log plots of charge vs. laser energy for different accelerating gradients (AD values) for the medium laser spot size. For a given logarithmic curve $logy = nlogx + C$, the coefficient A of $y = x^n$ can be calculated by using the relation $A = exp(C)$. In our case, $n = 2$ and A is the quadratic

coefficient. The inset in Fig. 5 shows the variation in the quadratic coefficient with the accelerating gradient.

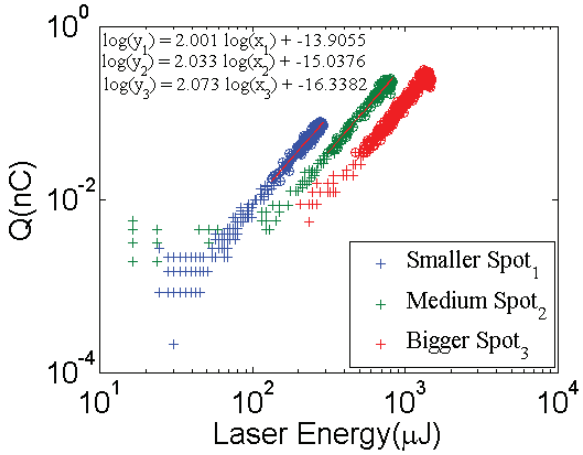

Figure 4: Logarithmic plots corresponding to the data presented in Fig. 3.

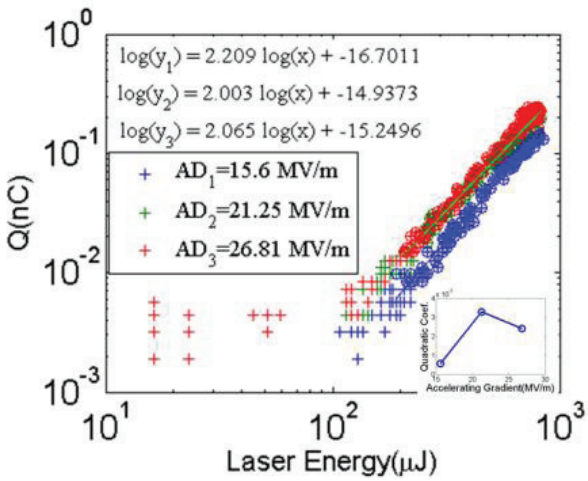

Figure 5: The effect of the accelerating gradient on the charge yield. Inset: The variation of the quadratic coefficient with the accelerating gradient.

Experimentally, we calculate the QE of a photocathode based on the correlation between the charge emitted Q by the given photocathode and the corresponding drive laser energy E as follows

$$QE \quad \frac{n(e)}{n(p)} \quad \frac{Q/e}{E/hc\lambda^{-1}} \quad \frac{Q}{E}\left(\frac{hc}{\lambda e}\right)$$

Where $n(e)$ is the number of electrons emitted, $n(p)$ is the number of photons impinged, λ is the wavelength of the drive laser, e is the electronic charge, λ is the wavelength of the laser, h is the Plank's constant, c is the velocity of light. Rewriting the above equation in more convenient units of charge and energy for the two wavelengths (of drive laser) of interest viz. 800 nm (IR) and 266 nm (UV) we get

$$QE_{UV} \quad 4.7\times10^{-6}\left(\frac{Q[pC]}{E[\mu J]}\right)$$

$$QE_{IR}(E) \quad 1.56\times10^{-6}\left(\frac{Q[pC]}{E[\mu J]}\right)$$

Figure 6 shows the charge vs. UV laser energy for the single photon emission from Cs_2Te.

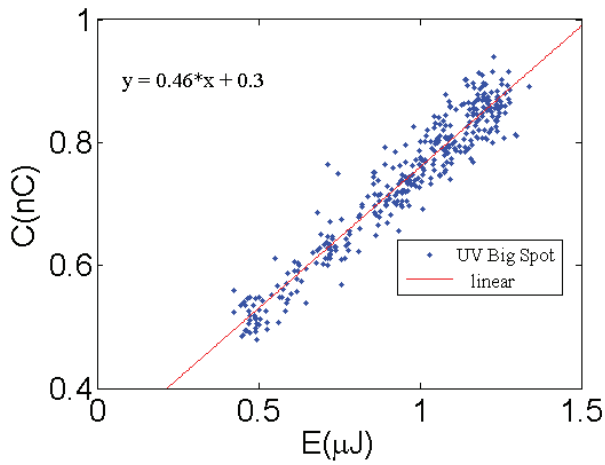

Figure 6: Charge vs. UV laser energy for Cs_2Te (single photon emission).

Typically, the QE is not defined for multiphoton emission as the ratio is not a constant like in the case of single photon emission. Or in other words increases with the laser energy, which possibly makes multiphoton emission preferable to obtain higher charge values at higher drive laser energy values, when compared to single photon emission. But we can define QE_{IR} as a function of E as in the previous equation and compare with that of UV.

ANDROID APPLICATION FOR MONITORING THE STATUS OF THE ADVANCED PHOTON SOURCE

M. Borland*, Westmont, IL, USA

Abstract

Smartphones and tablets are nearly ubiquitous and have the ability to quickly access and display data from network sources. This suggests their suitability for remote monitoring of a facility such as the Advanced Photon Source (APS). While one possibility is to access data using a web browser running on the device, native applications offer attractive features, such as improved display and background execution. We report on development of an Android application for monitoring the status of the APS. In addition to displaying data, the application can issue alerts when beam is lost or restored. Home screen widgets of various sizes are also provided. We describe not only the features of the application, but also give details of the implementation. The application is free of advertising and is available free of charge on the Google Play store.

INTRODUCTION

Like many synchrotron radiation facilities, the Advanced Photon Source (APS) operates thousands of hours per year. During operating periods, it is expected to provide beam 24 hours a day, seven days a week. Getting information about status to accelerator staff, beamline staff, and beamline users is thus very important. The ubiquity of smartphones and tablets provides a way to do this.

These devices are internet-enabled, so it is of course possible to get information via a web browser. However, using a native Android application provides several advantages. One can provide high-level status on the notification bar, which is visible without unlocking the phone or opening the application. One can provide a home-screen widget that provides more information than will fit on the notification bar. The notification and widget can both be used to launch the full application. Another advantage of the native application over browser-based information delivery is that the native application can run in the background and provide audible alerts of significant events.

Inspired by these ideas, we developed an Android application that provides both high-level and detailed status data about the APS. The Android platform was chosen for its open-source nature and the low cost of entry for devices and development. Also, the Android home-screen widget feature provides a superior way to display very high level data without opening the application. Unlike other smartphone platforms, the Android Software Development Kit (SDK) is free and available for essentially all platforms, which allowed using Linux for development.

The application is called APSStatus and available free of charge on the Google Play store. The application is also free of advertising.

*michael.d.borland@gmail.com

FEATURES AND CAPABILITIES

The APSStatus package includes a main application and three home-screen widgets. The main application is organized into a series of pages or tabs, each of which displays information of a certain type. Presently there are tabs for overall status, status messages, 24-hour and 1-week history plots, superconducting undulator status, power supply summary status, power supply detailed status, vacuum system status, rf system status, personnel safety system status, and front-end equipment protection system status. Figure 1 shows the main status screen. This is typical of the status screens, in that it features a heading with a prominent date and time stamp, which allows the user to easily ascertain if the data is fresh. Data is updated at 1 minute intervals.

Since not all of the selections of data will be of interest to all users, the application menu's "Tab Settings" selection allows the user to determine which tabs will be displayed.

Most of the tabs supply snapshots of data without any history. One exception is the status messages display, which displays the history of recent status updates issued by control room staff. Two other exceptions are the 24-hour and 1-week history tabs, which provide plots of beam current, beam lifetime, rms beam motion, number of shutters open, horizontal emittance, and vertical emittance. Figure 3 shows an example of the 1-week history display. Touching a plot will bring up a zoomed-in version with pinch-to-zoom and scrolling features.

In addition to the main application, the user can add one or more of the three home-screen widgets to their home screen. These display small selections of data and require less than 300 bytes per update, i.e., less than 0.4 MB per day. Hence, these can be left running and provide the most essential information at a glance.

The largest of these widgets, which has some special features, is shown in Figure 4. It shows the beam current color-coded by status, the number of bunches, the beam lifetime, the number of operating beamlines, the horizontal and vertical emittance, and the injection efficiency on the last top-up shot. Unlike the other widgets, this widget also posts the beam current to the notification bar, where it can be seen from any home screen and even when the screen is locked. The beam current notification is color-coded to indicate whether it is within the expected range for the present machine mode or not.

Another special feature of this widget is that it can provide audible alerts when beam is lost or restored. The alerts are configured from the main application's menu. The user

Copyright © 2013 CC-BY-3.0 and by the respective authors

can elect to be alerted when beam is lost, when it is absent for an extended time, and when it is restored. The user can also set a quiet-time preference to avoid being disturbed while sleeping, for example.

SOFTWARE DESIGN

Those who are uninterested in software design may wish to skip this section, as it has little to do with how the application is used or what it can do. This section also assumes some familiarity with Android development.

We used the Eclipse Integrated Development Environment (IDE), which is advantageous in that it helps one quickly learn both the Java language and the specific methods provided by Android. The web contains many resources, such as Android tutorials and user forums (e.g., StackExchange).

The main application is organized into a series of Fragment objects, which are grouped together as a single application. Each Fragment displays a screen with data of a particular type, e.g., power supplies or vacuum. The interface is built using Peter Kuterna's SwipeyTabs class and SwipeyTabsSampleActivity, which is an extension of the FragmentActivity class. SwipeyTabs provides a convenient mechanism for switching between related activities by clicking on a tab at the top of the screen or swiping the screen left or right.

SwipeyTabs keeps three Fragments active at any time. These are the Fragment presently being viewed, plus the Fragments to the left and right. If the user swipes or tabs to the Fragment on the right, say, the new Fragment is generally displayed instantaneously because it is already active. Meanwhile, the next Fragment is triggered so it is more likely to be ready when the user swipes again. (If the user swipes too quickly, this may not be the case.)

The data that is displayed by APSStatus and its various widgets is provided by the APS web server from files written by a node that has read access to EPICS process variables and write access to the web server's file space. A common choice for sharing data on the web is XML (eXtensible Markup Language) files and APSStatus was originally written to use such files. However, XML has a well-deserved reputation for verbosity, resulting in a very poor ratio of data delivered to bandwidth used. Since excessive use of bandwidth is highly undesirable for mobile devices, we switched to gzipped SDDS (Self-Describing Data Sets) files. These have the additional advantage that they are easily created using the SDDS tools [1, 2] that are already part of the APS control system. There is also a convenient SDDS library for Java that reads from a URL directly [3].

Fragments are at present divided into three types: (1) those that read and display data from an SDDS file. (2) those that retrieve and display bitmap images. (3) those that retrieve and display text from the server. Most Fragments are of Type 1.

Each Type 1 Fragment has a corresponding SDDS file on the server that provides its data. This is done in part because Fragments do not share data, so there is no point in reading data from a common source. Also, reading from a common source would invariably mean using more bandwidth than needed. Hence, each Fragment is supplied with a minimalist data file containing only the relevant information. Each file contains a time-stamp, which is prominently displayed along with the other data. This ensures that the user will be able to tell if the data is stale for some reason. The update interval of the data is 1 minute. Updates for each active Fragment are handled by separate threads.

The displays for Type 1 Fragments require only stock Android widgets. In order to accommodate various screen sizes, the root widget is a ScrollView, which permits vertical scrolling. Inside the ScrollView are TextView widgets, often packed into TableLayout widgets.

The Type 2 Fragments display a series of small bitmaps that are provided directly by the server, i.e., they do not retain or plot the history data themselves. When a small bitmap is pressed by the user, a larger bitmap of the same data is retrieved and displayed. This reduces use of bandwidth and memory by not transmitting and storing large bitmaps that may be of no interest.

In addition to the main application, there are three home-screen widgets that provide various selections of very high-level information. The home-screen widgets are implemented using the AppWidgetProvider class and run independently of the main application. As with the main application, the home-screen widgets have a 1 minute update interval. Touching any of these widgets will open the main application.

Of the three home-screen widgets, one is larger and provides more information. It also provides an alarm service, which is configured from the main application, and places information in the notification bar. The alarm settings are communicated from the main application to this widget using the SharedPreferences facility.

On the server side, a cron job runs at 1 minute intervals to make the various SDDS data files. For each data file, there is generally a separate request file that is used in an invocation of `sddscasr` to create a snapshot. The snapshots are processed to, in particular, convert status and floating point data to a uniform format. This simplifies coding on the application side and also reduces the size of the data transmitted. Small data files just for the home-screen widgets help minimize use of bandwidth.

Other cron jobs run at intervals to create the bitmaps needed by the history displays. These jobs used pre-existing scripts that invoke the program `sddsplot`.

CONCLUSIONS

We have created an Android application that provides status information about the Advanced Photon Source, including history graphs and detailed status of major subsystems. The application includes home-screen widgets, notification bar posts, and optional audible alerts of beam loss or restoration. Bandwidth use is minimized in part through use of gzipped SDDS files. The application is available free of cost on the Google Play store, and is free of advertising.

HIGH-POWER TESTS AND INITIAL ELECTRON BEAM MEASUREMENTS OF THE NEW HIGH-GRADIENT NORMAL CONDUCTING RF PHOTOINJECTOR SYSTEM FOR THE SINCROTRONE TRIESTE

L. Faillace#, R. Agustsson, P. Frigola, A. Verma, Radiabeam Technologies LLC, CA, USA
H. Badakov, A. Fukasawa, J. Rosenzweig, A. Yakub, Department of Physics and Astronomy, UCLA CA, USA
F. Cianciosi, P. Craievich, M. Trovo', Sincrotrone Trieste, Italy

Abstract

Radiabeam Technologies, in collaboration with UCLA, presents the development of a high gradient normal conducting radio frequency (NCRF) 1.6 cell photoinjector system, termed the Fermi Gun II, for the Sincrotrone Trieste (ST) facility. Designed to operate with a 120MV/m accelerating gradient, this single feed, fat lipped racetrack coupler design is modeled after the LCLS photoinjector with a novel demountable cathode which permits cost effective cathode exchange. Full overview of the project to date, installation, high-power RF conditioning and initial electron beam emittance measurements at Sincrotrone Trieste will be discussed along with basic design, engineering and manufacturing.

INTRODUCTION

Radiabeam is currently involved in the development of new technology aimed at high average power operation for a NCRF electron gun system, the FERMI II RF Gun, for the Sincrotrone Trieste facility operating at the frequency of 2.99801GHz with a repetition rate >50Hz.

The gun design was originally based on the UCLA-University of Roma-INFN-LNF [1] high repetition rate photoinjector for SPARX project, which borrowed the main features from the LCLS gun [2,3]. Nevertheless, the basic design was re-optimized by request of ST with two main changes: 1) an exchangeable cathode plate for easy exchange of different material samples; 2) single-feed for a cost-effective and more compact device.

RF GUN DESIGN

The RF design of the Gun has been performed by using the codes SuperFish [4] and HFSS [5]. Figure 1 shows half structure of the RF gun with surface electric field distribution calculated by HFSS. The RF power is fed through one waveguide only (top one); the symmetrical waveguide, acting as a dummy waveguide, forbids the propagation of the electromagnetic field that is below its cutoff value (i.e. the dummy waveguide has a width much smaller than the input one). The main purpose of the second waveguide is to cancel the field dipole component.

#faillace@radiabeam.com

Cell Design

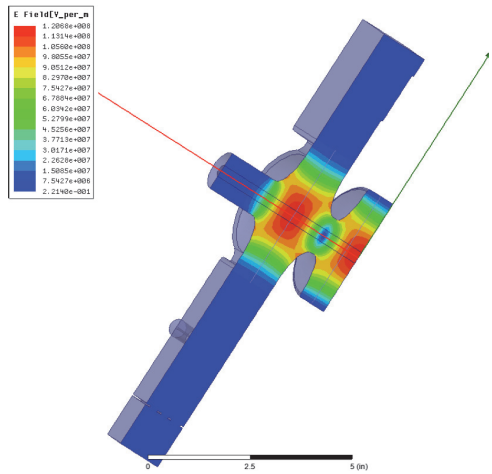

Figure 1: 3D model used for HFSS simulation. Surface electric field is shown.

The RF cavity shape, as proposed, has several innovative electromagnetic features, including Z-coupling and enhanced cell-to-cell coupling to produce higher mode separation, elliptical irises to reduce surface electric field, symmetric couplers for dipole mode minimization, racetrack geometry to minimize quadrupole field components. In contrast to the LCLS gun, which has these features, it is externally fed only by one side, avoiding the need of a power splitter and making the whole assembly much more compact, easier to handle and cost efficient.

In order to calculate the maximum surface electric field, we normalize the on-axis field to 120 MV/m at the cathode. The peak field on the iris is found to be 102 MV/m, below the breakdown safety threshold.

Per usual procedure, a first pass on the RF design was made with SUPERFISH and then HFSS was used to provide a complete picture of the RF performance, including mode frequencies, field balance, quality factor *Q,* shunt impedance and external coupling.

The design parameters achieved in simulation through this process are summarized below in Table 1.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Table 1: Main RF Parameters

Parameter	Simulated value
π-mode frequency	2.998 GHz
0-π mode separation	14.2 MHz
Quality factor Q_0	13,750
External coupling β	1.8
Shunt Impedance R_{Shunt}	60.8 MΩ/m
Peak Surface *E* (120 MV/m @cathode)	102 MV/m
Input power *P*	<10 MW

Dipole and Quadrupole Component

The dipole and quadrupole components of the RF field have been evaluated using HFSS. The symmetry of the Z-coupling structure guarantees cancellation of the RF dipole component, apart from a negligible (in high-*Q* standing wave devices) transient from the single-side RF feed. The quadrupole field, on the other hand, is managed by adjusting the "race-track" spacing.

GUN FABRICATION, TUNING AND LOW-POWER MEASUREMENTS

The RF Gun was machined in-house and all the brazing cycles at SLAC, followed by final tuning. The Gun after the final brazing step is shown in Figure 2.

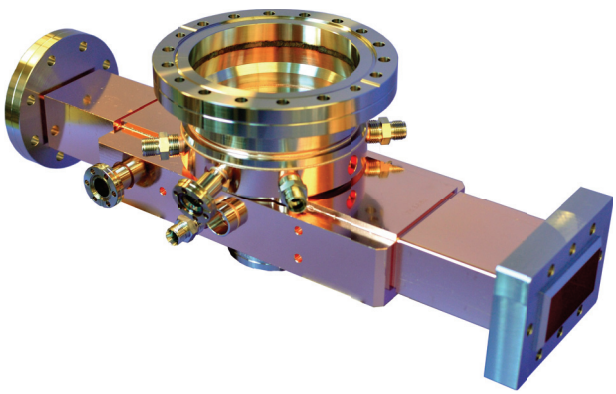

Figure 2: Picture of the Fermi II Gun after final brazing.

In order to check the simulated parameters, we performed low-power measurements by using a Vector Network Analyzer (VNA). The comparison is given in Table 2, showing good agreement.

Table 2: Comparison between Simulations and Measurements of the Main RF Parameters

	Measurement	HFSS
Frequency	2.99801 GHz (19 C, 40% humidity)	2.998GHz
Mode Separation	14.5 MHz	14.2 MHz
Q_0	13,350	13,750
Coupling beta	1.85	1.8

The reflection coefficient at the input RF waveguide is shown in Fig. 3. The tuning frequency was set to 2.99801, at 19°C and 40% humidity (assuming an operating temperature of 38°C).

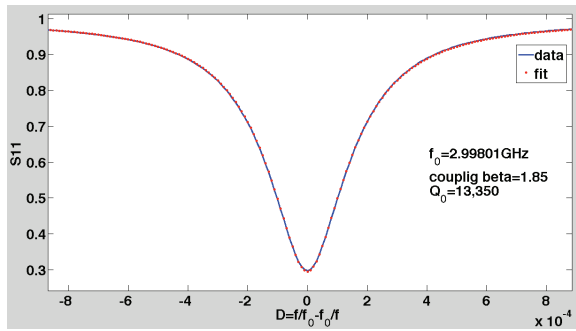

Figure 3: Reflection coefficient. Data (red dots) and fit (blue line).

The balance of the electric field profile was measured by means of the bead-drop procedure and using a 2mm dielectric spherical bead. The good agreement between data and fit is given in Fig. 4.

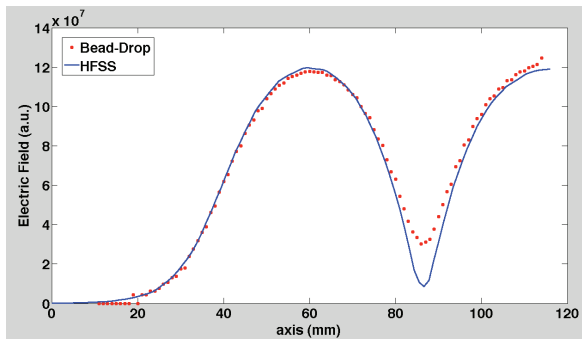

Figure 4: On-axis electric field profile. Data (red dots) and fit (blue line).

INSTALLATION AND HIGH-POWER RF CONDITIONING

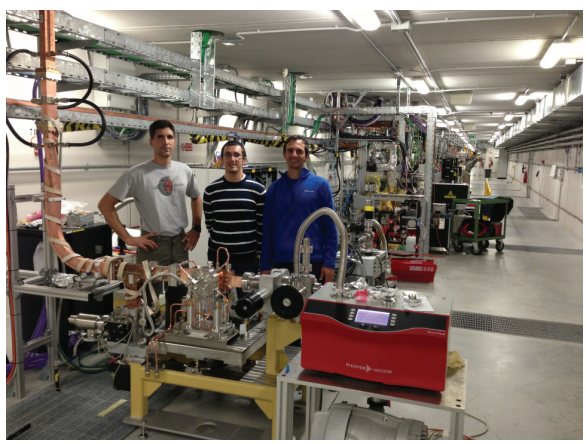

Figure 5: Installation of the Fermi II Gun inside the tunnel at Sincrotrone Trieste.

Copyright © 2013 CC-BY-3.0 and by the respective authors

The Fermi II Gun Installation started in Trieste on January 4th 2013 (Figure 5). The gun was brought under vacuum in a test area to check if any leaks were present as well as the frequency shift that resulted to be about 800 kHz, as expected.

A dedicated area for high-power gun testing is located behind the current RF gun station. The Fermi II gun was installed in this area to start high-power conditioning. The input power was raised up to 11MW and a repetition rate of 50Hz. The conditioning between 10Hz and 50Hz, given in the chart in Fig. 6, required a temperature variation of only -2°C. The vacuum base level was 2.4E-9 mbars.

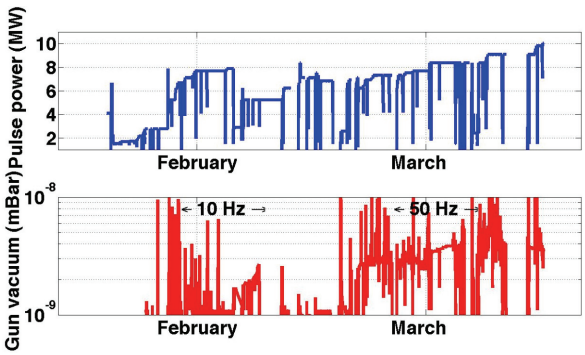

Figure 6: Monitoring of the high-power conditioning and vacuum levels.

The first electron beams were generated by using the laser profile shown in Figure 7.

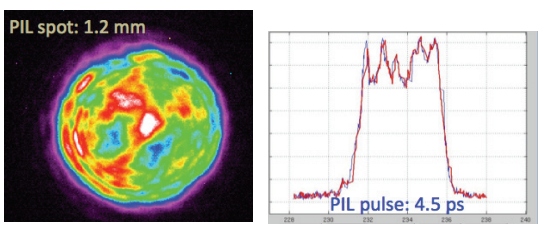

Figure 7: Left, laser spot transverse profile; right, pulse length profile.

The output energy was 5.1 MeV for 8MW of input RF power. Although the laser spot was not optimized yet, the quantum efficiency showed a good value of about QE=3.3E-5, see Figure 8.

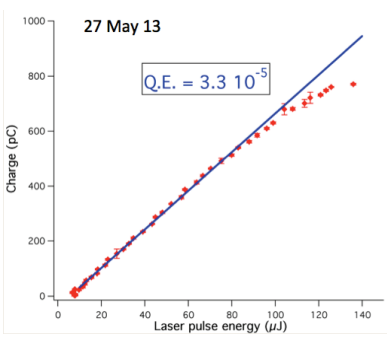

Figure 8: Charge yield as function of laser energy.

The first emittance measurement was performed with a 500 pC beam at 100 MeV, by using the quadrupole scan technique. In Figure 9, we show the result for the measured transverse normalized emittance on the vertical plane with a promising value of 0.67 microns.

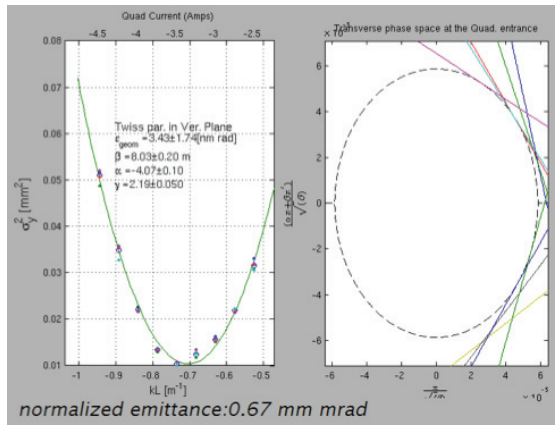

Figure 9: Initial emittance measurement of a 500pC beam.

CONCLUSIONS

We have presented the RF design, fabrication, high-power RF conditioning and initial beam measurements of the new Fermi II RF Gun. Innovative features to the class of RF Guns, such as elliptical irises and an exchangeable cathode system, improve the performance of this gun in terms of power handling and robustness. The removable cathode assembly showed good thermal performance even at 50Hz. The initial measurements of the beam normalized emittance are very promising.

ACKNOWLEDGMENT

I would like to thank Mauro Trovo' (ST) for providing material on the initial beam measurements.

INNOVATIVE LOW-ENERGY ULTRA-FAST ELECTRON DIFFRACTION (UED) SYSTEM*

E. Threlkeld, L. Faillace#, S. Boucher, RadiaBeam Technologies, Santa Monica, CA 90404, USA
P. Musumeci, University of California, Los Angeles, CA 90095, USA

Abstract

RadiaBeam, in collaboration with UCLA, is developing an innovative, inexpensive, low-energy ultra-fast electron diffraction (UED) system which allows us to reconstruct a single ultrafast event with a single pulse of electrons. Time resolved measurement of atomic motion is one of the frontiers of modern science, and advancements in this area will greatly improve our understanding of the basic processes in materials science, chemistry and biology. The high-frequency (GHz), high voltage, phase-locked RF field in the deflector allows temporal resolution as fine as sub-100 fs. In this paper, we show the complete design of the UED system based on this concept, including initial beam measurements.

INTRODUCTION

Time resolved measurement of atomic motion is one of the frontiers of modern science, and advancements in this area will greatly improve our understanding of the basic processes in materials science, chemistry and biology. One technique under active development in this area is ultrafast electron diffraction (UED), which has several distinct advantages over X-ray diffraction for certain applications. UED utilizes a less expensive source; the electrons are less damaging to the specimen (at comparable energies); the scattering length of electrons better matches the penetration depth of the probe laser; UED is more suitable for gas phase samples; and it allows direct measurement of atomic positions, since the electron scatter mostly from nuclei. UED has already been used to study solid-state phase transitions [1, 2], gas phase reactions [3, 4], strongly coupled systems [5, 6] and surface dynamics [7]. In light of these results, researchers are demanding ever-shorter electron bunches in order to improve the resolution of their UED measurements. However producing intense sub-ps pulses of electrons in the desired energy range (30 - 100 kV) is challenging, due to space-charged induced longitudinal spreading. To date, efforts in this area have concentrated on either minimizing the bunch charge, which reduces the signal-to-noise ratio (SNR), or on using higher-energy electron beams, which reduces the diffraction angle and increases the size and the cost of the system. RadiaBeam, in collaboration with UCLA, is developing an innovative, inexpensive, low to moderate energy UED system which allows to reconstruct a single ultrafast event with a single pulse of moderate energy electrons (100 keV). By implementing a fast Radio-Frequency (RF) deflecting cavity immediately after the sample, the diffracted electron beam can be "streaked," transforming the temporal evolution of the diffraction pattern into a transverse image (see Figure 1). The high-frequency (GHz), high voltage, phase-locked RF field in the deflector allows temporal resolution as fine as 100-fs and below, while the probe electron beam can remain comparatively long (10's of ps), and contain a large number of electrons (~10^8).

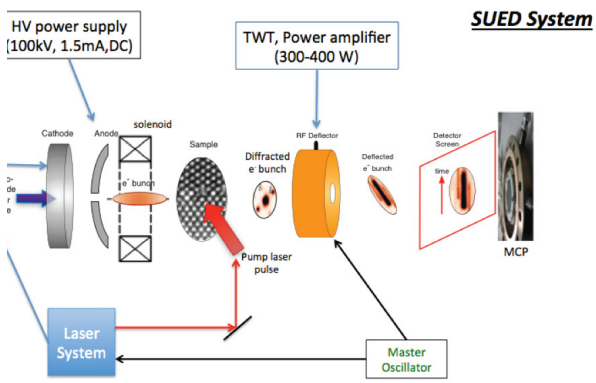

Figure 1: "streaked"- Ultra Electron Diffraction System.

ENGINEERING OF THE UED SYSTEM

The current setup of the UED system:

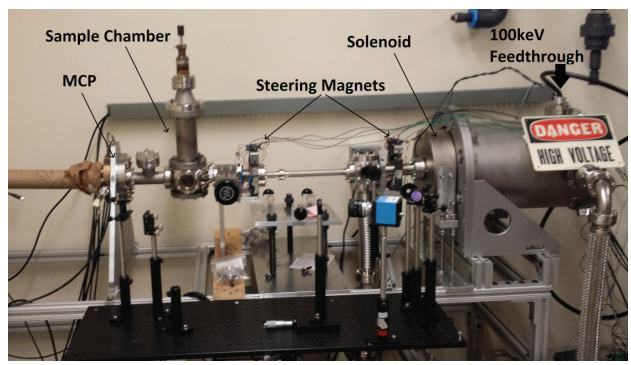

Figure 2: Current setup of the UED system.

The cathode location is set as z=0m. The solenoid is positioned at about z=6cm allowing a beam focusing point anywhere between the MCP (z=1m) and z=70cm. The sample is located at z=74cm and there is room for a second solenoid at z=40cm. Eventually the deflector can be put at z=50cm, just after the sample chamber to match previous resolution calculations.

PHOTOELECTRON GUN

The design of the 100 kV photocathode electron gun has been carried out by means of the 2D RF/Static simulation code SuperFish and the 2D gun design code

*Work supported by US DOE grant # DE-SC0006274
faillace@radiabeam.com

EGUN2. As a starting point, we chose the 100 kV electron gun developed at Eindhoven University of Technology [8].

The main issue, when dealing with high DC field values, is represented by the transition between air and vacuum (vacuum feed-through) as well as the vacuum level inside the gun vessel. Both issues, addressed in the present section, can be the cause of overvoltage and high risk of breakdowns.

Special attention must be put on the feed-through design. A safe configuration would be to lay a high-insulating material around the inner conductor that will be electrically attached to the aluminum cathode holder. Also the interface geometry (such as an exponential cup filled with a dielectric) will be necessary.

The 2D profile used in simulations is given in Figure 3. The cathode is a flat disc with a 1 cm diameter. The holder, a hollow cylinder, allows for both back and front illumination and replaceability of the cathode piece itself. In the same figure, the axial electric field distribution is also shown. The field value at the cathode is about 9.8 MV/m. The maximum value is located at the round edge of the holder (11.8 MV/m). The above mentioned values of electric field are safe as far as breakdown is concerned, according to experimental results [9], showing that a high voltage of 250 kV is considered the safety threshold value inside a gap (cathode-anode) of about 1cm.

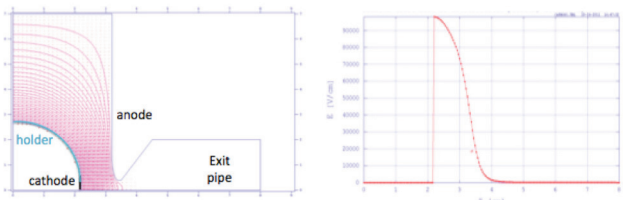

Figure 3: Left, 2D model from SuperFish (equipotential lines and field arrows are also shown); the cathode area is flat (1 cm dia.). Right, axial electric field (9.8 MV/m at the cathode).

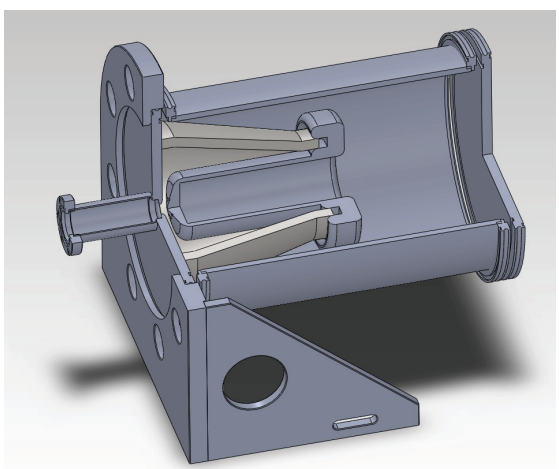

Figure 4: SolidWorks 3D model of the 100kV photo-gun.

A 3D mechanical model of the photo-gun, from SolidWorks, is shown in Figure 4. The replaceable cathode sample is made out of copper. The hollow cylindrical body that holds the cathode is made out of aluminum while the vacuum vessel, that the anode electrode is attached to, is stainless steel. In order to obtain very high vacuum level inside the gun (up to 10^{-14} mbar), a TMP pump will be used. The high-voltage feed-through and the TMP pump are attached to the vessel. The isolation between cathode and the anode is realized by using an insulating cone made out of Macor® (see: light grey conical piece in Figure 4).

PHOTOCATHODE DRIVE LASER

The laser used for this device is a Titanium-Sapphire 800nm 2GW (50fs pulse) source that goes through two BBO crystals (the first crystal is second harmonic generation while the second crystal is third harmonic generation) and gets converted to 266nm UV beam. This beam is sent to the photocathode using front illumination. A beam splitter is used to create a virtual cathode plane to enable measurement of the laser spot size with a CCD camera. A lens (f=50cm) is used to image onto the cathode an iris that can be used to adjust the spot size (see Figure 5).

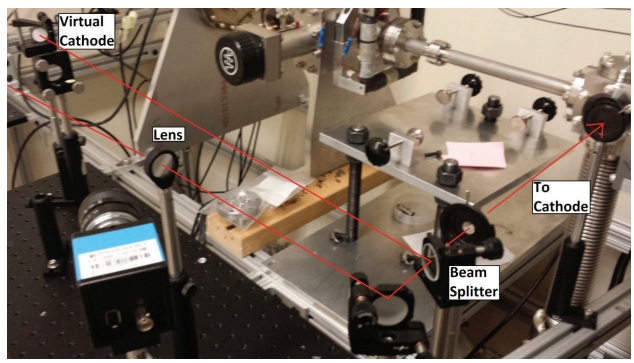

Figure 5: The optics just before the chamber including the imaging lens, beam splitter and virtual cathode.

BEAM CONTROL

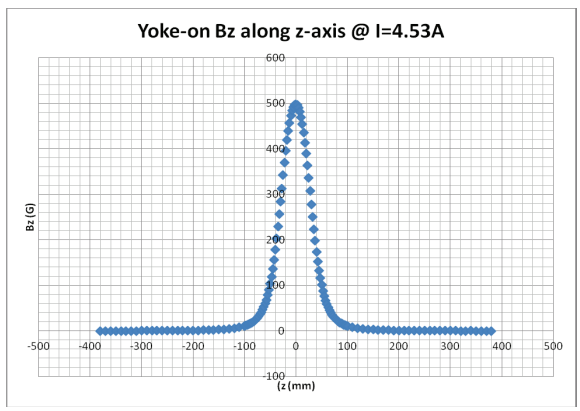

Figure 6: Plot of solenoid field at the center as a function of z.

Once the beam has been accelerated, it travels through the solenoid for focusing. See Figure 6 for the B vs Z of the solenoid. After, there are two 2-axis steering magnets for aiming and fine-tuning the position of the beam.

Copyright © 2013 CC-BY-3.0 and by the respective authors

DETECTOR SYSTEM

The micro channel plate (MCP) detector that will be used to image the beam is shown in Figure 7. The MCP basically works as an electron amplifier in which the incoming electrons generate secondary electrons. In this case, the incoming electrons enter channels in which they are accelerated by an electric field and generate the secondary electrons.

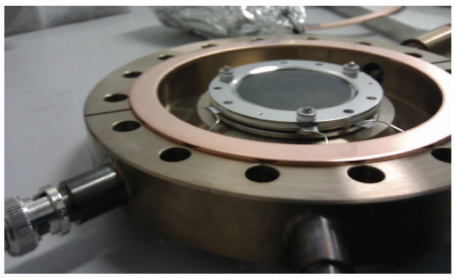

Figure 7: Multi Channel Plate Detector

The MCP is equipped with a phosphor screen that is imaged 1:1 onto the CCD camera, allowing a spatial resolution of 50 μm. The relation between the bunch duration and the length of the streak on the phosphor screen is obtained by integrating the Lorentz force that is acting on the electron bunch during its travel along the axis through the deflecting cavity. The MCP is located at the focusing point of the solenoid, in order to obtain a sharper diffraction pattern.

MEASUREMENTS

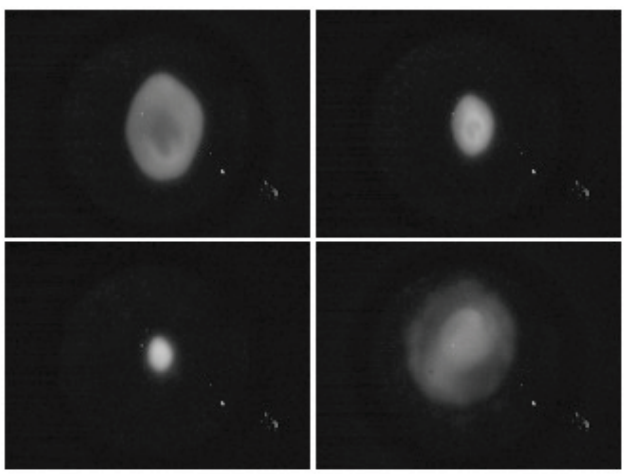

Figure 8: Beam images at different solenoid currents in order from top left to bottom right: 2.373A, 2.486A, 2.566A, 2.738A. The recurring white spots are dead pixels in the CCD camera.

In order to commission the system a solenoid scan was performed to compare the results with simulation and obtain first estimates on the beam parameters. We show in Fig. 8 a few representative images from the solenoid scan (Fig. 9). The minimum spot size at the MCP plane is obtained for a current of 2.566A. For these measurements the gun voltage was set at 40kV.

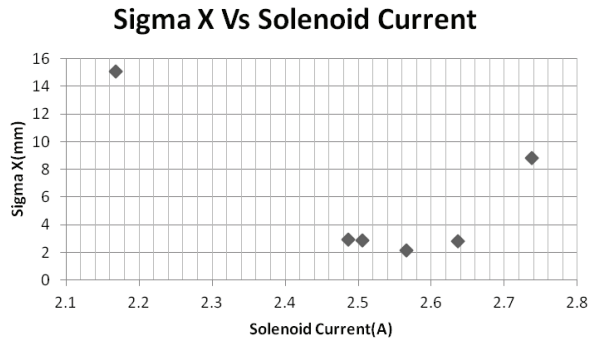

Figure 9: Measured Sigma X on the MCP as a function of solenoid current.

CONCLUSIONS

The UED technique has already been used to produce groundbreaking results in a number of areas of materials science and chemistry. It has been described as providing the capability to "make a movie" of events occurring on the atomic scale. Clearly, such a technology has the potential to enable new discoveries. The SUED system we are developing, with improved resolution and SNR, would enable even further breakthroughs in the understanding of ultrafast phenomena, stimulating new innovations in material science, chemistry and biology.

MODELING THE DEVELOPMENT AND MITIGATION OF CHARGE ACCUMULATION FOR PHOTO EMISSION ELECTRON GUNS*

C. Nieter†, D.A. Dimitrov, Y. Choi, Tech-X Corporation, Boulder, CO 80234, USA

Abstract

One potential problem with the operation of photo emission electron guns is the potential for charge to accumulate on the emission surface depending on how the biasing voltage is applied to the gun. If the voltage is applied away from the emission surface there is the potential for charge to accumulate on the emission surface since not all electrons will necessarily be emitted. This charge accumulation may affect the gun operation by reducing the accelerating field in the gun. We report on simulations that demonstrate this potential issue as well as simulations that test a potential solution where a secondary voltage is applied periodically to clear the accumulated charge.

INTRODUCTION

New design for photoinjectors has been proposed that will address the need for high current, high brightness beams for future particle accelerators [1, 2]. The design takes a primary electron beam from a conventional photocathode which is accelerated to a diamond window. The diamond window consists of a layer of diamond followed by a high-vacuum gap with an applied voltage across the window. The primary electrons scatter in the diamond generating cascade of secondary electrons. The electrons drift across the diamond where most of them are emitted into the vacuum gap and then into the accelerating cavity of the gun.

Since not all of the electrons are emitted from the diamond surface charge can build up at the diamond/vacuum interface. If enough charge builds up the field in the diamond can be shorted out preventing further electrons from drifting across the diamond. Experimental studies have shown for a primary electron beam whose pulse length is long enough there is a drop in the emission gain for the cathode [3]. It is believed that this drop off is due to electrons accumulating at the surface of the diamond reducing the electric field in the diamond.

We ran a series of simulations with the Vorpal multiphysics code [4] to study the process of charge accumulation in the diamond window from first principles. These simulations can be challenging due to the relative long time scales of the primary electron pulse length relative to the electron scattering rates in diamond. However, we were able to demonstrate the build up of charge at the surface and look at possible ways to clear the charge with a second voltage applied after the primary electron pulse has passed.

† nieter@txcorp.com

SIMULATIONS

We use the parameters given for the diamond window from Ref. [3] as a starting point for our simulations. To be able to complete the simulations in a reasonable amount of time the physical size was scaled down by a factor of 100 giving us a diamond thickness of 3 microns and the thickness of the full window (diamond plus vacuum gap) of 5.5 microns. Similarly the beam radius was reduced by a similar amount to 4 microns. We reduce the applied voltage by the same factor of 100 to keep the same electric field magnitude giving us a voltage of 30 volts across the diamond window.

We performed 3D simulations of the diamond window. The simulation domain was 5.5 microns in the direction of beam propagation and 10 microns in the transverse direction. We used Vorpal's electrostatic solver to solve for the electric field generated by the various applied voltages as well as the fields generated by the electrons themselves. The electrons are represented using the particle-in-cell (PIC) method with the addition of recently developed scattering models for electron propagation in diamond [5].

Since the time scales needed to cover the pulse width from from Ref. [3] are very long compared to the time scale needed to resolve the highest scattering rate for diamond we increased the beam current so the charge will accumulate faster in the simulations. We also apply a fully reflecting boundary condition for the particles at the diamond/vacuum interface effectively setting the emission probably at the surface to be zero. We run the simulation for the twice the pulse width so we can study the accumulation of the charge while the pulse is on and the dissipation of the charge after the pulse has passed.

Charge Accumulation Simulations

In the first simulation we maintain the voltage across the diamond window while the beam pulse is on. Once the beam pulse has passed we shut off the voltage across the diamond window. Figure 1 shows a scatter plot of the macroparticle positions projected into a plane with one direction along the direction of beam propagation in the simulation shortly before the voltage is shut off. This plot shows the charge accumulating at the diamond/vacuum interface.

In Figure 2 the electric field perpendicular to the diamond surface at the diamond/vacuum interface is plotted versus time. The magnitude of the electric field drops as more charge is introduced to the diamond and begins to accumulate at the diamond/vacuum interface. Eventually the field drops to zero as enough charge has accumulated to short out the field. Once the pulse has passed and the voltage across the diamond window is shut off the electric

Copyright © 2013 CC-BY-3.0 and by the respective authors

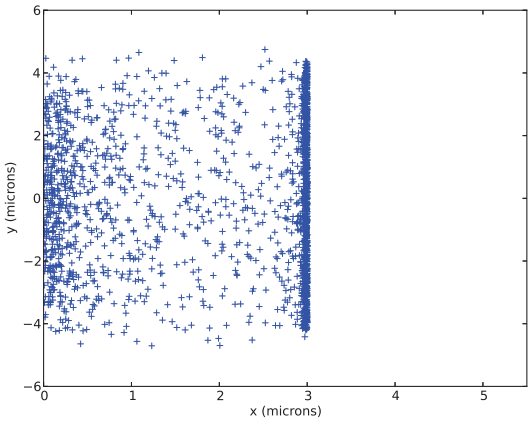

Figure 1: Macro-particles just before voltage across diamond window is shut off.

field changes sign as it is now the space charge of the electrons that dominates the electric field. The electrons that have now accumulated on the diamond surface are pushed back off by space charge forces. As the electrons leave the surface the magnitude of the electric field drops again but it begins to level off before reaching zero. This implies that a steady state may be reached or the rate of decrease could be slow enough that the charge accumulated may not be cleared before the next beam pulse hits the window negatively impacting the operation of the amplifier.

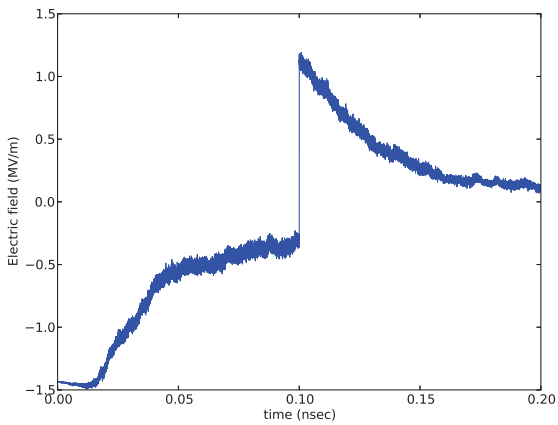

Figure 2: Electric field at diamond surface versus time.

Charge Clearing Simulations

A second simulation was run where after the beam pulsed as passed and the voltage across the diamond window is shut off a new voltage of the same magnitude is now applied parallel to the diamond surface. This produces an electric field parallel to the diamond surface that speeds up the clearing of the accumulated charge. This causes the charge transport to move parallel with the diamond surface and extract the electrons from the transverse sides of simulation. Figure 3 shows the number of macro-particles versus time for the original simulation (in green) and the new charge clearing simulation (in blue). The initial charge accumulation is the same for both simulations but the charge dissipates faster with the clearing voltage applied.

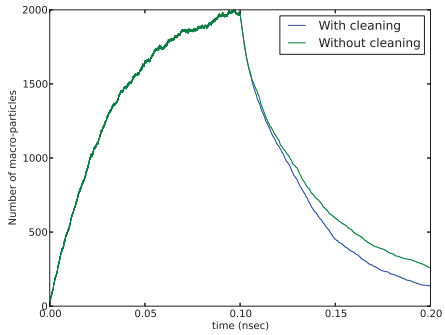

Figure 3: Number of macro-particles versus time for simulations with and without clearing voltage.

CONCLUSIONS

We have qualitatively shown that simulations can be used to study the process of charge accumulation in diamond amplifier designs proposed as part of new designs for photoinjectors. Both the build up and dissipation of the charge can be modeled and potential solutions to the charge accumulation can be studied.

Future plans include the addition of models for surface emission at the diamond/vacuum interface. This will better model both the process of charge accumulation and the process of charge dissipation after the voltage has been shut off since charges can now escape though the diamond/vacuum interface. Development work will be done to provide further flexibility in the particle boundaries so the clearing voltages can be applied directly to the diamond/vacuum interface.

Efforts will also be pursued to bring the simulation parameters closer to those found in a realistic device. These will include making use of HPC resources to allow for larger simulation sizes. Initial tests have shown that the diamond scattering may not require fully resolving the scattering rates since multiple scatter events can happen in a time step.

APS SUPERCONDUCTING UNDULATOR BEAM COMMISSIONING RESULTS*

Katherine C. Harkay#, Laura Boon, Michael Borland, Louis Emery, Glenn Decker, Roger Dejus, Jeffrey Dooling, Charles Doose, Joseph Gagliano, Quentin Hasse, Yury Ivanyushenkov, Matthew Kasa, Jonathan Lang, Douglas Robinson, Vadim Sajaev, Nicholas Sereno, Karen Schroeder, Yuko Shiroyanagi, Denise Skiadopoulos, Martin Smith, Emil Trakhtenberg, Aimin Xiao, Alexander Zholents, Efim Gluskin, ANL, Argonne, IL 60439, USA

Abstract

The first test superconducting undulator (SCU0) was successfully installed and commissioned at the Advanced Photon Source (APS) and is delivering 80- to 100-keV photons for user science. All the requirements before operating the SCU0 in the storage ring were satisfied during a short but detailed beam commissioning. The cryogenic system performed very well in the presence of the beam. The total beam-induced heat load on the SCU0 agreed well with the predictions, and the SCU0 is protected from excessive heat loads through a combination of orbit control and SCU0 alignment. When powered, the field integral measured with the beam agreed well with the magnet measurements. An induced quench caused very little beam motion and did not cause loss of the beam. The device was found to quench during unintentional beam dumps, but quench recovery is transparent to storage ring operation. There were no beam chamber vacuum pressure issues and no negative effect observed on the beam. Finally, the SCU0 was operated well beyond its design requirements, and no significant issues were identified. The beam commissioning results are described in this paper.

INTRODUCTION

Superconducting technology was used to build a fully functioning short-period test undulator (SCU0) at APS [1, 2]. Superconducting undulators allow a higher peak magnetic field compared to conventional devices, which can greatly benefit the light source community [3]. The SCU0 was designed and developed at APS in collaboration with Budker Institute of Nuclear Physics (BINP), Fermi National Accelerator Laboratory (FNAL), and U. Wisconsin, Madison. The SCU0 has a period length of 16 mm, magnetic gap of 9.5 mm, magnetic length of 0.34 m, and operates with photon energy in the first harmonic of 20-25 keV. The design operating current is 500 A, giving a design field of 0.64 T. The SCU0 incorporates several unique features, including an out-of-vacuum design, a beam chamber that is thermally isolated from the magnet cores, and a cryocooler cooling system. The SCU0, with a 2-m-long cryostat, was installed in the APS storage ring in Dec. 2012 (see Fig. 1).

SCU0 commissioning was completed over approx. 110 hr during an extended machine start-up period, and the device was released for user operation on Jan. 29, 2013.

Figure 1: SCU0 installed in the APS storage ring.

COMMISSIONING PLAN

Prior to installing the SCU0, a test chamber with virtually the same length, aperture, and transitions as the SCU0 was installed in the storage ring. Beam-induced heat loads on the test chamber and transitions were tested, and key design improvements were implemented for the SCU0; in particular, a standard-aperture bellows, rf liner, and gate valve replaced a 7.2-mm-aperture assembly on the chamber transition upstream of the SCU0.

A detailed beam commissioning plan was carried out, and all the requirements were satisfied: (a) unpowered SCU0 is transparent to normal user operation; i.e., does not measurably increase storage ring impedance, nor decrease injection efficiency or lifetime; (b) powered SCU0 only perturbs the beam within the specifications; and (c) SCU0 is sufficiently protected from beam-induced heat loads. There were several commissioning goals, including assessment of thermal and vacuum monitoring, alignment procedures, cryogenic performance, beam orbit stability, quench response, field correction, x-ray performance, and operation procedures.

SCU0 EFFECT ON THE BEAM

An unpowered SCU0 is transparent to the beam if its contribution to the storage ring impedance and/or local vacuum pressure neither decreases the beam lifetime or injection efficiency nor lowers the beam instability threshold. As expected from the successful test chamber results, the SCU0 chamber was also transparent: the single bunch limit of 16 mA was preserved, and 100 mA could be stored in all three user bunch patterns. The measured betatron tune shift with current, which is a measure of the transverse impedance, did not change within the expected experimental error. The beam lifetime and injection efficiency were both in the normal range after the standard startup procedures were carried out.

Vacuum System

There were no beam chamber vacuum pressure issues and no negative effect observed on the beam. The beam chamber was cleaned using standard UHV techniques, but was necessarily exposed to air during the magnetic measurements. After the components were installed in the storage ring, the system was roughed down to the 2×10^{-7} Torr range on a cold cathode gauge (CCG) located in the downstream transition. A 24-hr, 130ºC bakeout was performed on the transitions upstream and downstream of the SCU0. The CCG pressure after the bakeout and before the SCU0 was activated was 3 nTorr. After cooldown and prior to injecting beam, the vacuum pressure was measured as 0.4 nTorr. The first 100-mA beam caused pressure transients in the 10-nTorr range, but after about four days of cold beam operation (10 Amp-hr), the pressure stabilized at ~3 nTorr. After 200 Amp-hr, the pressure was ~0.8 nTorr.

Mechanical Vibration

The cryocooler vibration was measured at three different locations: on the SCU0 support girder, on the SCU0 vacuum vessel near the beam level, and on the beam chamber about 0.4 m upstream of the SCU0. The cryocooler vibration power spectrum has a resonant frequency of 8.4 Hz. On the chamber, the integrated vibrational spectra power density (in the frequency range of 2-100 Hz) increased from 0.38 μm rms with the cryocoolers off to 0.68 μm rms with the cryocoolers on, less than a factor of two increase. The cryocooler vibration was not observed to adversely affect the beam motion.

Powered SCU0

The requirements on the SCU0 field-error tolerance are the same as that for the other planar IDs installed in APS [4]. The field-integral error tolerance was specified using simulations that include full-time orbit correction and real-time orbit feedback. Both an absolute limit as well as a rate-of-change requirement [5] were specified. Magnet measurements show that the SCU0 meets the specifications for all design parameters except the skew quadrupole component; the specification was 50 G and the measured value was 120 G at 500 A [6]. The skew component is due to the geometry of the coil winding opposite the pole face (a new coil winding scheme will be used for the next device.) The skew quadrupole error produced a 10% change in beam coupling over a 700-A range, but this effect was easily corrected by implementing feed-forward using the adjacent skew quadupoles. The first field integral was determined using the beam by measuring the corrector effort while scanning the SCU0 current. The agreement between the beam and magnet measurements is within 10%, as shown in Fig. 2.

Quenches may produce a field disturbance on a time scale that is too fast for the real-time orbit feedback to correct. If the perturbation is very large, the resulting beam trajectory displacement could exceed the beam position limit detector (BPLD) limits and cause a beam dump. The specification was given as a tolerance on the quantity $\sqrt{I_1^2 + (I_2^2/\beta_U^2)}$, where I_1 and I_2 are the first- and second-field integrals, respectively, and β_U is the average beta function at the undulator ends. The magnet measurements show that the SCU0 meets this specification during a heater-induced quench. Beam tests were performed with fast and slow orbit feedbacks in open loop to better observe the effect of a quench. An induced quench caused very little beam motion, ~60 μm, and did not cause loss of the beam. In Fig. 3, slow orbit recovery occurs over about 0.5 sec after the quench.

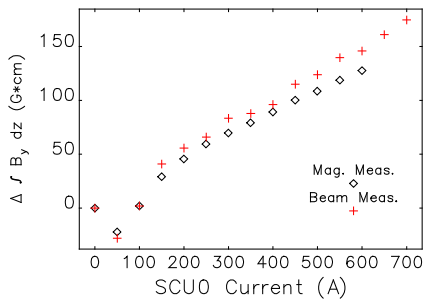

Figure 2: Field integral variation measured with beam.

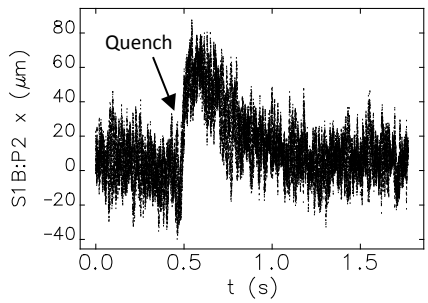

Figure 3: Effect of induced quench on the beam.

BEAM EFFECT ON THE SCU0

The total beam-induced heat load on the SCU0 agrees well with predictions (see Table 1), and the SCU0 is protected from excessive fault-induced heat loads through beam orbit control and SCU0 alignment. The cryogenic system performed very well in the presence of the beam, where magnet temperatures were maintained near 4 K while the beam chamber center temperatures were ≤13 K.

Beam-based Alignment

Precise alignment of the beam vacuum chamber with respect to both the electron beam orbit as well as synchrotron radiation generated in the upstream dipole magnet is extremely important. The beam vacuum chamber is instrumented with nine thermal sensors along its length [7]. Using the sensors and steering the beam, the chamber alignment was determined with 100-micron precision (see Fig. 4) [7]. This precision is more than 10 times better than what is achieved in a standard aperture scan. Other advantages of the thermal sensor beam-based alignment method include isolating the SCU0 alignment from other vacuum components in the orbit bump and providing good longitudinal spatial resolution.

Copyright © 2013 CC-BY-3.0 and by the respective authors

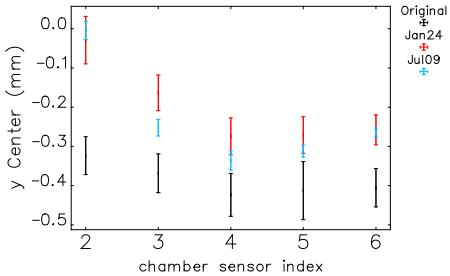

Figure 4: SCU0 chamber vertical alignment history (partial in-tunnel realignment shown in red).

Beam-induced Heat Load

Heat load predictions for standard 100-mA user operation were benchmarked using thermal sensors that measure temperatures at various locations in the SCU0 cryostat and along the electron beam chamber. Thermal analysis using the predicted electron beam heat loads, using three independent methods, agrees well with the observed measurements. Results are summarized in Table 1 for all three standard user bunch modes. For simplicity, the calculated values include only the dominant, image-current heating. In the chamber heater calibration, the predicted heat loads from Table 1 were converted to chamber temperatures by interpolating the heater data [8]. Using ANSYS, the heat load was modeled as a Gaussian image-current distribution. Agreement is excellent for both the central, Al part of the chamber as well as the SS warm-to-cold transitions [9]. Finally, the total 20-K heat load was measured using the bottom cryocooler 2nd-stage temperatures, fit to a model using vendor-supplied load map data [8]. There was no anomalous heat source; the agreement is remarkably within 1 K or 2 W.

Table 1: Predicted vs. Measured Center Chamber Temperatures and 20-K Heat Loads at 100 mA

No. of bunches	Chamb heater calib. (K)	ANSYS model (K)	Msrd. temp. (K)	Calc. heat load (W)	Msrd. heat load (W)
24	13.6	13.4	12.8	16.0	14.3
324	7.9	8.2	8.3	2.0	3.4
1+56	11.8	11.5	11.9	11.1	11.5

The device was found to quench due to beam losses during unintentional beam dumps. The SCU0 is powered off prior to intentional beam dumps. Over an 8-month operating period, only two quenches occurred with user-stored beam. These quenches did not cause any beam loss, and the cause is under investigation. Quench recovery is transparent to storage ring operation, and the impact of all quenches on SCU0 operation has been minimal due to rapid recovery.

PERFORMANCE

The SCU0 was operated at 650-700 A over 50% of the time, well beyond its 500-A design requirement. The SCU0 is routinely operated with 100-mA stored beam continuously near 650 A without a trip. The SCU0 was also operated at 150 mA, higher beam current than it was designed for, with no significant issues. Finally, no loss of He was observed over an 8-month operating period.

The x-ray source properties of the SCU0 were characterized by measuring the photon flux passing through a bent-Laue monochromator and comparing the SCU0 photon flux with that from an in-line 3.3-cm-period length permanent magnet hybrid undulator (U33). At 85 keV, the 0.34-m-long SCU0 produced ~45% higher photon flux than the 2.3-m-long U33. Figure 5 shows the simulated and measured photon flux at 85 keV for SCU0, and the measured photon flux for U33 (inset).

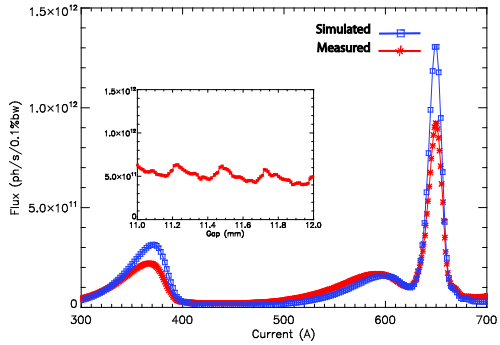

Figure 5: Photon flux comparisons at 85 keV. Main: Simulated and measured SCU0 photon flux. Inset: Measured photon flux of in-line U33.

SUMMARY

An almost decade-long R&D program on the development of superconducting undulators at the APS was successfully completed in 2012 with the installation into the APS storage ring of the first test undulator, SCU0. Beam commissioning was highly successful. The device has been in user operation since January 2013, delivering enhanced photon flux at energies above 50 keV.

ACKNOWLEDGMENT

We wish to thank the support of the APS management in long-term R&D and development of superconducting undulators. We also thank the APS team for their valuable contributions to the success of this project.

LOW EMITTANCE IN THE CORNELL ERL INJECTOR PROTOTYPE*

C. Gulliford, A. C. Bartnik, I. V. Bazarov, B. M. Dunham, for the Cornell ERL Team
CLASSE, Cornell University, Ithaca NY 14853 USA

Abstract

We present a detailed study of the six-dimensional phase space of the electron beam produced by the Cornell Energy Recovery Linac Photoinjector, a high-brightness, high repetition rate (1.3 GHz) DC photoemission source designed to drive a hard x-ray energy recovery linac (ERL). A complete simulation model of the injector has been constructed, verified by measurement, and optimized. Both the horizontal and vertical 2D transverse phase spaces, as well as the time-resolved (sliced) horizontal phase space, were simulated and directly measured at the end of the injector for 19 pC and 77 pC bunches at roughly 8 MeV. The resulting 90% normalized transverse emittances for 19 (77) pC/bunch were 0.23±0.02 (0.51±0.04) μm in the horizontal plane, and 0.14±0.01 (0.29±0.02) μm in the vertical plane, respectively. These emittances were measured with a corresponding bunch length of 2.1±0.1 (3.0±0.2) ps, respectively. In each case, the rms momentum spread was determined to be on the order of 10^{-3}. Excellent overall agreement between measurement and simulation has been demonstrated.

INTRODUCTION

Cornell University has recently designed, built, and commissioned a high repetition rate DC gun based photoinjector. One major goal for this project was the demonstration of low emittance at the end of the injector merger section. The results in this work demonstrate that it is possible to produce and transport beams from a DC source which have emittances at the point of injection approaching the diffraction limit for hard x-rays, and which have a bunch length and an energy spread within the parameter space required by the specifications of a full hard x-ray ERL. Table 1 shows these parameters for the Cornell Injector.

Table 1: List of Injector Design Specifications and Target Parameters

Parameter	Specification
Beam energy	5-15 MeV
Normalized emittance	$\epsilon_n \leq 0.3$ μm
RMS bunch length	$\sigma_t \leq 3$ ps
Bunch Charge	77 (19) pC
Average Current	100 (25) mA

One fundamental limit to achieving low emittance (high brightness) in a photoinjector occurs when the amount of charge extracted from the cathode nears the virtual cathode instability limit. A rough calculation shows that the lowest achievable emittance in this limit is proportional to the square root of the bunch charge q [1]:

$$\epsilon_n \propto \sqrt{q \cdot \frac{\mathrm{MTE}}{E_{\mathrm{cath}}}} \tag{1}$$

Here MTE and E_{cath} are the mean transverse energy of the cathode and the accelerating field at the cathode, respectively. Detailed simulations of well optimized DC gun photoinjectors support this square root dependence on the bunch charge and the cathode's MTE [2, 3]. In this paper, we show that the final measured emittance also scales in accordance with Eq. (1).

EXPERIMENTAL SET-UP

The injector features a high voltage DC gun operated at 350 kV, followed by emittance compensation solenoids and a buncher cavity. The beam is accelerated to 5-15 MeV using five superconducting srf cavities. The beamline section most relevant to this work is the B1 merger shown in detail in Fig. 1. The injector merger section is comprised of a conventional three-dipole achromat, a design chosen for its simplicity, and due to the limited space available for the injector experiment. The emittance measurement system (EMS) used for projected phase space measurements is the same two-slit system used in previous work [4]. For projected phase space measurements, the beamlet passed through the slits is collected using the Faraday cup at the end of the merger section. For time-resolved horizontal phase space measurements, the beamlet is passed through a horizontal deflecting cavity [5] in order to resolve the time axis of the beam on the viewscreen at the end of the merger [6]. The cathode used for this study was a GaAs wafer with a 4% quantum efficiency, and a MTE of 90 meV. The laser system used is a 50 MHz system, whose individual pulses have comparable pulse energy and duration to the our 1.3 GHz laser [7]. The final laser pulse train is chopped using a Pockells cell, and shaped using our temporal shaping system [8].

To arrive at the final optics used for these experiments, optimizations of a complete General Particle Tracer [9] model of the injector were carried out using a multi-objective genetic algorithm [2, 3]. For all optimizations, the gun voltage was fixed at 350 kV, and the beam energy was constrained to be $\leq$ 8 MeV to reduce neutron production from the tungsten slits in the EMS. The simulated temporal laser distribution was fixed to be roughly a flat-top

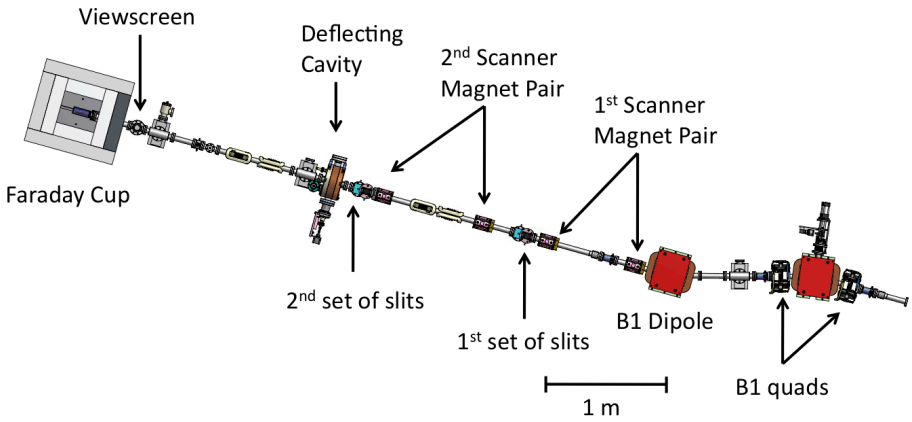

Figure 1: Top view of the B1 injector merger section showing the emittance measurement system.

with 8 ps rms length. Two settings, for 19 pC and 77 pC per bunch respectively, were derived from one optimization solution for 50 pC bunch charge, as this particular optics setting kept the beam sizes reasonably small through the entire injector. The final settings were loaded into the injector and the measured projected emittance was minimized by scanning both solenoid currents and adjusting the intensity cut off value in the measured transverse laser profile.

MEASUREMENTS

Data sets for 19 pC per bunch and 77 pC per bunch, corresponding to 25 mA and 100 mA average current when operating with the full 1.3 GHz repetition rate, were taken. Each data set consists of a measurement of the projected horizontal and vertical phase spaces, the time-resolved horizontal phase space, and the energy spread distribution. All data was taken at the end of the merger section except the energy spread data, which was measured near the entrance to the merger. From the projected phase spaces, the horizontal and vertical emittances as a function of beam fraction were computed. Similarly, from the time-resolved phase space data, the slice emittance was computed as a function of beam fraction, as well as the current profile along the bunch.

Tables 2 and 3 give the measured and simulated projected horizontal and vertical emittances for 19 (77) pC per bunch, respectively. The measured 19 (77) pC/bunch horizontal and vertical projected 100% emittances agreed with the GPT model to within 6 (5) % and 25 (8) %, respectively. Similarly, the measured horizontal and vertical 90% emittances agreed with GPT to within 21 (16) % and 27 (16) %, respectively. We point out that the measured horizontal and vertical 100%, 90%, and core emittances obey the expected scaling law $\epsilon_n \propto \sqrt{q}$. Also of note is the fact the horizontal core emittance for 77 pC meets the injector design specification for an ERL. In the vertical plane, both the 90% and core emittance meet this specification.

In order to satisfy the injector design requirements, it was important to verify that the emittance values were measured with an acceptable bunch length ($\sigma_t \leq 3$ ps). The rms bunch length was computed from the instantaneous current of each bunch measured with the time-resolved merger EMS. The rms bunch lengths for the 19 (77) pC per bunch settings were measured to be 2.1 ± 0.1 (3.0 ± 0.2) ps, respectively, while GPT gave bunch lengths of 2.2 (3.1) ps, respectively. The agreement between measurement and GPT was within 5% in both cases.

Table 4: Simulated and Measured RMS Energy Spread as a Function of Bunch Charge

Data Type	GPT Simulation	Measurement
19 pC/bunch, A4	0.16%	0.14 ± 0.01%
19 pC/bunch, B1	0.12%	N/A
77 pC/bunch, A4	0.27%	0.26 ± 0.01%
77 pC/bunch, B1	0.21%	N/A

The last quantity measured was the rms energy spread. To do so, the beam was sent through the A4 straight section, followed by a single dipole and viewscreen in the C2 section. Table 4 shows the simulated and measured rms energy spread in the straight section, as well as simulated values in the B1 merger. While the energy spread was not directly in the merger section, the agreement found between measurement and simulation for emittance and bunch length lead us to conclude that the values measured in the straight section at least provide an upper bound on the energy spread in the merger, following the same trend found in the simulation data.

CONCLUSION AND DISCUSSION

The projected and time-resolved phase spaces at the end of the Cornell ERL injector merger have been measured and simulated using the space charge code GPT for 19 pC and 77 pC bunch charges. In addition, the energy spread was measured in the straight section of the machine. Overall, we found excellent agreement between measurement and simulation. For both bunch charges, the agreement be-

tween the measured projected 100 and 90% emittance values was within 30% of the simulated values in both transverse planes. We point out that for 77 pC/bunch, the measured 90% emittance in vertical plane, as well as the core emittance in both planes, meets the ERL design specification of $\epsilon_n \leq 0.3\ \mu$m. The projected emittance in both transverse planes demonstrates the correct scaling with bunch charge shown in Eq. (1). The measured rms bunch length for both bunch charges was at or below the 3 ps specification, and agreed with simulation to within 5%. Finally, an estimation of the energy spread of the beam in merger was found by measuring the energy spread in the straight section. Agreement between the measured and simulated rms energy spread was within 13% for both bunch charges. These results represent a significant advancement in high-brightness photoinjectors.

In looking to further reduce emittance, simulations indicate that lower emittances and shorter bunch lengths at the end of the merger are possible at higher beam energies (roughly 12 MeV) [10, 11]. Eq. (1) shows two more directions for further improvement. The emittance in this equation can be reduced by lowering photocathode MTE, or by increasing the accelerating field at the cathode. Currently, there is an active cathode research program at Cornell University dedicated to improving cathode performance [12]. In parallel, Cornell is developing an improved DC gun, in order to overcome the current voltage limitation. Lastly, improved laser shaping will aid in creating bunches with more linear space charge fields. According to Eq. (1), as well as more detailed calculations reported in [3, 11], these improvements are expected to reduce the emittance in the photoinjector by roughly a factor of 3, resulting in a beam brightness roughly 10 times higher than reported here.

Abstract

The commissioning at the Lawrence Berkeley National Laboratory (LBNL) of a high-brightness high-repetition rate (MHz-class) photo-gun, based on a normal conducting 186 MHz (VHF-band) RF cavity operating in CW mode, is now completed. The gun has been designed to satisfy the requirements for operating high-repetition rate 4th generation light sources. Test of high quantum efficiency photocathodes with bunches of hundreds pC at MHz repetition rate are now underway. They include, Cs_2Te cathodes developed in collaboration with INFN-LASA and multialkali antimonides (CsK_2Sb), prepared by a collaborating group at LBNL. The present experimental results and the plan for future activities are presented.

INTRODUCTION

This paper describes the recent progress and experimental results obtained by the Advanced Photo-injector EXperiment (APEX) at the Lawrence Berkeley National Laboratory (LBNL).

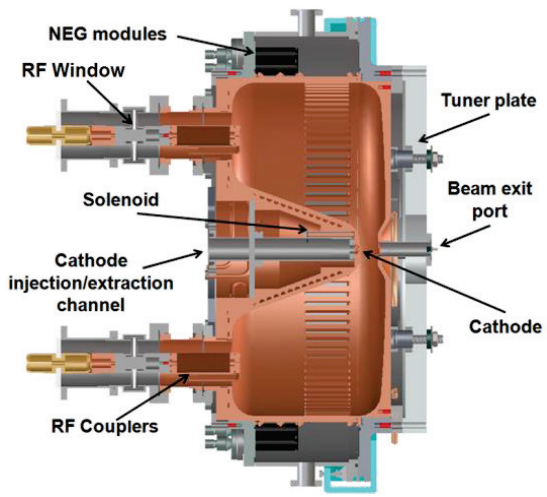

Figure 1: The VHF Gun cross sections.

The project main goal consists in the development and test of a new concept high-repetition rate high-brightness electron injector capable to operate in high-repetition rate free electron laser (FEL) and energy recovery linac (ERL) applications. The successful development of such an injector will critically impact the performance of future 4th generation light sources when high-repetition rates (> 10 kHz) are required, and of high repetition rate ultrafast electron diffraction (UED) and inverse Compton scattering (ICS) applications.

*Work supported by the Director of the Office of Science of the US Department of Energy under Contract no. DEAC02-05CH11231

The core of the system is represented by a normal-conducting (NC) continuous wave (CW) RF gun [1, 2] (see Fig. 1) where the electrons are generated by laser-induced photo-emission on high quantum efficiency (QE) photo-cathodes and accelerated by the cavity fields (~20 MV/m) to up to ~750 keV energy. The gun cavity has been designed to resonate at about 186 MHz (7^{th} subharmonic of 1.3 GHz) in the VHF frequency region. The low frequency choice makes the resonator size large enough to lower the power density on the structure walls at a level that conventional cooling techniques can be used when the cavity is run in CW mode.

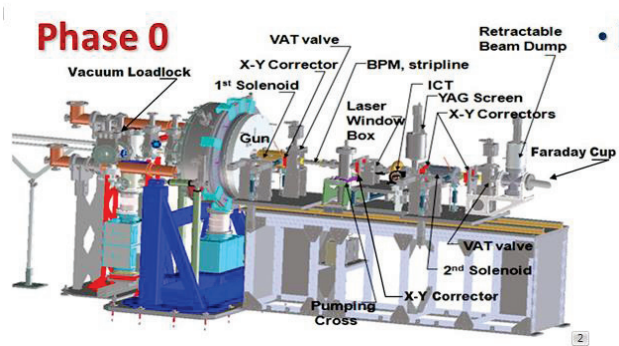

Figure 2: APEX Phase 0 CAD view.

A second advantage of the low frequency is the relatively long wavelength that allows for large apertures on the cavity walls with negligible distortion of the electromagnetic fields. Such apertures create the proper high-vacuum conductance path paving the way for the achievement of the very low pressures required by high-QE semiconductor cathodes (minimizing contamination and damage and hence ensuring longer QE lifetimes).

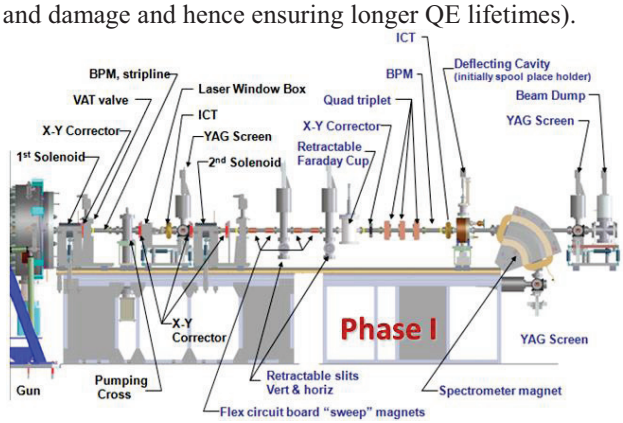

Figure 3: APEX Phase I CAD view.

Copyright © 2013 CC-BY-3.0 and by the respective authors

A last advantage of the VHF scheme is that it is based on mature and reliable RF and mechanical technology, a very important characteristic to achieve the reliability required to operate in a user facility.

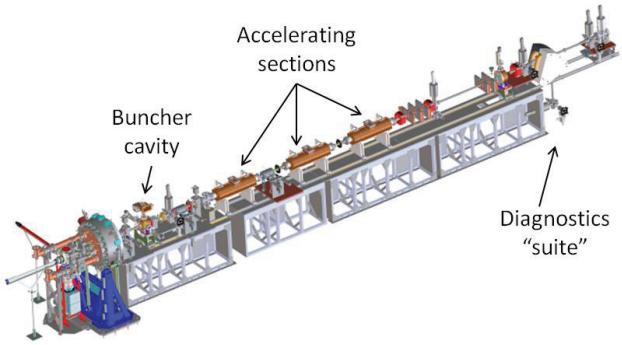

Figure 4: APEX Phase II CAD view.

The APEX project is organized in 3 main stages: Phases 0, I and II. Phase 0, shown in Fig. 2, is dedicated to the development and characterization performance of the gun, and to the testing and characterization of different types of cathodes. In Phase I, visible in Fig. 3, a complete suite of diagnostics [3] allows for the full 6D phase-space characterization of the electron beam at the gun energy. Beams of several hundreds of pC per bunch at MHz repetition rate will be characterized and compared with expected results from simulations. In Phase II, shown in Fig. 4, three pulsed NC 1.3 GHz accelerating sections [4] (a modified version of the AWA cavities at Argonne National Laboratory) and one 1.3 GHz buncher cavity are added to accelerate the beam up to about 30 MeV and compress it to the required lengths. Phase II configuration allows to reduce space charge forces at the level necessary to perform meaningful emittance measurements and be able to demonstrate the brightness performance of the gun. Due to cost and shielding limitations, Phase II operates in pulsed mode with 10 Hz repetition rate. Testing of different photocathodes will continue also during Phases I and II.

STATUS OF THE INSTALLATION

Phase 0 has been completely installed, and Figure 5 shows a picture of it inside the Beam Test Facility (BTF) at LBNL where the APEX project is located.

The vacuum loadlock system, which allows replacing cathodes without breaking the vacuum, is a clone of the system developed by INFN-LASA for PITZ and FLASH in Germany. The system is fully installed and successfully commissioned. The geometry of the extractable molybdenum cathode "plug", which supports the photo-emitting material, has been modified to allow for a smoother insertion in the gun and for minimizing the stress on the RF contact spring (see Fig. 6).

A vacuum leak in one of the two gun RF magnetic loop type couplers, revealed a design weakness in the part. The electrical contact between the coupler inner conductor and the loop cap, both copper parts, was ensured by the mechanical pressure created by two titanium screws. Due to the thermal stress generated when the cavity is switched on and off, the two copper parts gradually lost contact and all the current associated with the RF fields started to flow through the titanium screw creating overheating of the parts (see left part of Fig. 7).

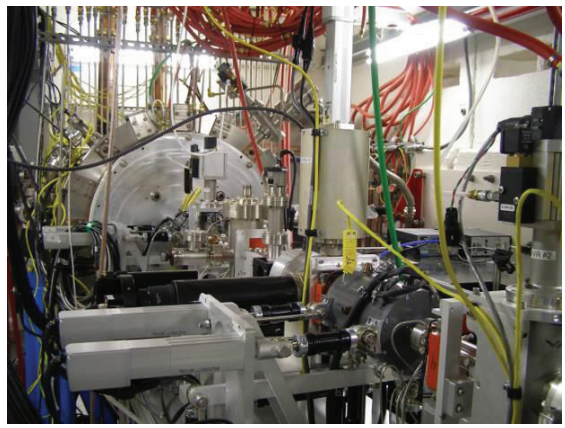

Figure 5: APEX Phase 0 installed in the BTF at LBNL.

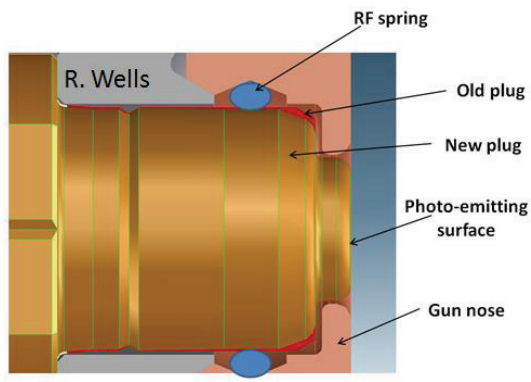

Figure 6: Comparison between the geometry of the previous (red) and new (gold color) cathode plugs.

The issue was serious enough that it was decided to completely redesign the couplers. The new design removed the screws, the copper parts were electron-beam welded together, and the copper cooling line cross section was enlarged for an increased flow of water.

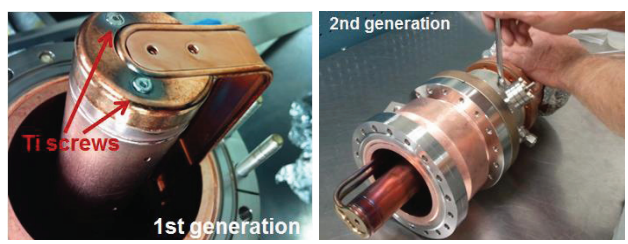

Figure 7: Left: 1st generation gun RF coupler. Right: the newly fabricated 2nd generation coupler being assembled.

The new design also addressed the presence of multipacting in the in vacuum coaxial line between the coupler loop and the RF window. The vacuum part of the coaxial was significantly shortened and all couplers components were coated with titanium nitride. In mid-

Copyright © 2013 CC-BY-3.0 and by the respective authors

February 2013, the two new couplers were installed and smoothly RF conditioned at full power in a few days. No evidence of multipacting was detected. Since then, the couplers have been reliably working at the nominal power.

The installation of the diagnostics suite components of Phase I is undergoing (in parallel with cathode tests) and systems as the double-slit emittance meter (based on a Cornell design), and the spectrometer are in advanced phase of installation (see Fig. 8). The 1.3 GHz deflecting cavity, a modified version of the Cornell design, required for "slice" transverse emittance and longitudinal phase space measurements is under fabrication at the LBNL mechanical shops.

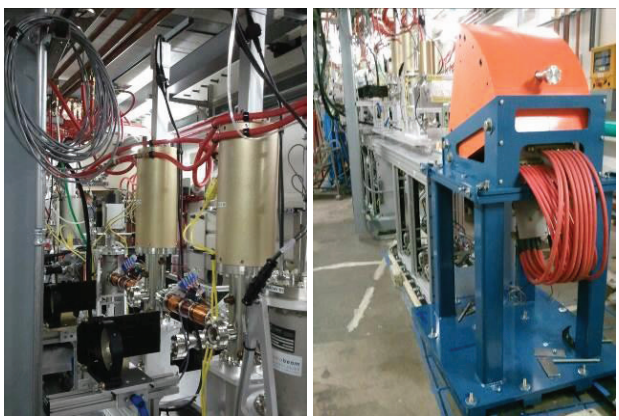

Figure 8: Phase I diagnostics systems in the BTF. Left: the 2-slit emittance meter. Right: the spectrometer dipole.

Phase II long delivery items, such as the klystron (Thales TV 2022F) and the related modulator (by DTI), have been ordered, and the complex RF distribution system, which distributes the 1.3 GHz RF power from the single klystron to the 3 accelerating sections, the buncher and the deflecting cavity, is fully designed (see Fig. 9), and parts are ready to be ordered.

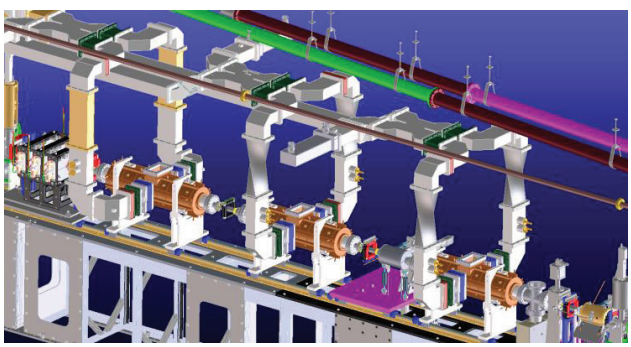

Figure 9: CAD view of part of the RF distribution system for APEX Phase II.

EXPERIMENTAL RESULTS

The VHF gun has been fully commissioned and demonstrated all major nominal parameters such as CW operation, accelerating field, beam energy, and vacuum performance. Detailed results of the gun commissioning have been reported elsewhere [5].

The photo-cathode drive laser, a ~1 W 1064 nm Yb-doped fiber-laser developed in collaboration with University of California Berkeley and Lawrence Livermore National Laboratory, is fully commissioned and in operation. The system, capable of MHz repetition rate operation with the required energies per pulse at the different wavelengths, includes 2nd and 4th harmonic generation, longitudinal and transverse pulse shaping, and pulse picking capabilities [6]. An additional commercial laser (Calmar) with higher power (~ 2 W in the infrared) is presently under installation.

The reliability of the VHF gun system, after almost 2 years of high power RF operation experience, revealed to be excellent. The large majority of the faults that rarely affect the system (once every few days) are due to cooling water supply fluctuations that trigger the interlock protection system.

The overall system performance stability is being tested. Figure 10 shows a relative RF power fluctuation in the VHF gun cavity of ~ 0.14% rms, indicating an accelerating field fluctuation of ~ 0.07%. Such result has been obtained by using a high-level MatLab feedback which reads the power in the cavity from the FPGA based LLRF system [7], and controls the RF power input to the RF amplifier for maintaining the power in cavity constant. The stability performance figure will be probably improved in the next future when the feedback will be implemented completely at the LLRF system level.

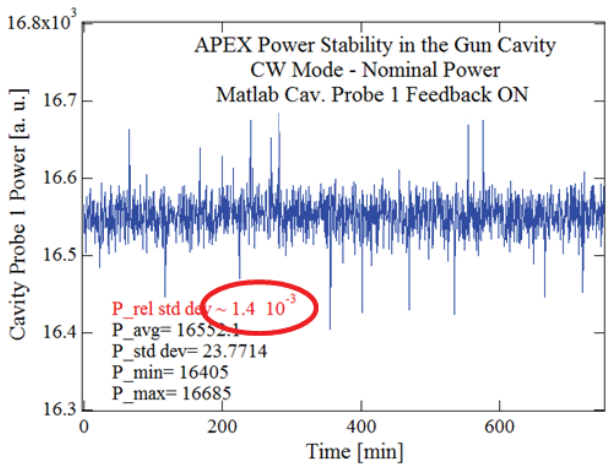

Figure 10: VHF Gun RF power fluctuation measurement.

The synchronization between the gun RF and the photocathode driving laser oscillator is performed by the LLRF system [7], and presently shows a measured time jitter of ~ 2 ps rms. Such a figure corresponds to a RF phase jitter (at the gun frequency) of ~ 0.15 degrees, and is dominated by the contribution of the non-ideally designed piezo/picomotor actuator controlling the position of one of mirrors in the laser oscillator cavity. Although the present jitter value is sufficiently small for the operation and tests to be performed at APEX, the near

Copyright © 2013 CC-BY-3.0 and by the respective authors

future upgrade to the new laser system (the Calmar laser mentioned above) should significantly decrease the jitter value.

The two main high-QE semiconductor photocathodes planned for testing include Cs_2Te produced by INFN/LASA (the same material used at the FLASH FEL in Germany), and the multi-alkali CsK_2Sb produced by a partner group at LBNL. Additional cathode materials are under consideration for future tests.

The completion of the vacuum loadlock system allowed to start the beam tests with the high-QE cathodes. After the activation of the 20 NEG modules in the gun (400 l/s pumping speed each, from SAES Getters), and several days of baking of the cavity [4], a vacuum pressure in the gun of ~ 1.0 10^{-11} Torr was obtained with no RF and of ~ 8.0 10^{-10} Torr when the RF is on at the nominal power. Partial pressures for "dangerous" molecules (H_2O, O, ...) are always 2 orders of magnitude smaller than the actual absolute pressure.

On March 18, 2013, the cathode tests initiated with one of the 3 available Cs_2Te cathodes prepared by LASA. Figure 11 shows the image of the very first beam from Cs_2Te on the YAG screen in the Phase 0 beamline (on March 18, 2013). The repetition rate was limited to 100 Hz to avoid damaging the screen, and because the fast equipment protection system (FEPS), required for high-current operation, was not commissioned yet. The charge monitors were not calibrated but the estimated charge per bunch was of several hundreds of pC.

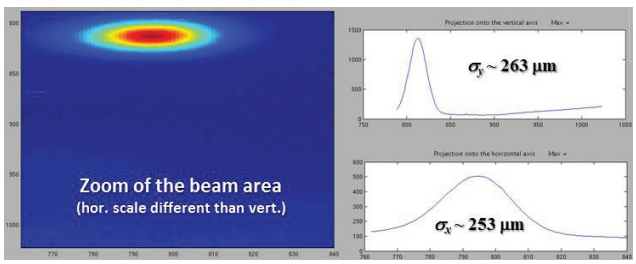

Figure 11: First high-charge beam from a Cs_2Te cathode.

In the subsequent days, following the successful commissioning of the FEPS and calibration of the current monitors, we started to operate at 1 MHz repetition rate. Figure 12 shows scope traces with 2 charge monitors (Bergoz ICTs) and a driving laser photodiode during one of these MHz runs.

At the end of April 2013, an almost continuous 1 MHz run of ~ 4 days integrated an extracted charge of ~ 40 C, roughly equivalent to the charge extracted from the same type of cathode during 3 months of FLASH operation. The top part of Fig. 13, shows the QE values measured during the run, and indicates a decrease of such a quantity from an initial ~ 10% to a final ~ 4%. Although preliminary, this is remarkably important result because it indicates a QE lifetime compatible with the operation of a MHz-class repetition rate x-ray FEL. Indeed, in a typical user facility scenario, the operation schedule includes a maintenance day for every week of user shifts. If the QE of the cathode stays higher than ~ 1% during such a period, then cathodes can be replaced (a ~20 minute operation) during the maintenance day with no impact on the user time.

The QE variations visible in the Figure are due to the fact that no laser pulse amplitude feedback was installed at the time, and the photon energy per pulse was drifting following the temperature variations associated with the alternating days and nights during the run, as visible in the bottom part of Fig. 13. The correlated charge-per-bunch variation is evident in the central part of the Figure.

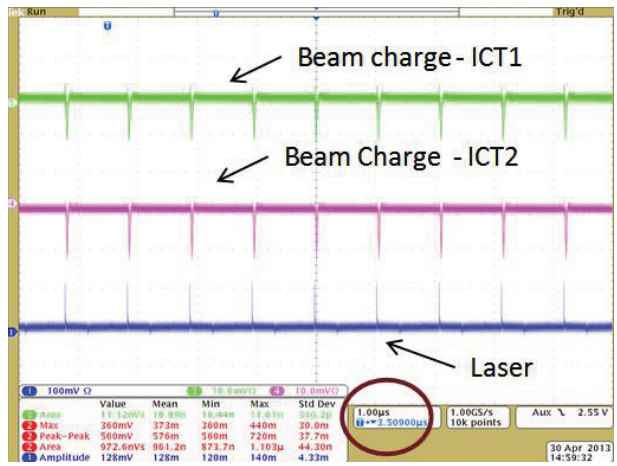

Figure 12: Scope traces from 2 charge monitors (ICTs) and a driving laser photodiode showing the 1 MHz time structure of the pulses.

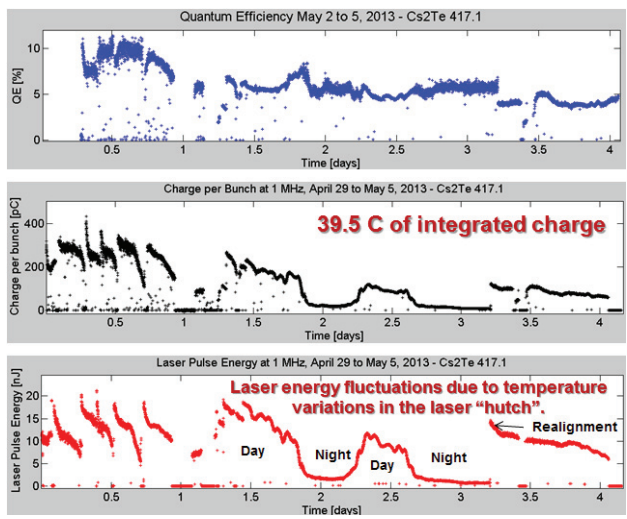

Figure 13: Results of a 4-day run with a Cs_2Te cathode at 1 MHz repetition rate. Top: QE values during the run. Center: charge per bunch, Bottom: laser energy per pulse

To stabilize the laser performance, we recently developed and installed two feedback systems to control the laser pulse energy and pointing. The systems use the image of the laser beam on the virtual cathode and the reading from a power meter to respectively control the horizontal and vertical angles of a mirror and a variable neutral density attenuator installed on a stage. The

Copyright © 2013 CC-BY-3.0 and by the respective authors

feedbacks have been successfully commissioned and the results of a 16 hour test are shown in Figure 14. With the laser stability now ensured by the new feedbacks, more systematic QE lifetime tests with the Cs_2Te will restart soon.

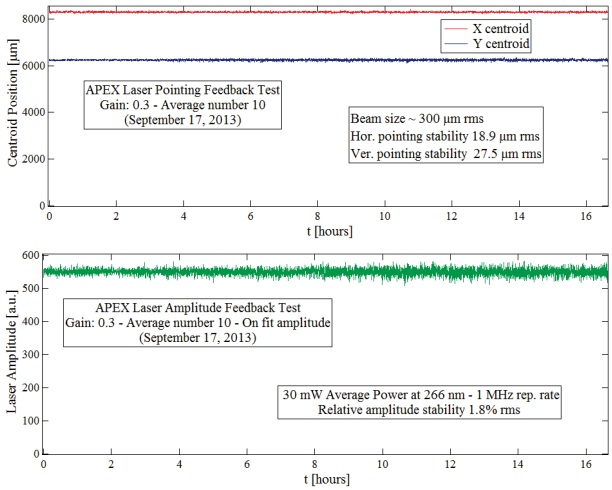

Figure 14: Test of the laser feedback systems. Top: pointing stability results. Bottom: energy per pulse results.

An initial preliminary thermal emittance measurement of the Cs_2Te cathode was performed by a solenoid scan at low charge per bunch (~900 fC) and at a beam energy of ~ 800 keV.

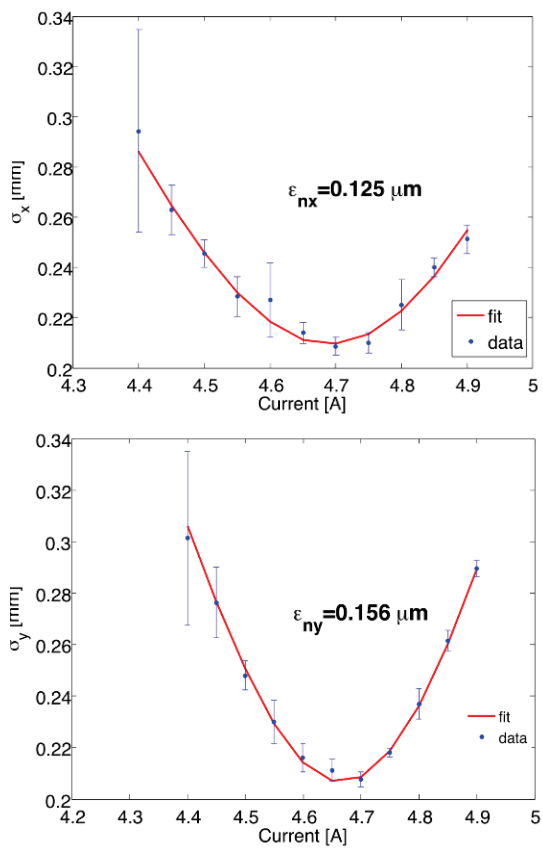

Figure 15: Cs_2Te cathode thermal emittance measurement by the solenoid scan technique. Top: horizontal plane result. Bottom: vertical plane result.

Figure 15 shows the results of the scan for both horizontal and vertical planes. For each of the solenoid current values, the average rms transverse size and standard deviation were calculated over ten individual beam images. The beam sizes at the virtual cathode during the measurements were of ~ 250 μm rms for the horizontal plane and of ~ 265 μm rms for the vertical one. The resulting normalized thermal emittance value for this preliminary measurement is:

$$\varepsilon_n/\sigma_R = 0.54 \pm 0.05 \text{ μm/mm}_{\text{rms}}$$

Such result is consistent with values measured by other groups. Additional more systematic measurements varying the laser transverse beam size at the cathode are scheduled for the near future.

FUTURE PLANS

After the completion of the tests with the presently installed Cs_2Te cathodes, CsK_2Sb multialkali cathodes will be inserted in the gun and characterized. One of such photocathodes, has been already successfully produced by our LBNL partner group and is ready for testing.

The installation (in the first half of 2014) of all the beam diagnostics systems included in APEX Phase I, will allow for the full 6D phase space characterization of beam at the gun energy, and for the comparison of the experimental results with the expected values predicted by the simulations.

Finally, in about 18 months from now (assuming the reception of the required funds), the completion of the installation of the Phase II components will allow for the final characterization of the brightness performance of the VHF gun.

ACKNOWLEDGMENTS

The authors want to express their appreciation for the support given to the project by the AFRD, ALS and Engineering Divisions of the Lawrence Berkeley National Laboratory.

EXPERIENCE WITH THE SNS LOSS MONITORING AND MACHINE PROTECTION

A. Zhukov, ORNL, Oak Ridge, TN, USA

Abstract

The Spallation Neutron Source (SNS) is a megawatt-class hadron accelerator. Beam loss monitoring is essential for machine protection, residual activation control and machine tuning. We discuss all parts of our beam loss monitoring system including its detectors, electronics, machine protection system (MPS) interface and its role in the accelerator tuning process. The system was designed more than 10 years ago, so we are now addressing obsolescence problems by designing a new FPGA based replacement. The plans for this next generation Beam Loss Monitor (BLM) system are presented.

INTRODUCTION

At SNS a 1ms long H^- beam (macro-pulse) consisting of ~1000 mini-pulses (700 nS pulse and 300 nS gap) is accelerated from 2.5 MeV to 1 GeV in a linac and then converted into H+ by a stripping foil for injection into a storage ring. The mini pulses are accumulated and the resulting, ~700 nS, accumulated beam pulse is extracted and then hits a mercury target. This process runs at 60 Hz and delivers up to 1.4 MW of power to the target. Average beam current is ~24 mA over 1 ms [1].

The SNS BLM system consists of 378 radiation detectors measuring secondary radiation due to beam loss. BLMs are used as MPS devices to shut down the current beam pulse if the integral loss is above threshold and to limit average loss to be under 1 W/m. The MPS system has to be software and timing independent to increase reliability.

Since the beam parameters are different in different parts of the machine, the nature of the losses are also very different.

DETECTORS

The BLM system is used as an MPS device as well as a beam tuning diagnostics. The same detectors are playing two roles and so have to combine reliability for MPS and flexibility for beam diagnostics. SNS uses ionization chambers (IC) as its main BLM device. This is due to their simple design and immunity to radiation damage. In addition to ICs we use several type of photomultiplier tube (PMT) based detectors. The neutron detectors (ND) are neutron sensitive detectors that are useful in low energy part of the linac (where ICs lack sensitivity). The ICs are not fast enough to provide macro-pulse structure to physicists so the PMTs can be used for such diagnostics purposes. Also all PMT devices can adjust their sensitivity significantly (factor of ~100-1000) by changing their HV bias.

Detector Distribution

BLMs are evenly distributed along the accelerator with a typical distance to the beam line of 0-90 cm. In addition to fixed detectors we found moveable detectors to be very useful for investigating unexpected activation patterns.

Table 1: BLM Distribution

Detector	DTL	CCL	SCL	HEBT	Ring	RTBT
IC	11	50	79	59	71	40
ND	12	8	23			
PMT	6	6	3			
DBLM		2	5			3

Figure 1 shows moveable BLMs placed in the transition area between warm and superconducting linacs.

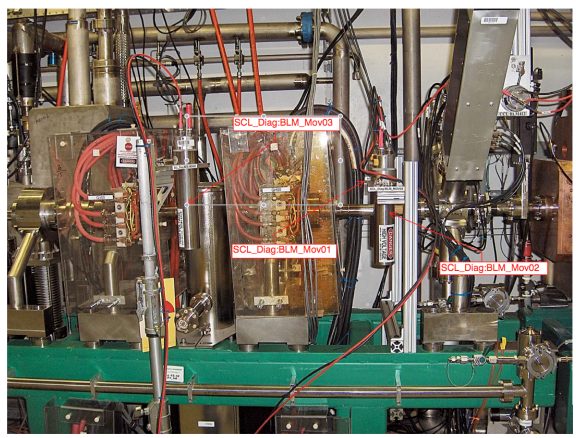

Figure 1: BLM placement for investigation of hot spot.

Detector Parameters

Most important detector parameters are shown in Table 2. Ionization chambers use daisy-chained HV lines since all of them have the same bias applied. All scintillator-based devices have dedicated HV power supply. In addition to signal and HV connections scintillator detectors have a test cable connected to an LED inside the detector. This connection allows testing and bias calibration for these detectors.

The slow response time of the neutron detector is caused by a polyethylene moderator that is needed to slow the neutrons down and increase cross section of neutron capture inside scintillator. Lead shielding around the scintillator helps to suppress sensitivity to x-rays (Fig. 2).

Table 2: BLM Parameters [2]

Detector	IC	ND	PMT
Type	Ionization chamber	Neutron sensitive plastic scintillator + PMT	plastic scintillator + PMT
Detector medium	Gas Ar, 113 cm^3	Polyethylene moderator, ZnS(Ag) scint	EJ-208 scintillator
Typical HV Bias, V	-1000	-700	-700
Typical Sensitivity	70 nC/Rad	80 pC/n/cm2	2 mA/R/hr
Response time	~2 uS	~50 uS	~10 nS
Connectors	Sig (BNC), HV (SHV)	Sig (BNC), HV (SHV), Test (BNC)	Sig (BNC), HV (SHV), Test (BNC)

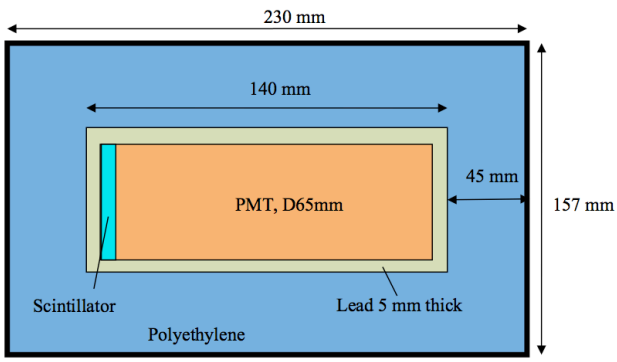

Figure 2: ND internals [2].

Detector Calibration

All ion chambers were calibrated with a gamma source. While that provided absolute calibration in terms of Rads per C of charge being measured, it was not very useful for estimating the fraction of beam being lost. For NDs we used a calibration with faraday cups imitating a full loss [3]. It agrees with simulation but doesn't emulate a real distributed loss.

In the SCL we were able to calibrate BLMs with a laser wire profile measurement device. The laser strips off an electron from the H^- and H^0 is subsequently lost. Knowing the number of H^0 created and measuring additional loss we concluded that SCL loss is around several 10^{-5} [4].

MACHINE PROTECTION AND CONTROLS

Front End Electronics

All detector types are effectively current sources and are interfaced to the same 8-channel analog front end (AFE) electronics that features transconductance amplifiers with jumper-settable gains (620, 6.2E3, 62E3 [Ohm]). The amplified signal is split between an MPS circuit (leaky integrator to integrate the total loss), a "view" circuit where the "fast" signal leaves the AFE and goes to a VME hosted ADC card where it is sampled at 100 kS/s (signal BW is 35 kHz) and the "slow" signal that is smoothed (BW 1 kHz) and also goes to a separate ADC channel [5]. Typical signals produced inside the AFE are shown on Fig. 3.

Hardware leaky integrators provides protection without relying on software or timing information. The system allows a shutdown of the macro-pulse within 15 uS of the integrated value exceeding a threshold. Software based integration over one second is used to limit average loss to stay below 1W/m and maintain residual activation of under 100 mRem/hr in the most parts of the tunnel.

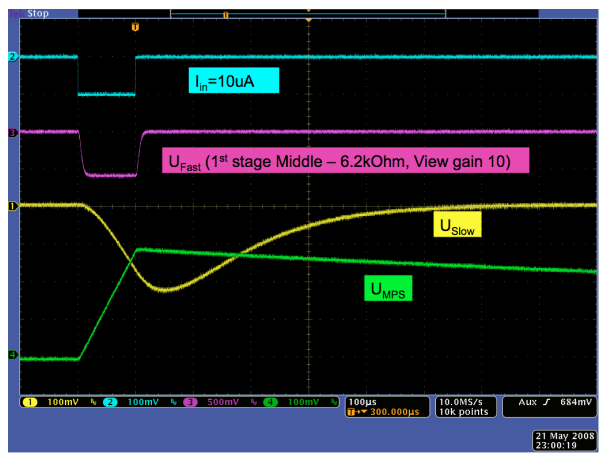

Figure 3: Signals in BLM AFE. Green shows MPS leaky integrator output.

The HV bias is shared by several (usually four) ICs that are daisy-chained in the accelerator tunnel. The HV is supplied by a VME HV module.

In addition to integrated loss, software monitors MPS detector health: gain settings, HV bias set points and read back, and HV bias current (that will detect cable problems in HV circuit).

Copyright © 2013 CC-BY-3.0 and by the respective authors

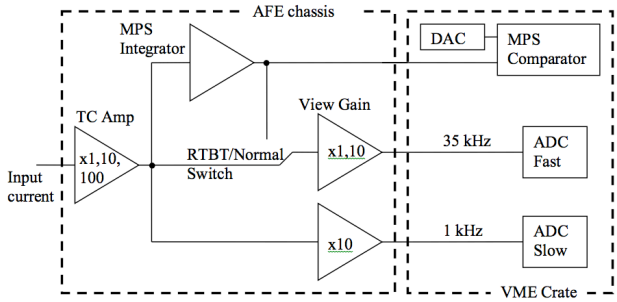

Figure 4: Analog front end [2].

Controls System [6]

The gain setting of the AFE is controlled and monitored by a VMIC VMIVME2510 64-bit digital IO module. The Machine Protection System (MPS) interface module compares AFE MPS loss to an MPS trip level and outputs the result to a separate MPS chassis. The MPS trip levels are set with the outputs of two Hytec8402 Industry Pack (IP) DAC cards (16 channels of 16-bit DAC each) residing on a GreenSpring VIPC616 IP Carrier board. There is a direct communication link from the Motorola MVME-5110 CPU board to the MPS Chassis through the PMC card attached to CPU board. Two ICS110B ADC cards read the AFE outputs of both the fast loss and slow loss signals. Each ICS110B card has 32 independent 24-bit Sigma-Delta ADCs. The ADC can sample up to 108 KHz (100 KHz is used). These data are then transferred and processed by the CPU board. The MVME-5110 features a 500MHz MPC7410 microprocessor, 512MB ECC SDRAM. The standard SNS timing configuration (V124S + V108S cards) provides a real-time data link of machine status as well as beam time synchronization and triggers. The VME crate used is an SNS-standard Weiner 21-slot crate.

The BLM IOC software is based on the Experimental Physics and Industrial Control System (EPICS) framework. Each programmable VME module in the crate has associated EPICS device driver software support which runs on the CPU board. For VME modules with common use at the SNS, beyond the BLM system (e.g. timing and MPS PMC), software is reused from the SNS standard software repository. Other BLM specific software drivers have been written for the remaining modules – the most significant and complex being that for the ICS110B ADC cards. The ICS110B driver is interrupt driven and relies on Direct Memory Access (DMA) for data transfer to the CPU card. It uses a specialized, hardware specific software driver. Alternating beam pulse data is captured by this ADC card into one of two internal "ping-pong" FIFO's. As one FIFO fills, the other, containing the prior pulse's data, is transferred via DMA to the CPU board and processed. For each 60 Hz beam pulse 400 samples (4 mS duration) are acquired for each fast and slow loss signal. Approximately 10 seconds of these data (600 pulses) are queued and internal to the system at any time. Various displays and display rates are available to visualize these data.

CAVITY X-RAYS

Beam loss is not the only source of radiation detected by BLMs. Significant x-ray background comes from RF cavities. To account for these x-rays, the SNS timing system generates a "blank" pulse every 10 seconds. During this blank pulse RF is switched on but there is no beam. The signal from the loss monitors is stored as a reference that is subtracted, in software, from the following normal pulses (with beam enabled). While this approach works, it cannot be used for fast protection because the leaky integrator cannot subtract the stored reference. This inherently compromises MPS because the loss limit set on the DAC has to include "losses" from x-rays.

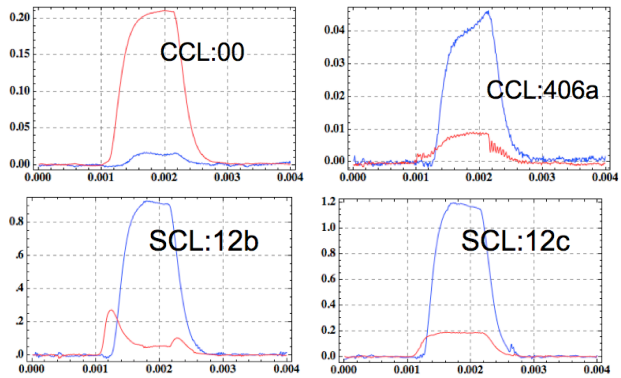

Figure 5: Loss waveforms showing Loss vs Time (s) in different locations. Red gives x-rays only signal (stored reference) and blue shows loss only signal (after subtraction of the reference).

As one can see in Fig. 5, the x-ray component is quite significant and can be even greater than the loss itself. A detector that is sensitive to neutrons and not sensitive to x-rays could be a possible solution. Unfortunately it is hard to create such a detector that would work in analog mode. We are currently experimenting with Dual BLM, which essentially consists of two scintillator-based detectors. One detector has increased sensitivity to neutrons and it measures neutrons and x-ray flux; the second detector measures x-rays only (its' neutron sensitivity is much lower than the first one). Thus by subtracting the "x-ray signal" from "neutron plus x-ray signal" we can get the signal from neutrons only.

NEXT GENERATION OF BLM SYSTEM

This BLM system was designed around 1999. The major problem now is part obsolescence. The AFE boards are using obsolete, discontinued parts and several VME boards are discontinued including the ADC board. Instead of designing replacement boards, we are developing a new system that will significantly differ from the current one.

We plan to use FPGA technology to add flexibility to the MPS setup. MPS functionality will be moved from software to FPGA. We will still have analog integration, but its output will be fed into the FPGA as well. Beam abort decision will be made inside the FPGA and software

Copyright © 2013 CC-BY-3.0 and by the respective authors

will be used for communication purposes only. Instead of having just two limits for single pulse loss and one second average loss we will have arbitrary integration windows that could be different for various regions of the accelerator following similar approach used in LHC [7]. For example, since the SCL requires a faster reaction time to high loss, the beam will be tripped if a single digitizer's sample exceeds a threshold level instead of the integral over several samples.

The multichannel AFE boards will be replaced with single channel modules (Fig. 6) of different types to accommodate different detectors.

Key features of a single channel AFE module:

- Analog subtraction using fader IC [8]
- PGA gain
- HV power supply
- Own MPS integrator
- DAC for threshold settings, HV control, subtraction control, test signal control
- Analog front end can have several options
  - Maximum configuration for Dual BLM (already designed and being under test)
  - Only MPS integrator and fixed gain amplifier for ion chamber with shared HV supply

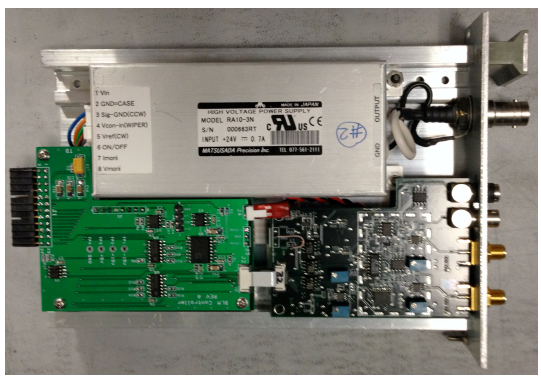

Figure 6: Single channel module with HV power supply and dual input for Dual BLM.

All modules will have amplified analog signals routed to the backplane and front panel for testing purposes. One chassis will host 8 (or 16) modules; analog signals in the same chassis will be digitized and processed in one FPGA (currently we consider cRIO system from National Instruments). This will add flexibility in defining trip conditions. We will be able to use the combination of losses from several detectors to determine if the beam is errant or not while having the MPS logic in hardware (FPGA). For example, the new system will be able to trip the beam if the weighted sum of losses exceeds a threshold; such testing can be performed on the fly on a point-by-point basis.

NON TYPICAL APPLICATIONS OF BLM

Fast BLMs for Beam Studies

We found it very useful to have fast BLMs (PMTs in Table 1). These devices are not connected to the MPS and are used for research only. They are fast enough to distinguish between mini-pulses of SNS beam. These detectors can be used as high time resolution devices for profile measurements. A PMT detects radiation caused by beam hitting a wire. Since it is not a beam line device it can be easily added anywhere in the tunnel. Another example where time resolution is essential is the injection area. Here PMTs can distinguish between loss from H^- hitting the foil and H^+ circulating in the ring.

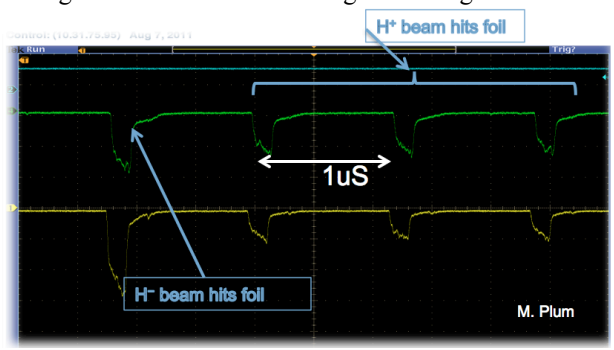

Figure 7: Fast BLM measurement revealing fine time structure of loss at injection area. One mini-pulse injected in the ring [9].

One of the main goals of the BLM system is controlling residual activation inside the accelerator tunnel. This is achieved by limiting one-second average loss. We also demonstrated that certain types of BLMs can be used to directly measure residual activation while beam is running. To achieve this we increase sensitivity of the scintillator-based detectors by ramping up their high voltage. Of course this causes saturation when beam is present (~ 1mS of 60 Hz period). But if we set the integration window to be well beyond the beam gate, the detectors are able to measure residual activation since there is no other radiation source when beam and RF are off. Figure 8 shows that one can see residual activation slowly decaying if beam is off for long time.

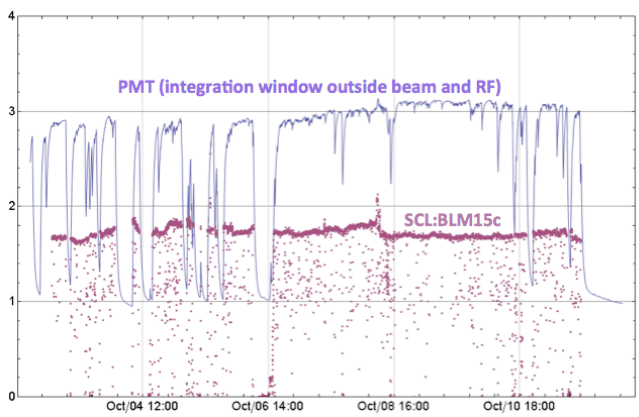

Figure 8: Residual activation in SCL measured by PMT vs. BLM (ion chamber) signal.

Installation of the new BLM system will make such residual activation measurement a standard procedure that will serve as additional guidance for tunnel surveys by radiation protection personnel.

Copyright © 2013 CC-BY-3.0 and by the respective authors

SUMMARY

The existing BLM system protects the SNS accelerator from beam related damage and controls residual activation by limiting average loss at specified 1 W/m level. The system covers all beam energies from 2.5 MeV to 1 GeV. The ionization chamber is the main detector used for MPS with dynamic range at least 10^5 and capable to measure down to 10^{-6} of fractional loss. It is capable to support beam power upgrades of at least doubling of beam power.

Low energy loss is hard to control with radiation detectors and other MPS devices are used in combination with the BLMs such as the differential BCM [10]. BLM systems are the main mechanism to trip errant beam; SCL downtime reduced by factor of six over last several years of operation by understanding causes of errant beam trips [1,10].

The system has proved to be quite reliable since SNS started operation in 2006. Total beam down time due to BLM malfunction is less than 12 hours; most of the downtime is related to software issues and VME power supplies failures.

Electronics obsolescence, including the ADC boards being discontinued, demands a system redesign. X-ray radiation from cavities presents an issue for hardware-implemented protection. Multi-channel AFE boards require beam shutdown for repair or troubleshooting. New FPGA-based [11] BLM system that will address the majority of these issues is currently under development.

ACKNOWLEDGMENT

ULTRA-SHORT ELECTRON BUNCH GENERATION BY A PHOTOCATHODE RF GUN*

M. Mizugaki#, Y. Koshiba, K. Sakaue, M. Washio, Waseda University, Tokyo, Japan

Abstract

We have been studying on the accelerator physics at Waseda University with BNL type 1.6cell RF gun. Such photocathode RF gun can generate low emittance and short bunch electron beam. Generating ultra-short electron bunch (shorter than 1ps) in a compact accelerator system would be meaningful because some applications need to be miniaturized, THz imaging, for example. However short the laser pulse is, the bunch length would be longer than 1ps due to the severe space charge effects. For the purpose of generating ultra-short electron bunch in compact system, we have newly designed Energy Chirping Cell attached RF gun (ECC RF gun). ECC is attached subsequently to the 1.6 cell. The role of ECC is to chirp the electron energy so that the electron bunch is compressed by velocity difference as it drifts. Simulation results show ECC RF gun can compress the electron bunch down to 200fs (rms) with 100pC electron charge. We have successfully measured the coherent THz light by synchrotron radiation and transition radiation. From these consequences, we infer that the bunch would be compressed into shorter than 500fs. In this paper, we report the results of the bunch length measuring experiments and future plans.

INTRODUCTION

At Waseda University, we have built a compact accelerator system (2m×3m), which consists of picosecond UV pulse laser and S-band Cs-Te photocathode RF electron gun . This RF gun is based on BNL type IV 1.6 cell cavity and capable accelerating high quality electron bunches up to the energy of 5MeV. In our system, the RF frequency is 2856MHz and Cs-Te is used for the cathode. Such photocathode RF guns can generate high-quality electron beam, that is to say low emittance, high brightness, and short pulse. At Waseda University, the beam has been used for applications such as pulse radiolysis experiment for radiation chemical reactions [1], soft X-ray generation via laser-Compton scattering [2] and a laser profiler [3]. Besides such beam applications, we have been developed an RF gun itself in cooperation with High Energy Accelerator Research Organization (KEK).

Ultra-short Electron Bunch

If ultra-short electron bunch (<1ps) is available from the RF gun, it leads some beam applications to be improved. At the least at Waseda, temporal resolution in pulse radiolysis system and luminosity in laser-Compton scattering will be improved. And in addition, ultra-short electron bunch is able to produce coherently enhanced THz radiation. At this time the intensity of THz radiation increases with the square of the bunch electron charge. Therefore in order to achieve high power THz radiation, it is necessary to keep a certain amount of the bunch charges besides bunch compression. The magnetic compression is widely used to compress energy chirped electron bunch. This method has made successful achievements [4], but leads the system to increase in size. The aim of our study is to generate ultra-short electron bunch by use of an RF gun alone.

BUNCH COMPRESSION

Generally in photocathode RF gun, the initial beam transverse/longitudinal profile can be controlled by the laser pulse. It seems that femtosecond laser would generate ultra-short bunch, but in simulation, we have confirmed that the bunch length gets longer than 1ps due to space charge effects. Therefore we have considered improving RF gun.

Energy Chirping Cell Attached RF Gun

Now we have newly designed an RF gun named Energy Chirping Cell attached RF gun (ECC RF gun) in order to achieve ultra-short bunch just with an RF gun itself [5][6].

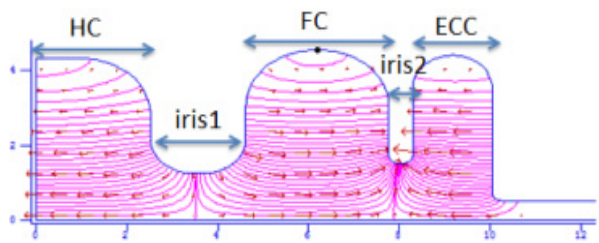

Figure 1: The cavity structure of the ECC RF gun.

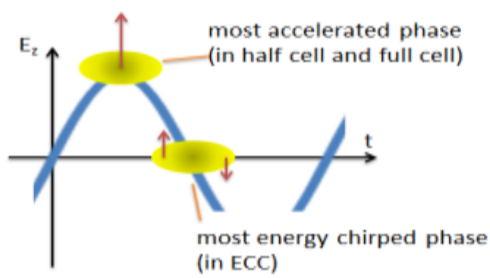

Figure 2: Off-crest acceleration in ECC.

As shown in Figure 1, the Energy Chirping Cell (ECC) is attached subsequently to the 1.6 cell: half cell and full cell. The ECC RF gun is designed to be operated in π mode, similar to the conventional RF gun. Figure 2 shows energy chirping is preceded at off-crest RF phase. In half cell and full cell, the bunch is accelerated around the crest, on the other hand the bunch energy is linearly modulated around zero-crossing phase in ECC.

Therefore in the ECC RF gun, the bunch is firstly accelerated up to around 4MeV in 1.6cell, after that the bunch energy is chirped linearly. The energy chirped bunch gets gradually compressed as it drifts. We have confirmed such velocity bunching by PARMELA and GPT, a beam tracking code. Shown in Figure 3, the bunch length in the longitudinal phase space gets most compressed down to around 200fs (rms) at the 3m from the cathode. At this time initial pulse width is 4.3ps (rms) and the bunch has enough charge (100pC). Moreover, initial RF phase significantly affects the ultra-short bunch generation. As shown in Figure 4, the bunch gets compressed only around 30 degree. And we show the simulation results in Table 5.

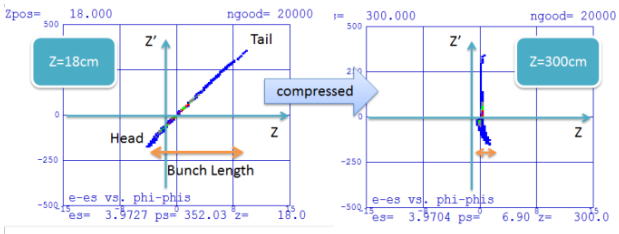

Figure 3:The longitudinal phase space distribution right after ECC (left), distance of 3m from cathode (right).

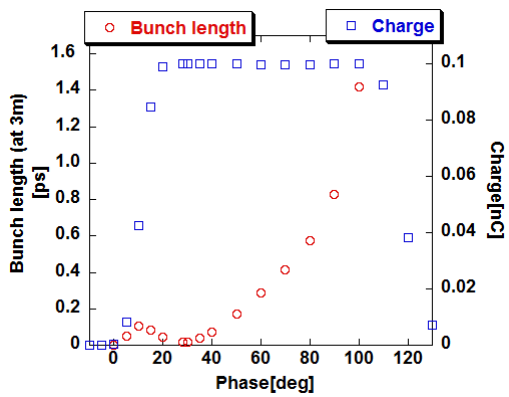

Figure 4: RF phase dependence of the bunch length.

Table 5: The Results of ECC RF Gun Simulation

Energy	3.98MeV
Charge	0.1nC
Minimum bunch length	158fs (rms)
The most compressed distance	3.07m
Normalized emittance	4.18πmm-mrad

By means of simulation, we have confirmed that the ECC RF gun generates ultra-short electron bunch, therefore we have started to manufacture the ECC RF gun. Figure 6 shows appearance of manufactured ECC RF gun.

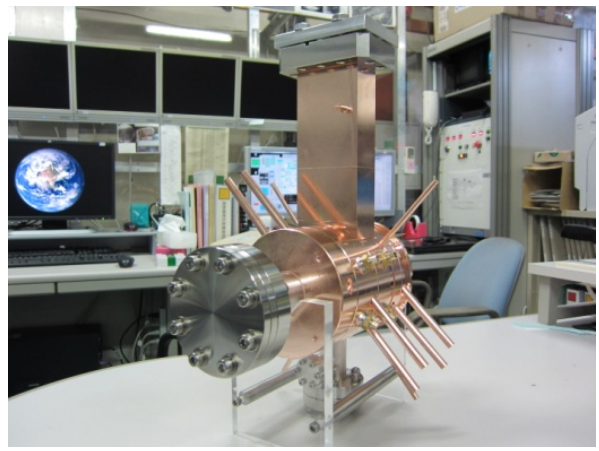

Figure 6: Manufactured ECC RF gun.

EXPERIMENTAL SETUP

We installed the ECC RF gun in our accelerator system. In order to measure a synchrotron radiation (SR), we built a beam line as illustrated in Figure 7. We put the bending magnet at the point of 3m from cathode, where the bunch got most compressed. And then SR passed through the z-cut quartz window, was measured by use of narrow band schottky barrier diodes (SBDs).

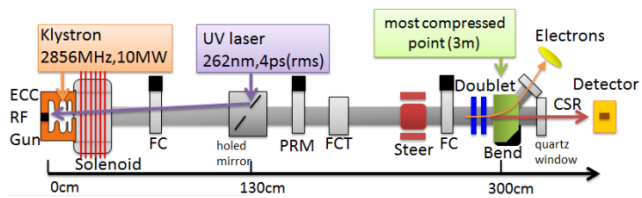

Figure 7: Experimental setup

Schottky Barrier Diode

In this spectroscopy experiment, we used several Schottky Barrier Diodes (SBDs), which have various narrow sensitive frequency ranges in THz region. The Table 8 shows the specs of these apparatuses.

Table 8: The Specifications of SBDs and BPF

Model	DXP-19	FAS-10SF-01	BPF
Manufacturer	Millitech	Wisewave	TYDEX
Sensitive range [THz]	0.04-0.06	0.075-0.11	0.18-0.22
Sensitivity [mV/mW]	1000	500	-
Name	0.05THz	0.1THz	0.2THz

Note that 0.2THz detector consists of 0.1THz SBD and 0.2THz BPF. 0.1THz SBD seems to have small sensitivity at 0.2THz.

EXPERIMENTAL RESULTS AND DISCUSSION

Coherent Synchrotron Radiation Measurement

When the bunch length σ_z is regarded as short enough as the wave length of the radiation, the radiation gets enhanced coherently with square of bunch charge. Assuming the bunch form as Gaussian, the power of the synchrotron radiation is expressed as;

$$P_{\mathrm{all}}(\omega) = N(1+(N-1)e^{-(\omega\sigma_z)^2})P_0(\omega) \quad (1)$$

where N is the number of electrons and therefore when bunch charge is 100pC, N is 6×10^8. $P_0(\omega)$ is power of the radiation from one electron and $P_{all}(\omega)$ is power from the bunch. The spectrum of the SR and CSR is calculated by SPECTRA as shown in Figure 9. 3.7MeV electron bunch can generate THz radiation in our beam line. In our setup, the cut-off frequency is 0.6 THz. But considering the bunch is kicked by a fridge weak magnetic field the cut-off frequency becomes as lower as 0.3 THz. It is also obvious from Figure 9 and Equation (1) that shorter bunch can generate CSR at higher frequency. Therefore we can estimate the bunch length by measuring CSR frequency.

We have confirmed Coherent Synchrotron Radiation (CSR) by plotting THz intensity as a function of the bunch charge in Figure 10. It is evident from the plots that

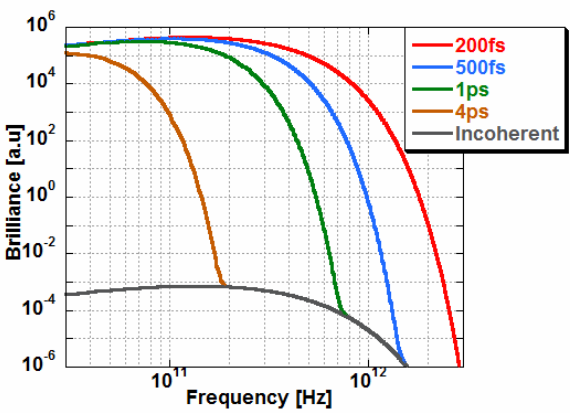

Figure 9: CSR spectrum calculated by SPECTRA (3.7MeV, 100pC).

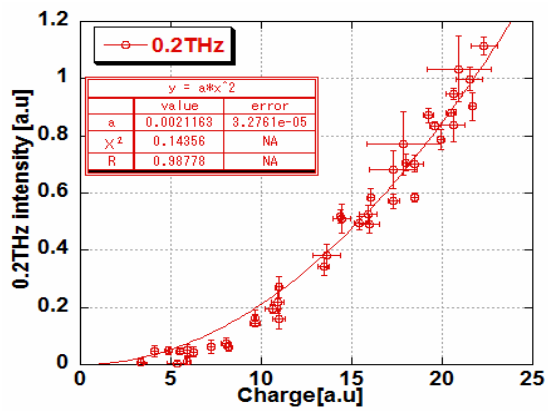

Figure 10: 0.2 THz coherent synchrotron radiation.

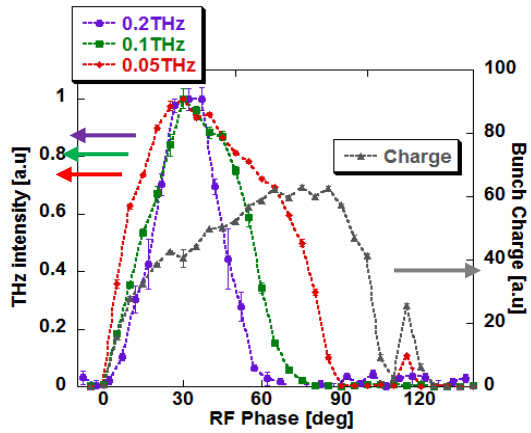

Figure 11: Phase dependence of several detectors.

we have obtained at least up to 0.2THz CSR.

We have successfully measured 3 various narrow THz regions, around 0.05THz, 0.1THz and 0.2THz. As shown in Figure 11, we compared the detectors. Each CSR has a peak at the 30 degree. Moreover, intensity plots become narrow as the frequency of the CSR becomes higher one. These are surely expected by the Figure 4.

From the CSR spectrum (Figure 9) and the successful results of 0.2 THz CSR detection (Figure 10), we can estimate the bunch length is shorter than 500fs. Moreover, having even 0.2 THz CSR the spread width intensity profile (Figure 11), this implies that the higher frequency CSR is produced at the optimum RF phase of 30 degree. We believe the bunch is exactly compressed down to the 200fs at the optimum phase.

SUMMARY AND FUTURE PLANS

In this paper, we described the ECC RF gun newly designed to generate ultra-short electron bunch. We have successfully measured the CSR, thus we estimated the bunch length was compressed down to 500fs (rms). As further bunch length measurement, we consider spectroscopy by use of an interferometer. In the near future, we intend to directly measure the bunch length by use of an RF deflector [7].

REGULATOR / HARD SWITCH MODULATOR*

Ian Roth#, Neal Butler, Marcel Gaudreau, Michael Kempkes
Diversified Technologies, Inc., 35 Wiggins Avenue, Bedford, MA 01730

Abstract

Diversified Technologies Inc. (DTI) is developing a long-pulse modulator to meet the requirements of the Spallation Neutron Source (SNS) at Oak Ridge National Laboratory and the European Spallation Source (ESS), planned for Lund, Sweden. The modulator will deliver pulses at 100 kV at a pulse width of 3.5 ms, and a droop of less than 1%. The modulator will be delivered to Oak Ridge for conditioning klystron tubes before they are installed in the SNS accelerator.

INTRODUCTION

DTI is developing a long-pulse modulator as an alternative to the present Converter Modulator at SNS. The new Regulator / Hard Switch Modulator has two objectives: conditioning klystron tubes at SNS, and demonstrating the technology needed for future superconducting accelerators, such as ESS. The modulator specifications are given in Table 1. The key technical issue is meeting the 1% flatness specification without a large capacitor bank, using the minimum additional hardware. To meet these requirements, DTI's modulator has a small non-dissipative regulator that produces a tightly-controlled flattop and eliminates flicker on the input grid. The regulator is the major development for this new modulator design.

Table 1: Modulator Specifications (The frequency will be limited by the low-power supply used for klystron conditioning.)

Voltage (kV)	100
Current (A)	50
Pulse width (ms)	3.5
Frequency (Hz)	14
Voltage flatness (%)	<1
Ripple (% peak-peak)	<0.1

SYSTEM

Overview

The mechanical layout of the modulator is shown in Figure 1, and a highly-simplified schematic diagram is shown in Figure 2. The major elements of the system are the switch, regulator, capacitor, and transformer. This modulator is a 'hybrid' design, with a solid-state switch driving a pulse transformer. This design was chosen to accommodate the ESS preference to avoid DC high voltage and oil-immersed switching elements. The modulator could readily have been designed without a transformer; DTI has built many hard-switched solid-state modulators that reliably switch pulses over 100 kV, at much higher current and average power than required here.

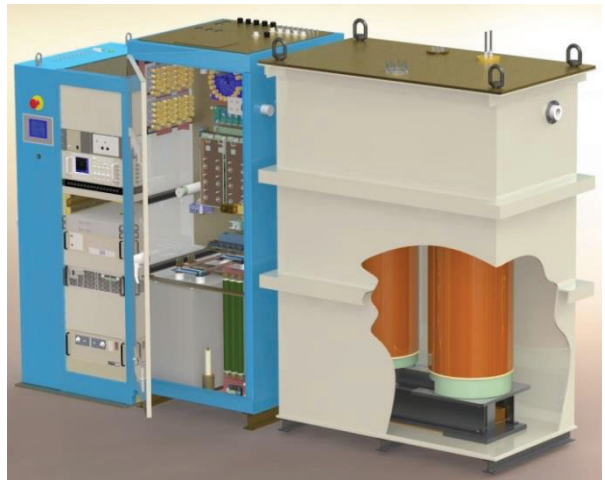

Figure 1: Mechanical layout of the system. The components are (from left to right) cabinet for PLC and AC power, rack-mount cabinet with power supplies and control boxes, power-conditioning cabinet (which contains the capacitor bank, switch, and regulator), and oil-filled transformer tank.

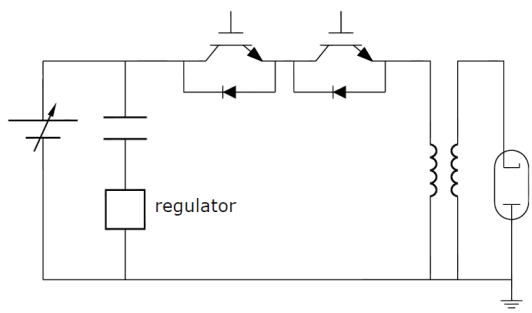

Figure 2: Highly-simplified schematic diagram. (The switch is made with seven IGBTs, not two.)

Switch

The switch is made with series-connected IGBTs, a well-established technology at DTI. The switch operates only once per pulse, in contrast to the 30 times needed by the SNS Converter Modulator. The lower switching frequency reduces the losses, and reduces the size of the switch.

The switch consists of seven modules in series; two of these are redundant. Since IGBTs fail short, if two modules short, the others will continue to support the voltage across the switch. The number of good IGBTs in the switch stack is monitored so that in the unlikely event

of a failure, repairs can be appropriately scheduled before a modulator failure occurs. The IGBTs are mounted on a cold plate to keep their temperature low, giving high reliability.

Regulator

The regulator is the key development for this program; it keeps the output voltage constant as the capacitor voltage droops. The regulator produces only the droop voltage (±7% of the output), rather than the full voltage produced by the converter modulator. This means that the regulator can be very small and efficient.

Representative voltage waveforms for this system are shown in Figure 3. The capacitor voltage droops during the pulse, then is recharged between pulses, returning to its original level. The regulator output is opposite to the variation in capacitor voltage. This produces both a flat output pulse and a constant power-supply voltage. As a result, the power supply can operate at constant current and constant power – and so does not produce flicker, regardless of the switching frequency. The regulator is non-dissipative, since it neither supplies nor sinks net power over a cycle.

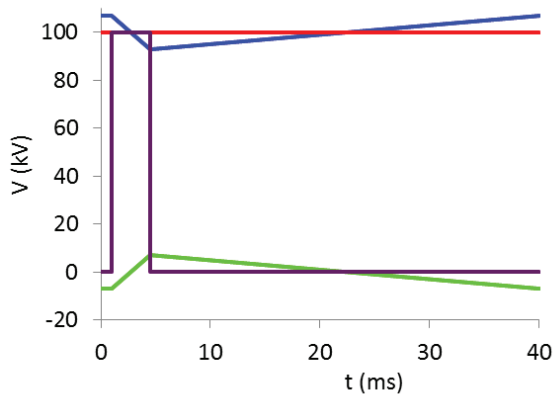

Figure 3: Voltage waveforms for the modulator system. Capacitor (blue), regulator (green), load (purple), main power supply (red).

The regulator is based on a full-bridge circuit rather than a half-bridge. A full bridge transfers all the energy in the filter inductor to the filter capacitor, unlike a half-bridge, which returns some of the energy to the bus capacitor. Because of this, a full-bridge can operate at a lower current (and correspondingly lower loss) than a half-bridge.

The bridge circuit has different phases of operation, depending on whether the modulator is pulsing or charging, and whether its output voltage is positive or negative. Operation during the first half of the pulse is shown in Figure 4. The A switch cycles on and off. When it is closed (top), current builds up in the inductor; when it is open (bottom), the current in the inductor discharges into the bus capacitor. The bridge circuit operates as a boost regulator, transferring energy from the filter capacitor (which is charged by the main capacitor) to the bus capacitor.

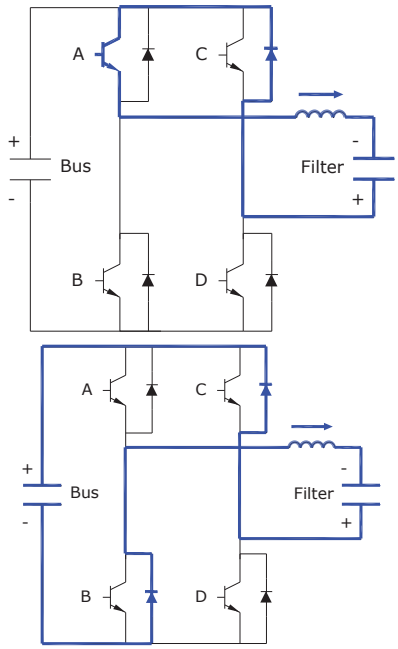

Figure 4: Regulator operation during the first half of the pulse, when the regulator output is negative. The blue traces show the current path. (Top) A switch is closed, and current builds up in the inductor. (Bottom) A switch is opened, and energy in the inductor discharges into the bus capacitor. Energy flows from the filter capacitor to the bus capacitor.

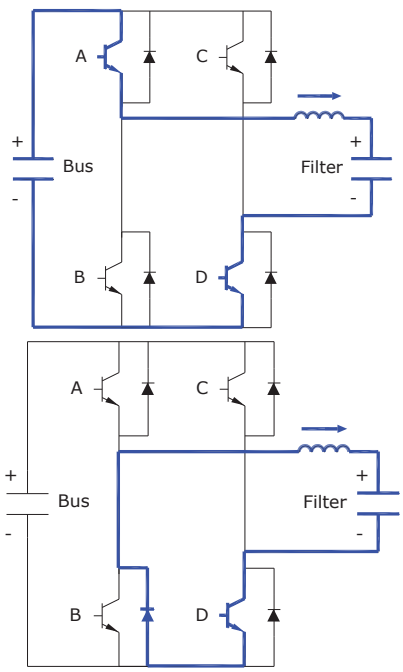

Figure 5: Regulator operation during the second half of the pulse, when the regulator output is positive. (Top) A and D switches are closed, and current builds up in the inductor. (Bottom) A switch is opened, and energy in the inductor discharges into the filter capacitor. Energy flows from the bus capacitor to the filter capacitor.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Operation during the second half of the pulse is shown in Figure 5. In this case the D switch is closed. When the A switch is closed (top), current builds up in the inductor; when the A switch is open (bottom), the current in the inductor discharges into the filter capacitor. In this case the bridge circuit operates as a buck regulator, transferring energy from the bus capacitor to the filter capacitor (and then to the load).

Operation during charging is similar, but with the C and B switches operating, rather than the A and D switches.

The regulator is made with two bridges in parallel, connected to a common filter capacitor. The IGBTs in the bridges switch at 100 kHz during pulsing, and 5 kHz during charging. Their switching is staggered, making an effective switching frequency of 200 kHz during pulsing.

We have demonstrated regulator operation at its full output power. (While the switch voltage was low for this test, the regulator operation depends only on the regulator voltage and current.) The output voltage without the regulator is shown in Figure 6; the capacitor droop is exaggerated from the actual modulator design, and is obvious. Waveforms with the regulator operating are shown in Figure 7. The regulator produces up to ±400 V, and is clearly compensating for the droop. The initial dip in the voltage waveform is due to the initial voltage drop across the switch; this will be eliminated by feedback compensation in the regulator controls.

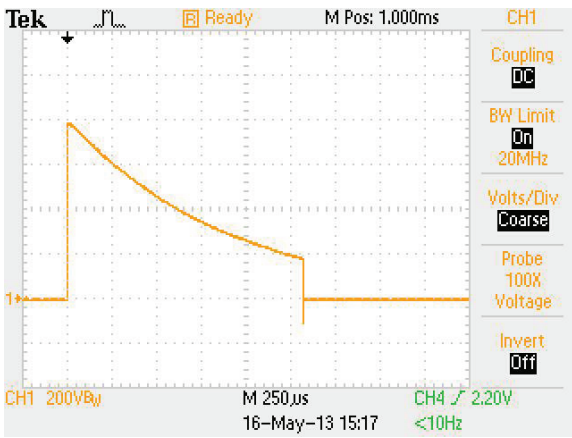

Figure 6: Pulse voltage without the regulator, 200 V/div, 250 µs/div.

Capacitor Bank

The capacitors are made with metallized film (also referred to as "self-healing"), allowing them to be roughly one-quarter of the volume and cost of capacitors made with film-foil technology. Metallized-film capacitors can tolerate arcs in the film, and so can operate at a relatively-high electric field. This is because when a metallized-film capacitor arcs, the metallization near the arc blows off, isolating the shorted section from the rest of the capacitor. The only impact is a small reduction in capacitance. In contrast, a film-foil capacitor cannot tolerate arcs, and must operate at a lower electric field. In general, the allowable current in metallized-film capacitors is lower than the current in a film-foil capacitor. However, the RMS current in the modulator (184 A) is low enough that is this not a concern.

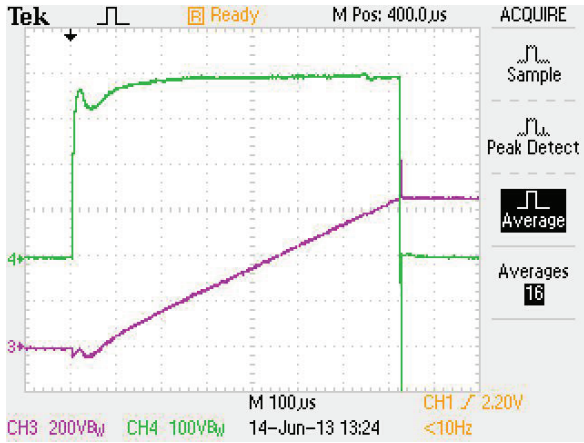

Figure 7: Pulse voltage (green) and regulator voltage (purple), 200 V/div, 250 µs/div.

The total bank capacitance is 4 mF; it stores 82 kJ at 6.4 kV. The bank is made of three 1333 µF capacitors in parallel, each 14" x 15" x 25" tall.

Transformer

The pulse transformer enables the DC power supply to operate at 6 kV, allowing the switch to be air-insulated. Since the pulse is 3.5 ms long, the transformer will be built like a power transformer, rather than the basket design typically used for microsecond pulses.

The long pulse width makes the transformer large, so the hybrid modulator is larger than a comparable hard-switch system. The leakage inductance of the transformer limits the pulse rise time. There is a design tradeoff between leakage inductance and size; reducing the leakage inductance increases the transformer size.

CONCLUSION

The droop control for long pulses provided by this regulator modulator makes it attractive for applications which would otherwise require prohibitively large and expensive capacitor banks, or more complex switching arrangements. The first system will be tested at DTI in early 2014, prior to its installation at SNS.

DTI's future efforts will include investigating directly-switched oil-cooled systems, and applying the regulator to correct pulse droop in long-pulse Marx modulators, rather than adding numerous corrector modules or complex Marx stages.

INDUCTIVELY COUPLED PULSED ENERGY EXTRACTION SYSTEM FOR 2G WIRE-BASED MAGNETS *

R. Agustsson#, J. Hartzell, S. Storms, RadiaBeam Technologies, Santa Monica, CA 90404

Abstract

This project seeks to develop a novel method for quench protection of high-temperature superconducting (HTS) magnets based on coupling the magnet with a high-power resonant coil. The quench protection is realized by applying an electromagnetic pulse through the resonant coil and disrupting the superconducting state in the conductor. This creates a large (10s of meters) normal zone in less than 10 ms thus ensuring even distribution of the energy dissipation. The proposed protection system does not involve generation of high voltage on the coil leads and does not contribute to cryogenic losses. The system is easily scaled to a magnet of arbitrary size. Preliminary design and POC bench top test preparations are presented below.

INTRODUCTION

Recent progress in high-field performance of the second-generation (2G) HTS conductors [1, 2] has enabled design and development of ultra-high field magnets. This is possible because YBCO, the core material of 2G wire, holds the record for the upper critical field, Hc2. A combination of high Hc2 and high mechanical strength (700 MPa yield strength [3] for SuperPower Hastelloy-based wire) position the 2G wire as the only viable conductor for ultra-high field, > 20 Tesla, superconducting magnets.

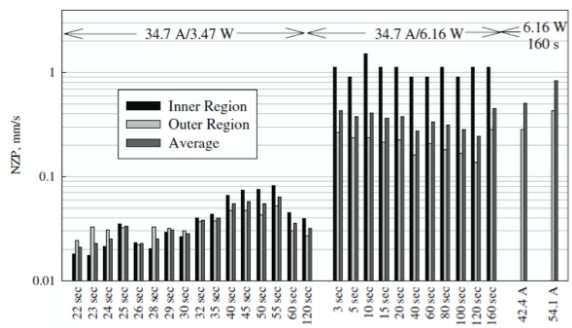

Figure 1: Typical NZP velocities measured in test 2G wire coils [4].

The key component of 2G wire is the epitaxial YBCO layer. This layer, which is only 1-1.5 micron thick, carries all the current of the superconductor. The major problem is its slow rate of Normal Zone Propagation (NZP). As shown in Figure 1, experimental measurement of NZP velocity in 2G wires yields values below 1 mm/s. Such a low propagation velocity results in concentrated energy dissipation and irreversible damage of the magnet during an unprotected quench. The problem is further exacerbated by the low thermal mass and poor thermal conductivity [5] of the YBCO layer. Thus carefully designed protection systems are required to protect 2G superconductors from catastrophic damage.

The established active and passive [6] quench protection systems for traditional low-temperature (LTS) magnets [7] are ill-suited for HTS magnets because their energy extraction is too slow. The measured NZP velocity means the stored energy has to be extracted or redistributed within a few seconds to prevent catastrophic damage. A traditional energy extraction system based on a dump resistor and a semiconducting switch would require several kilovolts on the coil to achieve fast extraction. Such a high voltage creates multiple problems for the interfacing electronics and the current source. Redistribution of the normal zone by resistive heaters is problematic since the thermal conductivity of insulating materials, used to separate the heater from the coil, drops at cryogenic temperatures due to the phonon freeze-out. This effect prevents efficient coupling of the heater elements to the superconductor.

TECHNICAL APPROACH

By inductively coupling a strong electromagnetic pulse via a resonant LC circuit, the normal zone propagation in the coil will be accelerated. The AC field induces currents in the superconducting layer with the current density exceeding that of the critical current density, J_c. This creates a large normal zone, uniformly distributing the dissipation through the magnet body. The method does not rely on thermal heating of the conductor, thus potentially enabling nearly instantaneous protection.

Quench Modeling

The 2G wire coil (in the following DC coil) was modeled as 120 mm OD, 80 mm ID double-pancacke stack. We used the following functional dependence to approximate the critical current field dependence: $I_c = I_0/(1+B/B_0)^a$, where I_0=300 A, critical current in self field, B_0=0.05 Tesla is the individual pinning field and a= 0.7 the pinning exponent. This is the typical I_c(H) behavior of SuperPower wire. The current density was calculated by dividing the current by the average area of the conductor, which was comprised of 50 micron Hastelloy substrate, 40 micron Copper stabilizer and 65

micron Kapton insulation. The DC coil was excited at 80 % of Ic, generation the maximum DC field of 0.3 Tesla. The AC coil is modeled as a 6 turn flat coil wound from 4 mm copper wire. The AC coil is excited with a 200 A current, which is applied as a short burst during the quench protection phase.

The DC field profile was generated in the standard magnetostatic module of COMSOL 3.5, using axial symmetry. The AC field penetration process had two components: interaction of the AC field with inductive currents in the copper stabilizer and penetration of AC field into the superconducting layer. The inductive current interaction was modeled by the COMSOL "Azimuthal Induction Currents" module in 2D axial symmetry geometry. The penetration into the superconductor was simulated by a custom script using well-known Brandt equations [8].

Penetration of AC field into the coil winding is limited by the skin-effect in the copper stabilizer layer. Figure 2c shows that the optimum 50% penetration is achieved at frequencies below 200 Hz. In the design we choose 150 Hz as the operation frequency. This combines manageable size of reactive components with deep winding penetration.

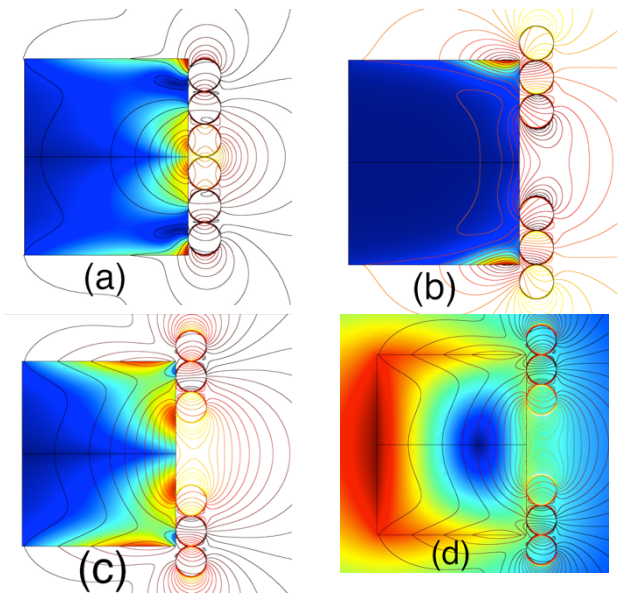

Figure 2: Resonant coil optimization showing field penetration color map and AC field contour map with initial geometry configuration (a), 1000Hz operation (b), final optimized geometry and frequency (c) and final DC magnetic field color map and AC field contour map (d).

Proof of Concept Design

The outputs from the optimal simulation results were slightly adjusted to account for simpler first pass implementation into the proof of concept (POC) system design and to use less HTS. Although slightly less penetration and NZP are expected due to this design change as seen in Figure 3, further Phase I efforts may approach the optimal design following initial system functional validation. The POC design parameters set the coil current at 100 A, resulting in a 0.1 T center, 0.22 T maximum field with a stored energy of 6.6J.

Double stack pancake coils with voltage taps for monitoring normal zone formation were envisioned. The stack would be sandwiched between G10 phenolic plates with slots cut in them for tap lead egress. The entire assembly will be immersed in a LN2 bath enclosed within a *Janis* cryochamber.

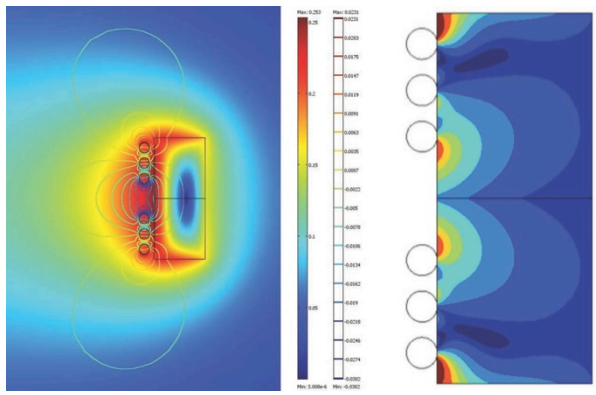

Figure 3: AC magnetic fields (left and shaded), DC magnetic fields (right contours) of the fabrication optimized simulations.

The main HTS coil is powered by a *TDK-Lamda* Genesys 3U 30V-333A power supply and the resonant coil is powered by a pair of *Kepco* BOP-10V-100A in parallel to provide the 200A resonant pulse. The main coil supply is protected with "low-side" switch (N-channel mosfet with the source tied to ground). The system only requires 150Hz pulsing and the *Kepco* BOP is capable of up to 800 Hz operation, permitting potential exploration of higher frequency spaces. This BOP replaced our original plan to build the resonant circuit, with the cost of the devices nearly equal to the projected parts and labor to build our own pulsed power supply.

For voltage tap monitoring, a *Measurement Computing* USB-2537 DAQ card was selected. This card can accommodate up to 64 single ended voltage channels that are needed for reasonable spatial resolution of the quench propagation. Moreover, this DAQ was also chosen for its 1 MS/s sampling speed and 16 bit resolution. Finally, the MC USB-2537 also offers a large common-mode voltage rejection of +/- 10 V, so that we can directly measure the voltage across all of the channels without signal isolation.

As the system utilizes 52 voltage taps on the super conducting coils, with an aggregate sampling speed of 1 MS/s, all 52 voltage taps can be sampled in just over 50 microseconds. Even with a factor of 2 allowance, 10 samples can be taken per tap every millisecond, thus defining the absolute temporal resolution limit of the system. Further, as the buffer size of the board is 1MS,

Copyright © 2013 CC-BY-3.0 and by the respective authors

all the data from a single event can be recorded without the necessity to clear the board buffer that would add further latency to the system.

FABRICATION AND INTEGRATION

A standard double stack pancake coil with HTS tape interconnects were manufactured at RadiaBeam Technologies. The turn to turn coil isolation was accomplished by co-winding the superconducting coil with kapton. To attach the voltage taps, a large copper block wrapped in heater tape was used as a warm backing plate while a precision temperature controllable soldering iron was used to heat the pre-tinned voltage taps until solder flow was observed. Pure Indium solder was used. The bare coil section was then carefully cleaned with isopropanol and lint free wipes prior to co-winding the kapton insulation tape. The pancake stack was dry wound on a custom-made mandrel, Figure 4 left, carefully designed to ensure the 10mm minimum bend radius of the HTS tape was not violated and ground wrapped with 0.006" DMD. The warm leads for the voltage taps were then soldered on and the assembled coil was sandwiched between a pair of G10 phenolic plates as seen in Figure 4 right. The warm leads are placed above the coil stack to ensure simpler assembly of the resonant coil around the perimeter of the assembly. The resonant coil was form wound in a flat pattern and bent to encompass the main HTS coil as shown in Figure 5, right.

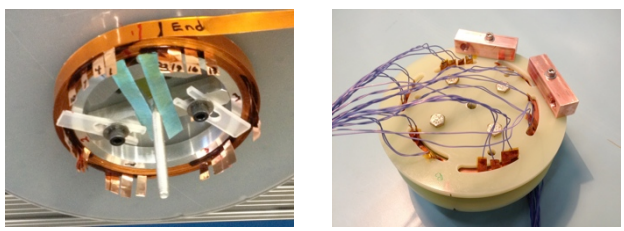

Figure 4: HTS coil on the winding fixture and shown with soldered voltage taps (left). Double pancake coil stack shown with tap leads soldered on and copper warm lead blocks.

EXPERIMENTAL PLANS

All the physical components have been completed and integrated into the cryostat as seen in Figure 5left. Final debugging of the controls and DAQ systems is currently ongoing with initial testing to start shortly. The experimental plans for testing this system will aim to search as broad a parameter space as possible. The main coil current, resonant coil current and frequency will be swept as we explore the system behavior. Further, various resonant coil geometries will be examined including the ideal optimized geometry as shown in Figure 2. Characterization of the NZP speed and optimizing the system to maximize the NZF will be the focus of these studies.

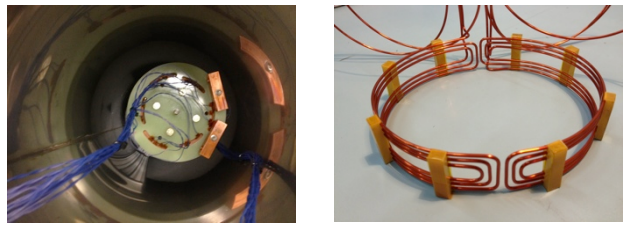

Figure 5: HTS coil placed cryochamber (left), resonant coils prior to forming around HTS coils (right).

CONCLUSIONS

The fundamental behavior of the induced quenching system has been examined through analytical studies and simulations demonstrating the potential viability of this system. Fabrication of the POC has been completed and the final debugging of the control system to be concluded in the very near future. The experimental work plan is in place with data to be acquired imminently.

PHYSICS OF POLARIZED PROTONS IN ACCELERATORS*

M. Bai
Brookhaven National Laboratory, Upton, NY 11973, USA

Abstract

Polarized proton beams have been one of the essential elements in fundamental research such as unveiling the deep secret of proton spin structure. Polarized proton beams can also be the tool for direct measurement of the proton's electric dipole moment (EDM). However, due to the interaction between spin motion and electric and magnetic fields, it is very challenging to overcome various depolarizing mechanisms through acceleration, and necessary spin manipulations at a store energy to meet the physics program requirements. Several decades of efforts have been devoted to develop techniques to preserve polarization and spin manipulation, as well as further our understanding of spin dynamics. These efforts directly led to the successful spin program at the Brookhaven Relativistic Heavy Ion Collider (RHIC), the world's first high energy polarized proton collider. This tutorial presentation introduces basic physics which governs the spin dynamics in accelerators. A brief history of polarized protons development, as well as what have been achieved at RHIC are also reported.

INTRODUCTION OF SPIN DYNAMICS BASICS

Just like charge and mass, spin is also an intrinsic property of elementary particles. Spin vector $\vec{S}$ for a particle is then defined as

$$\vec{S} = \langle\psi|\vec{\sigma}|\psi\rangle, \tag{1}$$

where $\vec{\sigma}$ is the Paul matrices, and ψ is the particle spin state. Proton, a spin of $\frac{1}{2}$ particle, has two eigenstates, i.e. $\psi_+ = |\frac{1}{2}, +\frac{1}{2}\rangle$ (up state) and $\psi_- = |\frac{1}{2}, -\frac{1}{2}\rangle$ (down state). The intrinsic magnetic moment of a particle is then given by

$$\vec{\mu} = g\frac{e}{2m}\vec{S} \tag{2}$$

where e and m are the electric charge and rest mass of the particle. g-factor for a perfect point-like particle is $\frac{1}{2}$. For proton, the anomalous g-factor $G = \frac{g-2}{2}$ is 1.7928474.

For a beam of spin-$\frac{1}{2}$ particles, polarization P, on the other hand, is a classical concept defined as

$$P = \frac{N_+ - N_-}{N_+ + N_-} \tag{3}$$

where $N_\pm$ are the number of particles in the two spin states, respectively [1].

In a circular accelerator, the spin motion is governed by the Thomas-BMT equation [2]. In the frame of particles orbital revolution, it is given by

$$\frac{d\vec{S}}{dt} = \frac{e}{\gamma m}\vec{S}\times[G\gamma\vec{B}_\perp + (1+G)\vec{B}_\parallel + (G\gamma + \frac{\gamma}{\gamma+1})\frac{\vec{E}\times\vec{\beta}}{c}], \tag{4}$$

where $\vec{S}$ is the spin vector in the particle's rest frame, $\vec{B}_\perp$ and $\vec{B}_\parallel$ are the transverse and longitudinal components of the magnetic fields in the laboratory frame with respect to the particle's velocity $\vec{\beta}c$, $\vec{E}$ is the electric field particle encounters and γ is the relativistic Lorentz factor. Here, Eq. 4 shows that in a perfect planar circular accelerator, the spin vector precesses $G\gamma$ times in one orbital revolution. $Q_s = G\gamma$ is then defined as spin tune.

In general, the effect on spin motion from electric field in an accelerator is negligible. Equation 4 can then also be expressed as

$$\frac{d\vec{S}}{ds} = \vec{n}\times\vec{S} = [G\gamma\hat{y} + G\gamma\frac{B_x}{B\rho}\hat{x} + (1+G)\frac{B_s}{B\rho}\hat{s}]\times\vec{S}, \tag{5}$$

where $\hat{x}$, $\hat{y}$, $\hat{s}$ are the unit vector along the direction of radial, vertical and longitudinal, respectively. $ds = \rho d\theta$, where θ is the bending angle. The equation of motion for the spin state in Eq. 1 also known as spinor for a $\frac{1}{2}$ particle is

$$\frac{d\psi}{d\theta} = -\frac{i}{2}(\vec{\sigma}\cdot\vec{n})\psi = -\frac{i}{2}H\psi. \tag{6}$$

For a constant H, Eq. 6 can be rigorously solved as

$$\psi(\theta_2) = e^{-\frac{i}{2}H(\theta_2-\theta_1)}\psi(\theta_1) = M(\theta_2-\theta_1)\psi(\theta_1) \tag{7}$$

where $M(\theta_2-\theta_1)$ is a 2×2 spinor transfer matrix. For a main bending sector dipole, the spinor transfer matrix is just $M(\theta_2-\theta_1) = e^{-\frac{i}{2}G\gamma(\theta_2-\theta_1)\sigma_3}$. For a thin quadruple, the spinor transfer matrix is $M = e^{-\frac{i}{2}(1+G\gamma)kly\sigma_1}$, where kl is the normalized integrated strength of the quadrupole and y is the vertical displacement of the particle from the center of the quadrupole [1]. For any spin rotator which rotates spin vector by ϕ around an axis $\hat{n}_{rot}$ is $M = e^{-\frac{i}{2}\phi\hat{n}_{rot}\cdot\vec{\sigma}}$. In general, in a circular accelerator, the one turn spin transfer matrix for a particle on the closed orbit is

$$M = e^{-\frac{i}{2}Q_s 2\pi\vec{\sigma}\cdot\hat{n}_{co}}, \tag{8}$$

where Q_s is the spin tune, and $\hat{n}_{co}$ is the stable spin direction. Equation 8 shows that for the particle's spin vector always returns to the same direction if it is initially aligned with the stable spin direction $\hat{n}_{co}$. Otherwise, the spin vector just simply precesses around the stable spin direction $\hat{n}_{co}$ Q_s times per orbital revolution. For a particle in a perfect circular accelerator where it only sees vertically aligned guiding magnetic fields, the stable spin direction is vertical and spin tune is $Q_s = G\gamma$, linearly proportional

* The work was performed under the US Department of Energy Contract No. DE-AC02-98CH1-886, and with support of RIKEN(Japan)

to the particle's energy. With the presence of any localized spin kick of ψ around an axis of n_e at location θ , the one turn transfer spinor transfer matrix of a particle on closed orbit then becomes

$$M(\theta+2\pi,\theta)=e^{-\frac{i}{2}G\gamma(2\pi-\theta)\sigma_3}e^{-\frac{i}{2}\phi\vec{\sigma}\cdot\hat{n}_e}e^{-\frac{i}{2}G\gamma\theta\sigma_3}, \quad (9)$$

and both spin tune and stable spin direction are changed [1].

In general, both spin tune and stable spin direction are function of particle's phase space coordinate, i.e.

$$\hat{n}_{co}(\vec{J}_z,\phi_z,\theta)=\hat{n}_{co}(\vec{J}_z,\phi_z+2\pi,\theta) \quad (10)$$

where $\vec{J}_z$ and , ϕ_z are particle's 6-D phase space coordinates. Spin tune is the number of spin precessions around $\hat{n}_{co}$ in one orbital revolution. Unless betatron tune is integer, spin tune and stable spin direction can no longer be computed by the simple one turn spin transfer matrix approach. Algorithms like SODOM, SLIM were developed to compute the stable spin direction for particles off closed orbit [3, 4]. For a single isolated resonance, an analytical solution of $\hat{n}_{co}$ was also found by Mane [5]. In the presence of overlapping resonances, the stable spin direction can be computed by numerical spin tracking using stroboscopic averaging developed by Heinemann and Hoffstaetter [6].

CHALLENGES IN ACCELERATING POLARIZED PROTONS TO HIGH ENERGY

Depolarizing Resonances

In a high energy planar accelerator, accelerating polarized protons operation is challenged by the presence of non-vertical magnetic fields due to magnetic field errors, quadrupole misalignments or vertical betatron oscillations, which kick the spin vector away from vertical direction. When the frequency of the perturbation on the spin motion coincides with the spin precession frequency, the kicks on the spin vector can be coherently added and result in polarization loss, i.e. a depolarizing spin resonance [1].

Depending on the source of the spin perturbing magnetic fields, there are two types of spin depolarizating resonances. The imperfection spin resonances at $G\gamma=k$ are due to dipole errors and quadrupole misalignments. Here k is an integer. The strength of this resonance is proportional to the size of the vertical closed orbit distortion. The intrinsic spin resonances at $G\gamma=kP\pm Q_y$, on the other hand, are driven by vertical betatron oscillation in the absence of coupling as well as other high order effects. Here, P is the super-periodicity of the machine and Q_y is the vertical betatron tune. The stronger the betatron oscillation, the stronger the intrinsic spin resonance. In general, for a resonance at $Q_s=K$, the resonance strength ϵ_K is defined as

$$\epsilon_K=\frac{1}{2\pi}\oint[(1+G\gamma)\frac{B_x}{B\rho}+(1+G)\frac{B_s}{B\rho}]e^{iK\theta}ds. \quad (11)$$

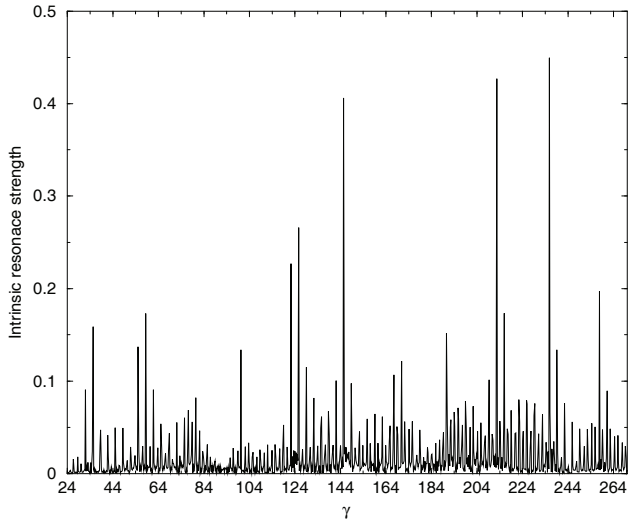

Figure 1: Strength of intrinsic spin resonances from injection energy to 250 GeV in RHIC. These are calculated from a RHIC lattice without any spin manipulation devices. The intrinsic spin resonance strength is calculated with a single particle at an emittance of 10π mm-mrad.

Evidently, for an imperfection resonance, its resonance strength is independent of particle's betatron oscillation amplitude. Intrinsic resonance strength, on the other hand, is different for particles at different betratron amplitude since they experience different magnetic field in a quadrupole. Fig. 1 shows the strength of intrinsic resonances as a function of energy in RHIC, calculated with Depol [7]. A total of 423 imperfection resonances lies between the RHIC injection energy and its designed store energy at 250 GeV, and the higher the beam energy, the stronger the imperfection resonance. The strong intrinsic spin resonances in RHIC are located at $81\pm(Q_y-12)$, $81+(Q_y-6)$, $2*81+(Q_y-12)$, $3*81-(Q_y-12)$ and $5*81\pm(Q_y-12)$. Clearly, no beam polarization can survive through all these depolarizing resonances.

The polarization change after crossing a resonance depends on the resonance strength as well as how fast the resonance is crossed. For a single isolated resonance, the ratio of the polarization after crossing the resonance P_f to the initial polarization P_i is given by the Froissart-Stora formula [8]

$$P_f=P_i(2e^{-\frac{\pi|\epsilon_k|^2}{2\alpha}}-1) \quad (12)$$

where $\alpha=\frac{dQ_s}{d\theta}$ is the resonance crossing rate and ϵ_k is the strength of the spin resonance. As indicated in Eq. 11, since intrinsic spin resonance strength is a function of the betatron oscillation amplitude, the average beam polarization of a Gaussian beam crossing an intrinsic resonance then becomes

$$P_f=P_i\frac{1-\frac{\pi|\epsilon_k|^2}{\alpha}}{1+\frac{\pi|\epsilon|^2}{\alpha}}, \quad (13)$$

Copyright © 2013 CC-BY-3.0 and by the respective authors

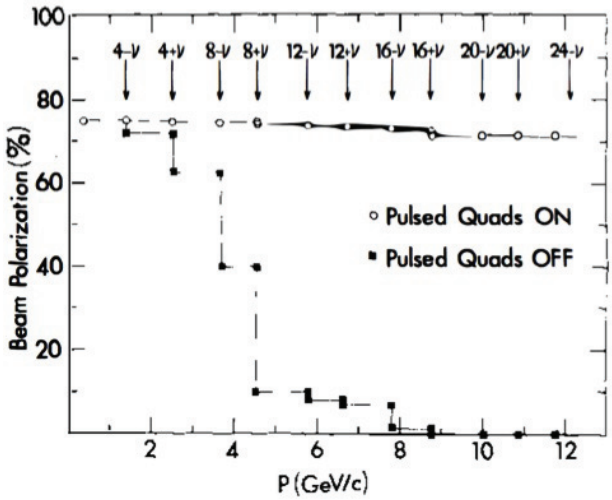

Figure 2: This plot shows the beam polarization as a function of the beam energy in the ZGS.

For a Gaussian beam, a polarization profile, i.e. polarization as function of betatron coordinates can be developed, of $P(x,x',y,y') = P_0 e^{\frac{x^2+x'^2}{2\sigma_{xp}^2}} e^{\frac{y^2+y'^2}{2\sigma_{yp}^2}}$ can be developed, The average beam polarization is $\langle P\rangle = P_0 \frac{1}{(1+R_x)(1+R_y)}$[9]. Here P_0 is the beam polarization of particle in the beam center, $\sigma_{x,p}$ and $\sigma_{y,p}$ are the rms size of horizontal and vertical polarization profile, respectively. $R_{x,y} = \sigma_{x,y}^2/\sigma_{x(y),p}^2$ where $\sigma_{x,y}$ is the rms beam size.

Overcome Imperfection Spin Resonance and Intrinsic Spin Resonance

Both imperfection resonances and intrinsic resonances can be overcome by correcting the closed orbit distortion at $G\gamma = K$ and fast jumping betatron tune at $G\gamma = kP \pm Q_y$ [1], respectively. Both techniques were first developed at the Argonne ZGS (Zero Gradient Synchrotron) [10, 11] in the early 70s. Fig. 2 shows the tune jump at each intrinsic resonance during acceleration. Both techniques were also applied to the AGS at BNL. With six fast tune jump quadrupoles and harmonic orbit corrections, polarized protons were accelerated to 22 GeV with 40% polarization in the AGS [12]. However, to achieve this, months of dedicated beam time were required [13].

For strong intrinsic spin resonances, one can use an RF dipole to excite a large amplitude coherent betatron oscillation to effectively enhances the intrinsic resonance strength and achieve full spin flip with regular resonance crossing rate. The advantage of this technique is to preserve the beam emittance by energizing the RF dipole adiabatically [14]. This technique was first successfully developed at the AGS [15] to obtain full spin flip at the four strong intrinsic resonances $G\gamma = 0 + Q_y$, $G\gamma = 12 + Q_y$ and $G\gamma = 36 \pm Q_y$. However, this technique is not applicable to weak intrinsic resonances due to the limit of physical aperture.

Partial Snake

For medium energy accelerators, the tedious and lengthy setup time of orbital harmonic correction for each imperfection resonance can be a serious impediment. Hence, an novel technique of using a partial snake, a magnetic which rotates spin vector around an axis in the horizontal plane by an angle of $\psi < 180^o$, to keep the spin tune away from all integers was proposed [16]. Equation 14 shows that spin tune, as a function of beam energy, becomes discontinuous at each integer. Hence, all imperfection resonances are avoided.

$$\cos(\pi \mathrm{Q_s}) = \cos(\mathrm{G}\gamma\pi)\cos(\frac{\psi}{2}). \qquad (14)$$

This technique was first developed at the BNL AGS [17]. A 5% solenoid snake, i.e. it rotates spin vector by 5% of 180^o, was installed in the AGS in the mid 1990s to overcome all the imperfection resonances [18].

In order to avoid the depolarization due to the weak resonances in the AGS, a dual partial snake scheme was developed in 2006. A 5.9% room temperature helical snake plus a super-conducting helical snake which can provide an maximum strength of 20% at the AGS extraction energy were installed located $\frac{1}{3}$ of the ring apart. With this configuration, spin tune then becomes [19]

$$\cos\pi \mathrm{Q_s} = \cos\mathrm{G}\gamma\pi\cos\frac{\psi_\mathrm{c}}{2}\cos\frac{\psi_\mathrm{w}}{2} - \cos\mathrm{G}\gamma\frac{\pi}{3}\sin\frac{\psi_1}{2}\sin\frac{\psi_2}{2}. \qquad (15)$$

Here, ψ_c and ψ_w are the amount of spin rotations of the strong super-conducting snake and the 5.9% snake, respectively. Equation 15 implies that not only the spin tune is forbidden in a gap around each integer but also that the width of the gap is modulated at an integer multiple of 3. The gap reaches its maximum width at each integer multiple of 3 where the two snakes are coherently added and otherwise reaches its minimum width when the two snakes are subtracted. Since the AGS has a super-periodicity of 12, all the strong intrinsic resonances are located at the integer multiple of 3 where the spin tune forbidden gap reaches its maximum. Hence, by placing the vertical betatron tune inside the spin tune forbidden gap, all imperfection and intrinsic spin resonances are avoided during the AGS acceleration [20].

Full Siberian Snake

To reach even higher energy polarized protons, it is operationally impossible to individually overcome each depolarizing resonance due to the amount of spin depolarizing resonances during the acceleration. Much stronger resonances also make it very difficult to preserve polarization with just partial snakes. Thanks to the invention of the Siberian snake by Derbenev and Kondratenko in 1976 [21], the polarized proton acceleration to high energies became practical. The Siberian snake is a special device which rotates the spin vector by 180° around an axis in the horizontal plane. Equation 9 shows in a ring with a single full snake, the spin tune becomes half integer, independent of

Copyright © 2013 CC-BY-3.0 and by the respective authors

beam energy and both imperfection resonances and intrinsic resonances are avoided [21]. This technique was first experimentally demonstrated in the cooler ring of Indiana University Cyclotron Facility in the 1980s[13].

For high energy accelerates like RHIC, intrinsic resonance can be so strong that more than one snakes are needed. In a ring with two full Siberian snakes located at 180^o apart from each other are used, the one turn spin transfer matrix is

$$M(\theta+2\pi,\theta)=e^{-\frac{i}{2}G\gamma(\pi-\theta)\sigma_3}(i\hat{n}_1\cdot\vec{\sigma})e^{-\frac{i}{2}\pi\sigma_3}(i\hat{n}_2\cdot\vec{\sigma})e^{-\frac{i}{2}\theta\sigma_3} \quad (16)$$

where $\hat{n}_1, 2$ are the axes of the two snakes, both are in the horizontal plane with an angle of $\Delta\phi$. It can easily show that the spin tune is $Q_s = \frac{1}{\pi}\Delta\phi$, where $\Delta\phi$ is the angle between the axes of the two snakes. With the axes of the two snakes perpendicular to each other, the spin precession tune is $\frac{1}{2}$. It is also easy to show that the stable spin direction stays vertical all around the ring. RHIC employs two full Siberian snakes in each of its two accelerators to preserve polarization through acceleration as well as collision at a store energy, and each RHIC snake consists of four helical dipoles [22].

The spin tune and stable spin direction mentioned above for one snake as well as dual snake setup are for a particle at zero betatron oscillation amplitude in a perfect ring. In reality, both spin tune and stable spin direction can become strongly dependent on the particle's phase space coordinates in the presence of strong spin depolarizing resonances, and can no longer be calculated through the simple one turn matrix approach as illustrated in Eq. 16. For a single isolated spin resonance case, an analytic solution was found by Mane [5]. Based on Mane's model, stable spin direction exhibits singularity at location of $mQ_y = Q_s + k$, and leads to significant depolarization. Here, m, k are integers, Q_y is the vertical betatron tune and Q_s is the spin precession tune. This is the so-called snake resonance, and was first observed during numerical simulation by Lee and Tepikian [23]. They are also experimentally observed at IUCF [24] as well as RHIC [25]. m is also called the order of the snake resonance. In an accelerator with only a single snake, an intrinsic spin resonance can drive both even order snake resonances (m is an even number) as well as odd order snake resonance (m is an odd number), and available betatron tune space for polarized beam operation can be rather limited.

With dual snake setup like RHIC, on the other hand, all the odd order snake resonances are eliminated and only the even order snake resonances exist in the absence of closed orbit distortion. This greatly opens up the available tune space for accelerating polarized beams. However, snake imperfections and imperfection resonances can bring back even order snake resonances, and result in significantly reduction of betatron tune space for preserving polarization. In addition, the imperfection of snake can deviate spin tune away from half integer, and causes each snake resonance to split [1]. Hence, optimizing snake configuration as well as minimizing closed orbit distortion are critical in avoiding snake resonances.

Careful choice and precise control of betatron tune to stay away from any snake resonances are critical to preserve polarization. For $Q_s = \frac{1}{2}$, one can see that snake resonance is forbidden at locations of $Q_y = \frac{n}{2m+1}$. For RHIC, $Q_y = 29.673$, at the vicinity of 3^{rd} order resonance, was chosen for accelerating polarized protons beyond 100 GeV, where three strong very strong intrinsic resonances are present.

In reality, the presence of snake imperfections and imperfections resonances brings back even order snake resonances. The imperfection of snake can deviate spin tune away from half integer, and causes each snake resonance to split [1]. Both can significantly shrink the available space for the betatron tune during the acceleration. Hence, optimizing snake configuration as well as minimizing closed orbit distortion are critical in minimizing polarization loss. In addition, it is also very critical to keep the spin tune as close to half integer as possible. In RHIC, spin tune shift can come from the error in the angle between the axes of the two snakes, and the horizontal orbital angle at the two snakes [26].

In the presence of very strong intrinsic resonance, i.e. $\epsilon_k > 0.5$, the snake resonances can be overwhelming and the tolerance on closed orbit and beam parameters can be at a level of impractical for operation. In this case, more snakes option should be explored. To accelerate He-3 in RHIC, because of the large anomalous g-factor, the intrinsic resonance for He-3 is about a factor of 2 stronger than the resonances for protons. Fig. 3 shows the snake resonance spectrum with current RHIC dual snake configuration. However, this can be greatly mitigated by adding two more pairs of snakes as shown in the bottom plot of Fig. 3. The 6-snake setup not only opens up available betatron tune spaces for acceleration, but also greatly relaxes the tolerance on other beam parameters [27]. As derivatived from the first order spin resonances like intrinsic resonance, the strength of snake resonance is tightly associated with strength of its driving resonance. Generally, the stronger the intrinsic resonance, the more harmful the snake resonance is. However, it is also worthwhile to point out the polarization crossing a snake resonance does not obey the Froissart-Stora formula. Currently, this is only studied through numerical spin tracking.

Polarization Lifetime

In high energy colliders like RHIC, at the store energy carefully chosen to be distant from major depolarizing resonances, both beams undergo beam-beam interaction, which leads to betatron tune shift as well as incoherent tune spread for each beam. For RHIC, the beam beam tune spread can be as large as 0.0075 per collision for polarized proton physics operation. This can populate particles in the beam sitting on a snake resonance, and polarization deterioration can happen during long hours of store as observed at RHIC [28].

Copyright © 2013 CC-BY-3.0 and by the respective authors

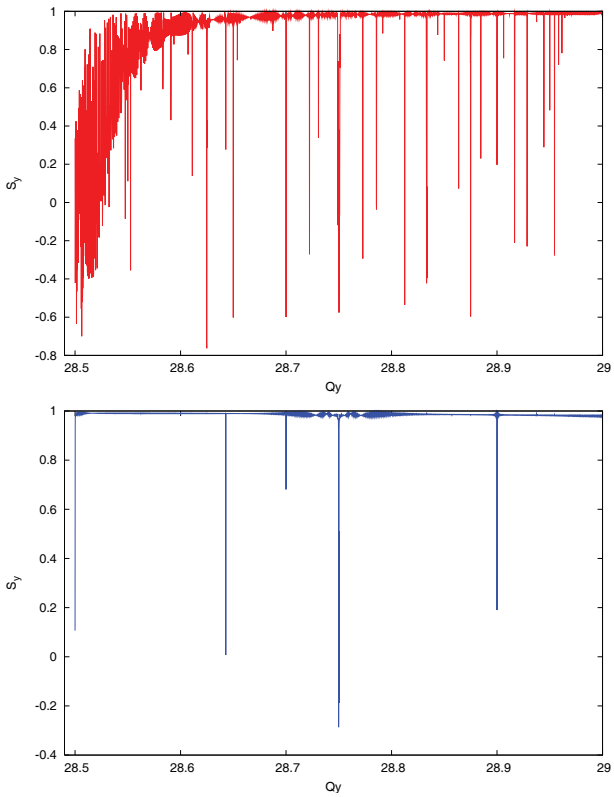

Figure 3: Top plot shows the snake resonance spectrum with RHIC dual snake setup, while bottom plot corresponds to 6-snake setup. Both plots show the vertical component of the spin vector as function of vertical betatron tune.

In addition to its impact on betatron motion, the beam-beam force also provides kick to spin motion. This effect was investigated by Batygin and others [29]. For a Gaussian distributed round relativistic beam, the electric field and magnetic field are $\vec{E} = \frac{qn}{2\pi\epsilon_0 r}[1 - (exp(-\frac{r^2}{2\sigma_2})]\hat{r}$ and $\vec{B} = \frac{1}{c}\vec{\beta} \times \vec{E}\hat{\phi}$, where qn is the charge line density of the beam, σ is the transverse beam rms size, $\hat{r}$ and $\hat{phi}$ are the unit vector along the radial and azimuthal direction of beam. The corresponding beam beam tune shift is $\xi = \frac{Nr_0\beta_*}{4\pi\gamma\sigma^2}$, where r_0 is the classic radius of the particle. Apply this to the Thomas-BMT equation, one can then estimate the maximum spin kick $2\pi\epsilon_{bb}$ from the beam-beam interaction as

$$\epsilon_{bb} = 2G\gamma\xi\sigma\frac{r}{\sigma}\frac{(1 - exp(-\frac{r^2}{2\sigma_2}))}{\frac{r^2}{2\sigma_2}}. \quad (17)$$

Fig. 4 shows the calculated maximum beam-beam spin kick as a function of distance from the center of beam for a beam of 15πmm-mrad emittance (95%, normalized) at RHIC store energy of $G\gamma = 487$. 0.7 m β-function at collision point and beam-beam tune shift $\xi = 0.01$ are assumed. In general, this is comparable to very weak lattice driven spin resonances. Thus, the beam-beam driven snake resonances are very weak for accelerators like RHIC that are equipped

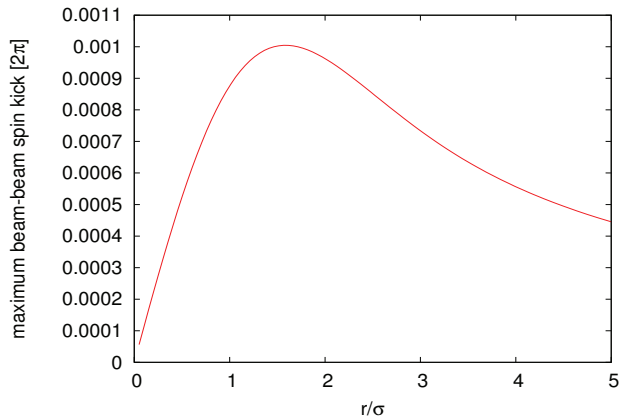

Figure 4: Maximum spin kick from beam-beam for a Gaussian round beam at RHIC store energy of $G\gamma = 487$. The β^* is 0.7m, and normalized 95% beam emittance is 15πmm-mrad for the calculation. The beam-beam parameter is chosen as 0.01 for this calculation.

with full snakes, and should be fully benign to beam polarization at store as long as the betatron tune stays away from the snake resonances. So far, detailed studies and analysis of the RHIC beam-beam impact on the polarization lifetime indicate that beam polarization deterioration at store is still due to the snake resonance at $5Q_y = Q_s + 3$ [28]. However, for accelerators with no snakes, beam-beam kick can drive additional spin resonances and result in polarization losses as observed at electro-positron collider LEP [30] and HERA, a polarized electron and proton collider [31]. Hence, it is critical for the choice of the working point, i.e. the tunes without collision to ensure long polarization lifetime.

CONCLUSION

Accelerating polarized protons to high energy is challenged by various depolarizing mechanisms driven by magnetic fields from manufacturing errors, misalignments, betatron oscillation and etc. Motivated by the need of having high energy polarized protons to study proton spin structure as well as other spin dependent physics, continuous efforts over the past couple of decades have been made in seeking ways to overcome spin depolarizing resonances and preserve polarization to high energy. Table 1 lists the achieved polarized proton performance at various facilities. The operating period for each facility is also listed. In Table 1, RHIC polarization is measured with an absolute polarimeter using H-jet [32]. It reflects the polarization averaged over a store, typically, 8 hours.

Physics of polarized protons in accelerators is a very rich topic, and this tutorial presentation can only cover the very basics of spin dynamics in a circular accelerator. The nonlinear aspects of spin dynamics, the effect of synchrotron radiation on polarization as well as challenges in robust numerical spin tracking are not covered in this presentation due to the complexity of each topic and limited space. STATUS OF THE FRIB FRONT END*

E. Pozdeyev#, N. Bultman, G. Machicoane, G. Morgan, X. Rao, and Q. Zhao
FRIB, East Lansing, MI 48824, USA

Abstract

The FRIB Front End will provide beams of stable ions with a mass up to uranium at a beam energy of 500 keV/u and intensity required to achieve a power of 400 kW on the fragmentation target. In this paper, we describe progress with the design and construction of the Front End and its systems.

DESIGN AND PERFORMANCE REQUIREMENTS

FRIB will be a premier multiuser nuclear physics facility providing stable ion beams accelerated to energies above 200 MeV/u and with a beam power on the target up to 400 kW [1]. These project requirements are translated into stringent requirements on the front end design and performance. The FRIB front end will provide stable ion beams up to uranium with an energy of 500 keV/u. The required intensity of uranium beam is 13.5 pμA and the charge state is 33+. This intensity is at the edge of performance demonstrated by modern ECR ion sources. To decrease technical risks and reduce operational stress on the sources, the front end is designed to transport two charge states simultaneously for all ions heavier than xenon with a charge state of 25 and higher. To control losses in the linac and meet experimental requirements the front end includes a collimation system to limit the transverse beam phase space. The longitudinal phase space is controlled by means of limiting the longitudinal acceptance of the RFQ. In addition, the front end will provide required variability of the bunch intensity by up to nine orders of magnitude to meet experimental needs. Beyond controlling the bunch intensity, it is also required to control the beam pulse length and the pulse repetition rate to simplify linac tuning and safely ramp up the beam power on the target.

High availability, maintainability, reliability, and tunability are required for the front end to operate FRIB as a national scientific user facility. These requirements, as well as project budget and schedule limitations require using proven, reliable technical solution as much as possible. However, those solutions frequently have to be taken to new levels with evolutionary changes and upgrades to demonstrate world-breaking performance required by the project.

Finally, to meet possible future programmatic demands the front end has to be upgradable and includes required provisions for future enhancements.

FRONT END LAYOUT

The FRIB front end includes two ECR sources, one of which is a room temperature 14 GHz source based on the ARTEMIS source developed at NSCL, and the other is a superconducting 28 GHz source based on VENUS design [2]. The beam extracted from the sources is transported through LEBT to the tunnel, where it is accelerated by an RFQ and injected into the SRF driver linac. The sources are placed on high voltage platforms that can be biased up to 100 kV to match the RFQ injection energy for all beams. Table 1 shows principle parameters of the Front End. The Front End layout is shown in Figure 1.

Table 1: Front End Principle Parameters

LEBT (before RFQ)	
Energy (keV/u)	12
Nominal beam current (eμA, typ.)	400
Emittance (πμm, 99.5%, norm.)	0.9
MEBT (after RFQ)	
Energy (keV/u)	500
Nominal current (eμA, typ.)	330
Emittance (πμm, 99.5%, norm.)	1.1
Long. Emittance (πkeV/u·ns, 99.5%)	1.5
Bunch repetition rate (MHz)	40.25, 80.5
Beam pulse length (μs)	0.6 – CW

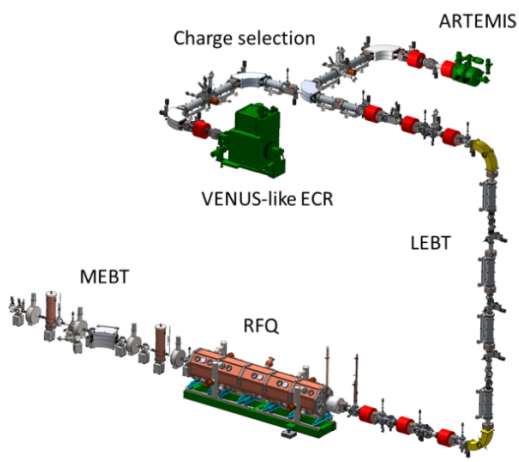

Figure 1: FRIB Front End layout.

FRONT END SYSTEMS

Ion Sources

The ARTEMIS ECR source, built at MSU and based on the AECR-U ECR developed at LBNL, operates at

*Work supported by the U.S. Department of Energy Office of Science under Cooperative Agreement DE-SC0000661 and grant #DE-FGO2-08ER41553

14.5 GHz with room temperature coils. The source will be used for commissioning FRIB and during some first years of operations for production of light and medium mass ions. Minimal re-configuration of the source is required to make the source compatible with operation on a high voltage platform and to boost its performance. The source currently produces 70 μA of Ar and Kr beams and will be able to generate up to 100 μA after upgrade.

The superconducting high-performance source will be based on the design of VENUS ECR ion source operating at a maximum frequency of 28 GHz. A world intensity record of 450 μA of U^{33+} was demonstrated by VENUS at LBNL in 2011. Figure 2 shows the M/Q scan with the source world-breaking record performance. The measured emittance for this charge state showed that 95% of the beam was within the FRIB acceptance.

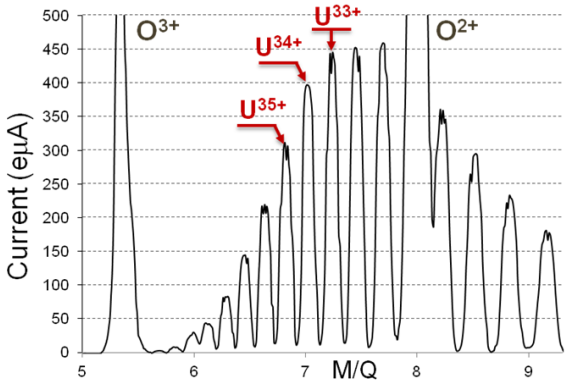

Figure 2: VENUS M/Q intensity scan for a uranium beam, demonstrating world record intensity of charge states 33+ and 34+.

The original VENUS cold mass design employs azimuthal bladders inflatable with liquid Indalloy to provide pre-stress. Once the metal is solid, the magnet could be disassembled only if the whole cold mass is warmed up above the metal's melting temperature, which has never been demonstrated. This design feature of the source was identified as a technical risk. To address the risk, a novel clamping scheme is pursued for the FRIB source. The scheme employs radial keys and water bladders to define the pre-stress state. This approach was developed by SUPERCON/LBNL for LARP high field magnets and allows for disassembling the magnet, changing components, and a fine control of the pre-stress state. A Collaboration between FRIB and LBNL was established to develop a design of the cold mass with radial keys.

In addition to the cold mass modifications, the cryostat will be modified comparatively to the original VENUS to include two GM-JT cryo-coolers to boost the cooling capacity from 6 W to 10 W to account for a higher dynamic heat load generated by the plasma Bremsstrahlung electrons and two Al-330 cryocoolers to cool the heat shield of the cryostat.

RFQ

The FRIB RFQ utilizes a 4-vane structure to accelerate single and two-charge state beams from 12 to 500 keV/u with estimated transmission efficiency above 80%. Table 2 shows main RFQ parameters.

Table 2: RFQ Principle Parameters

Frequency (MHz)	80.5
Injection/Output energy (keV/u)	12/500
Design charge-to-mass ratio	1/7-1/3
Accelerating voltage ramp (U, kV)	60 – 112
Surface electric field (Kilpatrick)	1.6
Quality factor	16500
Operational RF power (kW, O-U)	15-100
Dipole modes (closest, MHz)	78.3 / 83.2
Length (m)	5.04

The RFQ beam physics design is optimized to minimize the longitudinal emittance of the accelerated beam as described in [3][4]. To increase the RFQ output energy a linear accelerating voltage ramp is implemented. The linear voltage ramp is accomplished through proper sizing of the vane undercuts. Dipole mode suppression rods attached to the structure endplates are utilized to move dipole mode frequencies away from the accelerating mode frequency. The quadrupole and dipole mode local perturbations are fine-tuned during construction using 27 fixed mechanical slug tuners distributed along the length of the machine. A full 3D model of the RFQ, including undercuts, stabling rods, and the slug tuners, was implemented in the CST Microwave Studio (MWS) [5] to accurately select required parameters and simulate fields and surface losses.

Mechanical construction of the RFQ will be performed as a brazed structure with dual-circuit cooling water resonance control. Mechanical fabrication is performed in 5 longitudinal sections to optimize machining and handling. All components are made of high-conductivity copper and actively water cooled. The power is fed using a single magnetic-field loop-coupler drive. More information on the RFQ design can be found in [6].

Beam Transport and Other Systems

In 2007, VENUS demonstrated intensity required for FRIB for a 238U beam with the two charges states, 33+ and 34+, combined. Based on this result, the FRIB front end was designed achromatic, able to accelerate two charge states from an ion source to double intensity. Although recent tests demonstrated that significantly better performance from VENUS can be achieved, a decision was made to leave the front end design unchanged. To facilitate transport of two-charge state beams through the LEBT electrostatic quadrupoles and two 90° deflectors are used in the vertical transport line.

Copyright © 2013 CC-BY-3.0 and by the respective authors

The electrostatic quadrupoles were designed by Kurt Stiebing, manufactured by Roentdek Handles GMBH, and delivered to FRIB in August of 2013. The quadrupole assemblies were made of precision-stamped formed metal to reduce cost and weight of the assemblies. The measured manufacturing errors of the quadrupole assemblies are typically less than 200 μm that satisfies FRIB requirements. Figure 3 shows a photograph of a triplet assembly.

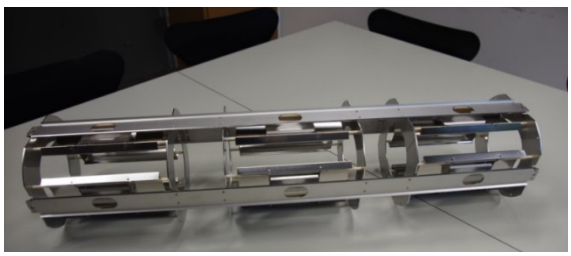

Figure 3: Electrostatic LEBT quadrupole triplet assembly. The length of the assembly is 91 cm.

Upstream of the RFQ, LEBT includes a multiharmonic buncher and a velocity equalizer, both are room-temperature low-power quarter wave resonator cavities. The former is used to bunch the DC beam and the latter is required to eliminate the energy spread of two charge state beams before injecting beams into the RFQ.

To reduce losses in the superconducting linac, the beam is collimated by several apertures in the LEBT. The front end includes a chopper to vary the duty cycle. The buncher will control the pulse length from several hundreds of ns to CW and the pulse frequency from 0 to 30 kHz. Several mesh screens installed in LEBT allow for reducing the beam intensity by up to nine orders of magnitude while keeping the nominal bunch frequency unchanged. Two 90° electrostatic deflectors in the vertical transport line are incorporated into the machine protection system. The voltage on the deflector electrodes is controlled by fast switches that receive the inhibit signal from the MPS with shut-off time below 1 μs.

Downstream of the RFQ, MEBT includes two room-temperature QWR bunchers, four SC solenoids, an energy analyzing dipole, and diagnostics. MEBT matches the beam to the SC linac and removes un-accelerated beam from the RFQ.

SUMMARY OF PROGRESS

The design of front end systems and early procurement of high priority items are ongoing. The low energy multi-harmonic buncher and electrostatic quads were manufactured and delivered. The commissioning source ARTMEIS is undergoing minor modifications to make it compatible with operations on a high voltage platform. The physics design and the preliminary engineering design of the RFQ have been completed. A design-build contract for the final design and manufacturing of the RFQ was awarded to industry. The final engineering design of the RFQ is in progress. Delivery of the RFQ and its high power test are expected in the summer of 2015. The design of the MEBT quarter wave resonators is in its final stage. Their procurement is expected to begin by the end of 2013. The design of the cold mass of the high performance source is being developed in collaboration with LBNL. It is important to emphasize that the high performance source is not required to start commissioning of the front end and will be brought online approximately a year after the start of commissioning but before the end of the project.

The front end design was integrated with civil facilities to allow for starting civil construction. Also, the front end was integrated with other accelerator and experimental systems. The design was value engineered. One example is the increase of the RFQ energy from the originally planned 300 keV/u to 500 keV/u by implementing voltage ramping that allowed eliminating one cryomodule. Commissioning of the front end with the room temperature source is expected to start in the fall of 2017.

Abstract

The ATLAS National User Facility at Argonne National Laboratory is the world's first CW superconducting ion linac. The accelerator is being continuously upgraded to extend its scientific reach. To increase the efficiency and intensity of both stable and radioactive beams [1], we have developed, built and installed a new normal conducting CW RFQ capable of providing a 295 keV/u for any ion from proton to uranium. The RFQ has been fully integrated into ATLAS and in routine operation since January 2013.

A new cryomodule containing 7 high-performance 72.75 MHz SC QWRs and 4 SC solenoids was completed this year and has been commissioned off-line. New design and fabrication techniques for these QWRs resulted in record voltages up to 4-5 MV per cavity and low residual resistances of 2-3 nΩ at 2K were demonstrated in individual cold tests of several QWRs. The primary purpose of the new cryomodule is to replace 3 old cryomodules and to increase the intensities of accelerated stable ion beams up to several hundred electrical micro amps. Beam commissioning is expected by the end of the year after significant modification of the accelerator tunnel for increased shielding and installation of a redesigned beam transport system.

CW RFQ

Last summer we commissioned a CW RFQ designed and built for the ATLAS Facility [2, 3]. Several innovative ideas were implemented in this CW RFQ. By selecting a multi-segment split-coaxial structure we have achieved moderate transverse dimensions for a 60.625 MHz resonator. For the design of the RFQ resonator and vane tip modulations we have developed a full 3D approach which includes MW-Studio and TRACK simulations of the entire structure [4]. A novel trapezoidal vane tip modulation is used in the acceleration section of the RFQ which resulted in increased shunt impedance. To form an axially symmetric beam exiting the RFQ, a very short output radial matcher, only $0.75\beta\lambda$ long, was developed. Figure 1 shows an internal view of the RFQ's last two segments. The openings in the vane and trapezoidal modulation of vane tips are clearly seen.

An advanced fabrication technology was applied for the construction of the RFQ which included precise machining and two-step high temperature brazing. Thanks to the high accuracy of the overall fabrication, the assembly of the 5-segment RFQ was straightforward and no additional alignment was required. The resonance frequency control system based on water temperature regulation showed excellent performance. The RF measurements show very good RF properties for the resonator, with a measured intrinsic Q equal to 94% of the simulated value for OFE copper. The multi-segment split-coaxial structure creates strong coupling between the quadrants and individual RFQ segments which reduces the effect of local frequency deviations on electromagnetic field distortions. Therefore, no bead-pull measurements were required to tune the accelerating field.

An O^{5+} ion beam extracted from an Electron Cyclotron Resonance (ECR) ion source was used for the RFQ commissioning. In off-line beam testing, we found excellent agreement of the measured beam parameters with the results of beam dynamics simulations [3]. The great success of this advanced design and fabrication technology is reflected in the measured beam parameters after the RFQ which are nearly identical to the simulated data.

After the successful off-line commissioning of the ATLAS CW RFQ accelerator with oxygen and helium beams, the device was moved, installed and integrated into the ATLAS system during the October-November 2012 period. Fig. 2 displays the current view of the ATLAS front end. The RFQ is directly attached to the first SC cryomodule. For the RFQ beam matching we have incorporated a MEBT which includes 3 SC solenoids and a SC cavity as a buncher [1]. Since January 2013, the RFQ is in routine operation. The beam parameters have been measured after the Positive Ion Injector (PII) of ATLAS which includes three SC cryomodules. The beam energy and time spectra have been measured using silicon barrier detectors (Fig. 3). The results of these measurements are consistent with the TRACK simulations. The efficiency of ATLAS beams on

target has doubled as compared to the pre-RFQ operation.

QWR CRYOMODULE

While split-ring resonators are successfully operated at ATLAS with low-intensity ion beams, they exhibit a fundamental limit in the acceleration of high-intensity beams due to RF steering. Therefore we are replacing 16 ATLAS split-ring resonators with 7 QWRs. Four years ago we put into operation a new cryomodule containing seven 109 MHz β_{OPT}=0.15 QWRs to provide an additional 15 MV voltage to ATLAS. Now, we have developed and built a new cryomodule consisting of seven β_G=0.077 QWRs at 72.75 MHz SC cavities and four 9-Tesla SC solenoids. The new high-performance cryomodule will replace three existing ATLAS cryomodules of split-ring cavities to increase the intensities of accelerated ion beams.

Compared to the previous generation of quarter-wave resonators, several innovations were implemented into the cavity design, fabrication and RF surface treatment. The cavity geometry is highly optimized to reduce both electric and magnetic peak fields: both outer and inner conductors are conical as shown in Fig. 4a. During the fabrication of the niobium components, a wire EDM technique instead of machining was used to maintain clean surfaces prior to electron-beam welding. Electropolishing of the cavities was performed for a completed cavity with the integral helium vessel installed. Each cavity is equipped with a newly-developed double-window 4-kW adjustable RF coupler with a nitrogen cooled cold window [5]. To minimize microphonics due to pendulum vibration of the central conductor, the central drift tube in each QWR has been electrically centred by tuning to the highest resonant frequency [6]. An additional reduction in microphonics is achieved by installing mechanical dampers inside the central conductor [7].

The new QWRs will create accelerating gradients a factor of three higher, on average, than the existing split-ring cavities, and are designed to provide an accelerating voltage of 2.5 MV per cavity which results in a 17.5 MV total voltage gain in this cryomodule. Four 72.75 MHz QWRs were cold tested prior to installation in the cryomodule and all of them provided more than 4 MV without quenching achieving E_{PEAK}>70 MV/m and B_{PEAK}>105 mT [7,8].

CRYOMODULE COMMISSIONING

After the completion of the assembly in a clean room (Fig. 4b), the cavity-solenoid string was pumped out, sealed and moved outside the clean room. The following assembly work included the attachment of the cavity string to the box cryostat lid, installation of slow tuners, installation of nitrogen and helium distribution systems, alignment of cavities and solenoids, and plumbing of nitrogen and helium cooling systems. The appropriate choice of alignment mechanisms resulted in an accuracy of solenoid end positioning within ±250 μm [9]. After a thorough leak check of the nitrogen and helium systems, the cavity assembly was loaded into the box cryostat (Fig. 4c).

Due to the much higher beam intensity in the upgraded ATLAS, the linac radiation shielding is being significantly enhanced by the installation of 1-meter thick concrete walls. Meanwhile, the cryomodule has been cooled down and RF tested off-line. The following major tasks have been accomplished during the off-line commissioning:

- Each cavity was cooled down quickly in the temperature range from 150K to 50K as shown in Fig. 5.

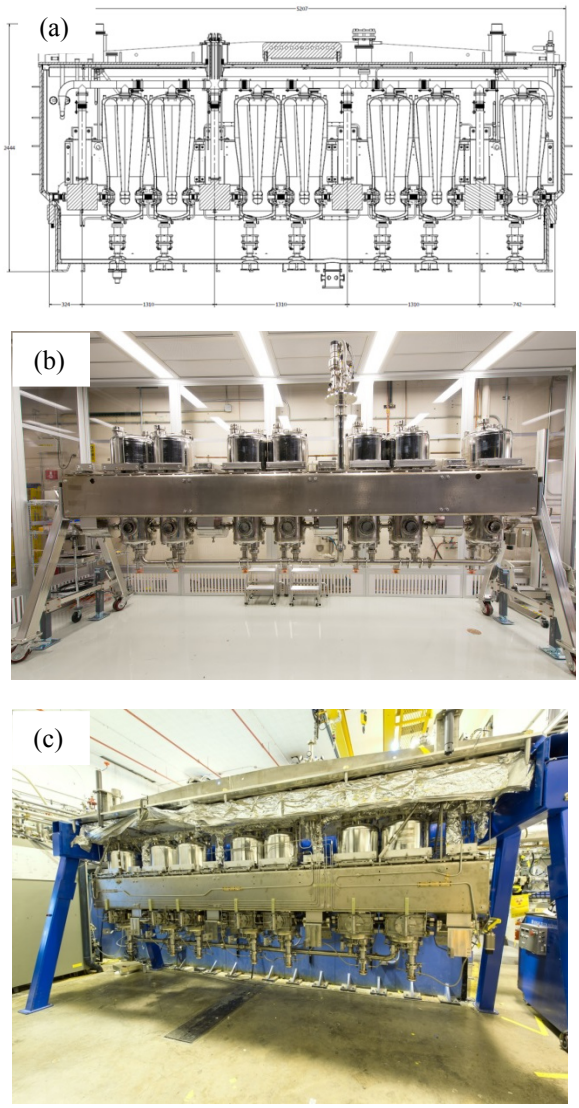

Figure 4: ATLAS intensity upgrade cryomodule. Side cross-sectional view (a), after completion of assembly in clean room (b) and after completion of full assembly prepared to load into the cryostat vacuum vessel (c).

- Due to the variable RF couplers, the multipactor conditioning took less than a couple of hours per cavity.
- RF testing demonstrated that each cavity is capable of providing an accelerating voltage greater than 3 MV.
- Microphonics were measured to be below 5 Hz at the 5σ-level in all cavities. Each cavity is equipped with a 4-kW RF amplifier and variable coupler which provide up to a 30 Hz bandwidth for RF control.
- The pneumatic slow tuner range varies from cavity to cavity and was from 17 kHz to 26 kHz at 70 psi. If necessary, the tuning range can be increased by applying up to 90 psi pressure to the helium gas used to drive the tuners.
- The cavities and solenoids are equipped with crosshair alignment targets. The latter were used for optical measurements of the cavity and solenoid positions in the cold cryomodule. At 4 K the solenoid alignment error was measured to be 80 μm rms.
- The static 4 K heat load of the entire assembly was measured to be 11 Watts which is an extremely low number for such a complex cryomodule.

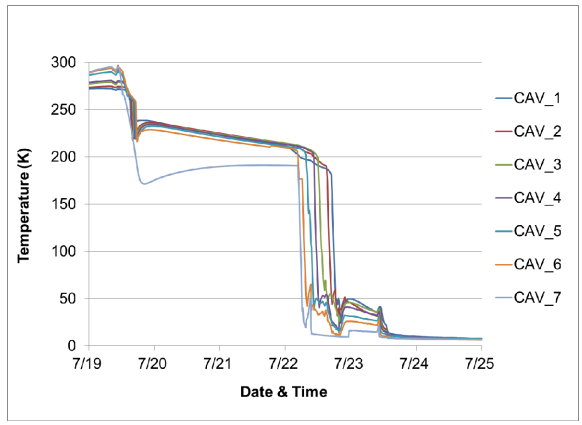

Figure 5: SC cavity temperatures vs time during the second cool down.

SUMMARY

A new CW RFQ with a suite of novel features has been developed, built and commissioned at ANL. The RFQ has doubled the ATLAS beam transport efficiency and demonstrated excellent performance since its integration into the accelerator in January 2013.

A new cryomodule with low-beta SC QWRs capable of providing 21 MV of accelerating voltage has been commissioned off-line and is being prepared for installation into the beamline. Beam commissioning through the new cryomodule is planned in December 2013.

Abstract

Ion acceleration of dopants and other ions is a critical and nearly universally employed tool for the fabrication of transistors in semiconductor devices and the various forms of electronic, photovoltaic and photonic materials. This paper reviews the major types of accelerators, ion sources, and scanning methods used in contemporary practice for ion implantation for electronic applications.

INTRODUCTION

The use of accelerated ions to dope and modify semiconductor materials, generally called ion implantation, is a core technology for the fabrication of integrated circuits (IC), which form the backbone of the global communications and advanced computation capabilities that have transformed modern life over the last half-century. The use of ion implanters in the IC industry, starting in the 1970s for precision doping of channel structures at doping densities of ~10^{-4} monolayers to set the threshold conditions for transistor switching, enabled the practical fabrication of complementary metal-oxide-semiconductor (CMOS) transistors that are now the dominant form of IC devices. Development of accelerator technologies capable of delivering highly stable and collimated ion beam currents, ranging from a few μA to 100 mA, and incident ion energies, ranging from 100 eV to ~10 MeV, have provided a broad and capable technology for fabrication of ICs for logic, memory, and analog operations, as well as an increasingly varied array of optical sensors and imaging devices. Ion implantation is now used for the overwhelming majority of applications for doping of semiconductor materials and in an increasing array of applications for creation and modification of electronic and photonic materials.

The yearly revenues from the sale of industrial ion implantation and materials modification tools are a US$1.5B market (in "normal" economic environments). In addition, there are substantial markets for suppliers of dopant species materials (~US$140M/year) and a diverse array of suppliers of spare and upgrade parts and services. Additional parts of the ion implantation commercial infrastructure include the suppliers of system components, magnets, power supplies, and vacuum pumps, and a varied array of metrology tools focused on process characterization and control applications.

The average number of commercial ion implantation systems sold per year, predominantly for fabrication of Si-based IC devices, has increased from ~250 to ~400 per year since 1980, as seen in Fig. 1. The year-to-year sales show large fluctuations due to the highly cyclic nature of IC fab construction trends, especially when driven by additional factors, such as shifts in dominant wafer sizes, introduction of new implanter machine types and IC devices, expansion into new global regions, and variations driven by general economic cycles. The combination of these technology and market factors has resulted in a rather steady "5-year" cycle in units sold per year over the last 3 decades.

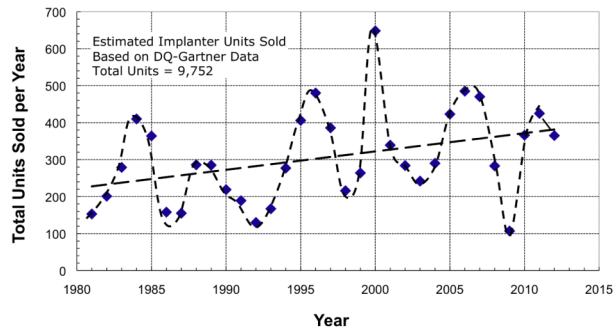

Figure 1: Estimates of the number of commercial ion implanters sold per year, mainly for IC fabrication. The data shown here are an underestimate, particularly for the earlier years.

SEMICONDUCTOR APPLICATIONS OF ION IMPLANTATION

The planar CMOS transistor, illustrated in Fig. 2, has been the workhorse device structure for IC devices for logic and memory applications since the mid-1980s.

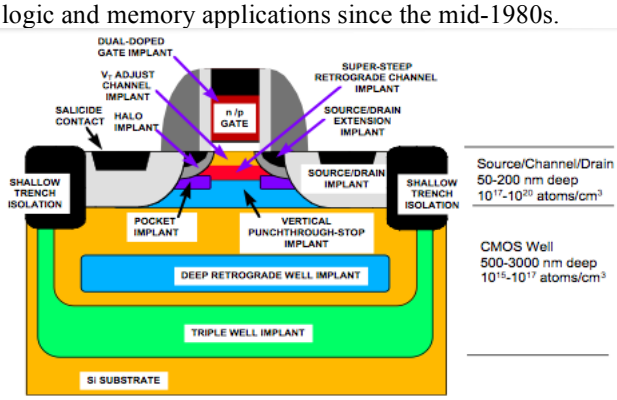

Figure 2: Sketch of major doped regions for a planar CMOS transistor.

For doping of near-surface (<100 nm) layers on Si with the common dopants B, As, and P, the beam energy

requirement for atomic species is a fraction of a keV to a few tens of keV. Increasingly, the ion species of choice for low energy (sub-keV) implants is some form of molecular ion containing up to 18 dopant atoms (for $B_{18}H_{22}$), allowing for beamline operation at proportionally higher energies and significantly higher total beam flux for higher production throughputs. For deeper profiles to form CMOS wells for transistors and optical imagers, ion energies range up to several MeV.

The initial applications for ion implantation were for low dose (10^{11} to 10^{12} ions/cm^2) doping of CMOS channels to set the transistor switching, or "threshold", conditions. These implants required relatively modest beam currents, with 100 to 500 μA being common for "medium-current" implanters. By 1980, higher current sources and beamlines were developed for "high-current" machines, to produce beams of 1 to 30 mA of dopant ions. These machines were capable of efficient implants with doses of ~5x10^{15} ions/cm^2 used for CMOS source/drain junctions, as well as emitter, buried layer, and collector implants for bipolar devices.

By the late 1980s, implantation machines capable of ion energies of ~1-2 MeV were being used for doping deep "retrograde" wells in CMOS devices, to suppress latch-up instabilities between neighboring well structures and to reduce radiation-generated "soft failures" in Dynamic Random-Access Memory (DRAM) arrays. With the evolution of complex doping schemes to suppress lateral punch-through between source and drain junctions in short channel (<100 nm) transistors, ion implanters were developed with capabilities for mid-10^{14} ions/cm^2 doping at beam incidence angles up to 45°, to provide additional well doping in a "halo" surrounding shallow source-drain extension (SDE) junctions.

The CMOS transistors of the current decade are three-dimensional structures, called FinFETs or tri-gate transistors. The majority of implants for these devices continue to be the same, with over 40 implant steps per device for doping and materials modification applications. However, some of these implants, such as the source/drain extensions, need to be "conformal" in order to uniformly dope the sidewalls and top surface of the fins.

ACCELERATOR DESIGNS

Given the broad range of energies and doses in use for CMOS transistor doping and other materials processing, a variety of accelerators with quite different designs and beam scanning methods are used for each of the specific application segments shown in Fig. 3. The typical classifications for these general machine types are:

- Medium current — ion beam currents between 10 μA and ~2 mA
- High current — ion beam currents up to ~30 mA; ~100 mA for SIMOX (Separation by Implantation of Oxygen) beams
- High energy — ion energies above 200 keV and up to 10 MeV
- Very high dose — efficient implant of doses greater than 10^{16} ions/cm^2.

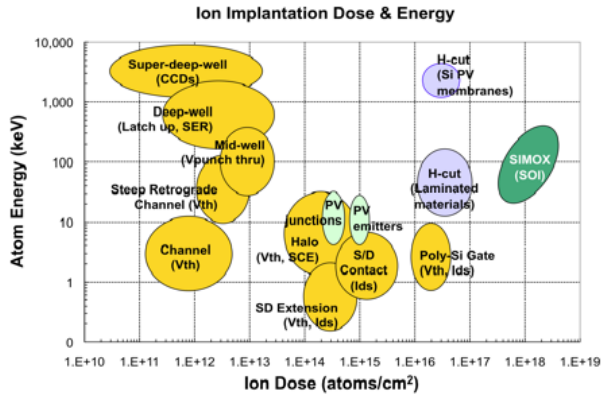

Figure 3: Dose and atom energy regions for CMOS transistor doping (gold), high dose hydrogen implants for Si layer splitting (lavender), and direct implantation of oxygen to form Silicon-on-Insulator (SOI) wafers (green).

Accelerator systems for ion implantation are provided commercially by a number of vendors, with the business being dominated by a few long-standing companies: Applied Materials/Varian Semiconductor Equipment (Gloucester, MA), the market leader; Nissin Ion Equipment (Kyoto, Japan), with a strong Asian market position; Advanced Ion Beam Technology (Hsinchu, Taiwan), a new high-current vendor; Axcelis Technologies (Danvers, MA), leading the high-energy market; and SEN Corporation (Shikoku, Japan), former Axcelis partner also with a strong Asian market presence. Other smaller vendors include Ion Beam Services (Rousset, France), a new Plasma Immersion Ion Implantation (PIII) and SiC implanter company; Ulvac Technologies (Japan), long-time vendor for research and development (R&D) tools; High Voltage Engineering (Netherlands) and National Electrostatics Corporation (Madison, WI), both supplying specialty R&D tools; and several radio frequency (RF) linac vendors known to be supplying R&D units for MeV proton beams for Si wafer cleaving for photovoltaic (PV) applications.

Beam current requirements for each machine type have increased as the wafer sizes and implanted areas increased from the early days of 75 mm diameter wafers to the present standard of 300 mm, with the contemplated increase to 450 mm after 2015. In addition, the increased requirements for dose accuracy (1% or better) and control of ion incidence angle (<0.5° for critical implants) place tight constraints on ion beam stability, scan uniformity, and beam collimation in the area near the wafer surface.

Beamline System Types

Each of the wide variety of ion implantation beamline designs contains certain general groups of functional components (see Fig. 4). The first major segment of an ion beamline includes a device known as an ion source to

Copyright © 2013 CC-BY-3.0 and by the respective authors

generate the ion species. The source is closely coupled to biased electrodes for extraction of the ions into the beamline and most often to some means of selecting a particular ion species for transport into the main accelerator section. The ion source usually is an arc-discharge plasma type, fed by a vapor of the atoms to be ionized, accelerated, and implanted. The "mass" selection is often accomplished by passage of the extracted ion beam through a magnetic field region with an exit path restricted by blocking apertures, or "slits", that allow only ions with a specific value of the product of mass and velocity/charge to continue down the beamline.

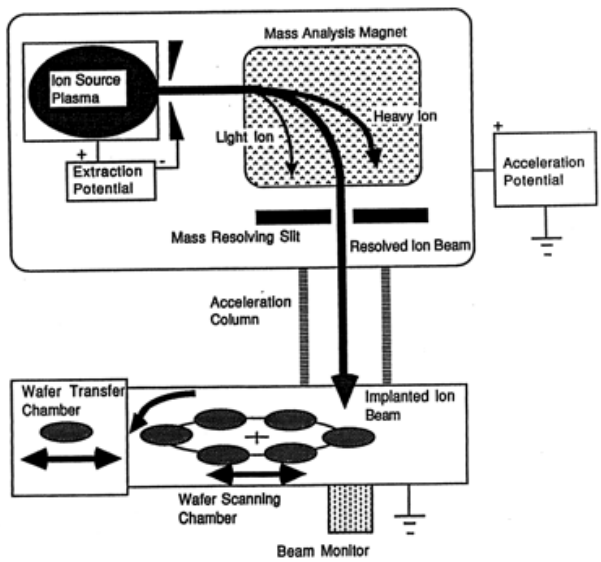

Figure 4: Major ion implantation beamline components.

If, as is often the case, the desired ion energy is different than the potential used to extract ions from the plasma source, the "selected" ion beam is accelerated (or decelerated) by additional sets of electrodes or RF fields. If the target surface is larger than the ion beam diameter and a uniform distribution of implanted dose is desired over the target surface, then some combination of beam scanning and wafer motion is used.

Finally, the implanted surface is coupled with some method for collecting the accumulated charge of the implanted ions, so that the delivered dose can be measured in a continuous fashion and the implant process can be stopped at the desired dose level. Sometimes the wafer is encased within a Faraday cup assembly, with appropriate methods of exclusion of extraneous charges from electrons and other ions within the beam plasma and charge losses due to secondary electrons and sputtered ions.

The design of an ion implantation beamline often needs additional components to satisfy the target requirements. These include components to make the scanned beam parallel at the surface of the target wafer and sources of electrons and ions to be injected into the ion beam plasma in the region close to the final target surface. These electrons and ions are needed to improve the space-charge balance in the ion beam, thus stabilizing the beam collimation and controlling the local potentials and current flows on the target surface.

The Varian VIISta 900XP [1], shown in Fig. 5, is an example of a medium-current beamline implanter with many of the components shown in Fig. 4. This beamline is capable of overall acceleration of single-charged ions to 300 kV (and P^{+3} ions to 900 keV) and contains a number of additional components, including a small deflection magnet and slit assembly placed directly after the source/extraction region and an electrode array for either accelerating or decelerating the selected ion beam prior to emerging from the main mass-selection (analyzer) magnet. The main function of the source filter magnet and slit is to prevent the P_2^+ and P_3^+ multimer ions (which can lead to energy and dose errors in P^{+2} and P^{+3} beams) from entering the main selection magnet and slit assembly and traveling to the target wafer.

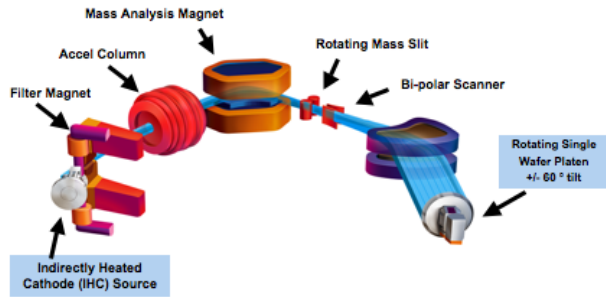

Figure 5: Beamline components of a Varian VIISta 900XP medium-current ion implanter.

Accel-Decel Beamlines

High-current beamlines, which are designed to maximize the ion flux delivered to the target wafer surface and often operate at low energies (1 keV or less), are usually shorter and contain fewer beamline components than medium-current designs. The short beamline path (often <2 m from source to wafer) and open geometries in the magnet analysis section result in improved ion transmission in "drift" mode with the only acceleration stage at the source extraction. To further increase the available ion flux for low energy (<1 keV) implants, an electrostatic deceleration lens is added just after the mass resolving slits. With the decel lens powered up, boron ion beams at energies as low as 0.2 keV can be delivered to the wafer surface with beam currents comparable to drift mode currents at 10x higher energies.

A limitation of this "accel-decel" mode of beam transport is that if dopant atom neutrals are formed by collisions with background gas molecules in the region following the mass analysis magnet and before the decel lens, neutral dopant atoms would be implanted at the extraction voltage energy along with the decelerated ions. This type of "energy contamination" is minimized by the operation of a turbopump in the region around the mass resolving slits (to reduce the ion neutralization rate from

Copyright © 2013 CC-BY-3.0 and by the respective authors

collisions with background gases) and by restricting the difference between the drift and decelerated ion energies.

Modulation of the ion energy along the beamline path is also a useful strategy to maximize beam transmission and facilitate beam shaping and focus. In the example of the AMAT/VSE VIISta Trident HC high-current implanter beamline shown in Fig. 6, a ribbon-shaped beam is formed by the extraction electrodes and focused at a mass resolving slit ("ion selection aperture") located downstream from the 90° mass analysis magnet [2]. The beam is then directed and shaped by another downstream magnet, prior to being implanted into a wafer scanned up and down in the ribbon beam. The ion beam can be decelerated at two stages along the way: directly after the mass resolving slits and after the final beam-shaping magnet.

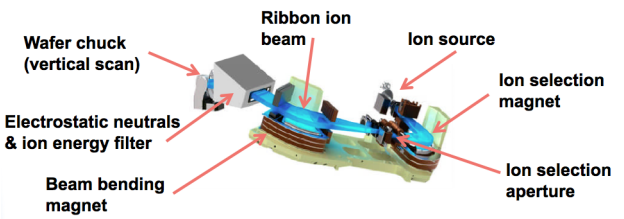

Figure 6: Example of advanced beamline architecture (AMAT/VSE VIISta Trident HC), which includes an inclined beamline, a neutrals and final ion energy filter just before the wafer, and a horizontally uniform ribbon beam for implanting a vertically scanned 300mm wafer that can be cryogenically cooled.

In a sophisticated combination of beam optics and system design, the AIBT high-current implanter, shown in Fig. 7, uses a number of electrodes to decelerate and deflect low-energy ions in a vertical ribbon beam along a "chicane" path (similar to turns in motorcycle racing tracks), before they emerge in front of the wafer scanning position [3]. Neutral dopant atoms that enter the decel stage continue undeflected into a beam trap. When higher energy ions are desired, the ribbon beam is switched back to a straight beam bath, thus bypassing the chicane decel electrode assembly.

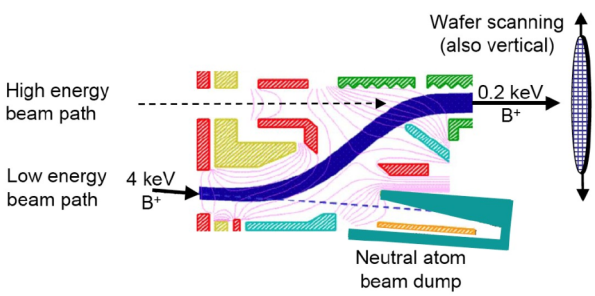

Figure 7: Schematic top view of the "chicane" beam path for deceleration of a vertical ribbon beam in the AIBT iPulsar high current implanter with a beam dump for neutral atom contaminants.

MeV Beamlines

When high-energy ions (>200 keV to several MeV) are needed, variations on either tandem or linear accelerators, developed in the 1930s for nuclear physics research, are used. In the tandem approach, multiple changes in the ion charge state along the beam path are induced to obtain a multiplication of the acceleration by a DC high-voltage potential, as seen in Fig. 8. First, positive ions are extracted from a plasma source and passed though a metallic vapor stream in order to form a beam of negative ions via collisional electron pickup. After undergoing mass selection in a magnet and slit assembly, the desired negative ions are accelerated toward a positive potential region, usually encased within a pressurized SF_6 atmosphere to allow for isolation of high potentials (up to several MV) in a compact chamber. At the center of this tandem beamline, the fast negative ions pass through a high level of Ar gas atoms, resulting in collisional charge exchange that transforms the negative ion beam to positive charged ions with various charge states. As the positive ions leave this shielded charge exchange region, they are accelerated away from the high positive potential in the center of the tandem. Single-charged positive ions leave the tandem beamline with a kinetic energy equal to twice the center positive potential. Double-charged positive ions have a final energy of three times the center potential. Useful, although low level, dopant beam currents with charge states up to +4 (with energy equal to 5 times the center potential) can be obtained for some ions with commercial tandem implanters. A magnetic selector segment placed at the exit of the tandem accelerator section allows only the ions with a desired charge state (and energy) to be passed to the target wafer.

In the Varian 3000XP tandem high-energy implanter shown in Fig. 8, positive ions are filtered by a magnetic field after the high-voltage acceleration stage to reject unwanted ions with undesirable energies and charge states [4]. The selected ions are then scanned along a horizontal beam path and directed through a magnetic beam-shaping element to produce a series of parallel beam paths at the wafer, which is moved up and down to produce vertical wafer scanning similar to the design shown in Fig. 5.

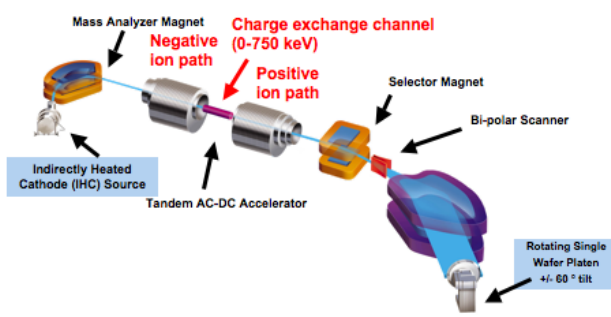

Figure 8: Schematic of the high-energy tandem accelerator beamline for the Varian 3000XP implanter with an operational range from 5 keV to 3 MeV.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Commercial tandem accelerators are in operation with 2 MV potentials providing 8 MeV B^{+3} ions for doping profiles extending ~10 μm into Si. At these boron ion energies, control of gamma and neutron radiation calls for careful shielding and selection of beamline component materials, active radiation monitors, and limits to operating beam currents.

Phase-synchronized linear accelerators have also been used for high-energy ion implanters for over 20 years. In the Axcelis Purion XE high-energy implanter shown in Fig. 9, twelve RF cavities resonating at 13.57 MHz with maximum potentials up to 80 kV each combine to provide a beamline with mA-level beam currents for single-charged dopant ions at energies of ~1.5 MeV [5]. Double-charged P^{+2} ions can be accelerated to 2.9 MeV with 0.7 particle-mA beam currents for deep n-well applications. The positive ion beam from a plasma ion source enters the linac section after passing through a 70° mass-selection magnet (on the left in Fig. 9). After the beam is bunched and accelerated through the linac assembly, it is filtered with a 58.5° magnet (on the right in Fig. 9), that is tuned to select ions with the desired energy for transmission to the beam and wafer scanning stages.

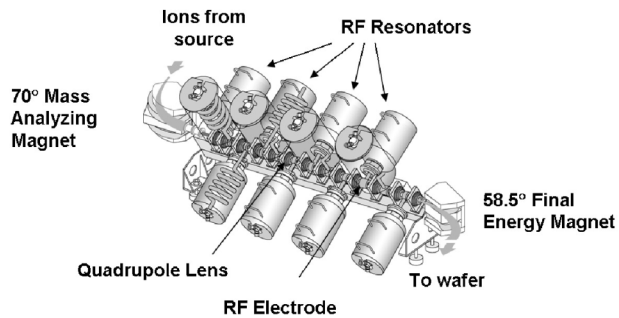

Figure 9: RF linac section of the Axcelis Purion XE high-energy implanter with an operation range from 5 keV to 1.5 MeV for B^+ (1.2 MeV for P^+ and 2.9 MeV for P^{+2}).

Plasma Immersion Ion Implanters

The systems used for very high dose (>10^{16} ions/cm^2) and low-energy (a few keV and less) implantation employ a radically simplified design. In PIII tools, the usual beamline components are eliminated, leaving only a means for generating a plasma containing dopant ions and a wafer mounted on a platen that can be biased. The ions in the plasma formed near the wafer are accelerated into the wafer surface by short (a few μs) negative potential pulses applied to the wafer platen at energies up to the maximum desired value.

PIII systems are remarkably compact in comparison to beamline accelerators, resembling the look of CVD and plasma etch systems. An example is shown in Fig. 10. The applications for these types of implanters include:

- High dose (~5x10^{16} B/cm^2) boron implants at energies of a few keV to counter-dope n^+ poly-Si to form p^+-doped gate electrodes in DRAM devices
- High dose doping of three-dimensional CMOS device structures, such as source-drain regions of finFETs
- High dose implantation of non-dopant ions for local enhancement or reduction of plasma etch rates and other materials modification applications.

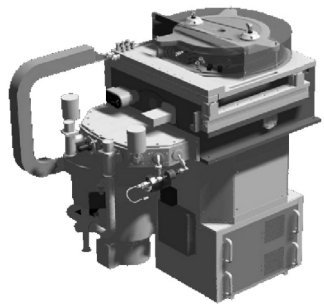

Figure 10: The Varian VIISta PLAD is an RF plasma doping tool, where a pulsed bias voltage is applied to the target wafer to implant ions from the plasma. The wafer bias voltages range from 0.1 to 10 kV [6].

SUMMARY

Ion implantation technology has been built on >40 years of experience, and accelerators are a key component of these tools. Even though commercial systems provide ion energies that span a range of 10^4 and implant doses that span a range of 10^8, the basic hardware designs are similar [7]. Implanter systems have evolved historically over time and will continue to evolve, as new device applications and CMOS device scaling brings more demanding requirements.

ELECTRON BEAM IRRADIATION APPLICATIONS

Sunil Sabharwal#
Radioisotope Products and radiation Technology Section
International Atomic Energy Agency
Vienna, Austria

Abstract

The irradiation of materials with electron beams or X rays is used extensively to enhance or modify their physical, chemical or biological properties. These electron beam "irradiators" cover a very wide range of accelerators technology, beam current and energies to produce a wide variety of products, mostly with polymers. They also are used for curing ink, coatings, and adhesives as well as for the sterilization of medical products, disinfection and preservation of food. The emerging applications include treatment of waste waters and flue gases, and degradation of plastics for use in coatings and inks. The status of applications and the role of IAEA in enhancing these will be presented.

INTRODUCTION

High energy ionizing radiation has the unique ability to produce reactive species like free radicals in a variety of materials that can be used to modify physico-chemical properties of materials for a variety of industrial applications. Over the last 50 years, the subject of radiation chemistry and accelerator physics have developed simultaneously and from industrial applications point of view, the progress in one area has generally led to the advancement in the other area. While the basic radiation chemistry studies using the pulse radiolysis studies using nano-scale pulse electron beam accelerators led to understanding the basic fundamental aspects of radiation chemistry, the commercial applications based on radiation crosslinking of polymers or inactivation of pathogenic bacteria emerged as the driving force for developing high energy high current accelerators to ensure that the fruits of radiation chemical research are utilized for industrial applications. Radiation technologies based on electron beam accelerators today are used for applications such as crosslinking of wire& cables, producing heat-shrink materials, surface curing of materials, sterilization of medical products and for food irradiation [1]. Currently, world-wide, there are over 1400 industrial electron accelerators in operation that are being widely used for applications such as polymer processing, surface curing, sterilization of medical products and food irradiation [2]. A conservative market survey indicates that these high current EB units are providing an estimated over US $85 billion value added unique high-value products for mankind in an environmentally friendly manner [3]. Pollution of air, water and land resources due to industrial and human activities constitutes a major threat to sustainable development. While burning of fossil fuels lead to formation of sulphur oxides (SO_2 and SO_3), nitrogen oxides (NO_x), water resources are being polluted with industrial and human waste. The industrial effluents carry chemical contaminations like heavy metals, organic pollutants, petro-chemicals, pesticides and dyes while discharge of sewage and sludge giving rise to microbiological and chemical contamination of the water bodies. In the last few years, extensive work has been carried out for utilizing radiation technology for environmental remediation. Pilot or plant scale electron beam facilities have been set up to demonstrate the application of this technology for treatment of such pollutants in an effective and efficient manner [4,5]. This paper presents the present status of the established as well as emerging applications and the challenges that the accelerator technologists need to address for further implementation of this technology in these emerging areas.

TYPICAL CHARACRISTICS OF ELECTRON ACCELERATORS FOR INDUSTRIAL APPLICATIONS

For industrial radiation processing, the two main characteristics of an electron beam accelerator are energy and current. While energy of the accelerator determines the thickness of the product that can be uniformly processed, the current determines the productivity or the throughput of the process that can be achieved. A wide range of electron beams with energies varying from 0.15 to 10 MeV are used in radiation processing for varying applications (Table 1). The electron beam accelerators used in the industry typically have beam power (the product of electron energy and current) ranging from 5 to about 100 kW, although more powerful accelerators (400 kW and higher) have also been set up in recent years to demonstrate certain applications or for commercial irradiation. Low-energy accelerators having energies from 0.15 to 0.5 MeV, are generally constructed as self-shielded systems in the production. They are used mainly for the treatment of surfaces and the irradiation of coatings and thin materials, such as polymeric films. Medium-energy accelerators produce electrons with energies of 0.5 – 5 MeV at powers of up to 300 – 350 kW. High-energy accelerators, which for processing purposes generate electron beams with energies of 5 – 10 MeV, are linear accelerators giving pulsed beams of up to 50 kW. Such accelerators are used for radiation sterilization of medical products and, to a lesser extent, for the radiation treatment of foodstuffs. The applications of electron accelerators are summarized in Table 1.

Table 1: EB Penetration for End Application

Application	Electron Energy	Typical Penetration (mm) for unit density product
Surface Curing	80–300 keV	0.4
Shrink Film	300–800 keV	2
Wire & Cable	0.4–3 MeV	5
Sterilization	3–10 MeV	38

FUNDAMENTAL PRINCIPLES FOR DEVELOPING ELECTRON BEAM TECHNOLOGY APPLICATIONS

Generation of radiation energy through electron beams is an expensive form of energy. It can therefore find applications under following conditions:

(i) Substantial benefits or change occur with a small input of energy. Polymerization reactions which are generally chain-reactions constitute one such class of reaction where radiation technologies can be used to initiate the chain reaction for a variety of industrial applications.

(ii) The small change produced results in a large change in the properties of the substrate. For example: in case of polymeric materials, the free radicals produced on polymer backbones can result in either joining of polymeric chains(crosslinking) or chain breakage (scission) resulting in dramatic change in the properties of the polymeric material. Similarly, the small change induced in the DNA structure may stop the reproduction of the microbial cell.

(iii) Situations where the value addition to the product is so high that cost of irradiation is not relevant

(iv) Where radiation is the only method of choice for the treatment process.

Based on these considerations, polymerization (surface curing), polymer modification, sterilization of medical products and food irradiation are the major established applications of electron beam technology.

ESTABLISHED APPLICATIONS OF ELECTRON ACCELERATORS

Polymer Modification

These applications are based on the ability of some polymeric materials, such as polyethylene to undergo crosslinking reaction between adjacent polymer chains, resembling vulcanization, resulting in improved thermal and mechanical properties as well as introduction of "memory effect" in polymeric materials after controlled irradiation. The electron beam crosslinking of the insulation jacketing on wire and cable is one of the most well established industrial uses of EB processing. Crosslink formation results in a three dimensional network structure in the polymeric material that prevents insulation from dripping off an overheated wire in case of a short circuit, or when exposed to elevated temperatures as in the case of an automotive engine or in case of a fire accident. The polymers that are typically used for such applications include polymers that cross-link on irradiation such as polyethylene, EVA or EPDM depending upon the end use application. Absorbed doses of the order of 100-150 kGy or higher are required to cross-link polyethylene wire and cable insulation. Crosslinking imparts two main properties to wire jacketing. if the wire become heated due to an electrical short circuit, the crosslinked jacketing will not melt off of the wire and thus will maintain its insulation. This is very important for under-the-hood wires used in automobiles. Second, when exposed to flames, the jacketing will not burn away nor drip and prevent or delay propagation of a fire.

Polymer cross-linking also forms the basis of radiation processing in the manufacture of heat-shrinkable plastic films and tubes. This application is based on the principle of "memory effect" in the crosslinked polymeric material. The crosslinked polymer deformed under stress at elevated temperatures, when reheated above its melting temperature remembers the shape before deformation and regains the shape before deformation. In a typical application, such materials are used to produce connectors for joining the wires or tubing. The crosslinked plastic behaves as a weak rubber that can be stretched or expanded by controlled mechanical or pneumatic differentials inside and outside the tubing. The stretched tubing is then quickly cooled to temperature below its melt transition temperature to allow the crystalline domains in the polymer to form again and hold the plastic in the stretched or expanded state. This tubing is then used to cover wire connections to be joined. When the tubing is heated during application, it contracts and conforms to the connector or object inside it. This simple application has resulted in forming a variety of high technology products such as heat recoverable closures for telecommunication splices, wraps for welded pipe joints and heat shrinkable food packaging film.

Radiation curing for printing inks especially with wide web presses for high volume production and for printed items requiring high quality graphics and colour highlights constitutes one of the most important applications of low energy electron beam accelerators and over 500 accelerators are used in the industry. Electrons from the accelerator generate free radicals in polymerisable monomers leading to simultaneous polymerization and crosslinking of the monomer onto the substrate. Since electron beam processing takes place at near ambient temperatures, drying of inks can be implemented even on heat sensitive plastic substrates. Absence of extractable initiators in EB curable inks and over print system allow development of over-print materials that are compliant with US Food & Drug Administration regulations for direct food contact and could replace film laminates used atop printed materials

Copyright © 2013 CC-BY-3.0 and by the respective authors

to prevent leaching of extractable for compliance with direct food contact regulations [6].

Sterilization of Medical Products and Food Irradiation

The use of electron beams for sterilization of medical products constituted one of the first commercial applications of radiation technology in 1950s. Since then, high energy 10 MeV accelerators have been used for many decades for sterilizing packaged medical devices. Mid energy accelerators at 3.0–5.0 MeV have also been used for medical device sterilization especially for products having a low bulk density so that the penetration of electrons is sufficient. The packages can be also be irradiated from two sides, thereby increasing the beam penetration to 2.4 times.. In recent years, X radiation produced from high energy high power electron beam accelerators (7 MeV, 700 kW). Even with a low conversion efficiency (typically 10%) for conversion to X rays, the facility allows production of 70 kW of X ray power that allows economic benefits for treatment of medical products by gamma radiation.

Food irradiation was one of the very first proposed uses of Roentgen's discovery of X rays and the subject has been investigated in details world over. The efficacy, minimal effect on nutritive value and general safety of irradiating food has been demonstrated over and over again. The World Health Organization (WHO) has long been on record as supportive of this method for processing food [7,8]. The industrial high energy electron beams (10 MeV) have been successfully used in irradiating food and foodstuffs to eliminate pathogens [9]. With increasing acceptance of food irradiation in many parts of the world, it is apparent that the use of electron beam accelerators for treatment of food is expected to increase in coming years.

EMERGING APPLICATIONS OF ELECTRON BEAM ACCELERATORS

The realization that the environmental problems associated with the development of human activities do not remain confined to local region, but also may affect people living far from contaminated sites has resulted in developing economically and technically feasible technologies for controlling solids, gaseous and liquid effluent streams. Radiation technology with electron beam accelerators with its unique ability to produce highly reactive species in an efficient manner has the capability to alleviate some of these problems and may play an important part in offering sustainable solutions. The unique features of this technology, being a room temperature and additive free process, makes radiation technology an environment-friendly process as compared to conventional thermo-chemical processes. Considerable efforts have been made in demonstrating use of radiation technology for environmental remediation. This includes application of radiation technology for simultaneous removal of sulphur oxides (SO_X) and oxides of nitrogen (NO_X) from flue gases. The electron beam technology for flue gas treatment has demonstrated very good removal efficiencies for the pollutants SO_X and NO_X. The by-product yield is of good quality with less moisture and is good for commercial fertilizer [4, 10].

Radiation processing of wastewater is non-chemical and uses short-lived reactive particles that can interact with a wide range of pollutants. Such reactive radicals are strong agents, oxidizing or reducing, that can transform the pollutants into liquid wastes. A pilot plant with an electron accelerator for treating textile dyeing wastewater was constructed in the Daegu Dyeing Complex (DYETEC) [11], and later an industrial plant for treatment of 10,000 m^3/day has been constructed and in successful operation [12]. A study on sludge hygienization using radiation is ongoing, and the experience of the research has shown that the process is simple, effective and easy to integrate with an existing sewage treatment plant, and that the radiation-hygienized sludge can be utilized as a fertilizer in agriculture [13].

CONCLUSION

The use of ionizing radiation has led to development of advanced polymeric materials for a wide range of applications in various industries. These include industries such as insulated wire and cable production, heat-shrink materials, surface curing, sterilization of medical products and food preservation. The commercial success of the technology is evident from the number of such machines operating and value added products that have emerged using this technology. The demonstration of electron beam based processes for treatment of flue gases and treatment of waste waters on an industrial scale is expected to offer unique solutions for environmental remediation in coming years. The development of reliable very high power electron beam machines will be crucial to extend the use of electron accelerators in these emerging applications.

OVERVIEW AND LESSONS LEARNED OF THE JEFFERSON LAB CRYOMODULE PRODUCTION FOR THE CEBAF 12GEV UPGRADE*

J. Hogan, A. Burrill, M. Drury, L. Harwood, C. Hovater, C. Reece and M. Wiseman
Thomas Jefferson National Accelerator Facility, Newport News, VA 23606, USA

Abstract

The Continuous Electron Beam Accelerator Facility (CEBAF) at Jefferson Lab is nearing completion of an energy upgrade from 6 to 12 GeV. An integral part of the upgrade is the addition of ten new cryomodules, each consisting of eight seven-cell superconducting radio-frequency (SRF) cavities. An average performance of 100+MV of acceleration per cryomodule is needed to achieve the 12 GeV beam energy goal. The production methodology was for industry to provide and deliver the major components to Jefferson Lab, where they were tested and assembled into cryomodules. The production process begins with an inspection upon receiving of all major components followed by individual performance qualification testing. The SRF cavities received their final chemical processing and cleaning at Jefferson Lab. The qualified components along with all associated hardware and instrumentation are assembled, tested, installed into CEBAF and run through an integrated system checkout in preparation for beam operations. The production process is complete and one of the first completed cryomodules has successfully produced 108 MV of acceleration with a linac beam current of 465 μA.

INTRODUCTION

The ten C100 cryomodules accounted for approximately one-quarter of the accelerator budget and 10% of the total budget for the 12 GeV upgrade project. The scope of the cryomodule production run consisted of the design, procurement, assembly, acceptance testing and a final integrated performance checkout with all associated CEBAF operating systems. The first superconducting radio frequency (SRF) niobium cavities were delivered in 2010. These SRF cavities were individually qualified in vertical dewars [1] at Jefferson Lab. In 2011, (ahead of the baseline schedule) the first two production 12GeV-C100 cryomodules were installed and commissioned in the CEBAF machine. These first two cryomodules accelerated and delivered beam for six months of physics experiments. In May 2012, one of the 12GeV-C100 cryomodules was successfully operated at a total energy of 108MV (with a linac current of 465uA) while delivering three-pass beam to the experimental halls [2]. This beam loaded performance demonstrated the design and production process of the C100 cryomodules would meet the 12 GeV requirements.

*Work supported by Jefferson Science Associates, LLC under U.S. DOE Contract No. DE-AC05-06OR23177. The U.S. Government retains a non-exclusive, paid-up, irrevocable, world-wide license to publish or reproduce this manuscript for U.S. Government purposes.

DESIGN

The original CEBAF cryomodule design consists of 8-five-cell cavities and produces a nominal voltage of 20 MV per cryomodule. 40 cryomodules (20/linac) were installed in the original CEBAF and produced enough voltage to run the machine at 4GeV. Over time the performance of these cryomodules was improved and optimized to increase CEBAF operation to 6GeV. The C100 cryomodule design consists of 8-seven-cell cavities and produces 100 MV per cryomodule (500 MV/linac). By adding the ten new C100 cryomodules and an additional 1/2-pass (tenth arc) to the existing accelerator, the maximum operating energy of CEBAF will be doubled from 6GeV to 12GeV.

Parameters

The C100 cryomodule design was developed over several years and is based on a set of early developmental cryomodules designed, built and operated in the Jefferson Lab CEBAF and FEL accelerators. The C100 cryomodule design parameters (see Table 1) were developed in concert with the other associated 12GeV accelerator system upgrades [3]; including the 4.6kW (at 2K) Central Helium Liquefier (CHL) [4], High power (13kW) radio-frequency klystrons (HPRF) and a new digital low-level radio-frequency (LLRF) control system [2].

Table 1: C100 Design Specifications

Parameter	Design Specification	Units
Slot length (includes warm section)	9.8	Meters (m)
Voltage/Cryomodule	108	MeV
2K heat load	<300	Watts
50K heat load	<300	Watts
HOM Damping (transverse)	$<2.4\times10^{10}$	Ohms/meter
HOM Damping (longitudinal)	$<6.5\times10^{11}$	Ohms
Cavity Gradient	19.2	MeV/m
Qo (@19.2 MV/m)	7.2E9	N/A

To meet the 12 GeV performance criteria, each of the ten cryomodules will need to provide 98 MeV of energy. In order to provide performance margin, the cryomodule is designed to produce 108 MeV. This additional performance capability provides the option to run some cryomodules higher in voltage in the event that more energy is needed to make up for lesser performing cryomodules. Similarly, the SRF niobium cavities were

Copyright © 2013 CC-BY-3.0 and by the respective authors

individually qualified at 19.2MV/m even though they only need to provide 17.5MV/m to meet the baseline performance. Subsequently, all of the cryomodule power related components (power couplers, cooling circuits, RF-windows, etc.) were also designed and specified to operate 10% above the baseline performance requirements.

Focused Areas of Design & Performance

The damping of higher order modes (HOM) in SRF cavities is a critical design parameter for recirculating accelerators. To mitigate against the possibility of having beam break-up (BBU) in the CEBAF accelerator an extensive effort was put into the measuring and characterizing the HOM spectrum of each cavity before it was built into a cryomodule [5]. Custom end-groups, that mimicked the boundary conditions the cavities would experience when assembled into a cryomodule, were designed and attached to each cavity during vertical testing (see Figure 1). These purpose built test end-groups allowed the HOM spectrum of each cavity to be characterized (and qualified) prior to being released for assembly into a cryomodule.

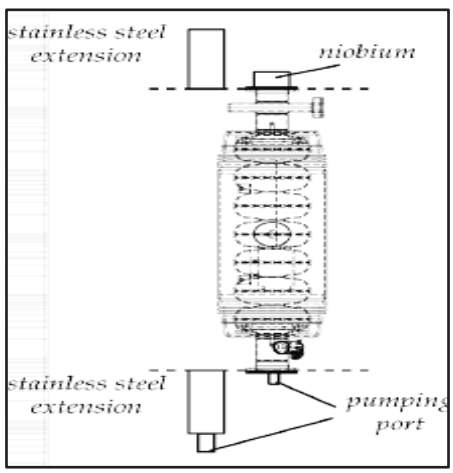

Figure 1: Custom SS end-groups assembled onto cavity during vertical testing.

The microphonic response of the SRF cavities to their environment is another design area that needed very careful attention. Excessive microphonic vibration creates dynamic detuning in the cavity and requires additional RF-power to keep the cavity on frequency with the power and control systems. In preparation for the 12 GeV project, a horizontal test bed (HTB) was assembled with two C100 cavities, helium vessels and tuners to investigate the microphonic response of the design. Results from this test demonstrated the design met the requirements.

Subsequently, the microphonic response was measured on the first production C100 cryomodule during final acceptance testing. Results from this acceptance test showed a higher than anticipated microphonic response. Upon further investigation, it was discovered the boundary conditions of the HTB did not fully represent the 'real' conditions of the C100 cryomodule. In response to these results, the tuner design was modified to reduce the microphonic response of the cavity/tuner system [6]. This cavity/tuner interface redesign was implemented on the final seven (of ten) cryomodules (see Figure 2).

At the point of implementation, production on the first three cryomodules had progressed beyond the point where the cavity/tuner interface could be retrofitted with the redesigned parts. Piezo elements will be used on these first three production units to minimize the additional detuning burden on the LLRF system.

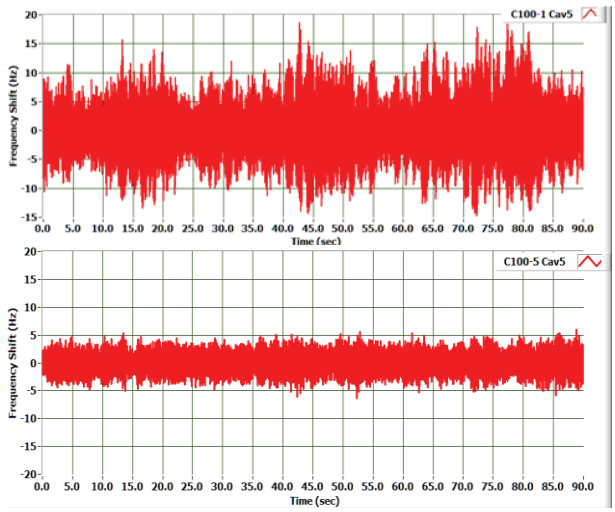

Figure 2: Microphonic detuning - Original design (top), redesigned (bottom) cavity/tuner system.

PRODUCTION

Cryomodule production began with the receiving inspections of the individual components that had been procured from industry. All components have established acceptance criteria that must be satisfied before components are released for use in cryomodule production. These receiving inspection criteria vary from simple visual inspections to multiple qualification processes including mandatory hold points for independent quality assurance.

The cavity qualification process was the first step in cryomodule production. Each C100 cavity was individually qualified after helium vessel welding in the Jefferson Lab SRF vertical test area (VTA). Each cavity was put through a standardized set of tests to verify the project performance parameters were met [7]. Each cavity must produce on average, 17.5 MV/m to meet the baseline performance goal of the 12 GeV project. To provide operational contingency, each cavity was qualified to 19.2 MV/m with a Qo of 7.2E9.

An administrative limit of 27 MV/m was periodically implemented on cavity qualification testing in order to reduce the risk of potentially degrading cavity performance and the need to re-test cavities (see Figure 3). Only one cavity (out of 86) failed to meet the gradient qualification goal of 19.2 MV/m. Two additional cavities were disqualified for use in production due to failure to meet the HOM damping and field flatness specifications.

Copyright © 2013 CC-BY-3.0 and by the respective authors

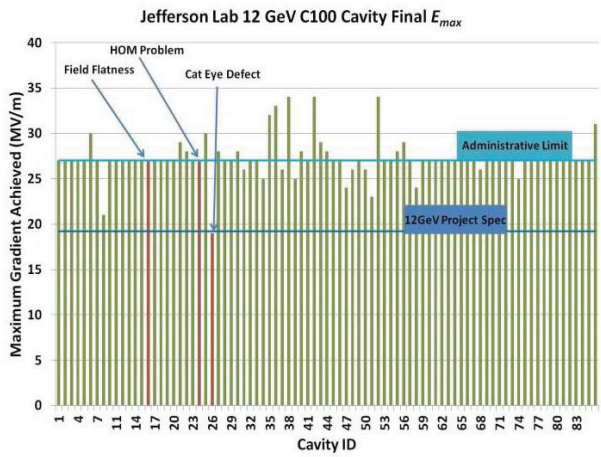

Figure 3: C100 cavity qualification in the VTA.

Once eight cavities were qualified for use in cryomodule production, they were assembled into a hermetically sealed cavity-string in a class 100 cleanroom (see Figure 4). The cavity string assembly was then moved to the cryomodule assembly area where the cold mass structure was constructed. Cold mass assembly includes the cold magnetic shielding (CRYOPERM), 2K helium piping, cold tuner section, instrumentation and multi-layer insulation (MLI).

Figure 4: Cavity string assembly in Class 100 cleanroom.

The cold mass assembly was then transferred to the space frame support structure with an integrated 50K thermal shield and MLI. The cavity string was then concentrically aligned to within 0.5mm. The final assembly consists of installing the vacuum vessel, cryogenic end cans, warm tuner sections and the waveguide fundamental power coupler assemblies. Once the cryomodule assembly was complete, a final QC check was performed to verify the mechanical, electrical and vacuum systems were functioning properly in preparation of final acceptance testing.

PERFORMANCE

Acceptance Testing

Each C100 cryomodule went through a final acceptance testing process in the Test Lab Cryomodule Testing Facility (CMTF) prior to being installed in the CEBAF machine. Acceptance testing is an operational checkout of the cavity performance and all of the cryomodule subsystems. Once all the cryogenic connections and control read-backs have been checked out, the C100 cryomodules were able to be slowly (10-20K/hr) cooled down from 300K to 4K without any degradation in performance due to Q-disease. This slow cooldown reduces the risk of creating a vacuum leak and allows for a lower temperature gradient within the cryomodule, thereby reducing the mechanical stresses associated with cooldown. Once the cryomodule was cooled to 4K, it was then pumped down to 2K for high power acceptance testing. Along with verifying all associated power and control signals were functioning properly, all the cryomodule operational parameters were measured for compliance with the design specifications.

High power RF was applied to each cavity to determine its maximum gradient (restricted only by an administrative limit of 25MV/m) while measuring the corresponding heat load (Qo). In addition, all the other operational systems such as tuners, HOM damping, cryogenic valves and instrumentation were qualified. One limitation is that high power can only be run into one cavity at a time. Therefore, the full cryomodule voltage must be estimated when based on acceptance testing results. With over twenty years of experience, these estimates have proven to be reliable for predicting operation in the tunnel.

Following final acceptance testing, the cryomodules were moved from the CMTF to the CEBAF tunnel for installation and commissioning. The installation process involves connecting the cryomodule to the cryogenic, RF-power, beamline vacuum and operational safety systems. Once all connections were complete and control signal read-backs have been verified, the cryomodule was again slow cooled to 4K, pumped down to 2K and refilled in preparation for the final integrated operational checkout and commissioning process [8].

As was done during acceptance testing, all the operational subsystems were checked out for proper function and the critical accelerating parameters were measured. To date 9 (of 10) of the C100 cryomodules have completed the commissioning process (see Table 2). The in-tunnel performances of all these cryomodules have exceeded the baseline required for 12 GeV operations. Two cryomodules did not achieved the design goal of 108 MV/m, however there is still more than adequate margin in the ensemble performance to meet the program goals.

Table 2: C100 Commissioning Results

Cryomodule No.	Commission in CEBAF (MeV)	Operation with Beam (MeV)
C100-01	104.3	94.5
C100-02	109.6	108
C100-03	118.4	Jan 2014
C100-04	105.8	Jan 2014
C100-05	109.9	Jan 2014
C100-06	108.2	Jan 2014
C100-07	108.4	Jan 2014
C100-08	Oct 2013	Jan 2014
C100-09	113.7	Jan 2014
C100-10	109.8	Jan 2014

Gradient with Beam Loading

As stated above, the first two C100 production cryomodules were installed into the CEBAF machine in the fall of 2011. They were run with beam for the full six month physics run. This runtime was very beneficial with regard to gaining real operational experience running the C100 cryomodules while delivering physics quality beam to the experimental halls [2]. During beam studies time, the gradients on the C100 cryomodules were pushed up in order to test the performance of the entire 'vertical slice' (cryomodule, cryogenics, rf-power, digital LLRF controls, etc.) of the accelerating zone.

During one of these beam studies opportunities, C100-02 was operated at a maximum voltage of 108 MV while delivering multi-pass beam to the experimental halls. Having successfully demonstrated this capability early in the 12 GeV project was very encouraging for the future operations of the CEBAF machine.

Cost

From a cost standpoint, cryomodule production is >99% complete. For the purpose of this paper, the final 12 GeV cryomodule costs are broken down into three categories; procurements, expenses and labor (see Figure 5). These costs include all activities from the initial procurement process through assembly, acceptance testing, installation and commissioning.

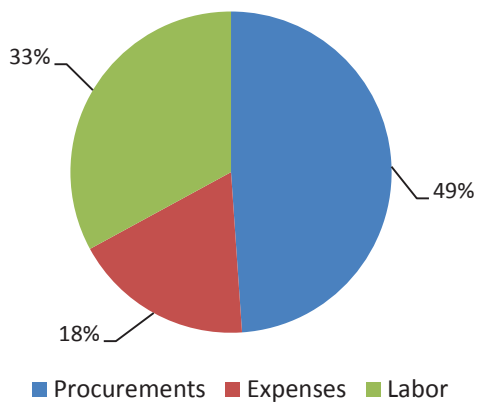

Figure 5: Cryomodule cost breakdown.

The procurement costs are the expenditures associated with the vendor subcontracts for the major cryomodule components such as the SRF-cavities, thermal & magnetic shields, tuners, helium vessels, space-frames, vacuum vessels and cryogenic end cans. The expenses category includes all "other" production costs such as consumables, minor procurements and travel to vendor sites. The labor costs include the labor associated with all cryomodule production activities from individual component QA receiving activities through assembly, installation and commissioning activities.

In order to better understand the level of effort that goes into cryomodule production activities, the labor costs are further broken down (see Figure 6). The labor breakdown shows that quality assurance accounts for approximately one-third of the total labor costs. These QA processes include the labor needed to create the procedures, perform the individual component receiving inspections, document the results and maintain the project database system.

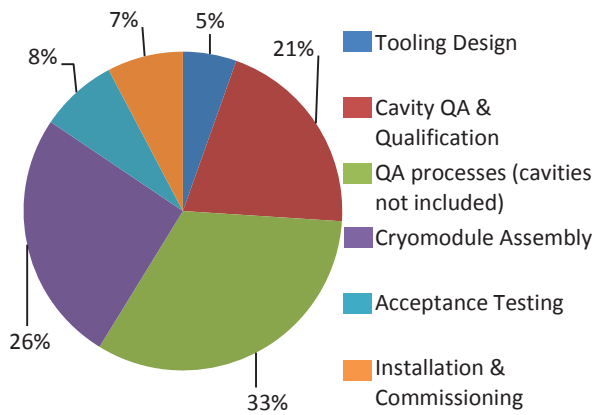

Figure 6: Cryomodule labor breakdown.

Cavity QA and qualification activities account for about one-fifth of the total labor costs. Each of the eighty-six cavities went through a thorough receiving inspection that includes both a dimensional check on a coordinate measurement machine (CMM) and an RF-check to verify that the cavity frequency and field flatness were within specification. Once accepted, the cavities were then run through final processing in preparation for qualification in the VTA. Vertical testing is a time consuming and expensive process, minimizing these testing cycles reduces both project cost and schedule. For this reason, a focused effort was dedicated to process control for cavity qualification. This aforethought and planning effort resulted in minimal retests for qualification (see Figure 7). 65% of all the C100 cavities were qualified on the first test cycle.

Copyright © 2013 CC-BY-3.0 and by the respective authors

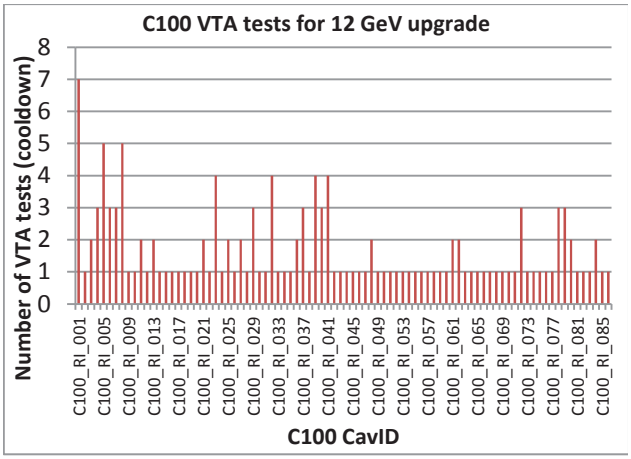

Figure 7: Cavity qualification test cycles in VTA.

Cryomodule assembly accounts for about one-quarter of the total labor costs. As stated above, the cryomodule assembly activities begin with the transfer of the cavity string from the cleanroom and run through final instrumentation checkout and leak check of the insulating vacuum (see Figure 8). There is a significant amount of skilled touch labor involved in these processes. The importance of the skilled staff to the success of this project cannot be understated; for this reason these resources need to be optimized. As with cavity qualification, a focused planning effort was dedicated to optimizing assembly activities and procedures to be efficient without compromising quality.

Figure 8: Cryomodule production group w/ C100-07&-08.

CONCLUSION

At the time this paper was written (Sep 2013), the 12 GeV-C100 cryomodule production run is virtually complete. All ten C100 cryomodules have been assembled, tested and installed in the CEBAF tunnel. Nine have completed their final integrated checkout and commissioning. The last cryomodule is scheduled to complete commissioning in October 2013.

CEBAF operations are scheduled to begin hot-checkout in November 2013. During this process all ten C100 cryomodules will be calibrated with the electron beam in preparation for 12 GeV physics. The lessons learned from the CEBAF 12 GeV Upgrade cryomodule production run include the importance of planning, prototyping, monitoring of performance throughout production and the clear definition of all acceptance criteria.

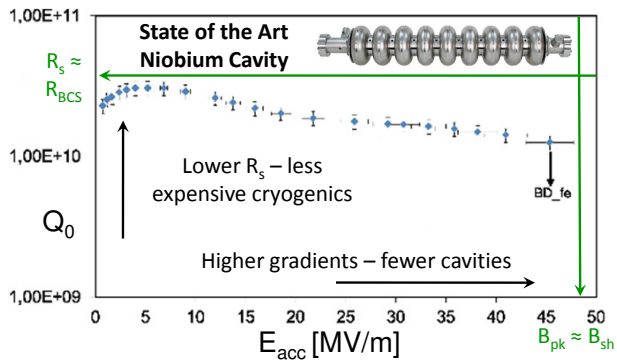
SRF CAVITIES BEYOND NIOBIUM: CHALLENGES AND POTENTIAL*

S. Posen† and M. Liepe
Cornell Laboratory for Accelerator-Based Sciences and Education, Ithaca, NY, USA

Abstract



With niobium cavities now approaching the fundamental limits of the material, SRF researchers have begun a significant R&D effort to develop alternative materials to continue to keep up with the demands of new accelerator facilities. In this paper, the benefits of new materials are explored, as well as the critiria for selecting superconductors to use for SRF applications. The materials Nb_3Sn and MgB_2 are discussed in detail, including an exciting new result from a Nb_3Sn cavity that shows the great potential of alternative SRF materials. NbN and multilayers are also briefly discussed. The current status and the outlook for the future of alternative materials are reviewed.

WHY LOOK BEYOND NIOBIUM?

To accelerate beams of charged particles, superconducting radio-frequency (SRF) cavities are the technology of choice for many facilities. They can reach large accelerating gradients E_{acc} on the order of tens of MV/m, and though they require cryogenics for cooling below the superconducting transition temperature T_c of the material they are made from, they achieve high wall-power-to-beam-power efficiency due to their small surface resistances R_s. Modern SRF facilities use cavities made of niobium, either formed from bulk sheets, or sputtered in films onto copper. Early niobium cavities could operate at only small gradients of a few MV/m, but through years of research, preparation techniques were developed to avoid non-fundamental limitations, such as multipacting and field emission [1]. State-of-the-art production methods regularly produce cavities that operate very close to the fundamental limits of niobium: they have surface resistances R_s very close to the ideal BCS value at operating temperatures, and they sustain electromangetic fields very close to the material's superheating field B_{sh}, the field at which vortices penetrate the superconductor—creating unmanageable levels of heating in RF fields—for an ideal surface [2]. In Fig. 1, the qualification curve of a high-performing TESLA 9-cell niobium cavity (the proposed cavity design for ILC) is plotted. The curve tracks two figures of merit: E_{acc} and Q_0, which is inversely proportional to R_s. It shows that this cavity performs very close to the fundamental limits of the material.

To continue to keep up with continually increasing demands of future accelerator driven sciences, SRF researchers have begun a significant effort to develop alternative materials, chosen to have higher fundamental limits than niobium. The optimal material may depend on the type of facility. For low-duty-cycle high energy linacs, an alternative material would be chosen that can sustain very large surface magnetic fields, as this is what fundamentally limits E_{acc}, and therefore sets the minimum number of cavities requied to reach a given energy. On the other hand, for modern CW SRF linac designs, cryogenics is the cost driver, not the number of cavities. For niobium, low R_s operation requires the cavity to be cooled to ~2 K, where cryogenic efficiency often pushes the cost-optimum arrangement to using only modest gradients, because losses go quadratically with E_{acc}. At ~2 K, cavities made from an alternative material with lower R_s than niobium would have smaller losses at a given E_{acc}, so they would allow the cryogenic plant to be smaller and require less grid power, or they could operate at higher gradients, and therefore require fewer cavities. Furthermore, the temperature dependent part of R_s scales with $e^{-T_c/T}$, so if the alternative material had a large T_c, low R_s operation could be possible at 4.2 K, greatly simplifying the cryogenic plant by allowing it to operate at atmospheric pressure. Low R_s operation at even higher temperatures would open up the possibility of using helium gas for cooling.

Figure 1: Q_0 vs E_{acc} for a High Performing ILC 9-cell Niobium Cavity [3]. The maximum E_{acc} and the Q_0 over the entire range are very close to the fundamental limits of the material.

Long term R&D will be needed to reach the full potential of these alternative materials, but already new results (which will be shown later) on a Nb_3Sn cavity fabricated by Cornell show performances now superior to niobium for some applications requiring modest fields only.

WHAT PROPERTIES TO LOOK FOR IN ALTERNATIVE MATERIALS?

To determine which superconductors are viable candidates for producing high-performing SRF cavities, one should look for certain properties. To achieve large E_{acc}, a large superheating field B_{sh} is desirable, as this is the relevant critical field for RF applications. This is different from B_{irr}—the irreversibility field at which at which vortices that have penetrated into the sample become depinned—which is relevant for magnet applications. In SRF cavities, the objective is to exclude flux, not to pin it inside the superconductor; pinned normal conducting vortex cores dissipate strongly in RF fields. It is energetically favorable for vortices to be inside the superconductor above the first critical field B_{c1}, and only an energy barrier prevents flux penetration above this field. For an ideal surface, the barrier disappears at B_{sh}, making it the ultimate limit for SRF applications, but surface defects with size on the order of the coherence length ξ—roughly, the spacial amplitude of the superconducting wavefunction—can reduce the barrier to vortex penetration, such that fields close to B_{sh} cannot be realized without vortex entry. It is therefore important to have a large enough ξ to not be affected by small defects that would be present even on a well prepared surface, e.g. grain boundaries. It has been an open question how large of ξ is large enough—niobium cavities have reached fields quite close to B_{sh} and its ξ is ∼20 nm—but recent results (presented in a later section) on a Nb_3Sn cavity have shown that operation well into the metastable regime where only the energy barrier prevents vortex penetration is possible for ξ∼3 nm.

For small R_s, one must first consider the temperature-dependent surface resistance from BCS theory, R_{BCS}. As discussed previously, $R_{BCS} \propto e^{-T_c/T}$, so it is important for materials to have high T_c. Materials that have small R_{BCS} also tend to have small normal resistivity ρ_n [4]. However, there is also a temperature independent part of R_s, the "residual resistance" R_{res}: $R_s(T) = R_{BCS}(T) + R_{res}$. The factors contributing to R_{res} are not well understood, but previous SRF experience has made it clear that weak links between grains contribute to large R_{res} [1].

To be useful for cavity operation, alternative materials must also possess the following qualities: 1) it must be possible to fabricate it in a way that it conforms to a complex geometry over large area; 2) it must have decent thermal conductivity (and be able to be deposited on a substrate with decent thermal conductivity) for cooling to avoid thermal runaway; 3) it must have minimal surface roughness to avoid field enhancement; 4) it must be able to be made clean (for example, it cannot release potentially field emitting dust, and there must be a method to clean surface contaminants without affecting quality).

Some of the most promising alternative SRF materials and relevant properties are shown in Table 1, along with those of niobium. Experimental references for these properties were chosen to try to display realistic properties for polycrystalline films. However, material parameters vary depending on how the superconductor is fabricated, and some improvement in SRF qualities can be expected with R&D.

Table 1: Material Properties of Niobium and Three Promising Alternative SRF Materials. The penetration depth λ is calculated using Eqn 3.131 in [5]. The coherence length ξ is calculated using the equations in [6]. For Nb a RRR of 10 was assumed. For MgB_2, λ and ξ are not calculated, as the experimental values are given in the reference. B_{sh} for Nb is found from [7] and for others calculated from [2]. For B_{sh} calculations, $B_c = \phi_0/(2\sqrt{2}\pi\xi\lambda)$ is used, where ϕ_0 is the flux quantum [5]. Nb data from [8], Nb_3Sn data from [9], NbN data from [10], and MgB_2 data from [11] and [12]. Note that the two gap nature of MgB_2 may require more careful analysis than is performed here.

Material	$\lambda(0)$ [nm]	$\xi(0)$ [nm]	B_{sh} [mT]	T_c [K]	ρ_n [μΩcm]
Nb	50	22	210	9.2	2
Nb_3Sn	111	4.2	410	18	8
MgB_2	185	4.9	210	40	0.1
NbN	375	2.9	160	16	144

Potential and Challenges

Nb_3Sn is a material with tremendous potential for SRF applications. It has extremely small R_s, as a result of its small ρ_n and large T_c∼18 K (twice as high as niobium), as well as its small R_{res}, shown in cavity measurements [13]. It also is an excellent candidate for achieving large E_{acc}, with very large predicted B_{sh}∼400 mT (again twice as high as niobium), and a decent ξ∼3-4 nm. Furthermore, it can be coated onto niobium substrates, allowing existing niobium cavities to be upgraded. It is also non-reactive with water, and it adheres strongly to niobium when coated onto it, so that Nb_3Sn cavities can be cleaned using the high-pressure-water-rinsing methods developed for niobium.

Nb_3Sn is brittle, and it has low thermal conductivity, so it has to be used in film form. Therefore it faces challenges associated with using SRF films. These are detailed in a later section.

Preparation Methods

The Nb_3Sn fabrication method that has produced the most encouraging SRF results is vapor diffusion. The technique was developed at Siemens AG [14] and University of Wuppertal [15], and it is now being employed by researchers at Cornell University [16] and Jefferson Lab [17]. A niobium cavity is placed in an ultra-high-vacuum furnace with a small amount of tin. The temperatures of both are

Copyright © 2013 CC-BY-3.0 and by the respective authors

raised to around 1000°C, so that the tin has a high enough vapor pressure to reach the cavity, and once it reaches the surface, the temperature is high enough to encourage diffusion and alloying.

Researchers at several institutions have recently attempted to fabricate Nb_3Sn using other methods: liquid tin dipping and multilayer sputtering at INFN [18]; cathodic arc deposition at Alameda Applied Sciences Corp. [19]; and pulsed laser deposition at KEK [20] (note that AASC and KEK fabricated MgB_2 via the same methods). However, so far these studies have not produced encouraging RF results.

Development Status

Jefferson Lab has fabricated Nb_3Sn samples with excellent T_c. They have also performed low-field R_s measurements in a 7.4 GHz host cavity. A dedicated furnace has been delivered, and is currently being commissioned to coat full single-cell cavities. The apparatus is shown in Fig. 2.

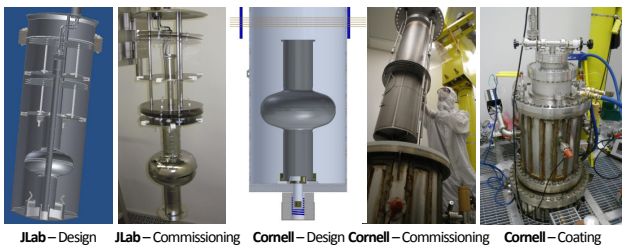

Figure 2: Apparatuses for coating cavities with Nb_3Sn at Jefferson Lab (left) and Cornell University (right).

The Nb_3Sn program at Cornell University (see coating apparatus in Fig. 2) has been ongoing for several years, and recently produced its second 1.3 GHz cavity, shown in Fig. 3, which showed exceptional performance in RF test [16]. As shown in Fig. 4, it achieved fields ∼12 MV/m at 4.2 K with a Q_0 of 10^{10}, 20 times higher than niobium. It is the first alternative material accelerator cavity to achieve significantly smaller R_s than niobium at useful gradients and temperatures. Previous Nb_3Sn cavities suffered from a strong increase in R_s with field, leading to speculation that the coherence length was too small, causing the barrier to vortex penetration to fail at surface imperfections. However, this new cavity proves that even with a ξ of only $\sim$ 3 nm, the energy barrier prevents observable vortex dissipation, the first clear indication that such a small ξ will not cause a fundamental limitation for cavities made from alternative materials.

MAGNESIUM DIBORIDE

Potential and Challenges

MgB_2 was discovered relatively recently, so it is not as well developed as Nb_3Sn, but it also has exciting potential. With a T_c of approximately 40 K, and a small ρ_n, it can have a very small R_{BCS} even well above liquid helium temperatures. Its superheating field is not clear at this early stage of development, but it could range from ∼200-600 mT, depending on the material properties. More development of SRF-quality MgB_2 films is needed to make a better estimate. It also has a decent ξ∼5 nm.

There are some challenges to developing MgB_2 as an SRF material. In fabrication, it is necessary to obtain a very small oxygen background in the coating chamber, as the magnesium is highly reactive with it. The coatings also react with water, which makes cleaning difficult. It might be necessary to coat an additional dielectric "capping" layer to allow a MgB_2 cavity to be cleaned. Additionally, because it is a two-gap material, its R_s is predicted to increase with field, but there might be methods to reduce this effect [21]. MgB_2, like Nb_3Sn is being developed in film form, so it will have the same film challenges detailed in a later section.

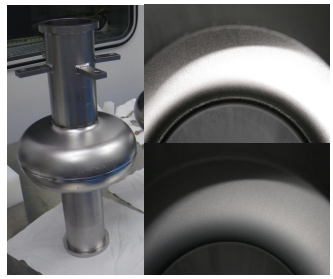

Figure 3: Cavity coated with Nb_3Sn at Cornell (left); view looking down into cavity before (top right) and after coating (bottom right). Notice the dark, matte gray appearance of the Nb_3Sn coating.

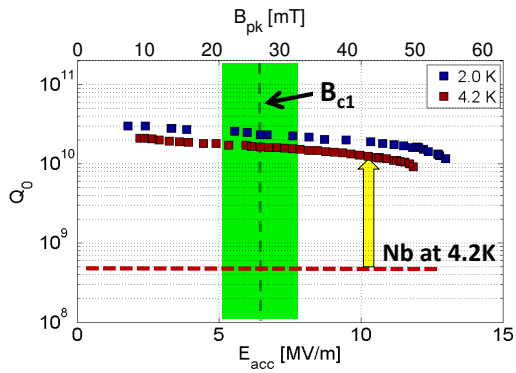

Figure 4: Q_0 vs E_{acc} for Cornell's Nb_3Sn cavity. At 10 MV/m, the Q_0 is a factor of 20 times higher than Nb at 4.2K. The maximum surface magnetic field is approximately 2 times higher than B_{c1}=27±5 mT, which was calculated using Ginzburg Landau theory from measured material parameters.

Preparation Methods

Excellent preliminary results have been obtained using hybrid physical chemical vapor deposition at Temple University [22] and using reactive co-sputtering at Superconducting Technologies Inc. (STI) [23].

Development Status

Coating of accelerator cavities with MgB_2 is being developed by X. Xi at Temple University [22]. Studies of samples produced at Temple have repeatably shown films with T_c very close to the ideal literature value, and ρ_n of only 0.1 μΩcm [12]. Encouraging RF results have been obtained by researchers at Los Alamos and MIT Lincoln labs on MgB_2 stripline and dielectric resonators fabricated by STI, as shown in Fig. 5. Measurements still need to be done at smaller frequencies to determine if R_{res} can be small enough for SRF cavities, and if this can be maintained up to useful fields.

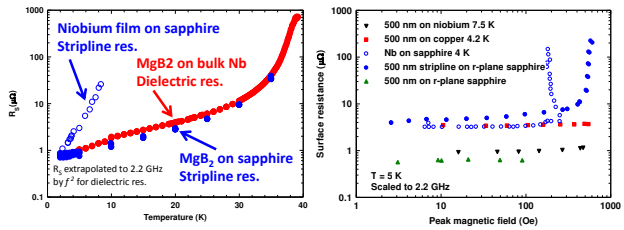

Figure 5: RF measurements of MgB_2 stripline and dielectric resonators show excellent R_s at high temperatures and high frequencies. Experimental data from D. Oates [23]. Note that scaling of the data from high frequencies may significantly underestimate the residual resistance at 2.2 GHz.

NIOBIUM NITRIDE

With a high T_c∼15-17 K, the δ phase of NbN has the potential to have R_{BCS} significantly smaller than niobium. For the relatively dirty films that are generally produced, it has a predicted B_{sh} of only around 150-200 mT, with a decent ξ∼3 nm. However, one additional argument in favor of pursuing NbN is that it might be possible to coat large niobium cavities in existing UHV furnaces—one of the methods of producing NbN involves bringing niobium to high temperatures in the presence of nitrogen gas, then quickly cooling it [24].

NbN has a very complex phase diagram, which makes it very challenging to achieve the superconducting δ phase. This is achievable with sputtering, but with heat treatment in a nitrogen atmosphere, no reliable procedure has been developed that could be applied to cavities. Recently an R_s reduction was observed in niobium cavities that were treated with nitrogen gas in a UHV furnace at Fermilab, and it was initially speculated that the cause was the growth of superconducting NbN. However, T_c and XRD measurements of samples revealed that another mechanism must have been responsible [25]. Another challenge is R_{res}—tests of sputtered NbN have shown a relatively high value. Additional investigations are needed to determine if this can be avoided.

MULTILAYERS

In 2006, A. Gurevich proposed that bulk films of alternative materials would be inferior to "SIS multilayer" films, which consist of alternating layers of thin superconductor (S) and insulator (I) on top of bulk superconductor, as shown in Fig. 6 [26]. It was suggested that the enhancement of the critical fields in thin films would help small-ξ materials to avoid vortex penetration from small surface defects. Several labs over the world have made excellent progress in the difficult process of fabricating SIS films, including CEA [27], Argonne [28], JLab [29], William and Mary [30], and Grenoble IPT [31]. However, recent theoretical work has shown that compared to bulk films, SIS multilayers can offer only a small enhancement of the superheating field, and only for a small parameter range [32].

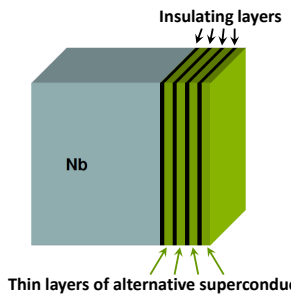

Figure 6: SIS multilayer structure proposed to protect alternative materials from vortex penetration. New theoretical work suggests that multilayers will not be superior to bulk films. Image adapted from [26].

FILM CHALLENGES

The alternative materials being researched are primarily used in film form over metal substrates. There are unique challenges associated with SRF films that are not encountered in cavities made form bulk material. The cooldown of a film cavity must be done slowly and uniformly to avoid temperature gradients over the surface. Gradients can cause thermocurrents due to the interface of the two materials, which in turn can create and trap flux that causes excess R_{res}. This also means that after a quench, the cavity must be warmed above T_c and cooled slowly again to regain a small R_s. Films cavities have fewer options available in case of a contaminated surface after coating—because the film is usually only a few μm thick, only light chemistry is available to clean the surface. Large cavities also present a significant challenge with films, since applying a film to a completed structure requires a very large coating apparatus. Coating pieces before welding is not possible in most cases because this would destroy the quality of the film at the weld.

OTHER MATERIALS

Other potentially promising materials not presented here but for which there has been some recent activity include V_3Si, Mo_3Re [33], and Nb_3GaAl [34]. In addition, though they have very complex structures, the oxypnictides are an exciting possibility. More research is needed into these materials to understand if they might be useful for SRF applications.

CONCLUSIONS

Alternative SRF materials offer lower R_s, higher T_c, and higher B_{sh} than niobium. Cavities made from these materials would be much more cryogenicically efficient (likely a factor of 10-100), and they are predicted to reach higher gradients (up to a factor of $\sim$2), meaning that fewer cavities would be required to reach a given beam energy. Many labs worldwide are contributing to the effort, and while it is expected to be a long term R&D project, there has been significant progress recently. A Nb_3Sn cavity produced at Cornell achieved a breakthrough performance: at 4.2 K and $\sim$12 MV/m, it had a Q_0 of 10^{10}, 20 times higher than Nb, making it the first alternative material accelerator cavity to far outperform niobium at useful gradients and temperatures. MgB_2 is also showing great promise in small-scale RF tests, and the first MgB_2 accelerator cavities are planned to be produced soon.

Abstract

SuperKEKB is the upgraded accelerator of KEKB aiming at an extremely high luminosity. The machine is designed on the basis of nano-beam scheme. The beam final focusing system is the most important element for achieving the luminosity of this accelerator. The system consists of 8 quadrupoles, 4 solenoids and 43 correctors.

INTRODUCTION

The target luminosity of SuperKEKB [1] is 40 times higher luminosity of 8×10^{35} cm^{-2} s^{-1} than that of KEKB. The 7 GeV electrons in the high-energy ring (HER) and the 4 GeV positrons in the low-energy ring (LER) collide at a single interaction point, IP, with a finite crossing angle of 83 mrad.

The accelerator is designed on the basis of the nano-beam scheme [2], and the final beam focusing system has been designed with superconducting quadrupole doublets for each beam. Since the positions of quadrupole magnets must be aligned very precisely within several nano meters, the alignment of quadrupoles is performed by the correctors [3]. In addition, from the requirement of beam optics, 43 corrector coils are installed in the system. The system has four compensation solenoids to reduce the effect of the detector solenoid field on the beams. All magnets and correctors are assembled into two cryostats.

In the paper, the design of the system is described.

SUPERCONDUCTING MAGNET SYSTEM

Magnet Layout in the IR

Figure 1 shows the layout of the superconducting magnets near the interaction point, IP [4]. The system consists of 8 main quadrupole magnets, 4 compensation solenoids, 35 corrector coils and 8 coils to cancel the leakage magnetic fields of QC1LP/RP. The main quadrupole magnets (QC1s and QC2s) are designed to form a quadrupole doublet for each beam. Table 1 shows the main parameters of the quadrupole magnets at the colliding energy of 11 GeV. The QC1LP/RP magnets are located at the closest position, +/- 935mm, to IP. They are quadrupole magnets without magnetic yokes in order to make the solenoid field profile for minimizing vertical beam emittance. The other quadrupole magnets have magnetic yokes.

Since the QC1LP/RP magnets are non-yoked magnets, the leakage field from the magnets to the e- beam line contains all field components as shown in Fig. 2. In order to cancel these components, the B_3, B_4, B_5 and B_6 cancel coils [3] are wound using the helium inner vessel as the coil bobbin. A small twist of the windings which produce the normal cancel components also generates the needed skew cancel components. The B_1 and B_2 field components are included in the optics design.

The compensation solenoids, ESL, ESR1, ESR2 and ESR3, are designed to cancel the Belle-II solenoid field integrally along the beam lines [5]. In the ESL and ESR1 solenoids, two or three quadrupoles are assembled, respectively, as shown in Fig. 1. In the right cryostat, the additional solenoids, ERS2 and ESR3, are also installed.

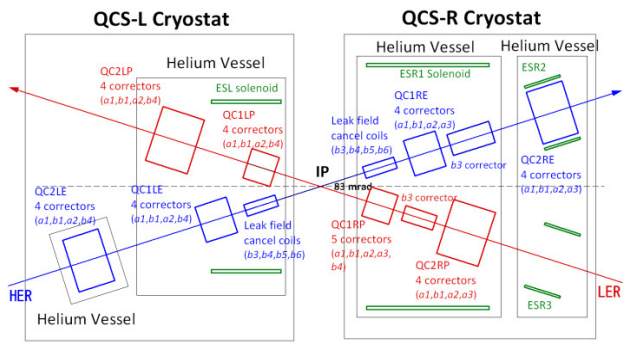

Figure 1: Layout of S.C. magnets near the IP of SuperKEKB.

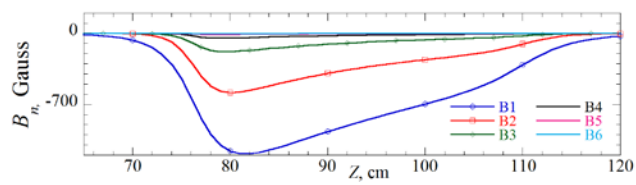

Figure 2: Leakage field profiles along the e- beam line.

Table 1: Main Quadrupole Parameters

Magnet	*GL*, T (T/m×m)	Type	*Z*, mm	*θ*, mrad
QC2RE	13.04 (31.12×0.419)	Yoke	2925	0
QC2RP	11.54 (28.15×0.410)	Yoke	1925	-2.114
QC1RE	25.39 (68.07×0.373)	Yoke	1410	0
QC1RP	22.96 (68.74×0.334)	no Yoke	935	7.204

Alignment of Quadrupole Magnets

In Table 1, the quadrupole centers from IP and the mid-plane angles to the horizontal plane are listed. The quadrupole magnets for LER are assembled with these angles in the cryostats. Since the solenoid field and the leakage field of QC1P magnets change the e- beam orbits, the beam orbits will be controlled by dipole correctors. In order to optimize the corrector system, the magnet axes of QC1s and QC2s are shifted as shown in Table 2. In the table, ΔY is the shift amount in vertical direction from the horizontal plane including IP and the negative sign means downward. The plus ΔX means the horizontal shift toward the outer direction of the accelerator ring.

Table 2: Shift Amount of Magnet Axis

Magnet	ΔY	Magnet	ΔX
QC1RP	-1.0 mm	QC1RE	-0.7 mm
QC2RP	-1.0 mm	QC2RE	-0.7 mm
QC1LP	-1.5 mm	QC1LE	+0.7 mm
QC2LP	-1.5 mm	QC2LE	+0.7 mm

QUADRUPOLE MAGNETS

The four cross sections of the quadrupole magnets are shown in Fig. 3. The magnet designs are different in order to accommodate the change of the beam pipe diameters in the cryostats. Table 3 shows the design parameters of the magnets. The numerical values are for colliding energy of 12 GeV. The magnets consist of two layer coils, and the cables are same specification except for the keystone angle. The QC1P magnets are designed without iron yokes because in the location of these magnets the solenoid fields by ESL and ESR1 integrally cancel the Belle-II solenoid field. The QC1E and QC2P magnets have Permendur yokes to avoid magnetic saturation in yokes due to local imperfection in cancelling Belle-II field by ESL and ESR1. For the QC2E magnets, the yoke material is iron because the separation between two beams is more than 200 mm.

Table 3: Design Parameters of QC1 and QC2 Magnets

	QC1 P	QC1 E	QC2 P	QC2 LE/RE
Magnetic yoke	No	Perm.	Perm.	Iron
Coil I.R., mm	25.0	33.0	53.8	59.3

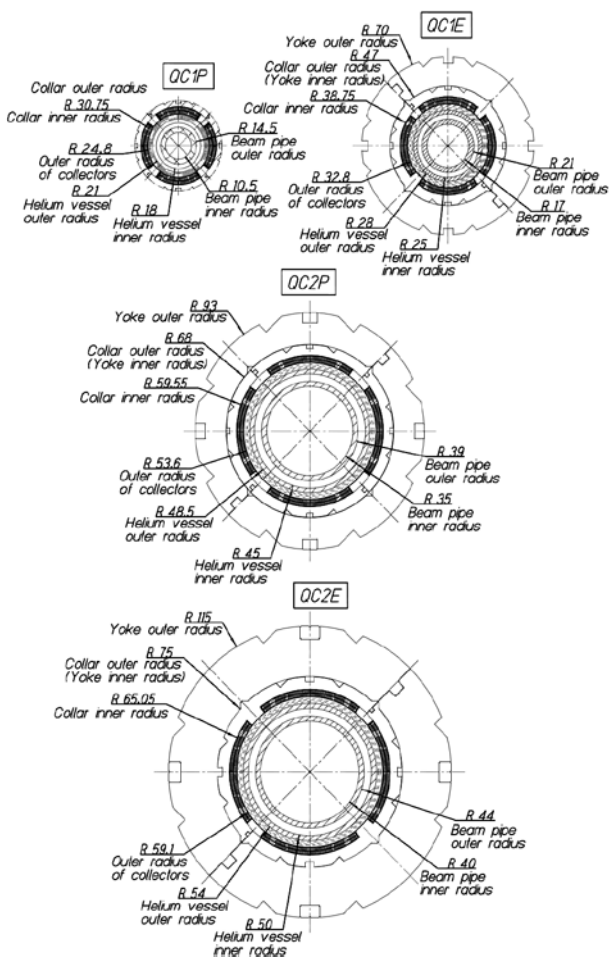

Figure 3: Quadrupole magnet cross sections.

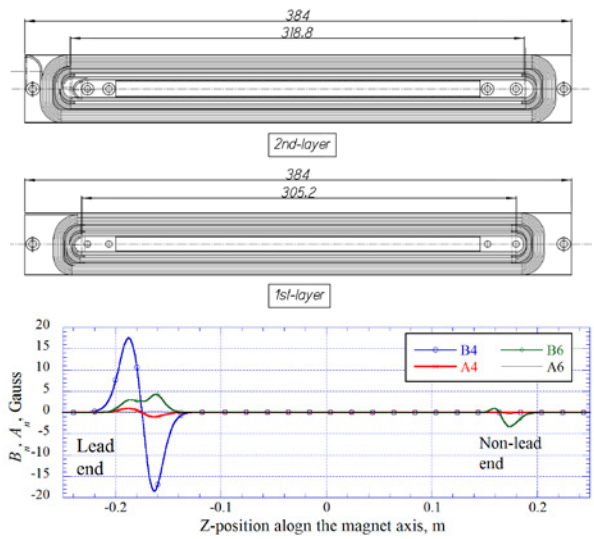

Figure 4: Coils of QC1P magnet and error field profiles.

In Fig. 4, the coils of QC1LP and the profiles of A_4, B_4, A_6 and B_6 components are shown. The coil ends are designed to reduce the absolute peaks of the error fields to less than 20 Gauss and the integral error fields to less than

Copyright © 2013 CC-BY-3.0 and by the respective authors

1 unit. From the asymmetry configuration of the lead end, the B_4 component has the peaks of +/- 18 Gauss. The Touschek life time are calculated with these field profiles. As the result, the lead ends of the magnets are positioned at the IP side in the cryostat because the smaller size beam at the IP side is less sensitive to the higher order error fields. The other quadrupole magnets are placed in the same way.

SUPERCONDUCTING CORRECTORS

The corrector specifications are summarized in Table 4. In Table 4, R_r is the reference radius, and A_n and B_n are the skew and normal correctors, respectively. The A_1 and B_1 correctors are designed to be able to shift the magnet axis in the range of 0.5 mm to 1.0 mm. The A_2 corrector can rotate the mid-plane angle of the quadrupoles from 12 mrad to 15 mrad. The sextupole A_3 and B_3 correctors cancel the error fields of the quadrupole magnets induced by magnet assembly errors. The required integral sextupole field strengths are equivalent to 1×10^{-3} of the quadrupole fields. R_r values of B_3 coils for LER and HER are 15 mm and 30 mm, respectively. Installation of sextupole correctors was decided from the results of QC1P/1E proto-type magnets [6]. The B_4 correctors increase the dynamic transverse aperture.

Table 4: Integral Field Strengths of Correctors

Magnet	R_r	A_1	B_1	A_2	A_3	B_3	B_4
	mm	T•m	T•m	T	T/m	T/m	T/m^2

QC1LE	15	0.027	0.046	0.75	-	-	60
QC2LE	35	0.015	0.015	0.37	-	-	60

COMPENSATION SOLENOIDS

Figure 5 shows the field profile of Belle-II solenoid and the combined field profile with ESL and ESRs. As shown in Fig. 5, Belle-II solenoid generates the solenoid field of 1.5 T, and the field is cancelled by the reverse solenoid fields in the areas of QC1LP and QC1RP. In order to produce the combined field profiles required by beam optics, ESL and ESR1 are divided into 12 and 15 small solenoids, and they produce the integral fields of 2.31 T•m and 3.69 T•m, respectively. These integral fields correspond to the integrated Belle-II solenoid fields from the IP. The maximum fields in ESL and ESR1 coils with the Belle-II fields are 3.4 T and 3.3 T, respectively.

Since QC1Es and QC2Ps have the Permendur yokes and the combined fields are designed to be less than 0.01 T, the residual solenoid fields are negligible on the beam lines. Between QC2RP and QC2RE, the Belle-II fringe field is in the range of 0.6 T because of no magnetic shields. The fringe field is cancelled by ESR2 or ESR3. The solenoid parameters are summarized in Table 5.

The design of the cryostat is difficult because the compensation solenoids have large repulsive electro-magnetic forces from the Belle-II field. The forces on ESL and ESR1 amount to 38 kN and 48 kN, respectively. The forces affect the magnet-cryostat alignment, and this is the next important problem to be solved.

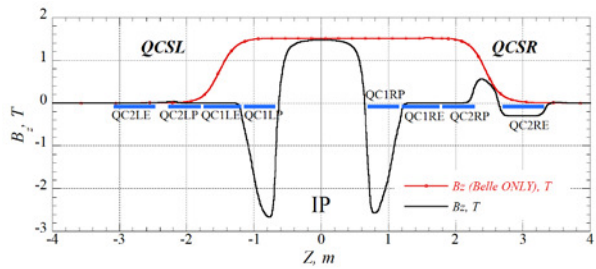

Figure 5: Solenoid field profiles along the beam lines.

SUMMARY

The final focusing superconducting magnet system of SuperKEKB has been designed after many steps of iteration. The designed system consists of 8 quadrupole magnets, 4 compensation solenoids and 43 corrector coils. They are now in the construction stage, and the completion of the system is scheduled in 2015.

RAPID CYCLING DIPOLE MAGNET*

H. Witte†, J.S. Berg, P. Kovach, M.D. Anerella, Brookhaven National Laboratory, Upton, NY, USA
M. L. Lopes, Fermilab, Batavia, IL, USA

Abstract

Accelerating muons to 750 GeV and higher is most efficiently accomplished using a hybrid synchrotron. Such a machine interleaves superconducting dipoles with bipolar dipoles ramping at an effective frequency of 400–1000 Hz and with maximum fields of around 1.8 T. Previous designs for the rapid cycling dipoles for this lattice have been based on grain oriented steel, which possesses good magnetic properties in the direction of the grains. Grain oriented steel however is highly anisotropic, which can potentially lead to field quality problems. In this paper we present an alternative design, which we expect to have lower losses, a higher peak field, and better field quality.

INTRODUCTION

A hybrid synchrotron is the most efficient known option for accelerating muons to their highest energies in a TeV-scale muon collider. A hybrid synchrotron bends particles by interleaving fixed field superconducting dipoles with bipolar rapid cycling dipoles. This permits rapid acceleration, to reduce muon decay, while making a significant number of RF cavity passes to achieve good efficiency. To maximize the RF efficiency, minimize decay, and maximize the energy range of a single ring, it is essential to have the highest field possible for both the superconducting and the rapid cycling dipoles.

A design accelerating muons from 375 to 750 GeV has been proposed [1] (shown schamatically in Fig. 1), which was a variation and refinement on earlier designs [2]. It has a circumference of 6300 m, with arc cells containing 2.7 m 8 T dipoles and 7.9 m rapid cycling dipoles. The field in the rapid cycling dipoles swings from -1.8 T to $+1.8$ T in 0.5 ms; there are about 2200 m of these dipoles in the ring. The beam will be accelerated 15 times per second.

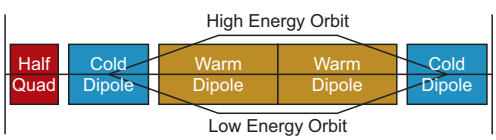

Figure 1: Structure of a quarter cell, showing the expected deviation of high and low energy closed orbits.

This report outlines a potential solution for the rapid cycling dipoles. We propose a solution operating at a frequency of 400 Hz (proposed in [2], gives more decays than [1]). The aperture required will be 60 mm horizontally (required for horizontal beam aperture) and 13 mm vertically (primarily to keep impedances reasonable). We also discuss a 25 mm vertical aperture, which might be required if a ceramic beam pipe is used.

MAGNET GEOMETRY

We consider the geometry shown in Fig. 2, which shows the 13 mm gap case. For a 25 mm gap the pole width increases to 132 mm because of field quality reasons. Each coil area is 87×30 mm^2 in cross-sectional area.

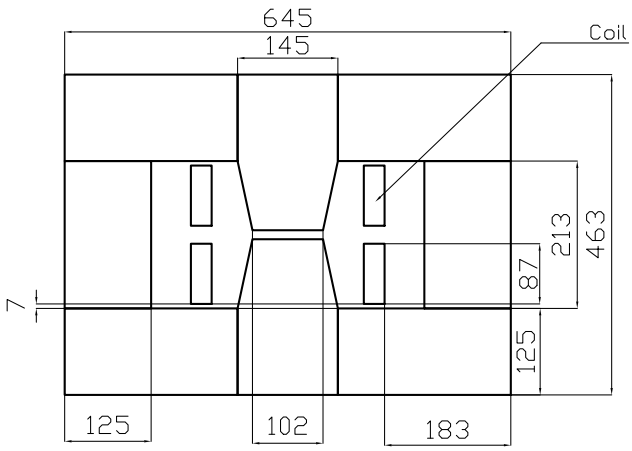

Figure 2: Geometry of the dipole magnet (in mm).

MATERIALS

Previous studies focused on grain-oriented 3% SiFe, which possesses good magnetic properties in the rolling direction [3]. A concern however is the high anisotropy of the material, which in studies has shown to affect the field quality.

For this study we focus on alternative isotropic materials, which promise lower losses while at the same time can achieve higher peak magnetic fields. The coil design employs two materials: 6.5 %SiFe and FeCo (49% Co, 1.9% V and 49% Fe). 6.5% SiFe, which has a relatively low magnetization saturation, is chosen for the very low losses. FeCo (with relatively large losses) has a very high magnetization saturation and is used for the poles of the magnet. For this design we consider Vacoflux 48 from Vac-

uumschmelze[1] and 10JNEX900 from JFE[2]. The material data for hysteresis, magnetization curves and loss calculations were obtained from the manufacturers [4, 5]. The laminates are assumed to be 100µm thick. For comparison reasons we also estimate performance and losses for a design using isotropic 3% SiFe with thicknesses of 178µ and 250µm [6, 7].

PERFORMANCE AND FIELD QUALITY

The magnet performance using the different materials was evaluated in a 2D non-linear static finite element simulation. For a field of 2T an average current density of 4 A/mm^2 is required (25 mm gap: 7.88 A/mm^2). Fig. 3 shows the expected field quality $\Delta B/B_0$ as a function of the peak magnetic field on the centre plane. The figure shows the obtained results for an all 3% SiFe yoke and FeCo/6.5 %SiFe (13 mm and 25 mm gap). As shown in the figure, the field quality using 3% SiFe starts to deteriorate for fields in excess of 1.5 T. Using FeCo in principle allows to achieve more than $1.9 - 2$ T assuming a required field quality of 1×10^{-3}.

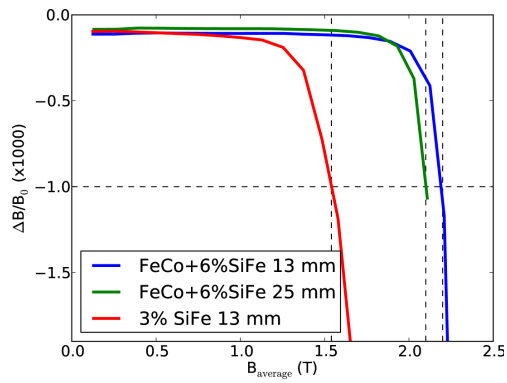

Figure 3: Field quality.

It was found that the field quality is unaffected by eddy currents in the yoke, hysteresis effects and mechanical tolerances other than the tolerance on the poles of the magnet.

POWER LOSSES

Resistive Losses in Coil

It was found that eddy current losses in the coils are a serious concern. To mitigate this the coils are placed in an area inside the yoke where field leakage is minimal. Instead of standard rectangular conductor (with a circular hole for water cooling) the coils are made of thin copper sheets, which are insulated against each other with 25µm thick Kapton tape. To determine the ideal thickness of the sheets a time-transient eddy current study was set-up. The simulation assumes that the coil area remains fixed, while the number of sheets is varied (and the thickness of each sheet is $d_{\mathrm{Sheet}} = w_{\mathrm{coil}}/N$, with N as the number of sheets).

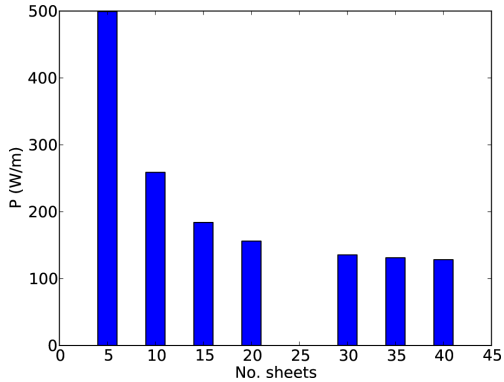

Figure 4: Power loss per m of magnet for different numbers of conducting sheets.

Fig. 4 shows the simulated power loss per pulse for a one meter long magnet. The figure shows that increasing the number of sheets up to 20 significantly reduces the power loss. A number of 30 sheets (each 1 mm thick) was chosen for the final design.

Core Losses

The core losses consist of eddy current losses, hysteresis losses and so-called anomalous losses. To estimate the core losses we rely on measured data from the manufacturers of the materials [4, 5]. Fig. 5 shows the results for an all 3% SiFe yoke with 178µ and 250µm thick laminates in comparison to a yoke made of 6.5% SiFe and FeCo. The losses are calculated assuming 2 km total dipole length in the ring.

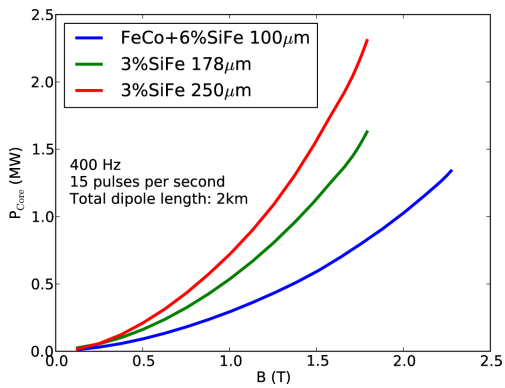

Figure 5: Core losses.

The figure shows that the here presented design is more efficient in comparison to a yoke made of 3% SiFe. For a peak field of 1.5 T the core losses are calculated to 0.5 MW for the entire ring in comparison to 1–1.5 MW for 3% SiFe. The core losses for 178µm thick 3% SiFe are expected to be lower than for 250µm thick laminates due to the better suppression of eddy currents.

[2] JFE Steel Corporation, Electrical Steel Section, Tokyo, Japan

Copyright © 2013 CC-BY-3.0 and by the respective authors

Total Power Loss

The total estimated power loss for the entire ring (core and coil losses, total dipole length 2 km) are shown in Fig. 6. The figure shows the losses assuming a 13 mm and 25 mm gap. The losses for the 178µm thick 3% SiFe laminates are shown as well. At 1.5 T the total losses using FeCo and 6.5 %SiFe are expected to be about 0.75 MW for the entire ring. At 2 T this increases to 1.5 MW. The power losses are lower by a factor of two or more in comparison to a design using 178µm thick 3% SiFe.

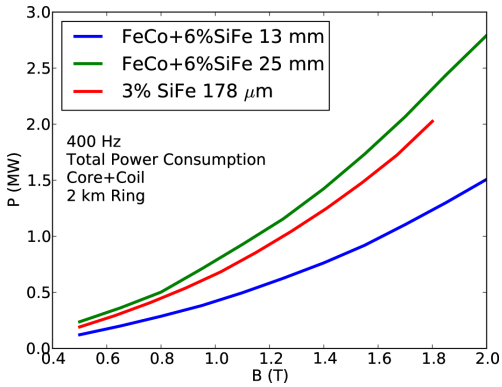

Figure 6: Total power loss for entire ring.

ENGINEERING CONSIDERATIONS

Mechanical Design

To contain the forces during operation the dipole magnet is housed in an external clamp. The peak forces during operation were evaluated using the Maxwell stress tensor and Biot-Savart-Law. It was found that the only significant force component acts on the poles, which is about 170 kN in vertical direction for a 1 m long magnet with a 13 mm gap (towards the centre of the magnet). The force acting on the coils is negligible.

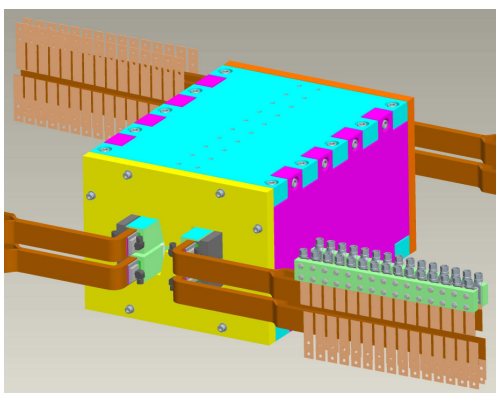

Figure 7: Rapid cycling dipole assembly.

The support structure of the magnet is designed to deal with the forces and to minimize the deflection to achieve the desired field quality. Fig. 7 shows the mechanical design of the dipole magnet.

Cooling

The average power dissipation in both the yoke as well as the coil is relatively low due to the repetition rate of 15 Hz. The coils can be conduction cooled on each side. A finite element simulation shows that the temperature gradient in the coil can be kept to 2 K or less provided 500 W (for a 1 m long dipole magnet) can be transferred to the coolant. The yoke can be conduction cooled via the external faces.

SUMMARY

A conceptual design of a dipole magnet is described in this paper which is suitable to be operated at 400 Hz with a repetition rate of 15 Hz. Using two different materials for the yoke (FeCo and 6.5 %SiFe), the losses can be minimized while at the same time achieving high magnetic fields. The presented design delivers a good field quality up to about 2T. For this field level the average power loss for an entire ring (2 km total dipole length) is about 1.5 MW.

It is planned to carry out activation studies of the yoke, which is a concern due to the cobalt content.

THE ILLINOIS ACCELERATOR RESEARCH CENTER

R. Kephart#, J. Anderson, C. Cooper, S. Henderson, C. Schmidt
Fermi National Accelerator Laboratory, Batavia, IL 60510, USA

Abstract

Particle accelerators are an enabling technology not only utilized in their traditional role for fundamental research, but also in such diverse fields as medicine, industrial processes, environmental mitigation, and national security. In recognition of this large impact on the US economy, the Fermi National Accelerator Laboratory (FNAL) has partnered with the Illinois Department of Commerce and Economic Opportunity (DCEO) and the Department of Energy's Office of High Energy Physics (DOE/OHEP) to build the Illinois Accelerator Research Center (IARC). Located on the Fermilab campus, this 83,000 square foot facility will house office, technical, and educational space in a state-of-the-art facility for accelerator research, development, and education. With a strong focus on industrial application of accelerator technologies, IARC will attract high-tech companies to Illinois and help train Illinois citizens in advanced technologies.

INTRODUCTION

IARC was conceived and proposed by Fermilab and DOE to the State of Illinois in 2007. The need for a US facility like IARC was recognized at the Accelerators for America's Future symposium held in Washington DC in Oct 2009. The 2010 report from this symposium contains a wealth of information on the basic justification for investment in accelerator applications as well as the opportunities for new accelerator applications for a facility like IARC [1]. Following the lead of this symposium, the 2012 Senate Water and Energy Bill encouraged DOE to pursue the development of accelerator applications more aggressively [2,3]. It requested DOE/OHEP to provide a plan to address the opportunities made evident in the Accelerators for America's Future symposium. In 2011, OHEP convened an Accelerator R&D Task Force to offer advice on the creation of such a plan. An interim report from this committee was presented at the High Energy Physics Advisory Panel (HEPAP) meeting in March 2012 [4]. The final report to the House and Senate Appropriations Subcommittees was completed in September 2012. Through this request by Congress, OHEP is now the designated steward of accelerator science and technology within the DOE Office of Science complex, with a new thrust toward applied technology.

Key to the success of IARC will be a shared understanding at the national, state, and local levels that translational technology, namely developing ideas from the laboratory into commercial practice, only happens when the proper environment is cultivated. The proper environment promotes friendly, flexible collaboration with industry and universities and provides sufficient seed resources such that non-traditional and multi-disciplinary efforts can flourish.

In 2014 Fermilab plans to increase its partnerships with industry via Work for Others (WFO) and Cooperative Research and Development Agreements (CRADA's). When the physical plant is completed for occupancy in 2015, the IARC facility will attract industrial partners to develop technology for accelerator applications, encourage development of intellectual property by laboratory and university accelerator staff, and provide a National Center for Accelerator Education. The goal is a successful IARC program that exploits and leverages resources from DOE OHEP, Small Business Innovation Research (SBIR) programs, DCEO, and other public funding with substantial private investment from industry and the venture capital community. These funds will be used to translate ideas in accelerator technology into new high tech products and industries and to create an educational program to train the skilled workforce to build and operate the accelerators of the future.

A key concept for the IARC program is that it serves as a portal to allow industrial access, not just to the IARC physical plant, but also to the facilities and technical expertise of the entire laboratory. A successful program at IARC will lower barriers for Laboratory – Industry cooperation on accelerator technology and applications and enable an entire new class of projects to be undertaken as Government-Industry partnerships.

MISSION STATEMENT

The mission of IARC is to partner with Industry, University, and Laboratory collaborators to promote the development of accelerator technology and applications, leading to new products, capabilities, and businesses. The IARC education program will support and enable the creation of the high technology workforce required for its mission.

THE VISION

The vision for IARC is the creation of a friendly, flexible environment to facilitate collaboration with industry, universities, and other national labs and to help provide sufficient seed resources such that non-traditional and multi-disciplinary efforts can flourish. The IARC environment will allow access and leverage of Fermilab's unique facilities and staff to create an innovation hub for new Accelerator based technologies and industries.

When the IARC physical plant is complete in 2015, the laboratory envisions attracting industrial partners to develop technology for industrial accelerator applications; encouraging the development of advanced innovative accelerator science and technology as well as intellectual

Copyright © 2013 CC-BY-3.0 and by the respective authors

property by laboratory and university staff; and creating a National Center for Accelerator Education.

The key components of the IARC mission and vision are:

- Partnerships with industry, university, and laboratory collaborators to promote the development of accelerator technology, projects, and applications.
- Creation and support of entirely new U.S. based high tech industry sectors based on accelerator technology that enables new products and capabilities.
- Partnerships with universities to create a national educational center for accelerator science and technology.

IARC'S VALUE TO INDUSTRY

IARC will offer value to U.S. industrial companies and entrepreneurs by:

- Helping to overcome the technical barriers that currently impede development of ideas into new accelerator based applications and businesses.
- Serving as a portal organization to provide industry with better access to the extensive expertise in accelerator science and technology available from the Fermilab staff as well as the staff at nearby Argonne National Laboratory.
- Providing access to the specialized and unique accelerator infrastructure at Fermilab.
- Enabling and encouraging collaborations to propose and demonstrate the use of accelerator technology for new applications or markets.
- Serving as a Center for Accelerator Education allowing industrial staff to acquire needed technical skills to pursue businesses based on accelerator technology

CAPABILITIES AVAILABLE TO INDUSTRY THROUGH IARC

IARC will provide unique infrastructure for the development of new accelerator based products and businesses. However, key to its success is the powerful core capabilities available at the entire laboratory. The Accelerator Sector at Fermilab is made up of nearly 700 Scientists, Engineers, and Technical staff. Staff members have extensive experience spanning decades of design, construction, and operation of some of the most technically challenging accelerator components, accelerator systems, and facilities in the world. A brief summary of some specific areas of expertise and excellence that currently exist at the laboratory are listed in Table 1.

Table 1: Fermilab Core Capabilities Available to IARC Partners

Core capabilities	Areas of Expertise
Accelerator Science	Beam dynamics and theory Simulation and Modeling Phase-space manipulation Energy Deposition
Accelerator Operation	Operation and commissioning of large, complex accelerator systems
Accelerator Technology **(design, fabrication, test)**	Linear and circular particle accelerators Superconducting RF cavities Superconducting magnets Cryomodules Conventional, and pulsed magnets Magnet field mapping Beam Cooling systems Design of high power targets High and low-level RF systems Cryogenic Refrigeration systems
Accelerator Engineering	Accelerator design & fabrication Accelerator integration & commissioning Accelerator system cost estimates Design of accelerator RF systems Radio Frequency system modeling Low and High power electrical systems Water cooling systems Energy deposition and activation Cryogenic Engineering
Particle Detectors	Advanced Detector development Beam test of detectors Custom ASIC development
Controls Engineering	Control systems modeling and design Control & Interlock systems Data acquisition systems VHDL, PLD, PLC, DSP programming
Computing	Management, analysis of large data sets High speed parallel (GRID) computing High speed networks Data Storage and Cloud computing

The Fermilab accelerator sector staff and that of nearby Argonne National Laboratory represent the largest collection of Accelerator capability in North America. Similarly, the challenging experimental particle physics program at Fermilab has created world class capabilities in particle detector development and in advanced computing.

FACILITIES AVAILABLE TO INDUSTRY THROUGH IARC

IARC, located in the heart of the Industrial and Technical area of the Fermilab campus, will consist of 36,000 square feet of heavy assembly, technical, and office space in an existing Heavy Assembly Building (HAB) plus 47,000 square feet of new technical, office, and educational space in the State of Illinois funded addition. These two buildings make up the IARC complex.

The OTE building will provide office space for scientists, engineers, and administrative staff from Fermilab and IARC industrial, university, and laboratory partners. The OTE building provides meeting rooms, a

Copyright © 2013 CC-BY-3.0 and by the respective authors

lecture hall, and technical lab space. The layout of OTE and the nearby Heavy Assembly Building (HAB) is shown in Figure 1, which also indicates IARC's location in relation to the buildings that make up the Fermilab "Industrial Complex".

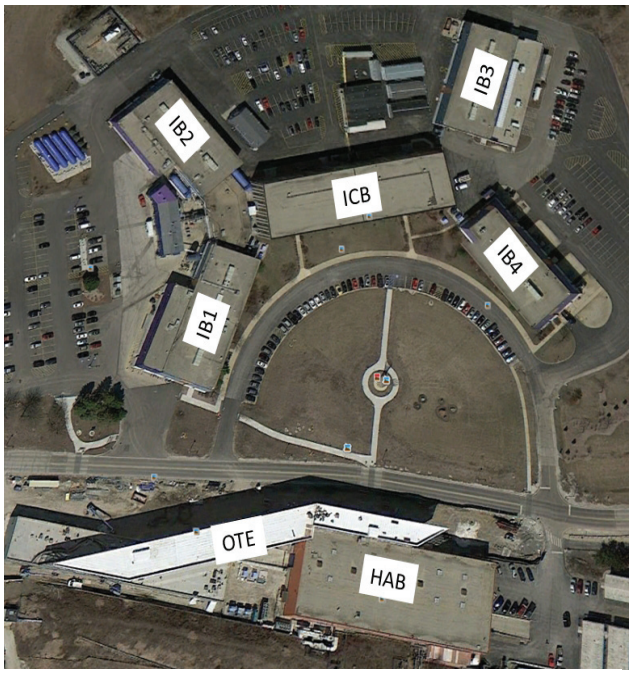

Figure 1: The IARC OTE & HAB Buildings shown in the Technical Division Complex.

The Industrial Complex houses the bulk of the Fermilab Technical Division (TD). TD staff located in the Industrial Complex includes experts in conventional and superconducting magnets, experts in warm and superconducting RF technology, and a powerful superconducting materials technology group. It is planned to move the Accelerator Physics Center (APC) to the OTE building with the goal of integrating FNAL staff with industrial and university partners encouraging exchange of information and true partnerships. APC has a long history of working with industrial partners on diverse topics. Members of the APC staff have strong Accelerator Physics, Beam simulation, and energy deposition capabilities.

The industrial complex includes extensive technical infrastructure for the development of accelerator components. Additional technical infrastructure at other locations on the Fermilab campus will also be available to IARC partners. Several test accelerators and beams will also be made available to IARC partners.

The IARC OTE Building can be seen in Figure 2. The IARC HAB, seen in Figure 3, was formerly used as the assembly building for the Collider Detector at Fermilab (CDF). CDF was a large 5000 ton experimental detector used at the Fermilab Tevatron collider. This building has a large assembly area equipped with 50 ton and 10 ton overhead crane coverage, and also has a deep pit that is ideal for testing or operating pilot scale accelerators or any similar equipment that will require radiation shielding. Extensive test and operation infrastructure already exists in this facility, including cryogenic refrigeration, low conductivity cooling water, and 1.5 MW of installed electrical power feeds. The HAB also has additional office space, meeting areas, and a technical shop with equipment for general machining.

Figure 2: Illinois Accelerator Research Center (Office Technical and Education addition) under construction at Fermilab.

Figure 3: Photo of the interior of the IARC Heavy Assembly Building.

A successful program at IARC will lower barriers for Laboratory – Industry cooperation on accelerator technology and applications and enable an entire new class of projects to be undertaken as Government-Industry partnerships. In this spirit we have compiled a list of the extensive technical infrastructure and test capabilities available at Fermilab via the IARC program. Table 2 lists fabrication and test capabilities at Fermilab, while Table 3 lists Fermilab test accelerator and beam test facilities.

Table 2: Fabrications and Test Capabilities at Fermilab

Facility	Capability	Specifications
Technical Division IB1	Superconducting RF cavity test facility.	3 vertical test Dewars 3.6 m in depth 0.86 m in diameter 1.4 K min temperature
	Conventional magnet test and mapping facility	3 horizontal test stands Pulsed power supply 750V, 25 kA, 2 HZ Complete magnet mapping capability
	Superconducting Magnet Test and Mapping facility.	Vertical Dewar 3.85 m deep 0.6 m diameter 1.8 K capability; Horizontal

Facility	Capability	Specifications
		SC magnet test stands 2 or 4 K SC magnet Power supply (30 KA, 30 V); Interlocks and DAQ
	Cryogenic System	Helium refrigerator: 1,500 watts at 4.5K or 300 l/hour liquefaction
Technical Division IB2	Conventional magnet fabrications and repair.	25 ft long curing and de-bonding ovens 7 ft dia, 250 F, vacuum furnace; Lamination stacking and winding of large conventional magnet coils
Technical Division IB3	Superconducting magnet development and fabrication	SC cable machine; SC cable winding line 7 meter curing presses Nb3Sn reaction ovens Analytical equipment: Scanning electron microscope with Energy Dispersive Spectroscopy, Laser confocal and contact surface profilometry, FT-IR/TGA, Stress/Strain equipment, Residual resistivity ratio testing
Technical Division IB4	Quality Control Cavity Processing Lab	Large CMM machines State of the art cavity tumbling machine Electro-polish tool for SRF cavities; Class 10 clean room High purity, high pressure water rinse, Small and large 1000 C vacuum furnaces
Technical Division ICB	High Bay Assembly Area	Large high bay area with two 30 Ton overhead cranes and extensive Cryomodule assembly infrastructure
Technical Division MP9	Large Clean Rooms Clean SRF assembly Large Vacuum Oven	Large class 10- class 100 clean room; Fixtures for the clean string assembly of SRF cryomodules, Titanium welding infrastructure Large 1000 C high vacuum oven.
Technical Division MDB	Dressed Cavity Test Facility	Test of dressed SRF cavities at 2 K with pulsed or CW RF. 3 stands in 4 Shielded reconfigurable enclosures 1800 W @ 4K of cryogenic refrigerators Large vacuum pump provides 100 W at 2 K.
ANL-Fermilab Cavity Processing Facility	Surface processing and clean assembly of SRF cavities	Class 10 clean room for assembly; 2 EP/BCP tools for chemical surface processing of SRF cavities; 2 high pressure rinse systems; Ultra-clean water system; Trained Fermilab and ANL staff Facility located at Argonne Nat Lab.
Accelerator Division CMTF	CryoModule Test Facility	Test of SRF cryomodules at cryogenic operating temperatures and with RF Power. The facility is equipped with two large cryogenic refrigerators and can easily be adapted for other cryogenic testing activities.
Technical Division Solenoid Test Facility IB1 & CHL	Testing of large cryogenic magnets powered and at operating temperature	Proximate to the Tevatron Central Helium Liquefier. This facility and its large test Dewar is capable of testing very large magnets at 4 Kelvin.

Table 3: Fermilab Test Accelerator and Beam Test Facilities

Facility	Description
NML Pulsed SRF Facility	Currently this facility consists of a 40 MeV photo-injector and a facility to allow cold test of single 1300 Mhz cryomodule. Proposed as the basis of a world class Advanced Accelerator R&D (AARD) program. (see ASTA below)
Advanced Super-conducting Test Accelerator (ASTA)	ASTA is envisioned to contain 3 to 6 ILC/PX 1300 MHz cryomodules each containing eight cavities. Beam lines and test areas will support a user facility for a world class advanced accelerator research program. ASTA will provide intense electron beams from 50 to 800 MeV/c energies. A small storage ring IOTA with the capability of storing either electrons or protons is also planned to explore new techniques to store intense beams. See: http://apc.fnal.gov/programs2/ASTA_TEMP/index.shtml
Fermilab Test Beam Facility (FTBF) At MDB	A high energy beam facility devoted to Detector R&D. The facility consists of two versatile beamlines (MTest and MCenter) in which users can test equipment or detectors. Details can be found at http://www-ppd.fnal.gov/FTBF/.
MuCool Test Area (MTA)	Used for R&D on ionization cooling components for the Muon Accelerator Program (MAP). The facility includes an experimental hall with radiation shielding, a 600 W cryogenic plant , access to 400-MeV high-intensity H- beam from the Fermilab Linac, 201 & 805 MHz RF power, a large-bore solenoid magnet, liquid helium and nitrogen, vacuum and hydrogen safety systems, Details can be found at http://mice.iit.edu/mta/.

Facility	Description
Project X Injector Experiment (PXIE)	PXIE is the integrated systems test for the Project X frontend. It is expected to accelerate a 1-mA CW beam up to 30 MeV with 1 mA average current. See: http://www-bdnew.fnal.gov/pxie/

SCHEDULE AND TIME LINE

The near term plans for IARC focus on construction of the IARC facilities and development of the business plan. This will be followed by launching the Accelerator Applications Program and then the Education Program.

The shell of the State funded OTE Building is finished and the building is scheduled to be complete in December of 2013. Building layouts that will optimize the different functions of IARC are being finalized so that outfitting of the OTE can begin in January of 2014. This will allow for beneficial occupancy of the OTE building in September of 2014.

Preparation of the HAB has 3 concurrent projects currently: Removal of old experimental equipment from the building, Life Safety Upgrades, and refurbishment. The main schedule driving element is decommissioning of the Tevatron CDF detector including heavy steel work and removal of over 2500 T of experimental equipment from the deep pit of HAB. Assuming adequate funding in FY14, it is envisioned that HAB Deconstruct and Decommission (D&D) will complete by the end of 2014. The HAB Life Safety Upgrades are scheduled to be complete in October of 2014.

Completion of OTE, HAB D&D, and HAB life safety projects will allow Industrial Partners to begin to utilize portions of the IARC facility in early 2015. The HAB Refurbishment project will modernize the 2nd and 3rd floors of HAB as the space is reconfigured into office, meeting, and technical spaces. A new HVAC system and controls, new insulated exterior, new windows and other modifications will allow the building to meet required energy and ADA standards.

In parallel with the construction of the IARC physical plant, the business plan and IARC program will be further developed by the IARC Staff, Fermilab Directorate, Fermilab DOE Site Office, and DOE Office of High Energy Physics leading to the launch of the formal IARC Accelerator Applications and Education programs.

THE PARTNERSHIP MANAGEMENT CHALLENGE

IARC is expected to drive significant changes in the way Fermilab interacts with industry. This Partnership Management Challenge has three major components:

- Forming new relationships
- Negotiating agreements
- Protecting Intellectual Property

Historically, Fermilab's communication program has focused on announcing scientific discoveries and promoting the Laboratory's technology transfer success stories to DOE, elected officials, industry, and the general public. As IARC develops, Fermilab will need a more comprehensive program to advertise licensing opportunities; coordinate events to attract new industrial partners; enlist the support and participation of industry groups and/or venture capital firms; and many other activities that require advanced marketing and sales techniques.

On a daily basis, IARC team members may be collaborating with other Fermilab scientists and engineers; industry or university partners; Department of Energy program managers or contracting officers; other research facilities, both U.S. and foreign; elected officials; or even the public. Each of these stakeholder groups has a different culture, a different language, and different expectations for partnering with the Lab. One of the top priorities for IARC and the Office of Partnerships and Technology Transfer (OPTT) is to establish simple and efficient processes for initiating, developing, negotiating, and administering a variety of partnership agreements that will meet the needs of these different stakeholder groups.

Ultimately, a key outcome of the IARC Program is to promote the commercialization of new technologies in support of U.S. competitiveness. In order to promote commercialization, these new technologies must be protected, which represents a major culture shift for Fermilab researchers. Intellectual property management is a very specialized field of knowledge covering the protection and licensing of intellectual property, such as copyrights, trademarks, patents, mask works, industrial design rights, tangible research products, and trade secrets. IARC Program management and OPTT are working together to develop an intellectual property management program that will provide the tools and training to help IARC team members work effectively in this new culture.

ACKNOWLEDGMENT

The authors would like to acknowledge Pier Oddone, for his personal support, Bob Hamm for his contributions to the business plan, Mike Weis, and Mark Bollinger, DOE Fermi Site Office for their strong support, and the Department of Energy, Office of High Energy Physics, and the Illinois Department of Commerce and Economic Opportunity without whose financial support the IARC would not exist.

Abstract

Although the growing utilization of computed tomography (CT)-based imaging has led to major advances in diagnostic capabilities, it has also resulted in higher cumulative radiation doses to patients. In order to fully exploit the benefits of high-resolution diagnostic CT scans while minimizing the risks of radiation-induced cancer, the realization of low-dose CT is crucial. Recent research has shown that the use of protons, rather than X-rays, for CT has the potential to greatly reduce the radiation dose delivered to the patient without reducing image quality. RadiaBeam Technologies, in collaboration with the Loma Linda University Medical Center and the University of Texas at Austin, is proposing the development of a proton CT scanner utilizing laser-driven ion acceleration (LDIA) techniques. The initial design of this system is presented.

NEED FOR LOW-DOSE CT

With over 62 million scans performed each year in the United States alone, computed tomography (CT) is a crucial tool for diagnostic radiology. Over the last 15 years, there has been a large increase in the utilization of diagnostic CT imaging procedures and therefore a subsequent increase in radiation exposure. As CT scans are responsible for nearly 50% of the radiation exposure from medical imaging in the U.S., the risks associated with its relatively high radiation dose, which can be two orders of magnitude greater than corresponding X-ray radiographs, become more and more of a concern [1]. Dose reduction is especially important for pediatric diagnosis, since children are both more sensitive to radiation and have more time for developing radiation-induced secondary cancers.

PROTON CT

Recent research has shown that the use of protons, rather than X-rays, for CT has the potential to reduce the radiation dose by an order of magnitude without reducing image quality [2], [3]. Ongoing studies of proton CT (pCT) at Loma Linda University Medical Center (LLUMC) are being performed to develop this technology for improving the accuracy of treatment planning in hadron therapy.

Principles of pCT

The first requirement for pCT is the production of a proton beam with high enough energy to fully penetrate the body part to be imaged. Protons with energies 200 - 250 MeV would be necessary for performing a typical head scan, while 330 MeV protons would be able to span most human torsos (60 cm range). Position-sensitive detectors are placed on either side of the subject to track the entry and exit points of each proton. The energy loss of individual protons is then measured with an energy detector/range counter, as shown in Figure 1.

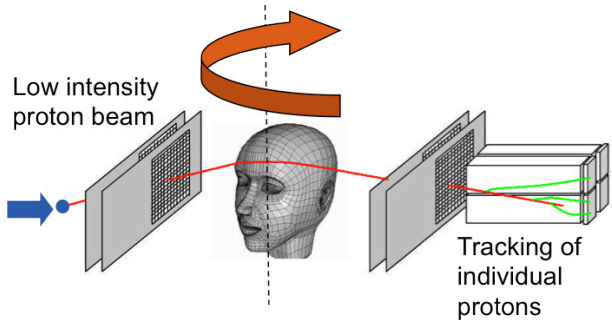

Figure 1: Conceptual design for a pCT scanner [Courtesy of R. Schulte, LLUMC].

Images can be created from the individual proton histories through the use of iterative reconstruction algorithms and path concepts such as the "most likely path" approach, as illustrated in Figure 2.

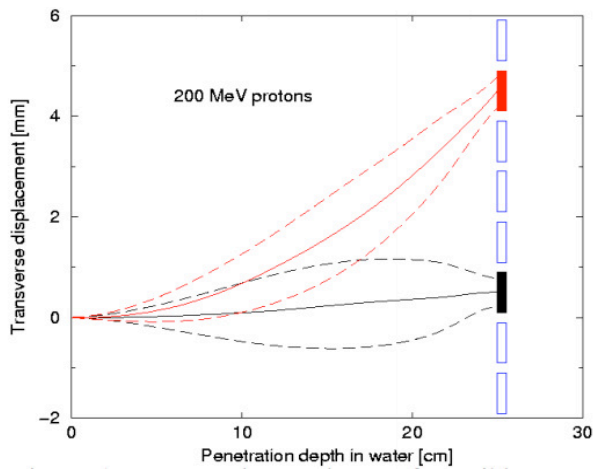

Figure 2: Monte Carlo simulation – solid lines: the most likely path of 200 MeV protons with exit displacements of 0 and 4 mm after traveling 25 cm in an object with water density; dashed lines: one sigma envelopes from Monte Carlo.

pCT Research at LLUMC

Over the last ten years, researchers at LLUMC have been developing pCT technology for improving the

Copyright © 2013 CC-BY-3.0 and by the respective authors

accuracy of treatment planning for hadron therapy. Currently, planning for proton therapy is done using X-ray CT, from which the relative stopping power of protons is reconstructed. However, there is a significant degree of error associated with this conversion that results in a range uncertainty between 3 and 5% for soft tissues [4]. This often causes conflict between the physician's desire to completely cover the tumor volume and the need to spare healthy surrounding tissue. When protons are used for treatment planning rather than X-rays, this conversion is bypassed and the stopping power can be reconstructed directly.

Between 2008 and 2010, LLUMC and their collaborators developed a Phase I scanner to prove the feasibility of pCT [5]. Rather than develop custom detectors for this prototype, they used the silicon strip detectors and data readout from the Fermi Space Telescope, which was a NASA GLAST Mission. They also used a multi-segmented crystal calorimeter for residual energy measurements, an FPGA-based data acquisition (DAQ) system, and a GPU-based reconstruction system. The scanner was then tested with different phantoms to demonstrate density resolution; the radiographs are shown in Figure 3.

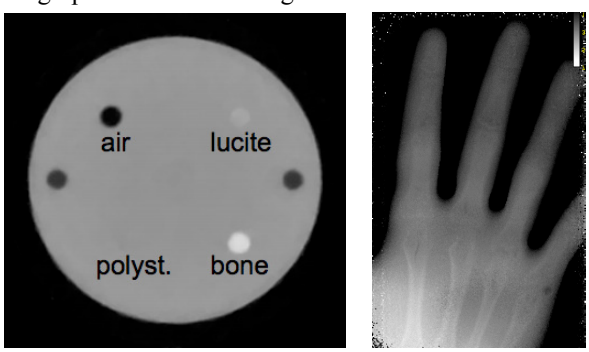

Figure 3: Left: Radiograph of a polystyrene head phantom with inserts of various densities (bone, polystyrene, Lucite, and air); right: radiograph of a hand phantom demonstrating high contrast between bone and soft tissue [Courtesy of R. Schulte, LLUMC].

In 2011, the group began the development of a Phase II pCT scanner featuring several major improvements. This scanner will have improved detectors with twice the active area (9 cm x 36 cm) and slim edges for reducing the dead space from overlapping silicon strips. It will also feature a simplified energy detector consisting of a 5-stage scintillator with a photomultiplier tube (PMT) readout scheme. The total scan time will be reduced to around five minutes through the development of a dedicated application-specific integrated readout (ASIC), and a GPU cluster will enable reconstruction in under ten minutes. This scanner is currently in the final stages of development.

DIAGNOSTIC PROTON CT

Although the research at LLUMC has clearly demonstrated the feasibility of pCT for improved treatment planning, the need for massive therapeutic proton accelerators and expensive proton gantries makes this development impractical for diagnostic applications. It can cost up to $150 million to build a proton therapy facility [6] (with an additional $21 million in yearly operational costs), compared to about $5 million for a conventional CT system.

In order for the diagnostic utilization of pCT to be possible, lighter, more compact accelerators that can be more easily rotated around the patient must be developed.

Advantages

The main advantage of diagnostic pCT is the major dose reduction from conventional X-ray CT. The estimated dose from a pCT scan is between 0.03 and 0.3 mGy, which is a potential reduction of about two orders of magnitude. This would justify the use of CT for a much broader range of diagnostic applications where the potential benefits were previously outweighed by the risks of excessive radiation exposure, such as pediatric diagnosis and patients with conditions requiring frequent imaging.

Another advantage of pCT over X-ray CT is its potential for quantitative imaging and its superior representation of electron density [4]. pCT has the potential to detect very small changes in density, which could make it useful for applications such as lung cancer screening. It could also provide better bone density measurements for patients with osteoporosis and improve detection of kidney or urinary stones, which are sometimes difficult to see on an X-ray image.

Collaboration

To meet this need, an international collaboration of scientists, doctors, and engineers has been established. The ultimate goal of this collaboration is the development of a compact diagnostic CT system for low-dose (sub-mSv) imaging. The institutions involved and their roles in the project are given in Table 1.

Table 1: Collaborating Institutions and Project Roles

Institution	Project role

Approach

The crucial reduction in system size and cost for diagnostic pCT may be feasible with the implementation of innovative Laser-Driven Ion Acceleration (LDIA) technology. LDIA of highly energetic ion beams is a cutting-edge area in advanced accelerator research. Electrostatic fields in excess of 10^{12} V/m, produced via charge separation within a small area of several micrometers defined by the laser beam's focus, are theoretically capable of accelerating protons or heavier ions to energies suitable for imaging.

Dr. Manuel Hegelich, the main collaborator at UT Austin, is an expert in LDIA and will be leading the research efforts for the acceleration scheme. Dr. Hegelich was previously at Los Alamos National Laboratory, where his group demonstrated laser-driven protons with record-breaking energies of over 160 MeV [7]. Although this is still not quite high enough for imaging, this project will be utilizing a much more powerful laser. With the Texas Petawatt Laser at UT Austin, the most powerful laser in the world, energies of over 300 MeV should be achievable.

There are several requirements that must be met in order to develop a useful, accurate, and commercially relevant system. These specifications are outlined in Table 2.

Table 2: Requirements for a Diagnostic pCT System

Specifications	
Energy	330 MeV
Intensity	10^6 protons/second
Detection rate	1 MHz
Size	Single room
Scan time	~5 minutes
Cost	Comparable to X-ray CT (~$5 million)

POTENTIAL CHALLENGES

Although previous research strongly suggests the feasibility of the proposed system, there are several aspects of this project that may present challenges. The biggest challenge will be the development of a novel acceleration scheme to achieve the necessary beam specifications for imaging. Current LDIA techniques can produce a high-energy beam, but with very high intensity (~10^9 protons/pulse) and extremely low repetition rate. This is essentially the opposite of an ideal beam for pCT, which would be a rapid stream of individual protons to simplify detection and reconstruction. There are several acceleration techniques currently being explored to overcome this problem, but if the intensity cannot be sufficiently reduced, there is also the option of improving the spatial resolution of the detectors. In other words, it may be possible to compensate for the inability to temporally resolve each proton history by instead resolving them better spatially.

The system must also be sufficiently fast to acquire the scan quickly enough to ensure patient comfort and perform the image reconstruction in a relatively short amount of time. To achieve this level of speed, a DAQ and reconstruction system similar to LLUMC's Phase II scanner will have to be developed, with a dedicated ASIC and GPU cluster.

Although the development of diagnostic pCT will require many years of research, development, and testing, the success of such a system would have a major impact on diagnostic imaging and patient safety. While there are some challenges in the implementation of this technology, as previously mentioned, this strong collaboration of institutions should have the necessary expertise and experience to overcome such hurdles.

OPTIMAL 3D QUADRUPOLE SHAPES*

R. Baartman, TRIUMF, 4004 Wesbrook Mall, Vancouver, BC, V6T 2A3, Canada

Abstract

The usual practice of constructing quadrupoles from truncated cylindrical hyperbolae is put into question. A new shape is proposed. This shape has an analytic potential function. The exact shape of the analytic quadrupole may be impractical, but in the short case where aspect ratio ≈ 1, pole shapes can be spherical. The optimal spherical radius is found to be 1.54 times the aperture radius. An example is also given demonstrating that in the long quad limit, the aberrations of order 5 and higher are much lower for the optimized shape.

A somewhat extended version of this paper has been published previously [1].

INTRODUCTION

The multipole elements commonly used to control charged particle beams correspond to solution terms of the Laplace equation $\nabla^2 V = 0$, namely, in polar coordinates (r, θ), $r^n \cos n\theta$ in the system where the potential on axis is zero. Thus $n = 2$ for a quadrupole, 3 for a sextupole, etc. This implicitly assumes the elements are infinitely extended in the axial (z) direction, and of course in real beamlines, they are not. For $n = 2$, the intended linear dependence of the fields upon transverse coordinate is thus broken by the finiteness of the quadrupole. This results in nonlinear force terms and aberrations.

It is not obvious how to axially terminate the poles of a quadrupole. Often, they are simply truncated. Does the shape in the longitudinal direction matter? And if so, what shape is optimal? For very long quadrupoles, it can be argued that hyperbolic equipotential surfaces given by $r^2 \cos 2\theta$ = constant are optimal. However, this is only true sufficiently far from the ends; for quadrupoles whose length is comparable to or shorter than the aperture, the 2-D hyperbolic shape is clearly not optimal. What then is the optimal shape of quadrupoles in the short limit? What is the optimal shape in the long limit? Answering these questions is the subject of this paper.

Hardness of the Fringe Field

In the limit where the fringe field extent is short compared with the focal length of the quadrupole, the lowest order aberration (cubic force) effect is independent of fringe field shape. This was shown in 1997 [2].

Let the strength function of the quadrupole be $k(z)$. Rigourously, this means $\partial_{xx} V = -\partial_{yy} V = k(z)$ along the axis $x = y = 0$, so that

$$V(x, y, z) \to \frac{k(z)}{2}(x^2 - y^2) \text{ as } (x, y) \to (0, 0), \quad (1)$$

In the "hard-edge" limit, k is a step function. But using a discontinuous step function instead of an analytic function to calculate the optics leads to dramatically incorrect results. It is thus regrettable that almost all the major higher order optics codes allow calculation of third order optics in the "no fringe field" case. This case is unphysical because it brings a particle from the field-free region outside the quadrupole instantaneously into the region where $k \neq 0$ without traversing intermediate fields. For example, for electrostatic quadrupoles, this violates conservation of energy as the potential energy is thereby incremented without changing the kinetic energy (in magnetic quadrupoles, angular momentum conservation is violated).

The beamline designer may have learned that the third order aberrations calculated without fringe fields are incorrect, but he/she is still left with the impression that the fringe field is at fault and customizing it in some way will improve the third order optics. Further, of quadrupoles with the same effective length, those with short fringe fields are erroneously thought to be superior even though this often means they have smaller aperture. In fact, such quadrupoles are inferior, as their fifth order aberrations are worse: it can be shown that in the hard-edge limit, fifth order aberrations are singular [3].

ANALYTIC QUAD

A technique for finding the potential in all space given only the strength function $k(z)$ is given by Derevjankin [4, this reference is in Russian, but referred to by Vasil'ev [5]]:

$$V(x, y, z) = -\Re\left\{\int_{z+iy}^{z+ix} dt \int_0^t k(\zeta) d\zeta\right\} \quad (2)$$

A particularly simple case that is realistic for short quads is

$$k(z) = \frac{K}{2}\,\mathrm{sech}^2 z. \quad (3)$$

We find:

$$V = \frac{K}{2}\,\Re\{-\log[\cos(x - iz)] + \log[\cos(y - iz)]\}. \quad (4)$$

See Fig. 1 where equipotential contours are plotted using as scaling potential $V_0 \equiv V(\frac{\pi}{4}, 0, 0) = \frac{K}{4}\log 2$. The transverse fields are locally nonlinear; at $z = 0$, $F_x \propto \tan x$, $F_y \propto \tan y$. Nevertheless, the integral of the transverse field is exactly linear:

$$\int_{-\infty}^{\infty} F_x dz = Kx, \quad (5)$$

and similarly, $\int F_y dz = -Ky$. The reason for this behaviour is that farther from axis, the transverse field is

stronger at $z = 0$, but weaker at the tails (it's 'peakier'). This is clarified in Fig. 2.

Integrated linearity from a locally nonlinear quad is not a surprise: from the symmetry and Laplace's equation, it can be shown that the following expansion holds:

$$V(x, y, z) = \frac{k}{2}(x^2 - y^2) - \frac{k''}{24}(x^4 - y^4) + \ldots \quad (6)$$

Taking derivatives to find the fields, and integrating for constant x, y, we see that Eq. 5 holds for any choice of $k(z)$.

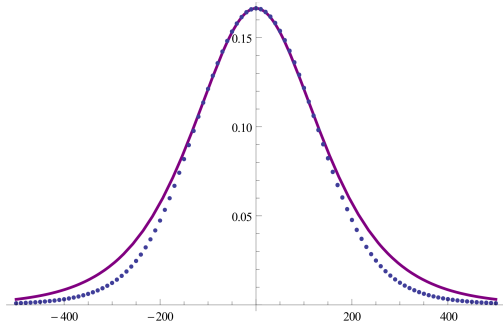

Figure 3: Magnetic field of the 12Q12 quadrupole (dots), measured at radius of 150 mm in the median plane vs. z in mm. The 12Q12 aperture radius is 155.6 mm, thus, $\sqrt{2}x = \sqrt{2}y = \frac{\pi}{4}\frac{150}{155.6}$. The continuous curve is the magnetic field at this same radius using Eq. 4, normalized to agree at $z = 0$.

EXAMPLE QUADRUPOLES

The potential V of the sech^2 quadrupole is periodic with period π in the x and y directions. At large z, the cancellation of this grid of alternating sign potentials ensures the rapid exponential falloff of the field. This is somewhat realistic. In the case of electrostatic quadrupoles, the ground planes dashed in Fig. 1 can be thought of as some approximation of the beam pipe. In magnetic quadrupoles the yoke takes the place of the ground surfaces. The yoke's proximity to the pole faces results in a characteristically quicker falloff as can be seen in Fig. 3, where the ideal sech^2 quadrupole is compared with a real quadrupole, namely, the TRIUMF 12Q12 (more on this quadrupole below).

Four choices of equipotential surfaces are shown in Fig. 4, oriented so that the quadrupole axis is vertical. Note the top left case is most like a long conventional quadrupole; the most significant difference being that the inside diameter varies along its length, as indicated by the $V = \pm\frac{V_0}{16}$ curves in the plot of Fig. 1. The lower right case in Fig. 4 would not give the correct fields without the 4 ground planes as the boundaries given by the 4 slender rods alone are insufficient. But the longer quadrupole (upper left in Fig. 4) case would work quite accurately without the ground planes.

As will be shown, this design has smaller aberrations than conventional designs, i.e. poles having constant xy cross section, truncated at each end. The only disadvantage is that the shape is rather more difficult to fabricate, having curvature on all directions.

Short Quadrupole Shapes

In the lower left of Fig. 4 (where the surfaces are strikingly similar in shape to four American regulation footballs) the potential of the shown surfaces is $\pm V_0$ and the curvature of the pole in the longitudinal direction is the same as in the transverse direction. This is an attractive feature because it allows as a good approximation for the pole to be symmetric along its axis, terminating in a spher-

Copyright © 2013 CC-BY-3.0 and by the respective authors

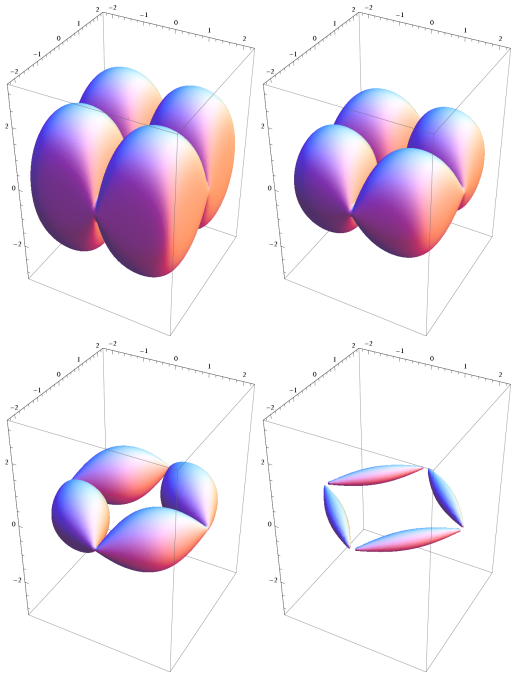

Figure 4: The coloured surfaces are 4 sets of equipotential surfaces of the potential (4). The quadrupole axis is vertical. In each case, the sides of the "box" containing the axes are also the 4 ground planes. All 4 give identical fields and the same sech^2 on-axis strength function if they are given the following potentials (left to right, top and then bottom), $\pm V_0/16, \pm V_0/4, \pm V_0, \pm 4V_0$ (adjacent surfaces have opposite sign).

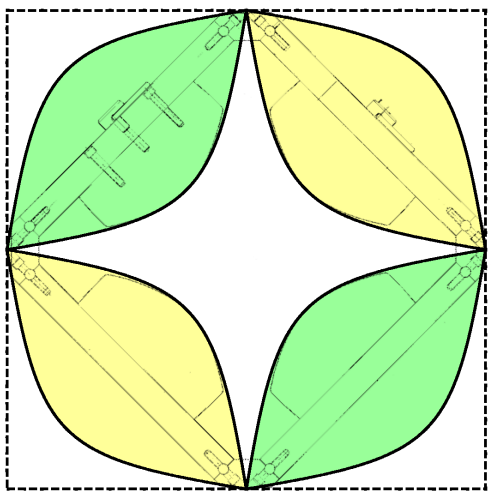

Figure 5: Cross section at $z = 0$ of the theoretical ideal sech^2 quadrupole (yellow and green) compared with drawing of the TRIUMF 12Q12 superposed. The yellow and green poles are circular in the orthogonal cross section, and hence shaped very much like the American football. The outer dashed square is at "ground" potential. Of the 12Q12 quadrupole, only the poles and the yoke are shown; coils are omitted. The black dot right of centre is the location of the Hall probe for measurements of Fig. 3.

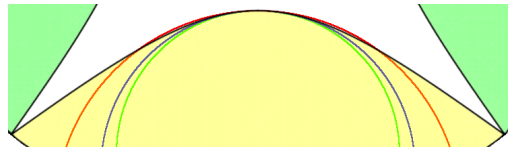

Figure 6: The "football" electrode with superposed, the circular arc of radius 1.15 times the aperture radius (green), $4/\pi$ (1.27) times the aperture radius (blue), and 1.54 times the aperture radius (red).

ical shape. What is the pole curvature that achieves this?

As the xy cross section is nearly hyperbolic, while the xz cross section is nearly a circle, it is clear that choosing a hyperboloid of revolution as shape is no better than choosing a spherical shape. The latter has the advantage that it is simpler to specify to the machinist.

As evident in the comparison in Fig. 5, the shape used for practicality, namely cylindrical poles terminating in a spherical pole-face, omits important parts of the "football" (the triangular regions either side of the poles in Fig. 5). This will have two effects: the quadrupole strength function $k(z)$ will not precisely follow a sech^2 law, and there will be some integrated 12-pole. The former is of little consequence, but the latter can cause aberration. However, just as with the case of the 2D quadrupole, we can alter the radius of curvature of the pole face to compensate the 12-pole. (20-pole and higher are not of course compensated in this technique but made slightly worse.)

In order to find the curvature radius that zeroes out the integrated 12-pole, Laplace's equation was solved for a 3D boundary model, using `OPERA`. I am indebted to Chris Philpott of Buckley Systems Ltd. (New Zealand) for performing the final optimization [6].

The result found is that the radius of curvature in units of the aperture radius is 1.54 ± 0.01:

$$\text{spherical pole-tip radius } = 1.54 \times (\text{aperture radius}). \quad (7)$$

The uncertainty arises from the grid coarseness and also from the variation due to surfaces "behind" the pole; surfaces which the engineer would be free to optimize for practicality. The potential on these surfaces also depends upon the insulator design in the case of electrostatic quadrupoles and the coil layout in the magnetic case.

This curvature is shown as the red curve in Fig. 6: one observes that it bulges past the "football" curve slightly on either side of centre. The blue curve is seen to properly match the "football" curve at the centre, and the green curvature, which is commonly used for such quadrupoles, is seen to not match the desired curvature at all. Reminder: the curvature of the ideal football shape in the direction orthogonal to the plane of the figure is essentially the blue curve.

The "12Q12" design

In the past, the short quadrupoles that have used rounded poles have used curvatures that are too sharp and as a result

Copyright © 2013 CC-BY-3.0 and by the respective authors

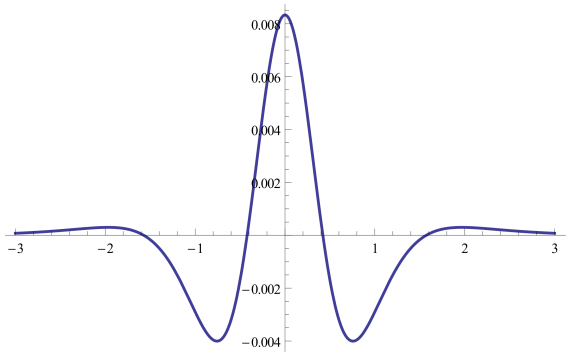

Figure 7: Fourth derivative of $k = \mathrm{sech}^2(z)$.

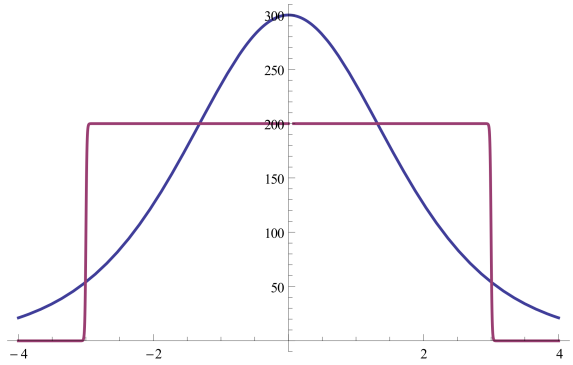

Figure 8: Gradient (in T/m) vs. z (in m) for the CERN LHC IP quadrupole (purple), compared with a sech^2 strength quadrupole of the same aperture (blue). Note that the latter quad would be impractical on two counts: its field extends outside the 6 m space allotted in the LHC, and it would need to be 1.5 times stronger at its peak. The comparison is only to illustrate that quads with optimally soft fringe fields have lower fifth and higher order aberrations.

the 12-pole does not integrate to zero. See Reeve et al. [7]. Of course, the point harmonic $A_6(z)$ is not zero, but $\propto k''''(z)$ even for the ideal pure quadrupole case. See Fig. 7 for $k = \mathrm{sech}^2(z)$. What is found in actuality is for example Fig. 11 of Reeve et al. (1976) [7]: the 12-pole looks like Fig. 7 on top of a nonzero background that is due to the incorrect pole curvature.

Recently, quadrupoles of the design "12Q12/1.5" were constructed by Scanditronix Magnet AB [8] for TRIUMF [9]. Their integrated multipole components were measured, also by Scanditronix, using a rotating coil. These magnets' radius of curvature near the pole centre is 1.14 times the aperture radius, which is too small by a factor 1.35, but this was partially offset by using a hyperboloid rather than a spherical shape. The 12-pole component was found to be roughly 20 times larger than the other multipoles: 0.0032 times the quadrupole field, at a radius of 94 mm, where the aperture radius is 155.6 mm.

Long Quadrupole Example

The aim of this example is to demonstrate that the conventional design quadrupole with a "tophat"-shaped strength function, has higher aberrations than the sech^2 quadrupole. Sech^2 quadrupoles need not be short. Refer to the $V = \pm\frac{V_0}{16}$ equipotentials in Fig. 1 to observe the shape of a long sech^2 quadrupole. The main difference in comparison with conventional quads is that the strength varies continuously along the quad. One method of obtaining this is to flare the aperture, varying it continuously from centre outward. Admittedly, this complicates the design and would increase the construction cost, especially for superconducting quads.

For illustration, we take as an extreme example the CERN LHC $\beta^\star$ quadrupoles. We take as round figures, a length of 6 m, aperture radius of 35 mm, gradient of 200 T/m, and use the Enge coefficients of the "LHCHGQ" [10]. We construct a model sech^2 quadrupole of the same integrated strength (1200 T), and same integrated squared strength of 240,000 T^2/m. This latter ensures that the third order aberrations are the same [2]. The Sech^2 strength function scaled to satisfy these two integrals is

$$k(z) = \left(300\,\frac{\mathrm{T}}{\mathrm{m}}\right)\,\mathrm{sech}^2\left(\frac{z}{2\,\mathrm{m}}\right) \tag{8}$$

Using COSY-∞ [11] and a proton energy of 7 TeV, we compared the aberrations to seventh order; these are shown in Table 1. (For the LHCHGQ, we had to modify slightly the COSY-∞ routine FFELE as the fringe field given in ref. [10] has an anomalously large extent). For the implementation of the sech^2 quadrupole in COSY-∞, see Ref. [1].

As expected, the third order aberrations are the same for the two types. The thin lens formula for the aberrations is [2]:

$$\begin{aligned}\Delta x' &= \frac{\int k^2 dz}{(B\rho)^2}\left(-\frac{1}{3}x^3 - xy^2\right) &(9)\\ &= -\frac{0.000147}{\mathrm{m}^3}x^3 - \frac{0.000440}{\mathrm{m}^3}xy^2\\ \Delta y' &= \frac{\int k^2 dz}{(B\rho)^2}\left(-x^2y - \frac{1}{3}y^3\right) &(10)\\ &= -\frac{0.000440}{\mathrm{m}^3}x^2y - \frac{0.000147}{\mathrm{m}^3}y^3\end{aligned}$$

These agree well with the values in Table 1, when the thick lens effect is taken into account. (This reduces the aberration effect in the focusing direction and exacerbates in the defocusing direction.)

But at higher than third order, the aberrations are not at all the same. The fifth order aberrations are about 200 times smaller for the sech^2 quadrupole, and the largest seventh order coefficients are roughly 100,000 times smaller for the sech^2 quadrupole. For ninth order, the ratio is 10^8.

It is doubtful that a superconducting quadrupole with Eq. 8 as strength function is at all feasible, and in any case would be too long to fit into the interaction region of the LHC. Further, there is nothing to suggest that the

Table 1: Aberration coefficients of the LHC "high gradient quadrupole", compared with quadrupole of sech^2 strength function. m and n are the exponents of x and y; for example, the fourth line is the coefficients for x^2y.

aberrations calculated for the LHCHGQ quads in any way limit the performance of the LHC. However, this comparative study puts to rest the notion that quadrupoles with smoothly varying strength function, being in a sense "all fringe field" [7], are optically inferior to more conventional quadrupoles with harder edges. In fact, quite the opposite is true.

The $k(z) \propto \text{sech}^2 z/D$ case is not special; any smoothly varying k would have similar low aberration properties. The advantage of the sech^2 case is that there is a handy, simple expression for the potential, and at least in the case of very short quads, this expression is a good approximation.

Thus our results can be understood as follows. In the traditional design, the poles terminate abruptly, and this results in aberrations that scale with the ratio of beam size to aperture, raised to a power appropriate for the order of the aberration. In the case of the design proposed here, the aberrations scale with the ratio of beam size to quadrupole length, raised to that same power.

CONCLUSIONS

We have derived an analytic potential for quadrupoles, both long and short. The strength function, instead of stepping up abruptly at the entrance and down at the exit, varies smoothly throughout the quadrupole. We have shown that this results in lower field aberrations.

NEW METHOD FOR POINT-CHARGE WAKEFIELD CALCULATION*

Boris Podobedov#, Brookhaven National Laboratory, Upton, NY 11973, USA
Gennady Stupakov, SLAC National Accelerator Laboratory, Menlo Park, CA 94025, USA

Abstract

Extending our approach recently described in [1] we present a new method to accurately calculate point-charge geometric wakefields from wake potentials due to a much longer bunch, typically obtained with a time-domain EM field solver. By allowing a relatively long bunch in the EM solver, this method can significantly reduce the need for computer resources as well as drastically shorten the computing time. On top of that, the method provides valuable physics insights. Since the method, applied to longitudinal wakes, was described in [1], the goal of this paper is to extend it to transverse wakes.

METHOD DESCRIPTION

Knowledge of geometric wakefields is critically important for studies of accelerator beam dynamics. While analytical solutions are known for a number of simple geometries, detailed wakefield calculations for realistic vacuum chamber components are typically done utilizing time domain EM solvers. They compute the fields due to finite length bunches, forcing one to use extremely fine mesh (small fraction of the bunch length) to compute wakes at small distances. This is where the longitudinal wakes are usually dominated by singularities, so that a wake potential due a bunch of rms length σ scales as $W_{\parallel}^{\sigma}(z) \propto \sigma^{-q}$, $q>0$ [2,3]. Utilizing fine meshes has severe implications for computer memory requirements as well as calculation speed. Furthermore, EM solvers cannot calculate point-charge wakes, $W_{\parallel}^{\delta}(z)$ and $W_{\perp}^{\delta}(z)$, - functions that often provide significant physics insights and simplify beam dynamics analysis.

Recently we developed a method to calculate arbitrarily short bunch wakes, including point-charge, from the wake potentials due to a relatively long bunch, thus avoiding the fine mesh requirements in the EM solver. For longitudinal wakes the method is applied as follows [1].

1. Determine analytical singular wake model for a given geometry. For collimator and cavity type structures these are usually given by the optical and diffraction models respectively, see i.e. [2].
2. Determine the length parameter λ_g, which is the first $z\neq 0$ location where $W_{\parallel}^{\delta}(z=\lambda_g)$ has a discontinuity or a singularity of its higher derivative with respect to z. The recipe is given in [1] and it is illustrated below.
3. Pick $\sigma_0 \ll \lambda_g$ (but not too short to keep the computation time reasonable) and calculate the wake potential $W_{\parallel}^{\sigma_0}(z)$ with an EM solver.
4. Subtract the singular wake model from the result:
$$D_{\parallel}^{\sigma_0}(z) = W_{\parallel}^{\sigma_0}(z) - W_{\parallel,s}^{\sigma_0}(z). \quad (1)$$
5. Fit the remainder as follows:
$$D_{\parallel}^{\sigma_0}(z \le 3\sigma_0) = \frac{\alpha+\beta z}{2}\left(1+\mathrm{erf}\left(\frac{z}{\sqrt{2}\sigma_0}\right)\right) + \frac{\beta\sigma_0}{\sqrt{2\pi}}\exp\left(-\frac{z^2}{2\sigma_0^2}\right), \quad (2)$$
where α and β are fit parameters. Fit range used here, $|z/\sigma_0|\le 3$, works very well. However, this choice is rather flexible and may be influenced by practical trade-offs, i.e. fit quality vs. computation time. Maximum z, however, must obey λ_g-z_{max}>few σ_0.
6. For arbitrary short $\sigma \le \sigma_0$, the wake is given by:
$$W_{\parallel}^{\sigma}(z \le 3\sigma_0) = \frac{\alpha+\beta z}{2}\left(1+\mathrm{erf}\left(\frac{z}{\sqrt{2}\sigma}\right)\right) + \frac{\beta\sigma}{\sqrt{2\pi}}\exp\left(-\frac{z^2}{2\sigma^2}\right) + W_{\parallel,s}^{\sigma}(z), \quad (3)$$
$$W_{\parallel}^{\sigma}(z > 3\sigma_0) = W_{\parallel}^{\sigma_0}(z). \quad (4)$$
7. Similarly, for the point-charge:
$$W_{\parallel}^{\delta}(z \le 3\sigma_0) = (\alpha+\beta z)H(z) + W_{\parallel,s}^{\delta}(z), \quad (5)$$
$$W_{\parallel}^{\delta}(z > 3\sigma_0) = W_{\parallel}^{\sigma_0}(z), \quad (6)$$
where $H(z>0)=1$ is the step-function required by causality ($z<0$ is ahead of the bunch).

Summarizing the steps above, the method basically states that for $0<z<\lambda_g$ the point-charge wakefield (with subtracted singular part) is a smooth, slowly varying function. For $0<z\ll\lambda_g$ it is well approximated by a linear polynomial with coefficients easily found by fitting.

PARAMETER λ_g

λ_g can be determined by a straightforward geometric analysis combined with the causality principle [1]. Figure 1 illustrates how to find λ_g for a simple axially symmetric cavity. In the left pipe, a bunch moving with the speed of light c, carries only static EM fields. As the bunch enters the cavity, the fields get disturbed, exciting the radiation of EM waves. Some wave-fronts (i.e. red or orange)

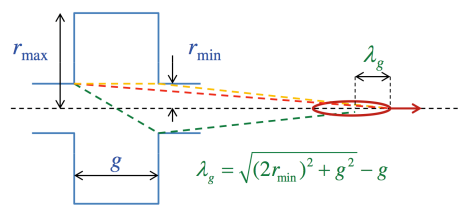

Figure 1: λ_g for a cavity with $r_{max}/r_{min}\ge 2$ and $g/r_{min}\ge 2^{-1/2}$.

eventually catch up with the bunch head, thus affecting $W_{\parallel}^{\delta}(z)$ for all values of z. Other wave-fronts (i.e. green) reflect and get delayed, so they can only affect $W_{\parallel}^{\delta}(z \geq d)$, where d is the delay times c.

Each type of reflections has two extreme values, d_e, of the delay, $d_e=d_{min}$ and $d_e=d_{max}$. For instance, all the rays that reflect once off the 2nd cross-sectional step at $r=r_{min}$, are delayed between $d_{min}=0$ (orange ray) and $d_{max}=(4r_{min}^2+g^2)^{1/2}-g$ (green). In general, parameters d_{min} and d_{max} define the z-range where a given reflection type affects $W_{\parallel}^{\delta}(z)$. Thus the points $z=d_e$ contain the discontinuities of the $W_{\parallel}^{\delta}(z)$ function or the singularities of its higher derivatives with respect to z.

The parameter λ_g can thus be found as the minimum of all the non-zero d_e values over all the possible reflection types. For the geometry of Fig. 1, the reflections off the 2nd cross-sectional step have the minimum positive d_e (for the green ray), compared to all the other reflection types, so λ_g is given by the formula shown in the figure.

For shallow cavities, outer-wall reflections result in yet smaller $d_e>0$, causing the replacement, $r_{min}\rightarrow r_{max}-r_{min}$, in the formula for λ_g. Finally, the smallest d_e for a short cavity is due to double reflections between the cavity side-walls, resulting in $\lambda_g=2g$. These three cases include all the possible formulas for λ_g for any r_{max}, r_{min} and g.

For complex geometries the number of different reflection types can be large, but since λ_g is defined by the minimum delay, identifying the relevant type is straightforward [1].

EXTENTION TO TRANSVERSE WAKES

The method above is directly applicable to transverse wakes except for a couple of simple changes. First, since these wakes are not singular, formally step 4 becomes obsolete. Nevertheless, if a short-bunch asymptotic wake model is known, subtracting it and then fitting the residual, $D_{\perp}^{\sigma_0}(z)$, may sometimes result in a better model of the point-charge wake. This will be illustrated later.

Second, the transverse counterpart of (5) should be generally written with an additional parameter κ,

$$W_{\perp}^{\delta}(z \leq 3\sigma_0) = \left(\kappa + \alpha z + \beta z^2\right) H(z), \qquad (7)$$

thus modifying (3) and (2) to, respectively, (8) and (9):

$$W_{\perp}^{\sigma}(z \leq 3\sigma_0) = \frac{\kappa+\alpha z+\beta(z^2+\sigma^2)}{2}\left(1+\mathrm{erf}\left(\frac{z}{\sqrt{2}\sigma}\right)\right) + \frac{(\alpha+z\beta)\sigma}{\sqrt{2\pi}}\exp\left(-\frac{z^2}{2\sigma^2}\right), \qquad (8)$$

$$D_{\perp}^{\sigma_0}(z \leq 3\sigma_0) = \frac{\kappa+\alpha z+\beta(z^2+\sigma_0^2)}{2}\left(1+\mathrm{erf}\left(\frac{z}{\sqrt{2}\sigma_0}\right)\right) + \frac{(\alpha+z\beta)\sigma_0}{\sqrt{2\pi}}\exp\left(-\frac{z^2}{2\sigma_0^2}\right). \qquad (9)$$

Note that here, the transverse wake parameters α and β are different from those in the (m=0) longitudinal wake above. Rather, they are related to the corresponding parameters of the m=1 longitudinal wake. Also, in most cases, $W_{\perp}^{\delta}(0)=0$ [3], so the parameter κ is often zero.

Finally, the transverse and the longitudinal wakes for a given structure must have the same parameter λ_g.

EXAMPLE FOR STEP-OUT GEOMETRY

We start by analyzing longitudinal wake potentials due to an axially symmetric step-out structure (Fig. 2, inset). Three wake potentials, computed with time domain EM solver ECHO [4] (used through the rest of this paper), are plotted in Fig. 2 (top).

As σ decreases, the wake potential inside the bunch attains larger negative values ($W_{\parallel}^{\sigma}(z)<0$ corresponds to the energy loss of the particle with longitudinal coordinate z). In the limit $\sigma\rightarrow 0$ this wake potential diverges as σ^{-1} and its singular part is given by the optical model, see i.e. [2],

$$W_{\parallel,s}^{\sigma}(z) = W_{\parallel,opt}^{\sigma}(z) = -\frac{Z_0 c}{(2\pi)^{1/2}\pi\sigma}\ln\frac{r_{max}}{r_{min}}e^{-\frac{z^2}{2\sigma^2}}, \qquad (10)$$

$$W_{\parallel,s}^{\delta}(z) = W_{\parallel,opt}^{\delta}(z) = -\frac{Z_0 c}{\pi}\ln\frac{r_{max}}{r_{min}}\delta(z), \qquad (11)$$

where Z_0 is the free space impedance.

The same ECHO wake potentials with (10) subtracted, are plotted at the bottom of Fig. 2 (dots). Clearly at $\sigma\rightarrow 0$ these curves approach a well-defined limit shown by the solid black line. This limit function has a discontinuity at z=0, and in the vicinity it can be well approximated by (cf. (5))

$$D_{\parallel}^{\delta}(z) = \left(\alpha+\beta z\right)H(z). \qquad (12)$$

Thus, if we determine the parameters α and β, we find the (short-range) point-charge wakefield, which can be written as (5) with the singular part replaced with (11).

For this particular geometry $\lambda_g = 2r_{min} = 2$ cm [1]. Following steps 3-5 above, we pick σ_0=2 mm<<λ_g, calculate $W_{\parallel}^{\sigma_0}(z)$ with ECHO and then determine the parameters α and β by fitting (2). All solid curves in Fig. 2 (bottom) are plotted using these values of α and β.

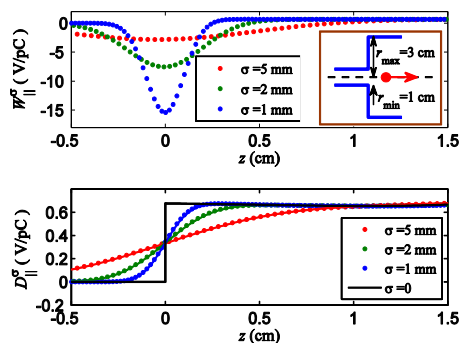

Figure 2: (inset) step-out geometry; (top) ECHO wake potentials; (bottom) same with singular parts subtracted (dots), and (solid) wakes reconstructed from $W_{\parallel,ECHO}^{2mm}$.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Specifically, the green and blue curves plot (2) with the shown values of σ, while the black curve for the point-charge is the plot of (12). At z>6 mm, all three curves merge together as per (4) and (6). Finally, the red curve, with σ=5mm>σ_0, plots a (numerically performed) convolution of the Gaussian bunch shape with $D_{\|}^{\delta}(z)$ given by the black curve.

Figure 2 illustrates how to find the short-bunch wakes, including the point-charge, from EM solver results due to a relatively long bunch. While even for this simple case no analytical formula exists for $D_{\|}^{\delta}(z)$, the accuracy of this method can be tested further by performing ECHO calculations with shorter and shorter bunch, and observing the results converge to the black curve [1].

Similarly, point-charge wakefield reconstruction can be performed for transverse wakefields, which we will now illustrate for the same geometry of Fig. 2. As stated earlier, transverse wakes are non-singular, so step 4 could be skipped. Then the coefficients α, β and κ are found by fitting the σ_0=2 mm transverse ECHO wake with (9). Substituted in (7)-(8) they define the short-bunch wakes, including the point-charge one. At z>3σ_0 these wakes are given by the transverse analogs of (4) and (6).

Figure 3 shows the wake potentials found in this manner (solid) agreeing very well with the direct calculations by ECHO (dots). In addition, the point-charge wake (black line), agrees well, near z=0, with the optical model, [2],

$$W_{\perp,opt}^{\delta}(z) = -\frac{Z_0 c}{\pi}(r_{\min}^{-2} - r_{\max}^{-2})H(z). \qquad (13)$$

In fact, the fitted coefficient κ is within 2×10^{-4} of the value given by (13) (for z>0), which confirms the robustness of our fitting procedure.

Of course, the point-charge wake model found by our method gives a much better approximation away from the origin, where the transverse wake significantly deviates from the step-function behaviour of the optical model.

Alternatively, before the fitting, we could subtract the asymptotic wake due to (13), $W_{\perp,opt}^{2\text{mm}}(z)$. This fit, with κ set to 0, produces very close results to the fit above, i.e. the fitted parameters α are within 0.5% from each other. Therefore, in this example subtracting the asymptotic model is optional. Sometimes, however, asymptotic models are known only up to a numerical coefficient. In such cases fitting for the parameter κ is a must.

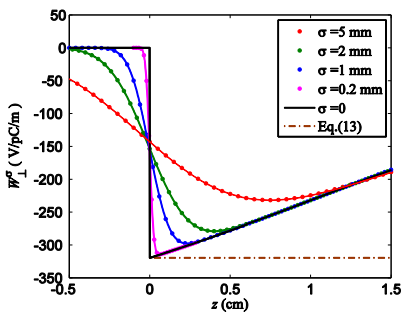

Figure 3: (dots) transverse ECHO wake potentials, and (solid) wakes reconstructed from $W_{\perp,ECHO}^{2\text{mm}}$.

EXAMPLE FOR CAVITY GEOMETRY

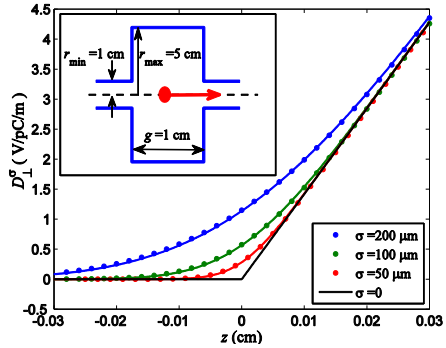

Figure 4: (inset) geometry; (dots) wakes calculated by ECHO and (solid) reconstructed from $W_{\perp,ECHO}^{1\text{mm}}$.

Here we apply the method to an axially symmetric cavity plotted in Fig. 4. Longitudinal wake reconstruction for this structure was described in [1]. For this geometry λ_g≈1.24 cm (see Fig. 1). To proceed with the transverse wake reconstruction, we take σ_0=1mm<<λ_g, and calculate $W_{\perp,ECHO}^{1\text{mm}}$. We then subtract the short-bunch wake asymptotic, $W_{\perp,d}^{1\text{mm}}$, given by the diffraction model, [2],

$$W_{\perp,d}^{\delta}(z) = 2k_d z^{1/2} \quad (z>0), \qquad (14)$$

$$W_{\perp,d}^{\sigma}(z) = k_d \sigma^{-1/2} \int f\left(z/\sigma\right) dz, \qquad (15)$$

where $f(s) = e^{-s^2/4}\sqrt{\frac{\pi}{8}|s|}(\mathrm{I}_{-1/4}(\frac{s^2}{4}) + \mathrm{sign}(s)\,\mathrm{I}_{1/4}(\frac{s^2}{4}))$,

$k_d = -Z_0 c \pi^{-2} r_{\min}^{-3}\sqrt{2g}$, and $\mathrm{I}_{\pm1/4}$ are the Bessel functions.

Unlike the previous example, here subtracting the short-bunch asymptotic substantially improves the final wake model. Indeed, according to (14), the short-bunch wakes are dominated by the $z^{1/2}$ term, which is fitted poorly by a polynomial function.

We proceed by fitting the residual, $D_{\perp,ECHO}^{\sigma_0}(z \le 3\sigma_0)$, to obtain the parameters α and β, and then reconstruct the point-charge wake, (7). With $W_{\perp,d}^{\delta}$ subtracted, it is plotted in Fig. 4 (solid black). Figure 4 also shows that the reconstructed short bunch wakes (solid color) agree perfectly with the direct ECHO calculations (dots).

In conclusion, we extended the point-charge wake reconstruction method of [1] to transverse wakes.

SPACE CHARGE MODELS FOR PARTICLE TRACKING ON LONG TIME SCALES*

J.A. Holmes, S. Cousineau, A. Shishlo, ORNL, Oak Ridge, TN, 37830, USA
R. Potts, University of Tennessee, Knoxville, TN 37996, USA

Abstract

In order to efficiently track charged particles over long times, most tracking codes use either analytic charge distributions or particle-in-cell (PIC) methods based on fast Fourier transforms (FFTs). While useful for theoretical studies, analytic distribution models do not allow accurate simulation of real machines. PIC calculations can utilize realistic space charge distributions, but these methods suffer from the presence of discretization errors. We examine the situation for particle tracking with space charge over long times, and consider possible ideas to improve the accuracy of such calculations.

INTRODUCTION

Space charge physics has been successfully incorporated into numerous computational particle-tracking studies of linacs, accumulator rings, and rapid cycling synchrotrons. These space charge models have allowed the successful simulation of phenomena that would have been impossible otherwise. Particle-tracking simulations for these machines all involve following particle distributions over short to moderate time scales. With the emergence of ever-higher beam intensities, it is now necessary to incorporate space charge effects into simulations of storage rings [1]. Calculations for storage rings require tracking beams for far longer times than those in linacs, accumulator rings, or rapid cycling synchrotrons. These long time scales place severe requirements on the speed and accuracy of the physics models and call for innovative methods of solution. For example, Lie Algebraic methods have been used with great success in single particle tracking to provide fast symplectic high order maps for storage rings. Although it is difficult to conceive of full turn maps for collective effects, such as space charge, advances will be necessary to incorporate this physics reliably into storage ring applications.

The problems of simulating space charge over long times arise partly from simplifications in the physics required to obtain a computational model and, more seriously, from the numerical properties of the model so obtained. From the physics perspective, a beam consists of many identical indistinguishable particles interacting quantum mechanically with each other and with their surroundings. In order to perform tracking studies, we make a series of approximations to arrive at a picture in which we treat the beam as a collection of distinguishable particles moving and interacting with each other and their surroundings primarily according to classical physics. Within this picture, space charge is the inter-particle Coulomb force, and its evaluation requires the solution of Poisson's equation.

Thus, even at the outset, space charge models represent a very simplified picture of reality. Their success in predicting and describing the physics of accelerators on short to intermediate time scales is some testimony to the validity of these approximations. However, for extension to long time scales, we must keep in mind that many other effects, such as lattice imperfections and nonlinearities, wake forces, neutral gas ionization and scattering, electron cloud interaction, intrabeam scattering, beam loss, and others may be important. These effects may be relatively unimportant at short or intermediate time scales, but critical at longer times. To study them in the presence of space charge, it is necessary understand and to mitigate the numerically induced noise and errors in the space charge models. The challenge of simulating space charge over long times lies in the representation of the beam distribution and the discretization of the problem.

CHOICE OF PHYSICAL MODEL

The first issue in space charge modeling is to determine what type of model contains physics sufficient to your needs. One criterion is the dimensionality of the model. 1D longitudinal models are used in longitudinal beam dynamics codes and also in conjunction with 2D transverse space charge calculations in 3D tracking codes. 2D transverse models, including bunch factor effects, are the most widely used for calculation in rings. If transverse properties vary longitudinally or transverse impedances are of interest, 2.5D models are necessary. These consist of a series of 2D model slices along the longitudinal direction that are connected by a common boundary condition. 2.5D models provide both the longitudinal and transverse space charge force components. All the above models are valid only for long bunches in which the bunch length greatly exceeds the beam pipe radius. Finally, there are full 3D space charge models. These are essential for short bunches, where the longitudinal and transverse dimensions are comparable, and are widely used in linac studies. Computational requirements rise steeply with the dimensionality of the model, so it is important to adopt the simplest model that contains the necessary physics.

REPRESENTATION AND DISCRETIZATION

Important issues that limit the applicability of space charge models are their representation of the beam distribution and the numerical discretization of the problem. Because the space charge forces depend on the charge distribution in the beam, the representation of the beam distribution in a simulation is very important. One simple class of space charge models, called envelope or particle core models, represents the space charge distribution as a uniform ellipsoidal core that propagates according to the envelope equation. The tracked particles feel the space charge force due to the propagating core. This force is linear inside the core. Envelope models are computationally fast and easy to apply. They have been used to study halo generation by mismatched beams and also the approach to the half integer resonance. One limitation of such models is that a constant emittance is specified in the envelope and thus constrains the evolution of the core. Accordingly, envelope models are simple, but far from realistic.

Conceptually, the opposite approach is to use the numerical distribution of tracked particles to provide the space charge forces. The implication in using this approach is that the tracked beam distribution realistically describes the actual beam distribution, which may require tracking many particles. Such methods, often called particle-in-cell (PIC) methods because of the techniques employed to evaluate the collective forces, are much more computationally intensive than envelope models and, as we shall see, they introduce discretization at more levels.

An intermediate class of methods for handling space charge involves the use of analytic or smoothed distributions for space charge evaluation, where the parameters of the smoothed distribution are fitted to those of a tracked beam consisting of particles. Such hybrid methods can, in principle, enjoy the speed and simplicity of envelope models while having parameters that evolve with the tracked beam distribution. A disadvantage could be that, depending on the details of chosen analytic representation or smoothing function, important features of the tracked distribution may be lost.

Any numerical space charge model will suffer from discretization error, but some methods are subject to more error than others. Time discretization is a feature of any space charge simulation, regardless of beam representation. While space charge forces act continuously in classical dynamics, simulations apply them as impulses, separated by single particle transport. If the time between impulses is too large, accuracy is lost. For example, nearby particles may become anomalously close in the single particle transport step. At the very least, it is necessary to include many space charge evaluations per betatron or synchrotron oscillation.

An additional level of discretization occurs when using the tracked particles directly to provide the charge/current distribution. Real accelerator bunches typically have 10^8 – 10^{14} particles, while accelerator simulations may use 10^4 – 10^9 macroparticles, with the lower end of this range being typical on workstations or small clusters. The impacts are an increased graininess of the force distribution and an increased potential for large binary collisions. Both of these effects introduce noise, or diffusion, into the particle evolution. The problem of the enhanced binary collisions is often handled by introducing into the inter-particle force Green's functions artificial smoothing parameters that reduce the force at close range.

A final source of discretization in many PIC methods relates to the use of spatial meshes. The straightforward direct evaluation of pairwise forces between N particles requires $O(N^2)$ computational work. Faster O(~N) methods have been developed. The most popular of these methods involve the distribution of the particle charges to a selected set of mesh points. This is followed by the solution of the resulting potential or forces at the mesh points, and then the interpolation of the forces back to the particle locations. Computational meshes are used in multigrid methods and also in algorithms using fast Fourier transforms (FFTs). Many of these are described in Refs. [2] and [3]. The approximations in distributing the charges to the mesh points and then interpolating the resulting forces from the mesh points back to the particles introduce additional noise into the space charge calculation that can be seen in the motion of individual particles. This is illustrated in Fig. 1, where the horizontal motion of three particles, initially at (x,y) = (3,0), (0,0), and (0,3) mm, selected from a cylindrical constant density beam of radius 7 mm in a uniform focusing channel, is plotted over 1000 betatron oscillations at the bear tune. The space charge tune reduction here is about one third. The space charge solution is carried out using a 2D FFT-based PIC solver. Without discretization noise, the amplitudes would remain constant. However, even with 400000 particles in a 2D problem, the effects of noise in diffusing the individual particle orbits are soon apparent.

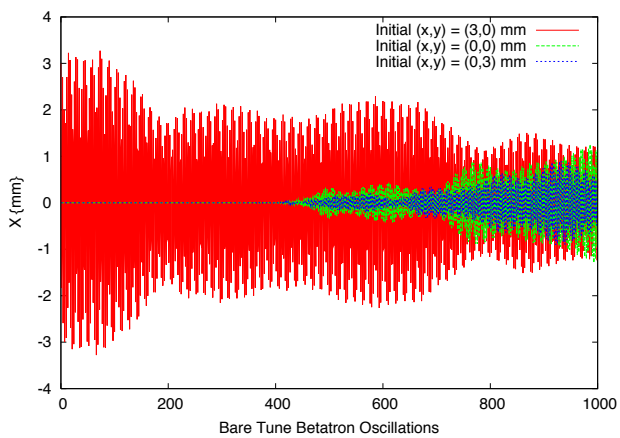

Figure 1. Horizontal motion of three particles in a uniform focusing channel with constant space charge, calculated using an FFT-based PIC algorithm. Without discretization noise, the amplitudes would remain constant.

Within the realm of fast grid-based methods, techniques have been devised to reduce the noise by using the grid for evaluating the forces of distant particles and calculating the forces due to nearby particles pairwise [2].

Copyright © 2013 CC-BY-3.0 and by the respective authors

Another fast method that uses pairwise force evaluations for nearby particles eliminates grid-based discretization errors completely. The fast multipole method [4] expands the individual particle potentials as multipoles at the centers of a collection of square gridded cells containing the particles. These expansions are then shifted and accumulated through a hierarchy of coarser "parent cells" and the resulting totals are converted to Taylor series expansions as they are shifted backwards through the hierarchy of "child cells". The result is a set of local Taylor series expansions for the potential and force within each starting cell. This method solves the N-body force evaluation to machine precision when enough terms are retained in the multipole and Taylor series expansions. Even so, the discretization effects of the time step and the numerical particle distribution remain.

OPTIONS FOR LONG TIME SCALES

Given the problems of properly representing the beam distribution and reducing the discretization noise, the question remains: What steps can be taken to extend space charge calculations reliably to long time scales? One possibility is the sledgehammer approach. It is possible to use smaller time steps, more particles, and finer meshes to reduce the level of noise due to discretization. This is feasible to some extent with the help of modern computer technology: clusters, GPUs, etc. Still, this approach is expensive and only delays the inevitable effects of the numerical noise. Another approach to reduce noise from discretization is to eliminate the discretization. At present, FFT-based methods are extremely popular for solving Poisson's equation. The fast multipole method can eliminate grid discretization errors associated with FFTs. However, the effects of the graininess of the particle distribution and discrete time steps are still present. Another approach with grid-based methods is to study different binning or smoothing algorithms for distributing space charge from the numerical particle distribution to the grid. Like low pass filters, such methods can alleviate noise due to gridding and the particle representation. One example is the template method of Vorobiev (presentation in Ref. [1]) in which the binned point charges on the grid are replaced by smoothed elements. Simplified or analytic distributions, based on statistically calculated parameters of the macroparticle distribution, are also worth exploring. For example, Figure 2 shows the evolution of the vertical beam size in three different tracking calculations through the SNS MEBT. Two of the calculations were carried out using grid-based 3D space charge models (PICNIC and SCHEFF) in the Parmila code, and the third utilized a uniform ellipsoid with parameters taken from tracking a distribution with 10% as many particles as in the 3D calculations. The RMS beam sizes from the three methods are virtually identical, although the ellipsoidal calculation required only 20% as much computer time as PICNIC and 40% as much as SCHEFF. Of course, these linac calculations are for short times, but similar hybrid models should be explored for calculations at long times.

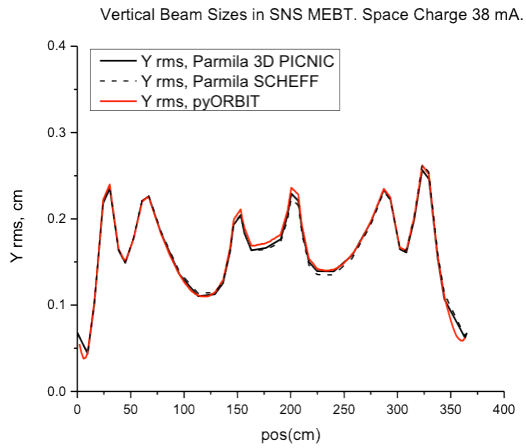

Figure 2. Vertical beam sizes from particle tracking calculations in the SNS MEBT. Space charge models include 3D PICNIC and SCHEFF PIC solvers and an ellipsoidal uniform density model with parameters set to those of a tracked distribution.

We are exploring all of these approaches in the ORBIT Code. At present, we have completed writing and are now testing a fast multipole method package. The intent is to compare the speed and numerical noise of this method with those of our existing FFT-based PIC solvers. In the future we plan to develop a number of fast hybrid models for long time scale calculations. All of these methods must be compared through careful benchmarking. As a final remark, we note that an excellent set of benchmark tests for space charge has been developed by Giuliano Franchetti, and can be found on-line [5]. These provide a thorough set of tests for space charge models, including some that involve long time scales.

Abstract

Time-resolved temperature mapping of a superconducting cavity can give valuable information on the limiting process of the cavity performance. A fast temperature mapping system has been developed at Argonne National Laboratory (ANL) for a superconducting deflecting cavity test. The time resolution of the temperature mapping could be up to 50 μs. Not only the spatial distribution of surface heating but also the thermodynamics can be recorded, which helps to understand the limitation mechanism. This new temperature mapping system has helped us to understand the rf performance limitations during the cavity vertical tests. Based on the findings from the temperature mapping, proper cavity treatment has been applied and the cavity performances have been improved.

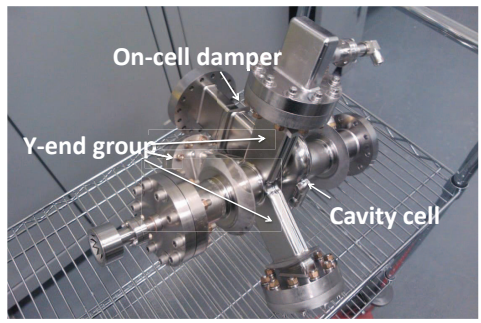

Figure 1: The APS superconducting deflecting cavity during assembling in a clean room. The cavity has a Y-end group on the beam pipe and a on-cell waveguide damper.

INTRODUCTION

The Advanced Photon Source (APS) at Argonne National Lab (ANL) has considered using the superconducting deflection technique to generate x-rays on the order of 2 ps or less [1]. A single-cell cavity design has been chosen as the baseline design and four superconducting deflecting cavities have been fabricated, as shown in Fig. 1. The cavity is a single squashed-cell cavity with an on-cell waveguide damper and a Y-end group on the beam pipe [2]. To provide sufficient deflecting modulation to the beam, a single-cavity deflecting voltage needs to reach 0.5 MV, which corresponds to a peak surface magnetic field of 106 mT. To accomplish this challenging goal, it is very important to understand the cavity performance limitations. Generally speaking, a number of processes, such as multipacting, field-emission, Q-slope, and thermal quench, might limit the superconducting cavity performance. All of these processes will eventually generate heat on the cavity wall. Temperature mapping is presently one of the most effective tools to gain insight into the cavity limitations.

Most conventional temperature mapping systems work for L-band accelerators [3][4]. Hundreds of sensors are required to cover the cavity surface. However, the sampling rate is limited to a few Hz, which is not fast enough to get a resolved signal. The APS deflecting cavity operates at 2815 MHz. The cavity size is much more compact compared to the L-band cavity, thus a fewer number of sensors are needed to cover the high magnetic field surface. A new time-resolved temperature mapping system has been developed for the APS deflecting cavity. It consists of 24 temperature sensors with a time resolution as high as 50 μs. A number of cavity tests made using this system have helped us understand cavity performance limitations. Compared to conventional temperature mapping, time-resolved temperature signals are much superior in classifying the limitations in terms of thermal dynamics. These findings from temperature mapping have led us to improve the cavity performance with the following treatment.

SENSOR MOUNTING AND DATA ACQUISITION

We used sensors made from Allen-Bradley carbon resistors. This resistor has a high thermal sensitivity of 10Ω/mK around 2 K. To thermally isolate the sensor from the helium bath, the resistor was enclosed in a G-10 container filled with epoxy. In order to make good thermal contact and provide electrical isolation to the cavity surface, the top surface of the resistor was ground away until the carbon was exposed and then a thin layer of a GE-varnish, toluene and alcohol mixture was applied.

The APS deflecting cavity operates at dipole mode, and the highest surface magnetic field region is the iris between the cavity cell and the Y-end group. The sensors were mounted around the cavity based on the surface magnetic field distribution, as shown in Fig. 2. Proper mounting techniques were developed. A cryogenic cable tie was applied as a band to mount the sensors around the iris. Two semi-circle bands made of cryogenic fiberglass weres used to attach the sensors on the cavity cell. Apiezon N grease

is applied to all the sensor contacts to ensure good thermal contact with the cavity.

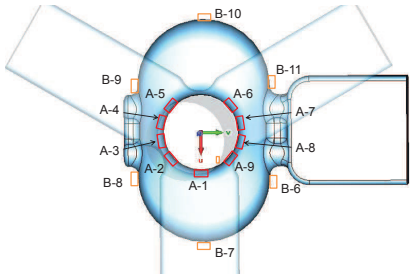

Figure 2: Sensor layout around the cell and the iris looking from the Y-end group side. The iris on the other side has similar sensors around the iris.

The data acquisition is based on a National Instrument data acquisition (DAQ) device. However, direct connection of the sensor to the DAQ will result in excessive current to the sensor. A proper circuit is designed to excite the sensors with a 15-μA current. As shown in Fig. 3 , the resistance values of the sensors are measured in terms of the voltage drop across the resistor. The cavity field level can be measured in terms of the output voltage of the cavity transmitted power crystal detector. All the data is processed and recorded by a LabVIEW program.

The software has three operation modes: calibration mode, continuous measurement mode, and pulse measurement mode. The calibration mode records how the resistance of different sensors changes with the helium gas pressure reading. Those correlations are used to calculate the temperature rise during the measurement. The calibration mode operates during the helium-bath cooling from 4 K to 2 K. The sampling rate is only 0.5 Hz, but the accuracy is better than 0.3 mK. During the cavity test, the software usually operates in continuous measurement mode. It quickly records the resistance values of different sensors. Then the temperature is calculated using the calibrated correlations. The sampling rate of continuous mode is 300 Hz with an accuracy of 2 mK, which is fast and accurate enough to obtain time-resolved heating. The pulse mode records the sensor reading with highest possible resolution up to 50 μs. However, the accuracy is limited to about 10 mK and the measurement only lasts for 2 seconds. This mode is designed to give the highest time-resolution.

CAVITY VERTICAL TEST WITH TIME-RESOLVED TEMPERATURE MAPPING

Eight cavity vertical tests have been performed with this temperature mapping system, and it has helped to identify the limitations of the cavity performances. With the help of this system, a number of defect mechanisms have been identified that have lead us to find appropriate treatment techniques to eliminate the obstacles and improve the cavity performance.

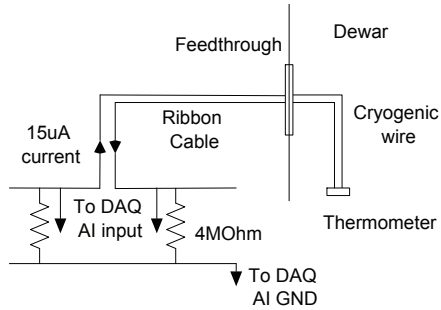

Figure 3: Schematic of the measurement circuit. A 15 μA current is used to excite the thermometer, and the voltage drop across the resistor is used to measure the resistance value.

Multipacting

The thermodynamics of multipacting (MP) on the cavity wall can be obtained using this system. It can be identified as an abrupt pulse heating when the field level reaches a barrier and then has a small and abrupt drop. An example is given in Fig. 4. Sensors A-3 and A-8 detected pulse heating signals during the vertical test when the cavity surface peak magnetic field first approached 85 mT.

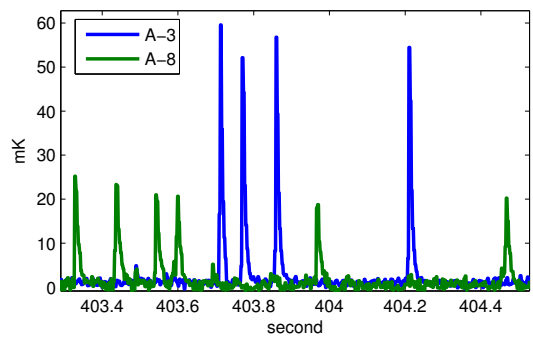

Figure 4: A soft MP barrier occurred at the A-3 and A-8 sensors when the maximum surface M-field approached 85 mT. Pulse heating can be detected when MP occurs

It can be seen that multipacting induced pulsed heatings at A-3 and A-8. They did not happen at the same time. On the other hand, both the A-3 and A-8 sensors were located at high magnetic field regions. The multipacting at either point is likely one-point multipacting.

All the multipacting found in the cavity tests turned out to be soft. The thermodynamic during multipacting processing was also obtained. The processing lasted from tens of seconds to several minutes. After that, the processing subsided and the Q gradually returned to normal. A continuous but not stable heating signal could be detected by time-resolved temperature mapping during the processing. Figure 5 shows an example of temperature signals during multipacting processing. The pulse heating signals became a continuous heating signal when the processing started. The processing happened at two points: the

Copyright © 2013 CC-BY-3.0 and by the respective authors

A-3 sensor location and the A-8 sensor location. An interesting phenomenon was that the processing at A-3 and A-8 took place alternately, which formed a rectangular-shaped temperature-rise signal. The processing gradually decayed as the temperature went down, and cavity Q gradually increased back to a normal level.

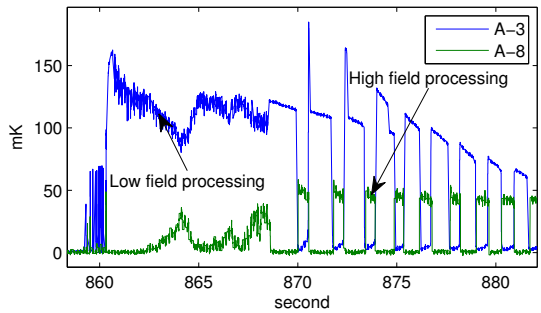

Figure 5: MP processing happened at A-3 and A-8 sensor when peak magnetic field approached 95 mT. The sudden "turn on" of the processing is shown with pulse heating changing into a continuous heating signal.

High-Field Q-Slope

High-field Q-slope was found in one of the cavities starting at 70 mT. The temperature mapping showed the Y-end group iris had a strong heating signal all around the iris [5]. The time-resolved signal showed the heating magnitude was constant at a given cavity field level. After the cavity showed a Q-slope at high field, the temperature rose exponentially in the power law ranging from 10 to 16. Those findings were consistent with the finding of Q-slope with convectional temperature mapping.

Quench Detection

Quench detection becomes more accurate with time-resolved temperature mapping. The thermodynamics of quench can be recorded. Figure 6 gives an example of quench. When quench happened, the A-3 sensor set at the location of the quench measured a pulse heating reading as soon as the cavity field dropped to zero. The pulse heating magnitude was very high (the highest reading was about 1.5K), which lasted about 50 ms. The sensors within 0,5 inch detected a small pulse reading of tens of mK. However, other hot spot temperatures would drop as the cavity quenched. The thermodynamics demonstrated by the time-resolved temperature mapping could help to determine the quench location with good accuracy.

CAVITY PERFORMANCE IMPROVEMENT

Of the four fabricated deflecting cavities, two of them have been explored in detail with this temperature mapping system. It has successfully located the defect spots or

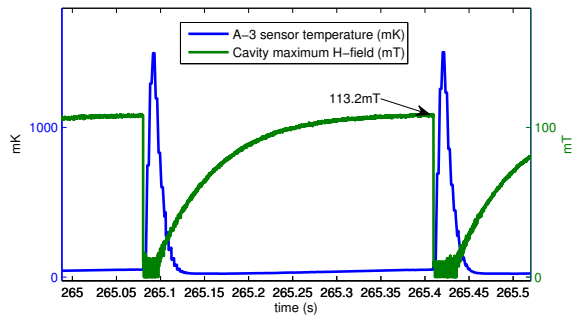

Figure 6: Quench pulse heating signal, the quench location temperature heating can go as high as 1.5K.

the heating area, and helped us to understand the performance limitations. Based on the findings from temperature mapping, the following treatments have helped to improve performance [6]. In one cavity, global heating was detected around the iris. A 40μm EP has helped to remove the Q-slope and improve the quench limit. In the other cavity, quench was detected at one spot on the cavity equator when the peak magnetic field approached 95 mT. A welding defect was found at the spot by optical inspection. The subsequent cosmetic E-beam welding smoothed the area and improved the gradient. Both of the cavities have reached design specifications.

SUMMARY

We described a time-resolved temperature mapping system to characterize the performance limitations of the APS deflecting cavity. Time-resolved temperature signals can be used to gain further insight into these limitations. Detailed studies were performed in two deflecting cavities. Based on our findings, proper treatment was applied and cavity performance reached design criteria in both cavities.

Abstract

The Advanced Photon Source has considered using a deflecting-cavity-based scheme to produce short pulse x-rays. A deflecting cavity design has been completed. To verify the simulation result on this cavity, a copper prototype of the design has been fabricated for bench measurement. In this paper, we report our measurement results on this cavity. All the cavity modes below 5 GHz were identified by comparing the field distributions with calculations along different beam paths. After adding the damper, the measured Q_{ext}s of those modes were consistent with calculated values, which demonstrated that the cavity damping scheme was sufficient to reduce the wake impedances well below the safety thresholds.

INTRODUCTION

The Advanced Photon Source (APS) at Argonne National Lab (ANL) has considered using a superconducting deflecting-cavity-based scheme to generate x-rays on the order of 2 ps or less [1]. The unwanted cavity modes in cavities can drive coupled-bunch instabilities in high-current storage rings. Thus sufficient damping of those modes was very important. It is equally important to maximize the operating mode parameters and provide sufficient transverse kick to the beam. A cavity design has been proposed, as shown in Fig. 1. This cavity design is a single squashed-cell cavity with an on-cell waveguide damper and a Y-end group on the beam pipe [2]. The on-cell waveguide serves as lower-order mode (LOM) damper. One of the Y-end group waveguide damper works as a fundamental power coupler (FPC) and the other two dampers as higher-order mode (HOM) dampers. The cavity operates at 2815 MHz.

Extensive simulations have been performed, and we have demonstrated that the wake impedances are well below the stability thresholds [3]. In this paper, bench measurements were performed to verify numerical calculations. There were mainly two steps in the bench measurement. The first step was to identify the modes by measuring the field distributions using on-axis and off-axis bead-pulls. The second step was to characterize the damping performance by using actual high-power waveguide damper prototypes [4].

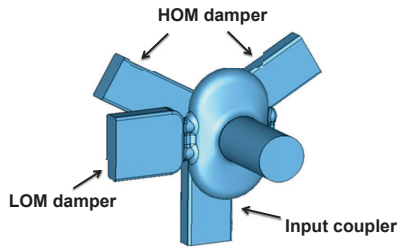

Figure 1: The APS deflecting cavity design.

COPPER PROTOTYPE CAVITY MEASUREMENT

Measurement Technique

The cavity modes were characterized by the Slater perturbation technique. With a small perturbing object, usually a dielectric bead or metal needle, passing through the cavity beam pipe, the longitudinal electrical field $E_z(r,\theta)$ along the beam path can be measured in terms of the frequency shift due to the perturbation. For a dielectric bead, the frequency perturbation can be related to the electric field strength as follows:

$$-\frac{\Delta\omega}{\omega} = g_1 e_{\parallel}^2 + g_2 e_{\perp}^2, \qquad (1)$$

where the coefficients g_1 and g_2 are geometric factors. They depend upon the bead size, material, and geometry. Eq. 1 shows that the electrical field in both longitudinal and transverse directions will contribute to the frequency change when the bead passes through the cavity. But for the R/Q measurement, only the longitudinal electrical field is of interest. In the APS deflecting cavity, there are many modes that have strong transverse electrical field compared to the longitudinal electrical field along the beam path. To get an accurate measurement of the R/Q, a slender bead with a length at least ten times larger than the diameter is required due to its insensitivity to the transverse electrical field with $g_1 \gg g_2$ [5]. However, our bead length needs to be relatively small to have adequate longitudinal resolution due to the compactness of the cavity. Given that, it is very difficult to have such a bead that can separate the transverse and longitudinal electrical fields. After exploring different beads and techniques, we selected a uniform dielectric bead with $g_1 \approx g_2$ to measure the electric field amplitude $E_{abs}(r,\theta)$ along different paths. Before the bead-pull mea-

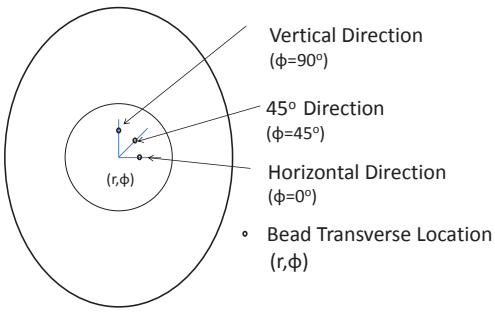

Figure 3: Bead pull measurement along different paths in horizontal, vertical, and 45^o directions.

surement on the copper prototype, we calibrated the beads with a pillbox cavity, in which the field distributions of different modes had been well understood. The geometric factors $g1$ and $g2$ were obtained by the monopole mode and dipole mode measurements.

Even though the azimuthal symmetry is broken in the APS deflecting cavity, the cavity modes can still be approximately classified as monopole mode, dipole mode, and quadrupole mode. It is hard to get the mode identity based on the field distribution E_{abs} on a single path. To fully characterize the mode azimuthal property (monopole, dipole, or higher) and identify the mode, bead-pull measurements were performed with different transverse offsets in different directions, as shown in Fig. 2 and Fig. 3. We focused on the horizontal , vertical, and 45^o angle displacement. The bead-pull measurements were performed using an Agilent E6362B network analyzer with a Labview program. With all waveguide ports and beam pipe ports shorted and sealed, the cavity mode was excited by a probe inserted through the beam pipe, and the signal was picked up through a probe on the waveguide damper or a probe inserted into the other side of the beam pipe. The frequency shift due to the bead perturbation was measured in terms of the phase shift, which was more sensitive than direct measurement. Different probes were developed for mode excitation. By changing the probes and varying the probe orientation, it was possible to enhance the profile of the mode we were measuring and reject the interfering mode.

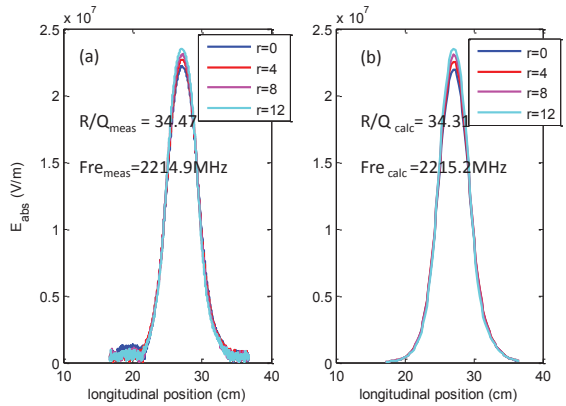

Figure 4: Measured (a) and calculated (b) field distribution of the TM010$_{like}$ mode along different paths with an increasing horizontal offset r. The measured R/Q value is very consistent with simulation.

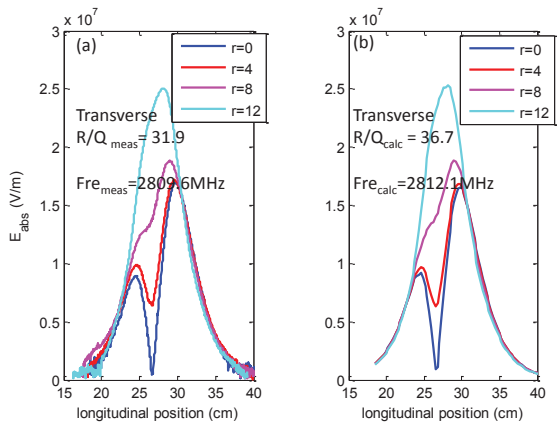

Figure 5: Measured (a) and calculated (b) field distribution of the TM110y$_{like}$ mode along different beam paths with an increasing vertical offset r.

Mode Characterization

Comparison of E_{abs} along different paths turned out to be a very effective way to identify all the cavity modes. Figure 4 compares calculated and measured field distributions of the monopole TM010$_{like}$ mode along different horizontal paths. This mode was the lowest mode of the cavity and it had very strong beam coupling. Due to the strong coupling with on-cell waveguide damper, the field amplitude had a gradient along the horizontal direction, which was confirmed by both calculation and bead-pull measurement. There was negligible transverse electrical field effect, and the R/Q measurement gave a very consistent result with the simulation. Figure 5 shows the field distributions of the operating dipole mode along different vertical paths. The measured field amplitude was the superposition of the longitudinal electrical field and the transverse electrical field; it was very hard to separate the longitudinal

$TE211b_{like}$	4599.7	1376	4610.4	1425

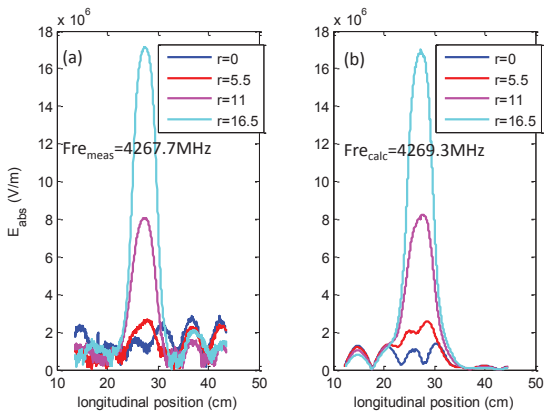

Figure 6: Measured (a) and calculated (b) field distribution of the $TM210_{like}$ mode along different beam paths with an increasing 45^o offset.

effect. Thus the measured transverse R/Q was less consistent with the simulation. Figure 6 shows the field distributions of the quadrupole $TM210_{like}$ mode along different 45^o paths. Around the cavity center, the field strength was very low but the field strength inside cavity increased significantly with a growing offset r in 45^o direction, as demonstrated in simulation and bead-pull measurement.

Mode Damping

After the cavity modes were identified by the bead-pull, all the waveguide couplers were connected with the proper loads. Q was measured by S_{21} transmission between the probes either inserted into the beam pipe or on the waveguide damper. After adding the damper, the loaded Qs of the cavity modes (except the operating mode) were much lower. Normally, we started the measurement with the same probes mounted in the same positions around the cavity as we did in the previous measurement when all the waveguides were shorted. The Q_{ext}s could be derived by the difference of the inverses of the measured Q_{load}s. If the mode Q_{ext} was very low, the probe location was adjusted to have stronger coupling. Table 1 compares the measured Qs with the calculation by ACE3P. It could be shown that the measured Q_{ext}s of the cavity mode were quite consistent with the simulation results.

One thing to note is that the measurement of the operation mode $TM110_y$ was different. The mode had a weak coupling with all the waveguides. To measure the coupling, a matched tophat was used on the waveguide coupler. The transmission S_{21} between the matched tophat and the tuned beam pipe probe was used to calculate the coupling through the waveguide.

SUMMARY

A copper prototype cavity has been fabricated and extensive measurements have been performed on the cavity. The bead-pull measurements were performed for all the modes below 5 GHz. The cavity modes were identified by comparing the measured field distributions with calculations along different paths. The field distribution of different modes were consistent with the calculated results. After adding the prototype damper, the measured Q_{ext}s were in agreement with the simulation results, which indicates that the fabricated cavity could meet the design criteria and the wake impedances were well below the stability thresholds for operating in the APS storage ring with 150-mA current.

ACKNOWLEDGMENT

The authors are particularly grateful to Tim Jonasson, William Yoder, and Charles Montiel for their help in cavity measurements.

Abstract

A β=0.085 quarter wave resonator (QWR) with resonant frequency=80.5 MHz is used in the Facility of Rare Isotope Beam (FRIB). Its baseline structure is designed to achieve the FRIB specifications with optimum cost to performance ratio. Electro-magnetic optimization is introduced in this paper to modify its internal geometry to reach instead maximum accelerating gradient, while preserving the original flange to flange length. Reduced peak magnetic field and increased shunt impedance are well achieved in the optimization while keeping the same stored energy. The maximum accelerating voltage is raised accordingly. Multipacting and steering are also analyzed for the optimized cavity. This resonator could be used in the ReA linac at MSU and in all applications where the maximum accelerating voltage should be achieved in a limited space, or where the accelerator cost is mainly driven by the resonator gradient.

INTRODUCTION

The baseline structure of FRIB QWR cavity is designed to achieve its goal with optimum cost to performance ratio. By further optimizing the baseline cavity, we aimed at a cavity design (that we nicknamed "race car") which provides significantly more accelerating gradient (E_a) still being affordable in cost, like an economy car in the auto world. The optimization is achieved mainly by reducing the peak magnetic field B_p and increasing the cavity shunt impedance R_{sh}. Lower B_p can speed up the "car" to higher cavity gradient, and increased R_{sh} allows keeping power consumption low, like saving "gasoline" for the "car". With high gradient, low-β resonators like this "race car" design, compact accelerators which can reach several MeV per nucleon in a limited space can be built for different applications. In this paper, section 1 introduces the method and procedure of the electromagnetic optimization. Section 2 discusses multipacting and beam steering issues before and after the optimization.

ELECTRO-MAGNETIC OPTIMIZATION

The main goal of the optimization is reducing the peak magnetic field (B_p) and increasing shunt impedance (R_{sh}/Q) while keeping good values for the stored energy, the peak electric field (E_p) and the geometric factor ($R_s \times Q$). To achieve the "economy" concept, we should limit rising of the cavity cost as little as possible. Thus, we maintained the radius of cavity outer conductor and optimized the cavity inner part.

Performance of FRIB QWR

Before cavity optimization, simulation was performed to get the parameters of FRIB QWR with MWS [1]. Table 1 shows the simulation results (effective length=βλ).

Table 1: Cavity Parameters of FRIB QWR

Parameter	Value	Units
Frequency	80.50	MHz
E_p/E_a	5.9	Abs.
B_p/E_a	12.6	mT/(MV/m)
R_{sh}/Q	452	Ω
$R_s \times Q$	22.3	Ω

In superconducting low-β resonators, the highest reported surface peak fields before quench are approximately 80 MV/m and 150 mT in cw mode. So there is a tradeoff between E_p and B_p that should be taken into account when designing a cavity, and B_p/E_p~1.8 should be nearly an optimum. For the FRIB β=0.085 QWR, B_p/E_p=2.14 which means the cavity can be expected to quench at high accelerating gradient due to B_p. To raise the maximum achievable gradient to this cavity, the most effective method is reducing its B_p.

Procedures of Optimization

First step:

The peak magnetic field of FRIB QWR is located at the inner conductor near the short plate (Fig. 1). To reduce the B_p/E_p, we optimized the structure of inner conductor by scanning two geometric parameters (R_1 and L_1 in Fig.2).

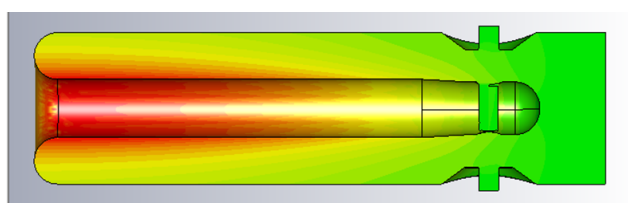

Figure 1: Magnetic field distribution of the FRIB QWR. Red means B_p. Cavity stored energy is normalized at 1J.

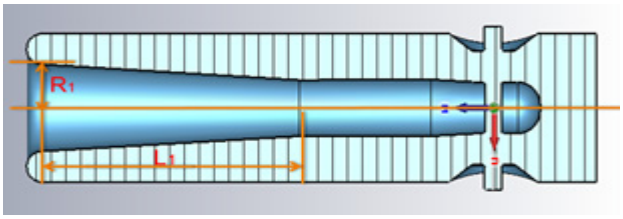

Figure 2: Diagram of the first step optimization.

The optimized parameters chosen are: R1=90 mm (the original value is 52 mm), L1=450 mm (As a reference: total length of the cavity is 1041 mm). After the first step, Bp/Ep is reduced significantly. But shunt impedance is lowered and cavity frequency is increased.

Second step:

We reduced the radius of inner conductor (R2 in Fig. 3) to increase shunt impedance and increased L2 to tune the resonant frequency back to 80.5 MHz. Optimization from scanning four parameters (R1, R2, L1 and L2) and the optimized parameters are chosen: R1=80 mm, R2=30 mm (the original value is 52 mm), L1=793 mm, L2=951 mm (the original value is 821 mm; cavity length extends 130 mm).

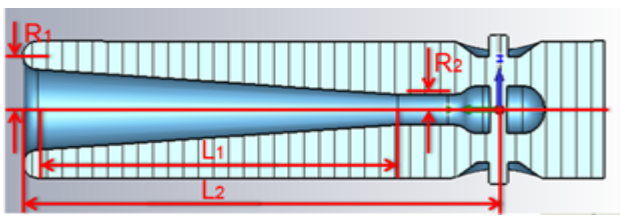

Figure 3: Diagram of the second step optimization.

Third step:

We tried to reduce the peak electric field to further improve cavity performance. E_p was located in the region of the inner conductor (IC) drift tube (nicknamed "donut"), so we optimized its shape. We tried three kinds of donuts during the optimization (see Fig. 4). Because the simulation results reconfirmed that even with tapered IC the original donut has minimum E_p, we kept it.

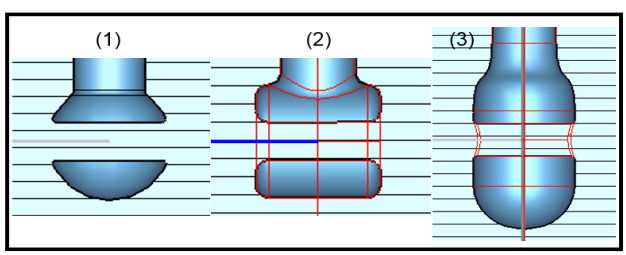

Figure 4: Three kinds of donuts in the third step optimization. (1) sphere donut, (2) cylindrical donut, (3) the original donut.

A final re-optimization was done by tuning all parameters together.

After these optimization steps, the cavity parameters resulted significantly modified regarding the maximum gradient capabilities, with rather limited rise of cost. We called this cavity design "race car" and its parameters are shown in Table 2 (effective length=βλ).

Table 2: Cavity Parameters of "race car"

Parameter	Value	Units
Frequency	80.48	MHz
E_p/E_a	5.8	Abs.
B_p/E_a	8.6	mT/(MV/m)
R_{sh}/Q	548	Ω
$R_s \times Q$	20.6	Ω

Comparing Table 2 with Table 1, the improvements from the FRIB QWR to the "race car" are as following: 1) peak magnetic field was reduced significantly; 2) shunt impedance was increased. We can see that B_p/E_p~1.5, significantly below 1.8. However, since staying at 1.8 would not reduce E_p anyhow, we decided to minimize B_p as much as allowed by our outer conductor diameter.

Thus, if we assume cavity will not quench below E_p=80 MV/m, the "race car" should provide a maximum accelerating gradient of 13.8MV/m if the effective length is defined as L_{eff}≡βλ=0.317 m, and 16.3 MV/m if L_{eff}≡D=0.27 m, where D is the real outer conductor diameter. If we assume – according to the ReA cavities test results – that operation at B_p=100 mT could be safely achieved, an acceleration of 3.7 MV in a cavity which is only 27 cm long might be feasible, if E_p=67 MV/m can be maintained as foreseen for elliptical cavities. This voltage until now for this range of beta was planned in operation only with cavities of considerably larger size.

MULTIPACTING AND BEAM STEERING

The "race car" design exceeds the expected FRIB cavity operation gradient, but some issues, such as multipacting and beam steering, needed to be studied carefully.

Multipacting Analysis

In the FRIB QWR, there are two types of multipacting: one is located at short plate [2], the other one is between inner and outer conductor (IC and OC). Both of them in clean cavities can be suppressed in a short time by RF conditioning during RF tests. For the "race car" cavity, the tapered IC may enhance multipacting near the short plate.

In Fig. 5, simulation of the FRIB QWR's multipacting was verified by the cavity vertical tests [3]. Thus, we can use simulations to predict multipacting of the "race car".

Copyright © 2013 CC-BY-3.0 and by the respective authors

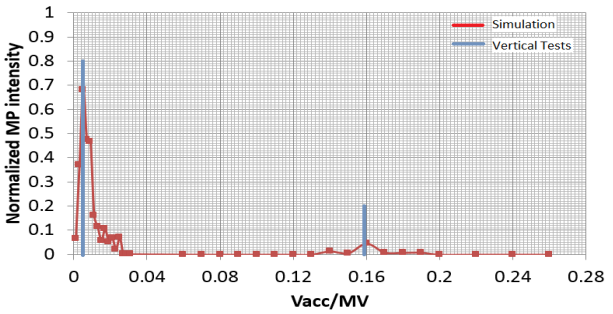

Figure 5: Multipacting barrier in simulation and vertical tests. In simulation, normalized MP intensity is proportion to the total number of secondary electrons in 10 RF cycles. In vertical tests, it is proportion to the frequency of multipacting (the number of multipacting processing tests over the total number of tests). The multipacting at lower accelerating gradient occurs between IC and OC while the higher one is on the short plate.

We simulated multipacting for both the FRIB QWR and the "race car", and compared them in Fig. 6. As a result, taper did enhance multipacting on the short plate. The multipacting barrier on short plate of the "race car" is shifted to a higher gradient and becomes wider. But the overall multipacting intensity doesn't increase much (maximum value increases from 0.7 to 1 in Fig. 6). Thus, the "race car" design might need more time than the FRIB one for RF conditioning to suppress multipacting.

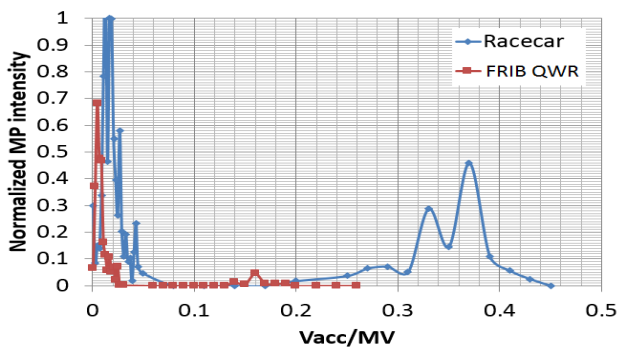

Figure 6: Multipacting comparison between FRIB QWR and "race car" by simulations. Normalized MP intensity is proportion to total number of secondary electrons in 10 RF cycles.

Beam Steering Analysis

In the FRIB QWR, beam steering can be corrected by offsetting the cavity down 1.5 mm [4]. Since in the "race car" radius of the inner conductor curvature is reduced from 52 mm to 30 mm above the beam axis, the vertical electric field distribution (E_y) is changed (see Fig. 7) and so the beam steering. Comparing with the FRIB QWR, the steering becomes weaker for $\beta<0.085$ but larger for $\beta>0.085$ (see Fig. 8). The disadvantage is that the previous correction method with the "race car" is not as good as with the FRIB cavity, although looking acceptable. Beam port shaping for better correction can be considered if necessary.

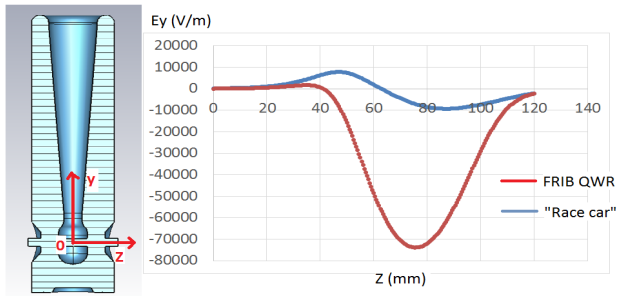

Figure 7: Ey comparison between the FRIB QWR and the "race car" cavity.

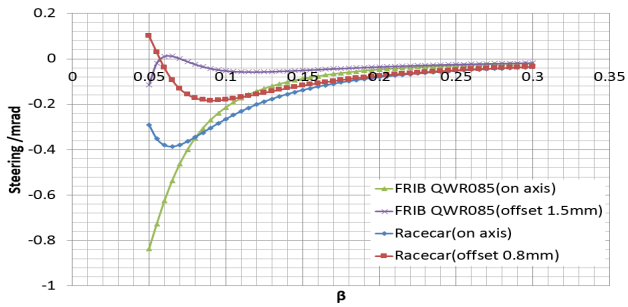

Figure 8: Steering and the correction comparison between the FRIB QWR and the "race car". By offsetting cavity down 1.5 mm we will have a minimum steering for the FRIB QWR, while for the "race car", the required correction will be 0.8 mm.

CONCLUSION

By simultaneously reducing peak magnetic field and increasing shunt impedance, the FRIB β=0.085 QWR geometry was optimized for maximum acceleration gradient without increasing the cavity longitudinal dimensions but only the vertical length by about 130mm. The cost increase for this new geometry appears to be rather affordable. This resonator type might benefit the ReA linac at MSU and other applications where maximum acceleration must be achieved in a limited space. Both multipacting and beam steering issues have been thoroughly studied with simulations. The construction of a prototype is planned for next year.

HYDROGEN DEGASSING STUDY DURING THE HEAT TREATMENT OF 1.3-GHZ SRF CAVITIES

M.J. Joung[1#], H.J. Kim[1], A. Rowe[2], M. Wong[2]
[1]IBS, Daejeon, South Korea
[2]Fermi National Accelerator Laboratory, Batavia, USA

Abstract

Superconducting radio frequency (SRF) cavities undergo a number of processes as part of its manufacturing procedure in order to optimize their performance. Among these processes is a high temperature hydrogen degas heat treatment used to prevent 'Q' decrease. The heat treatment occurs in the processing sequence after either chemically or mechanically polishing the cavity. This paper summarizes the hydrogen measurements during the heat treatment of a sample of chemically and mechanically polished single-cell and nine-cell 1.3-GHz cavities. The hydrogen measurements are analyzed according the polishing method, the polishing history, the amount of time that the cavity was baked at 800°C, and the temperature ramp rate.

INTRODUCTION

The performance of superconducting radio frequency cavities is most important fact for a high gradient accelerator. However it is limited by field emission and thermal magnetic breakdown.[1] Most of the SRF cavities receive surface treatment to improve the performance of the cavity. A high temperature heat treatment degases the hydrogen gas that comes from the polishing process. High temperature heat treatment provides some stress-relief in the material in addition to degassing hydrogen gas [2] Hydrogen degassing studies were carried out at Jefferson Laboratory and Institut fuer Kernphysik using defference cavity. [3-4] The goal of the analysis in this paper was to evaluate whether a dependency exists between the cavity surface processing techniques, the kind of cavity and the hydrogen evolution during the heat treatment. The different polishing techniques and sequence are described. The methodology of determining the amount of degassed hydrogen is explained. Finally, the conclusion shows a comparison of the hydrogen amount.

DESCRIPTION OF CAVITIES & PROCESSING HISTORY

Nineteen single cell cavities and three nine-cell cavities, all 1.3-GHz cavities, were analyzed. All had a variety of processing steps. The cavities were polished using either EP (Electropolishing) or CBP (Centrifugal Barrel Polishing, or tumbling) to a mirror finish. [5]

The EP process polishes the surface using electrical current in acid solution at 30°C. It is a type of chemical polishing. The CBP (or tumbling) process polishes the surface using material (media) for many hours between 30°C and 50°C. It is a type of mechanical polishing.

The 800°C heat treatment takes place after the cavities were polished. During the heat treatment the temperature ramp rate was either 3°C per minute or 10°C per minute and the soak time at 800°C was either 2 hours or 3 hours. Table 1 shows the various sequences that different cavities experienced. It is noted that the amount of material removed during polishing did not correlate with the amount of degassed hydrogen.

Table 1: Polishing and Bake Sequences for the Cavities

Cavity No.	Process
1, 2, 3, 4, 9, 11, 13, 14, 15, 16, 17, 18, 20, 23, 25, 26	EP / bake
10, 12	CBP / bake
7, 19	EP / CBP / EP / bake
6	EP / CBP / bake
22, 24	CBP / EP / bake
5	CBP / bake / EP / bake

MEASURING AND CALCULATING THE H_2 AMOUNT

The vacuum furnace has a SRS 100 residual gas analyzer that measures the partial pressures of gasses during a bake. The RGA sits outside the furnace's hot zone and on the opposite end of the chamber's cryopumps. Figure 1 shows the hydrogen partial pressure curves for an electropolished cavity, a tumbled cavity and the baseline from an empty chamber for a temperature soak of 3 hours and a ramp rate of 3°C per minute. Of interest is the pressure data within the temperature range of 300°C to 300°C, as is shown in Figure 1.

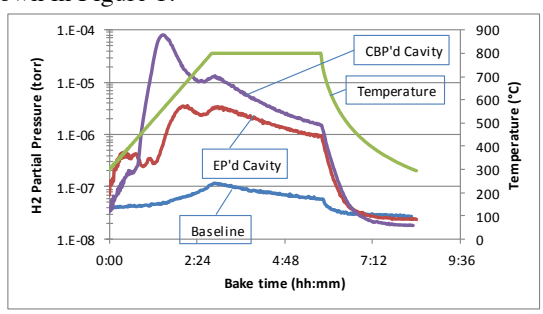

Figure 1: Typical H_2 partial pressures of an electropolished cavity, a tumbled cavity, and an empty chamber within 300°C to 300°C.

Copyright © 2013 CC-BY-3.0 and by the respective authors

A baseline hydrogen pressure curve was established by baking an empty furnace chamber. The empty chamber sat at room temperature at a vacuum pressure on the order of 1E-8 torr for eighteen days before the bake cycle started.

To calculate the total amount of degassed hydrogen from a cavity during a bake, the cavity's hydrogen pressure curve was integrated. The baseline hydrogen curve is also integrated, and the difference between the two values is the shaded area shown in Figure 2. This value is then multiplied by the effective pumping speed (~500 L/s) within the furnace to provide the total degassed hydrogen in units of torr-L.

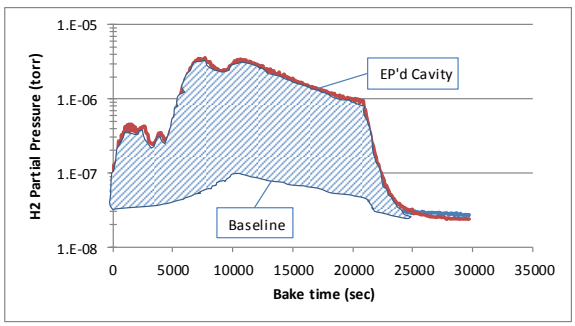

Figure 2: Area between the cavity and baseline H_2 pressure curves.

HYDROGEN ANALYSIS

Between Tumbled Cavity and EP Cavity

This section shows that tumbled cavity has a larger amount of hydrogen than the electropolished cavity. The tumbled cavities showed a hydrogen peak at temperatures between 500°C and 600°C. The hydrogen peak was typically an order of magnitude higher than the hydrogen level during the 800°C soak. Figure 2 compares the hydrogen amount for tumbled and electropolished cavities that had a three hour soak and a temperature ramp rate of 3°C per minute (cavities numbered 1 through 12). Cavities numbered 6, 7, 10, 11 and 12 were tumbled cavities. The rest of the cavities were electropolished.

Figure 3 shows the large of amount of hydrogen in the tumbled cavities compared with the electropolished cavities. It is likely that an electropolished cavity emits a small amount of hydrogen compared to the tumbled cavity. The H^+ ions that are produced tend to go into the cathode rather than the niobium surface. Also, the oxide surface layer which is produced during EP process prevents H^+ ions from penetrating easily into the niobium material. On the other hands, during the CBP process, the niobium oxide layer disappears and the H^+ ions can penetrate into the niobium material. Once the CBP process is complete, the oxide layer is reformed. During the heat treatment process, the oxide layer is removed and any hydrogen loaded into the niobium is released.

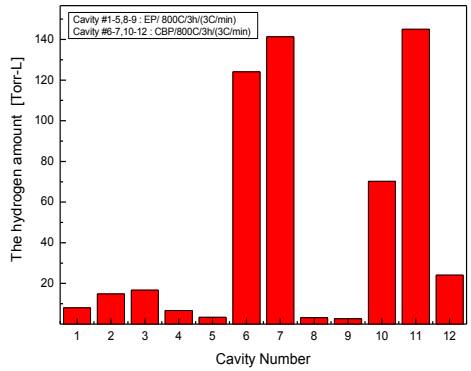

Figure 3: Comparing degassed H_2 in electropolished vs. tumbled cavities.

Between the Single-Cell Cavity and Nine-Cell Cavity

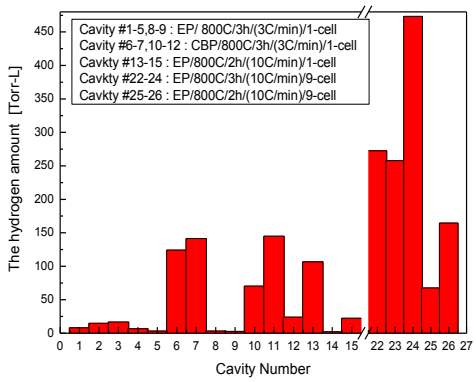

Figure 4: Comparing degassed H_2 in single-cell vs. nine-cell cavities.

Figure 4 shows the amount of hydrogen when comparing the single cell and nine cell cavities. Cavities 16-20 are single-cell cavities, and the cavities 22-24 are nine-cell cavities. Cavities 19, 22 and 24 are tumbled cavities. The nine-cell cavities show the degassed hydrogen amount more than nine times of the hydrogen amount from single-cell cavities, as expected.

By Polishing History

Each cavity received different kinds of polishing and polishing time, listed in Table 1. Two observations were found by comparing the polishing histories of the cavities. One observation confirms again that the amount of degassed hydrogen comes from the electropolished cavity is significantly less than the amount of hydrogen from the cavity that received CBP. The second observation is that the hydrogen amount from CBP cavity is larger no matter how many EP processes it received. So it turned out that EP process cannot remove hydrogen gas that comes from the CBP process. But when there is a baking process between CBP process and EP process, the baking process removes the hydrogen gas from the cavity that is left from the CBP process.

Copyright © 2013 CC-BY-3.0 and by the respective authors

CONCLUSIONS

This paper describes how the hydrogen data was collected and how the amount of hydrogen was calculated. The degassed hydrogen amount from electropolished and tumbled cavity was analyzed. It was confirmed that tumbled cavities degas a large of hydrogen gas compared with electropolished cavities and the basic principle was explained in the section of hydrogen analysis. It was found that the EP process cannot remove hydrogen gas that comes from the CBP process. Once the cavity received CBP process before baking, regardless of whether or when the cavity was EP'd the cavities degases a large of hydrogen amount. In comparing the single cell and nine-cell cavities, it was expected that the degassed hydrogen amount would be more, correlating with surface area. The amount of hydrogen from nine-cell cavities was much than expected. More studies will be done to understand the reason. The increasing rate of hydrogen amount to determine the real pump capacity and calculating the RGA accuracy has to be studied further in order to optimize the heat treatment process.

MEASUREMENT OF A SUPERCONDUCTING SOLENOID WITH APPLICATIONS TO LOW-BETA SRF CRYOMODULES*

S.H. Kim#, M.P. Kelly, Z.A. Conway, P.N. Ostroumov, ANL, Argonne, IL 60439, USA

Abstract

Proton and heavy-ion linacs with superconducting cavities require compact lattices to suppress emittance growth in the low-velocity region. For beam focusing superconducting solenoids are superior in this regard to normal conducting quadrupoles. A superconducting solenoid with integral x-y steering coils has been fabricated for the Project-X Injector Experiment (PXIE) half-wave resonator cryomodule. It is capable of generating 6 T solenoidal fields and dipole steering fields of 30 T·mm field integrals in both of transverse directions. We experimentally investigated issues for practical use of this solenoid in cryomodules including: 1) the superposition of dipole steering fields on solenoidal fields, 2) the magnetic axis of the solenoid with respect to the mechanical references in cryogenic temperatures, and 3) the residual magnetic field generated by the solenoid on the superconducting RF cavity surfaces even after degaussing; a 72 MHz quarter wave resonator was used for this experiment. In this paper, we present details of experimental setup and results.

INTRODUCTION

Proton and ion linacs require a compact focusing lattice in the low-velocity region to minimize the required real-estate and to minimize emittance growth and corresponding beam loss [1]. Superconducting solenoids are superior in this regard to normal conducting quadrupoles. To reduce the real-estate requirements further dipole steering coils are integrated with solenoids [2]. This superconducting solenoid with dipole steering coils is to be installed in a cryomodule with superconducting RF cavities so the following questions regarding beam and cavity performance need to be verified: 1) Are the dipole fields linearly superposed with the solenoid fields? 2) Is the solenoid aligned to the beam in the cryomodule? 3) Are the residual magnetic fields generated by the solenoids small enough not to degrade the cavity Q-factor?

We studied these issues with a superconducting solenoid prototype fabricated for the Project-X Injector Experiment (PXIE) Half-Wave Resonator (HWR) cryomodule [3]. This solenoid generates 6 T solenoidal fields and each pair of the dipole steering coils integrated with the solenoid produces up to 30 T·mm integrated deflecting fields. In this paper, we will briefly introduce the solenoid used in these experiments and present the dipole field measurements with and without the solenoidal field to discuss field superposition. Then, we will present magnetic axis measurements relative to the mechanical axis and discuss accuracy of this measurement method. Another alignment issue, the alignment of the solenoid to the beam axis in the cryomodule, is not discussed in this paper [4]. Next, measurements of the residual magnetic fields generated by the solenoid on the surface of a 72 MHz superconducting Quarter-Wave Resonator (QWR) will be presented with a discussion of the degaussing employed to reduce the residual magnetic fields on the cavity surface. Finally, a summary of these experimental results will conclude this paper.

FIELD PROFILES AND SUPERPOSITION

The solenoid contains two bucking coils at either end. The bucking coils are wired in series with the main solenoid to produce an opposing field polarity relative to the solenoidal field. There are no iron return yokes or magnetic shields surrounding the solenoid. The bucking coils minimize the axial fringe fields and stray fields on the cavity surfaces. The measured axial field profile is shown in Fig. 1. The measured solenoid field in the high field region is in good agreement with the design values; this ensures that the focal length will be the same as the designed value. The fringe fields are slightly higher than the design but are still small enough for the residual magnetic fields around the cavity wall to be successfully reduced by degaussing as will be discussed later in this paper.

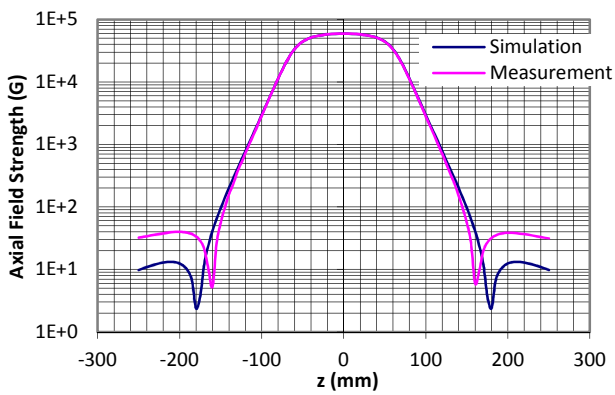

Figure 1: Axial field profiles on the axis. z is the longitudinal position which is 0 in the middle of the solenoid. Note that the magnetic field drops at z = ±160 mm in the measured data and at z = ±180 mm in the simulated response correspond to a polarity change in the axial field.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Each dipole steering coil is composed of two racetrack shaped coils located outside of the solenoid coil; one is oriented vertically and the other is oriented horizontally. The dipole fields are measured on the z-axis of the solenoid bore with and without the solenoid field on. When the solenoid is energized to 6 T, the dipole field is 5~7% higher than when the solenoid is off, Fig. 2. With no current the solenoid coil, which is composed of multi-filamentary NbTi strands twisted within a copper matrix, is supposed to partly shield the dipole fields. However, the operating solenoid field of 6 T is high enough relative to the lower critical field of NbTi such that the dipole fields will be stable in actual operation. In the measurements presented here, the solenoid was turned on and off at each data point shown in Fig. 2. Notice that the measured field is axially symmetric with respect to the middle of the solenoid so the dipole coil is mechanically stable against Lorentz forces produced by the solenoid.

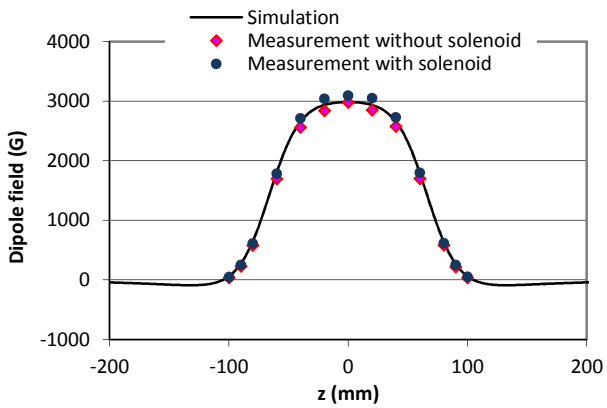

Figure 2: Dipole field profiles of simulation and measurement with and without solenoid fields.

MAGNETIC AXIS OF SOLENOID

The magnetic axis, here defined as the center of the solenoidal equipotential lines, is derived from an angular scan of the radial magnetic field using a hall probe. We measured the radial component of the magnetic field at two longitudinal positions, z = ±64 mm. These locations satisfy the following conditions; 1) the radial field is linear and 2) the radial field strength is large enough relative to the axial field component which reduces measurement errors arising from the misalignment of the probe. Because of the linearity this field sinusoidally oscillates with the azimuthal angle if the magnetic center has an offset from the mechanical center of the solenoid bore which is the center of probe rotation. The relationship between the magnetic field parameters and geometries is given by:

$$\Delta B/B_0 = d/R, \qquad (1)$$

where ΔB is the field amplitude, B_0 is the field offset of the measured magnetic fields, d is the offset of the magnetic center from the mechanical center, and R is the radius of the angular scan.

The measurement results are shown in Fig. 3, the measured offsets are 0.32 mm at z = -64 mm and 0.27 mm at z = +64 mm where R = 16 mm. The phase of each cosine curve corresponds to the angular offset of the magnetic center relative to the x-axis of the solenoid; so the magnetic center is located 145 degrees (z = -64 mm) and 115 degree (z = 64 mm) from the x-axis of the solenoid. Uncertainty in the longitudinal position of the measurements is the source of the field-offset difference between two curves in Fig. 3.

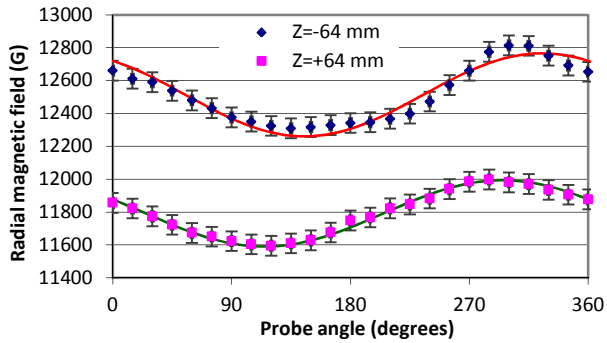

Figure 3: Angular scan of radial magnetic field to find the magnetic axis with respect to the mechanical axis (probe angle is 0 on the x-axis of the solenoid) measured at two different longitudinal positions.

Errors in these measurements are given by these factors: 1) uncertainty of the probe position in the radial and longitudinal directions, 2) misalignment of the hall probe, 3) contribution of the second or higher order of d/R because eq. (1) is derived with the first order approximation of d/R, 4) instrument errors of the probes and the gauss-meter, and 5) wobbling of the rotating rod on which the probes are attached during the angular scan. The factors from the first to the fourth totally give a fractional error of 5% in the result of d, which is negligible because typical transverse alignment tolerance of this solenoid is 0.25 mm. However, the last factor, which originates from the gap between the rotating rod and the rotation guide as shown in Fig. 4, gives uncertainty in the offset by the same amount of the gap distance which is ±70 μm after correction by thermal contraction. Multiple scans per angle would reduce this error statistically. It is measured once per angle in this study.

RESIDUAL MAGNETIC FIELDS

The solenoid test with the QWR is done to observe any residual magnetic field which is possibly generated by materials around the cavity, such as the helium jacket and the solenoid housing, magnetized after solenoid operation. To minimize the residual magnetic field, we degaussed the solenoid with a temporally sinusoidal current profile whose envelope is exponentially decayed with a decay time of 5 times the sinusoidal oscillation period and it finished when the field amplitude of the last degaussing cycle was 7 G in the middle of the solenoid.

Copyright © 2013 CC-BY-3.0 and by the respective authors

We installed the solenoid with the cavity in a cryostat as shown in Fig. 5 and measured magnetic fields during and after solenoid degaussing at two representative locations: one on the axis where the solenoid field is a maximum and the other on the cavity wall, which is the higher position in Fig. 5, where the RF magnetic field is a maximum when we use the PXIE HWR.

On the cavity wall, the magnetic field measured during the degaussing behaved like a hysteresis curve which is supposed to be dominated by the NbTi in the solenoid coil [5] and it came to the center of the hysteresis curve after degaussing was finished; therefore, there is no residual magnetic field after degaussing at that position except for leakage of the earth's magnetic fields, which cannot be degaussed by the solenoid, no matter what was magnetized during solenoid operation. On the other hand, the probe installed on the axis is too coarse to measure the residual magnetic field by accuracy of tens of mG because it is for measuring high level fields; note that the maximum field is 75 G on the axis whereas it is 55 mG on the cavity wall. The residual field on the axis was measured again after warming up scanning the low field probe and it was found that there were ~100 mG residual fields around the solenoid and the source of these fields was inside the solenoid housing; other than that, there are no significant residual field more than 10 mG except for leakage of earth's magnetic fields. For accurate measurements, we set the solenoid alone inside a good magnetic shield. The measurement results are shown in Fig. 6. Even though there still remain the residual magnetic fields inside the solenoid, the degaussing worked successfully so that the residual field at the position of the cavity surface is 2~3 mG.

SUMMARY

With the PXIE solenoid, we experimentally verified that 1) the dipole field of the steering coil is well superposed to the solenoid field and this coil is mechanically stable on solenoid operation, 2) the magnetic axis can be found with accuracy of less than 100 μm by scanning hall probes, 3) residual fields generated by the solenoid can be reduced to a few mG at the cavity surface by degaussing the solenoid.

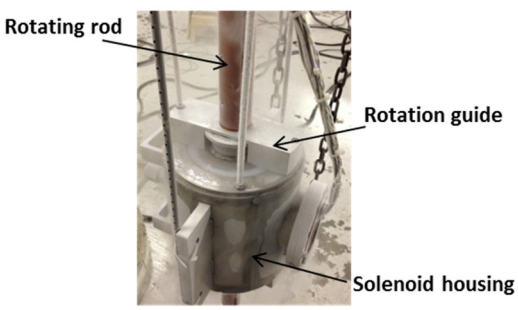

Figure 4: Setup for angular scan of the radial magnetic field. Hall probes are attached on the rotating rod which is composed of bakelite while the rotation guide is composed of aluminium and the solenoid housing is composed of stainless steel.

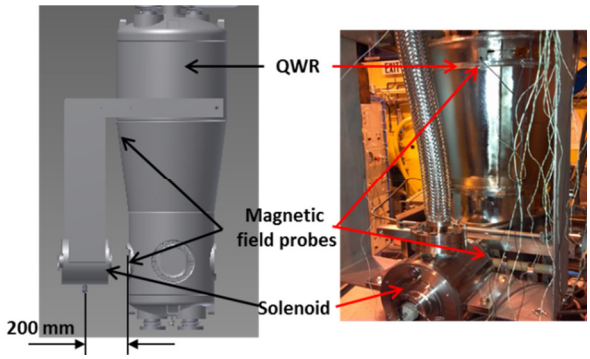

Figure 5: Magnetic field measurement setup in the cryostat. The QWR is hung on the cryostat lid. Each probe measures the magnetic field normal direction to the cavity wall; higher position on the cavity wall: low field probe (Bardington Fluxgate Magnetometer, Mag-01), lower position on the axis: high field probe (Lakeshore Hall Probe, HMCT-3160).

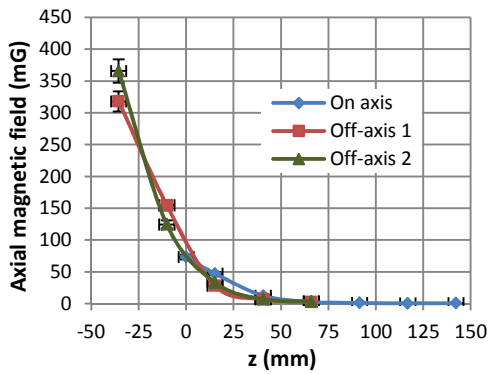

Figure 6: Axial scans of the residual magnetic field generated by magnetized materials in the solenoid. It is measured with the solenoid alone. The solenoid flange is placed at z=0 and the cavity flange will be placed at z=75 mm. The radial position of the "off-axis" scan is r=56 mm where the measured residual magnetic field is maximum.

Abstract

A 5-cell SRF cavity operating at 704 MHz will be used for Coherent Electron Cooling Proof of Principle (CeC PoP) system under development for the Relativistic Heavy Ion Collider (RHIC) at Brookhaven National Laboratory. The CeC PoP experiment will demonstrate the new technique of cooling proton and ion beams that may increase the beam luminosity in certain cases, by as much as tenfold. The 704 MHz cavity will accelerate 2 MeV electrons from a 112 MHz SRF gun up 22 MeV. Novel mechanical designs, including a super fluid heat exchanger, helium vessel, vacuum vessel, tuner mechanism, and fundamental power coupler (FPC) are presented. Structural and modal analysis, using ANSYS [1] were performed to confirm the cavity chamber and helium vessel structural stability and to calculate the tuning sensitivity of the cavity. This paper provides an overview of the design, the project status and schedule of the 704 MHz 5-cell SRF for CeC PoP experiment.

INTRODUCTION

The BNL3 5-cell 704 MHz SRF linac that is being designed and fabricated in collaboration between BNL and Niowave, will be used as the main 20 MeV accelerator for CeC PoP experiment under construction at IP2 of RHIC at BNL [2]. Phase II of this experiment is to be completed by the end of shutdown 2014 and will include the 704 MHz SRF linac. At the same time, with this project, BNL is pursuing R&D towards the electron-ion collider (eRHIC). This paper provides an overview of the design and structural analysis of the 704 MHz SRF linac. Two 5-cell Niobium cavities have been fabricated. The first one, BNL3-1 was manufactured by AES and the second one, BNL3-2 by Niowave.

704 MHZ DESIGN

Design Features

The 704 MHz 5-cell cavity cryostat consists of an internal phase separator, control valves, 5-cell cavity, two magnetic shields and a helium gas cooled thermal shield, a superfluid heat exchanger and an electrical heater. The helium supply and return lines are bayonet connections for quick assembly [3]. The layout of the 704 MHz SRF 5-cell SRF linac is shown in Figure 1.

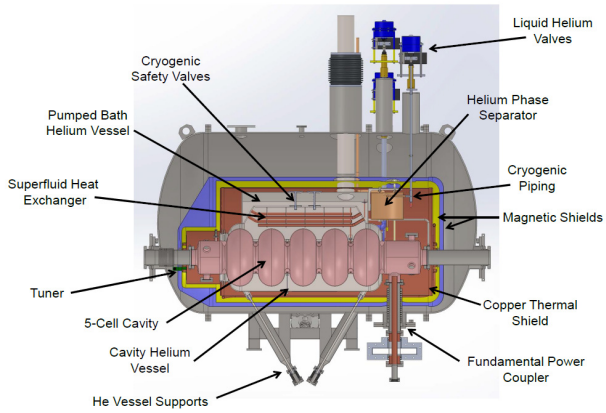

Figure 1: Layout of the 704 MHz SRF cryomodule.

The bottom of the helium vessel is a cylinder that incorporates the 5-cell cavity with the upper section modified to include the superfluid heat exchanger. Due to space constraint at IP2, the helium vessel was designed with the minimum real estate possible in order to keep the cryostat within the available space. The stiffeners shown in Figure 2 were added to the side of the helium vessel in order to reduce the deformation which translates to the cavity by deforming it through the supports attached to the helium vessel.

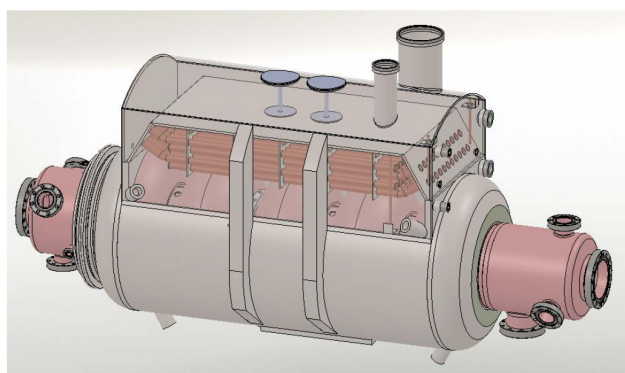

Figure 2: Layout of the 704 MHz cavity in a helium vessel.

Cavity Support

The support for the 5-cell cavity was designed in order to increase the natural frequency of the cavity in the helium vessel. The cavity is supported by three 1/8" Grade 5 titanium rods, symmetrically distributed around the beam axis. The support is located after the second

cell, closer to the tuning bellows as shown in Figure 1. The support was designed to have no effect on the mechanical tuning of the cavity.

Mechanical Tuning System

The BNL3 cavity mechanical frequency tuning system was adopted from a design that has been successfully implemented by Dresden in Germany for their superconducting RF Photo-Injector [4]. The main reasons to use this design is for the mechanical advantage of the lever arms, the large tuning range, high resolution, hysteresis-free and linear operation. The design was modified to integrate a piezoelectric actuator for fast tuning and to accommodate larger cavity dimensions.

Fundamental Power Coupler

The fundamental power coupler is used to deliver up to 20 kW CW RF power to the SRF cavity. A cylindrical ceramic window is used to transmit the RF power from a reduced-height WR1150 waveguide to a coaxial line and to seal the cavity vacuum. The outer conductor of the coaxial line will be cooled by 5 K helium gas, and the RF window and inner conductor will be cooled by water. The final model of the fundamental power coupler is shown in Figure 3. The window material is 96% alumina with a dielectric constant of 9.4. The simulated S parameters are shown in Figure 4.

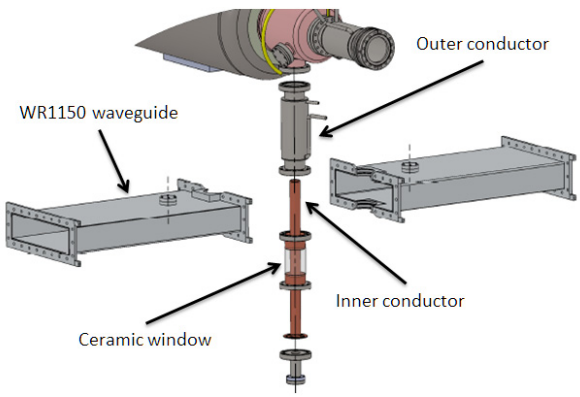

Figure 3: Fundamental power coupler model.

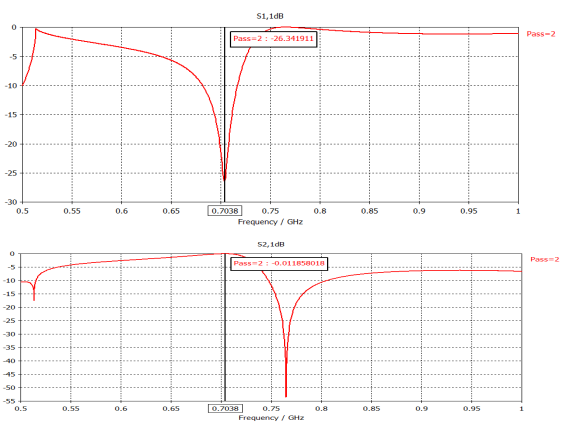

Figure 4: S-parameters for the FPC.

ANALYSIS

5-Cell Cavity

As mentioned earlier, structural and modal analyses, using ANSYS were performed to confirm the cavity chamber and He vessel structural stability and to calculate the tuning sensitivity of the cavity. When helium pressure is applied on the cavity, its deformed shape will change the resonance frequency. The sensitivity of the cavity is 10 Hz/mbar bases on the analysis. The location of the stiffeners between the cavities of the 5-cells had to be validated at maximum pressure condition (23 psia relief valve set pressure).

The second part of the analysis was to find the maximum allowable deformation of the cavity before yielding. One end was fixed in all degrees of freedom while allowing the other end to only move in the y direction. A 384 lbs force deformed the cavity by 0.442 mm with a maximum stress of 7507.4 psi. The yield strength of Niobium is 7500 psi. This corresponds to a tuning sensitivity of 171.6 kHz/mm. The relaxed and deformed shapes of the cavity are shown in Figure 5.

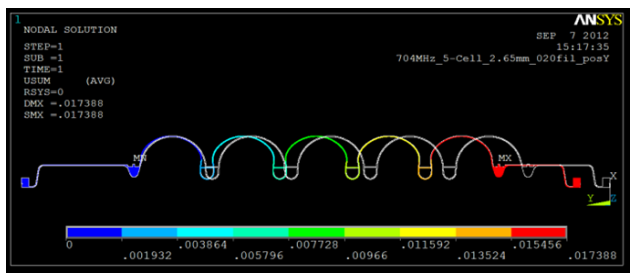

Figure 5: Relaxed and deformed shapes of the cavity.

Tuning Bellows

The tuning bellows was designed using titanium Ti-6Al-4V Grade 5 because of its high tensile yield strength of 120000 psi. The analysis was done at the maximum pressure condition (23 psia relief valve set pressure) applied on the inside of the bellows. The applied pressure resulted in a total deformation of .0065" and a maximum stress of 19927 psi in the convolutions of the bellows. Based on the results from the analysis, the helium vessel is determined to be safe under operating condition (14.7 psi) and the maximum condition (23 psi).

Modal Analysis

The goal was to design the struts to support the helium vessel and 5-cell cavity inside the vacuum cryostat, in order to keep the natural frequency above or close to 90 Hz. In the analysis, the three struts were at a 60° angle from the horizontal, symmetrically placed around the helium vessel about the axis of the beam on each side of the centre plane. Instead of using a solid rod for the struts, they are made of hollow ½" OD 0.022" WT Tube Ti Grade 2 in order to reduce the heat leak into the helium vessel and stiffening the structure. Based on the results from the analysis, the first mode reached 88.3 Hz. Although it is below 90 Hz, it is determined to be

sufficient. Table 1 shows the results from ANSYS simulations.

Table 1: Mode Frequencies from ANSYS Modal Analysis

Mode	Frequency [Hz]
1	88.3
2	113.8
3	150.7

Helium Vessel

The deformation of the side of the helium vessel affects the 5-cell cavity by applying a force on it through the cavity support and deforming it. Under the maximum pressure condition (23 psi relief valve set pressure) the location of the stiffeners on the side of the helium vessel, shown in Figure 3, was optimized using ANSYS. The shape and size of the stiffeners was limited to the space available inside the heat shields. The maximum deformation of the helium vessel is 0.015", which deforms the 5-cell cavity by 0.007" in the radial direction. The maximum stress in all the components affected, are within the allowable limits. The deformed shapes of the helium vessel and 5-cell cavity are shown in Figure 6 and Figure 7.

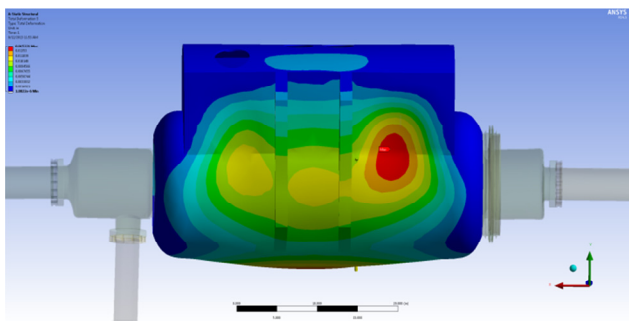

Figure 6: Deformed shape of the helium vessel.

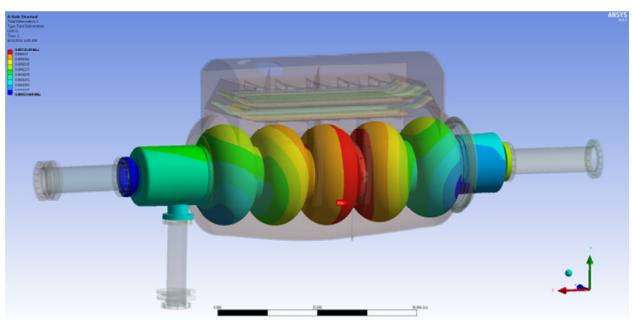

Figure 7: Deformed shape of the 5-cell cavity.

FABRICATION

Bulk buffer chemical polishing (BCP) of BNL3-1 (120 μm) was completed at AES and the cavity was baked at BNL at 600°C for 24 hrs. After baking, the cavity was sent back to AES for light BCP and HPR. BNL3-1 cavity is shown in Figure 8.

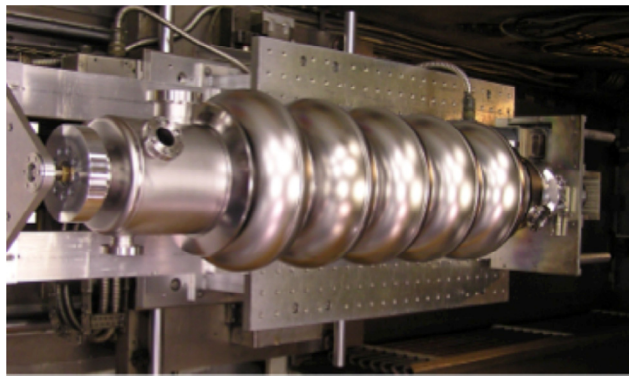

Figure 8: BNL3-1 cavity.

The second cavity, BNL3-2, and a cryomodule for CeC PoP are on order from Niowave. The fabrication and processing (bulk BCP, 600ºC vacuum bake, light BCP and HPR) of the cavity was completed recently at Niowave and BNL. The test in our vertical test facility for both cavities is scheduled for later this year. The better performed one of the two cavities will be integrated in the cryomodule.

CONCLUSION

The superfluid heat-exchanger, the tuner system and the cryogenic components make the mechanical design a challenging task. A preliminary design review of the cryomodule was completed in September at Niowave. We are working closely with Niowave to finalize the design and integration of the tuner system in the cryostat. The fabrication of the helium vessel and several components attached to the helium vessel is schedule to begin within the next couple weeks. The 704 MHz SRF linac is scheduled to be installed during RHIC summer shutdown 2014.

2) Stony Brook University, Stony Brook, NY 11794, U.S.A.

Abstract

A Quarter-Wave Resonator (QWR) type SRF gun operating at 112 MHz will be used for Coherent Electron Cooling Proof of Principle (CeC PoP) system under development for the Relativistic Heavy Ion Collider (RHIC) at Brookhaven National Laboratory (BNL). The CeC PoP experiment will demonstrate the new technique of cooling proton and ion beams that may increase the beam luminosity in certain cases, by as much as tenfold. The 112 MHz cavity is designed to generate a 2 MeV, high charge (several nC), low repetition rate (78 kHz) electron beam using a new fundamental power coupler (FPC) design approach. Structural and thermal analysis, using ANSYS were performed to confirm the FPC structural stability and to calculate the deflection due to heat load from RF power generation. This paper provides an overview of the design, structural and thermal analysis, test results, and FPC tuning drive system for the 112 MHz gun.

INTRODUCTION

A 112 MHz superconducting quarter-wave resonator will be used as the injector for CeC PoP experiment under construction at IP2 of RHIC at BNL [1]. Phase I of this experiment is to be completed by the end of RHIC shutdown 2013 and will include the 112 MHz superconducting QWR and the fundamental power coupler that will be discussed in details in this paper. The paper provides an overview of the design, structural and thermal analysis, test results, and FPC tuning drive system for the 112 MHz gun.

112 MHZ FPC DESIGN AND FABRICATION

Design

The FPC is a coaxial structure, which provides tunable RF coupling and presents small interference to the electron beam output [2]. The FPC design couples the RF power into the cavity from the exit beam pipe of the cavity and allows the electron beam to travel through the hollow inner conductor of the FPC. An external linear motion system will be used to adjust the penetration of the coupling tube in order to fine tune the frequency of the cavity as well as to adjust the coupling strength [2]. The FPC was design to meet all the parameters listed in Table 1.

Table 1: Parameters of the Fundamental Power Coupler for 112 MHz QWR SRF gun

RF frequency	112 MHz
Frequency tuning range with FPC	3 kHz
FPC travel range	40 mm
Q_{ext} of FPC, min.	1.25×10^7
Max. RF power loss on the FPC inner conductor	898.6 W
Max. RF power loss on the FPC outer conductor	554.6 W
Available RF power	2 kW

The complete and detailed layout of the 112 MHz QWR and the FPC are shown in Figure 1 and Figure 2.

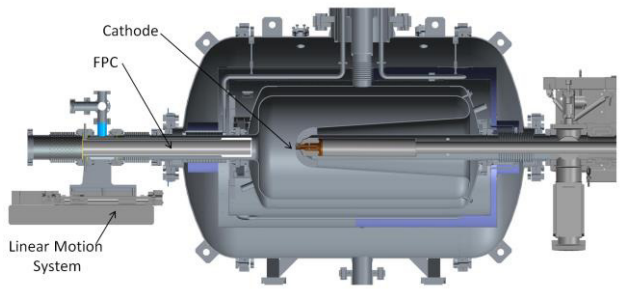

Figure 1: Layout of 112 MHz FPC in the QWR.

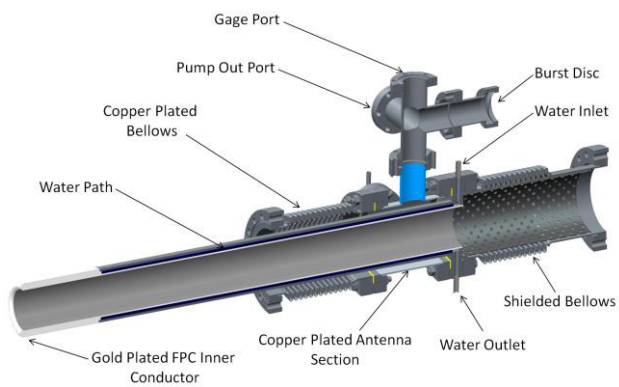

Figure 2: Detailed Layout of 112 MHz FPC.

In order to power the FPC, a BeCu connector was designed. The connector threads into the inner conductor of the FPC and slides inside an air cooled 7/16 UHF UHV cryogenic feedthrough designed by BNL. The FPC will be powered on both sides as shown in Figure 3.

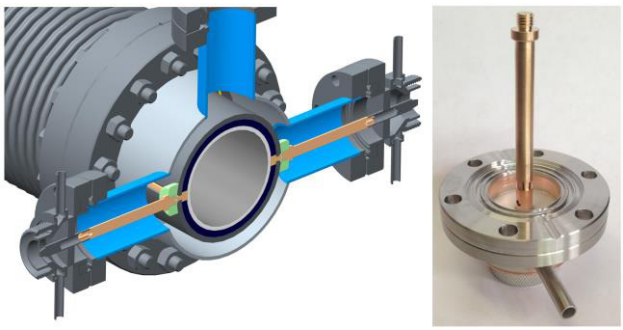

Figure 3: View of the vacuum feedthrough for connection of the coaxial cable to the FPC.

Analysis

One issue with the FPC design was to provide adequate cooling for removing heat due to RF power losses on the surfaces of the inner and outer conductor when the gun is operating. The outer conductor includes the copper plated bellows. Structural and thermal analyses, using ANSYS, were performed to confirm the FPC structural stability and to calculate the deflection and maximum temperature due to heat load from RF power generation. The distribution of RF power dissipated on the FPC inner and outer conductors is shown in Table 2.

Table 2: Distribution of RF power loses on the FPC

RF Power Loses	Value
On inner conductor hollow section	894.3 W
On inner conductor solid section	4.3 W
On bellows of outer conductor	554.6 W
On flange	21.9 W

In order to find out if cooling was needed for the bellows on the outer conductor of the FPC, ANSYS was used to determine the maximum temperature on the overall system. Several heat fluxes were applied on the inner surfaces corresponding to the values in Table 1 and a natural convection by air. A heat transfer coefficient of 15 W/m^{2}K was applied on the outer surfaces. A maximum temperature of 460 K was observed at the depth of the convolution. The result from ANSYS for the natural convection cooling of the outer conduction of the FPC is shown in Figure 4.

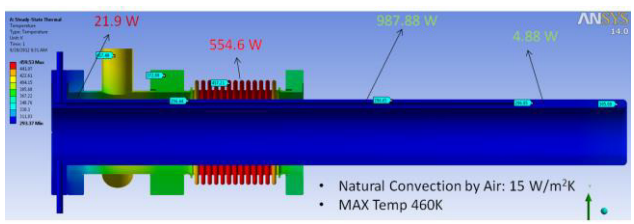

Figure 4: Temperature profile on the overall FPC.

The inner conductor of the FPC will be cooled using a temperature controlled water source. As shown in Figure 1, the inner conductor has a solid and hollow section. The solid section is designed to stiffen the structure and space out the channels from the 4K region of the QWR. The hollow section consists of two water channels, one on the upper half and the other one on the lower half. Both channels are connected towards the solid end of the FPC. The water flows through the upper half first and exits through the lower half of the FPC with a calculated temperature difference of approximately 1 K between inlet and outlet. The cooling system parameters are shown in Table 3.

Table 3: Cooling System Parameters FPC

Parameters	Value
Water volume flow rate, Q	4 GPM
Pressure drop	< 2 PSI
Local heat transfer coefficient, h	3217.4 W/m^{2}K
Inlet-Outlet temperature difference	0.88 K

The ANSYS results shown below in Figures 5, 6, and 7 indicate that the FPC will reach a maximum temperature of 305 K and a maximum deflection of 0.001" [3].

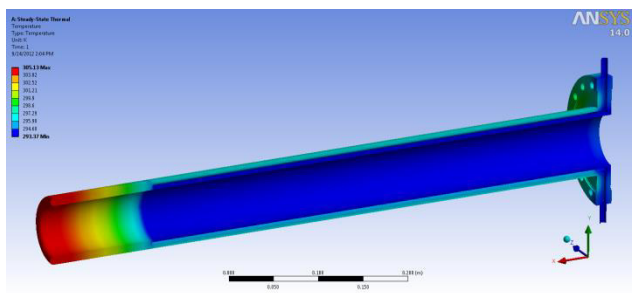

Figure 5: Temperature profile on the FPC inner conductor.

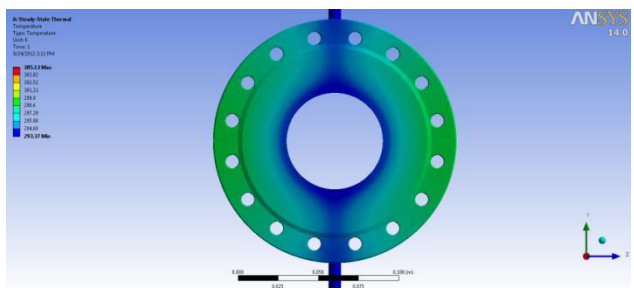

Figure 6: Temperature profile on the FPC water inlet/outlet flange.

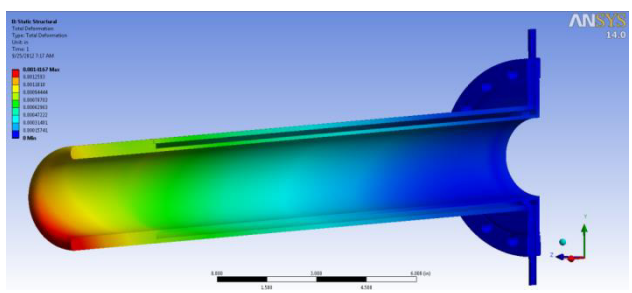

Figure 7: Deflection of FPC under thermal and structural load.

Fabrication

The FPC was designed by BNL and fabricated in collaboration with Stony Brook University. The copper plated and the shielded bellows of the outer conductor of the FPC shown in Figure 2 were designed to provide a 1 inch travel with a low spring constant of 84 lbs/in in order to reduce the moments on the linear motion system. The plated bellows shown in Figure 8 have a minimum of 25 µm thick layer of copper on the inside of the convolutions.

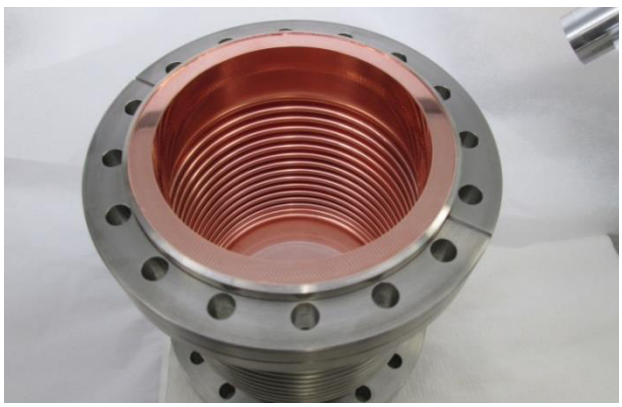

Figure 8: 112 MHz FPC copper plated bellows.

The inner conductor of the FPC was fabricated using 304 stainless steel because of its mechanical properties and for manufacturing purposes. The final assembly was copper plated with a 25 µm thick layer for the RF path, then plated with a 1 µm thick layer of gold to maintain a mirrored surface finish and bring the emissivity to as low as 0.02. This is done in order to reduce heat radiation to the 4 K environment of the 112 MHz superconducting QWR gun and prevent the cooling water from freezing in case of a failure.

Figure 9: 112 MHz FPC gold plated inner conductor.

112 MHZ FPC MOTION SYSTEM

The linear stage motion system for the FPC was designed and fabricated in collaboration between BNL and Ibex Engineering. The design uses a granite base in order to reduce deflection and vibration. The linear stage was successfully tested and met all the requirements listed in Table 4.

Table 4: Parameters of 112 MHz FPC linear stage

Parameters	Value
Travel range	40 mm
Response frequency	10 Hz
Position resolution	500 nm
Positioning accuracy	± 5 µm
Repeatability (no backlash- and hysteresis-free)	< ±500 nm
Straightness over travel range	± 5 mm
Flatness over travel range	± 5 mm
Speed	> 1 mm/s
Acceleration	> 60 mm/s^2
Position readback resolution	< 1 µm
Moment M1 transverse to the direction of travel	250 lbs.in
Moment M2 in the direction of travel	1000 lbs.in

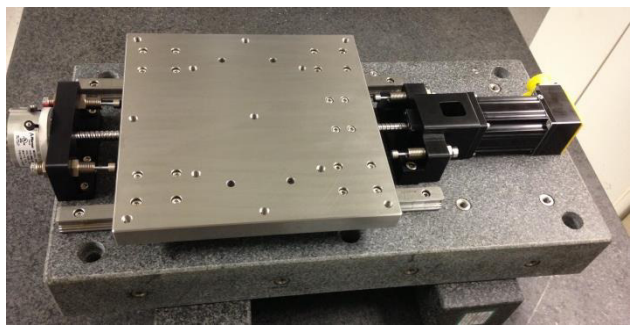

Figure 10: 112 MHz FPC linear motion system.

CONCLUSION

We successfully designed and manufactured all the components of the FPC. Most of the components have been tested individually to ensure that they meet all the requirements. The 112 MHz superconducting QWR gun is scheduled to be tested with the FPC and the cathode stalk during RHIC Run14. A safety interlock system is being designed to blow the cooling water in the FPC to prevent catastrophic failure, with the water freezing, in case of RF power loss.

A TEMPERATURE-MAPPING SYSTEM FOR MULTI-CELL SRF ACCELERATING CAVITIES*

M. Ge, G. Hoffstaetter, F. Furuta, E. Smith, M. Liepe, S. Posen, H. Padamsee, D. Hartill, X. Mi,
Cornell University, Ithaca, NY 14850, USA.

Abstract

A Temperature mapping (T-map) system for Superconducting Radio Frequency (SRF) cavities consists of a thermometer array positioned precisely on an exterior cavity wall, capable of detecting small increases in temperature; therefore it is a powerful tool for research on the quality factor (Q_0) of SRF cavities. A new multi-cell T-mapping system has been developed at Cornell University. The system has nearly two thousand thermometers to cover 7-cell SRF cavities for Cornell's ERL project. A 1mK resolution of the temperature increase ΔT is achieved. A 9-cell cavity of TESLA geometry was tested with the T-map system.

INTRODUCTION

The quality factor (Q_0) of Superconducting Radio Frequency (SRF) cavities is a critical topic in the SRF field. High-Q cavities are able to save cryogenic capacities of accelerators. The definition of Q_0 is given by equation (1), where w is the angular frequency of the cavity, U is its stored energy, P_{loss} is the power loss on the cavity surface. The Q_0-value ranks the cavity's efficiency. If we define a geometry factor (G) as function (2), the Q_0 may be written as the ratio of the geometry factor and the surface resistance (R_s).

$$Q_0 = \frac{\omega U}{P_{loss}} = \frac{G}{R_s} \tag{1}$$

$$G = \frac{\omega\mu_0 \int_V \left|\vec{H}\right|^2 dV}{\int_A \left|\vec{H}\right|^2 dA} \tag{2}$$

The geometry factor is a constant determined by cavity geometry shapes, thus the Q_0 is dictated by cavity surface-resistance.

The T-map system, a thermometer array uniformly attached on a cavity exterior surface, is a powerful tool for surface resistance research. It is able to detect tiny heating on cavity wall during feeding RF power into cavity. Hence by the heating map of whole cavity, it is possible to calculate power loss and surface resistance, furthermore to calculate the Q_0-value of the cavity. The Q_0 of a multi-cell SRF cavity measured from RF is derived from the total value of all cells. The relationship between total Q_0 of a 9-cell cavity and Q_0-value of each cell at pi-mode is given by equation (3)

$$\frac{1}{Q_0^{tot}} = \frac{1}{n}\sum_{n=1}^{9} \frac{1}{Q_n^{cell}} \tag{3}$$

*This work has been supported by NSF award PHY-0969959 and DOE award DOE/SC00008431

Here Q_0^{tot} is total Q_0 of a 9-cell cavity, and Q_n^{tot} is Q_0 of cell n. The total Q_0 is unable to reflect which cell has low-Q and degrades the whole cavity. However, T-map can diagnose the Q_0-value of each cell by summing each cell's power loss. Hence T-map gives more information about cavity performance than RF measurement alone.

T-mapping history can be traced back to the 1980s. Cornell University was a pioneer in developing a 1-cell T-map system for 1.5GHz SRF cavity research [1, 2, and 3]. Now Jefferson Lab and Fermilab also have 1-cell or 2-cell T-map systems. These systems are used for fundamental SRF research via single-cell cavities. Therefore the development of a multi-cell T-mapping system is necessary and ultra-important. DESY and Los Alamos have multi-cell T-mapping systems for ILC 9-cell cavities [4, 5]. Those systems are mainly used to detect quench location.

TEMPERATURE-MAPPING SYSTEM DESCRIPTION

This multi-cell T-mapping system has been developed for the Cornell ERL project which requires the Q_0-value of 7-cell cavities to achieve 2×10^{10} at accelerating gradient 16MV/m [6]. For a 1.3GHz SRF cavity, the heating from RF causes on average about a 10mK temperature rise on the exterior wall at 25MV/m in a 2K helium bath [7]. Thus the resolution of this T-map is required to be approximately 1mK.

Thermometers and Boards

The Cornell multi-cell T-map has nearly two thousand thermometers. The temperature sensor is a 100Ω carbon Allen-Bradley resistor (5% 1/8 W). Carbon is a semiconductor, its resistance increases exponentially when temperature drops. Figure 1 (a) shows the schematic of sensor and its picture. APIEZON grease was applied on the varnished side of the thermometers prior to inserting the boards in cages. The sensor is able to detect the temperature rise of the cavity wall with 25% efficiency [3]. Two sets of 3-cell boards and one set of 1-cell boards were used for 7-cell SRF cavity. A 3-cell board has two channels addressed to the sensors for 3-cells. The sensor boards are spaced azimuthally every 15° around the cavity; totally it has 24 boards around the azimuth. Each cell is covered by an 11×24 thermometer array. Figure 1 (b) shows a 3-cell and a 1-cell board. The quantity of thermometers for the whole 7-cell cavity is 1848. Cornell constructed a new test insert for hanging the multi-cell cavity with full T-map. In Figure 1 (c) the left image shows the Cornell multi-cell T-map attached on middle 7-cells of a 1.3GHz 9-cell cavity; the right image is a picture showing several boards removed to expose the cavity. The

Copyright © 2013 CC-BY-3.0 and by the respective authors

insert has a feedthrough on the top-plate for extracting T-mapping cables out of the Dewar. A coupler motor and Ion pump were built on the insert as well, which allows us to adjust the coupler position as well as to keep the cavity under high-vacuum during the RF test. Three well-calibrated Cernox thermometers were attached on the insert for T-map calibration.

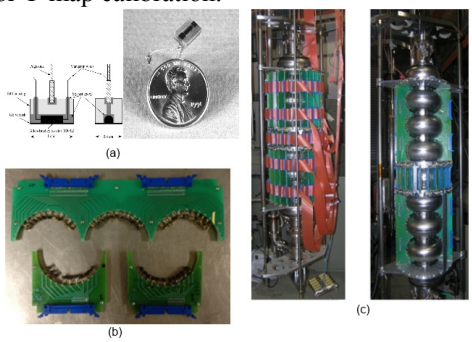

Figure 1: (a) Thermometer schematic, (b) T-map boards, (c) T-map insert.

CRYOGENIC TEST

We tested a 1.3GHz 9-cell cavity which is TESLA shape with the T-mapping system. The cavity was vertically electro-polished about 5μm, followed by high pressure water rinsing and clean assembly in a class 10 clean room. No 120°C baking was applied on the cavity.

Calibration and Sensitivity

A well-calibrated Lakeshore Cernox thermometer is utilized as a temperature reference for the helium bath during cooling down from 4.2K to 1.6K. Figure 2 (a) is a sensor's calibration curve.

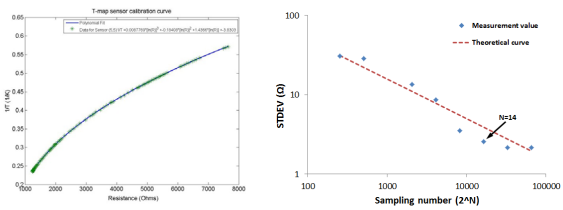

Figure 2 (a): 1/T vs. resistance curve during cooling down, (b) standard deviation vs. sampling number.

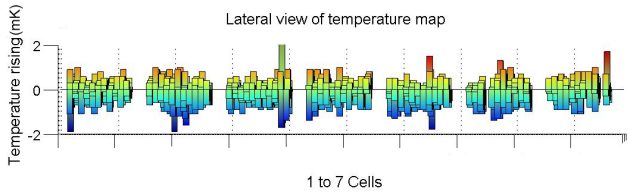
A polynomial function was adopted to fit the curve, shown in equation (4).

$$\frac{1}{T} = a_n x^3 + b_n x^2 + c_n x + d_n \qquad (4)$$
$$x = ln(R)$$

Here T is the bath temperature, R is the resistance of the carbon resistor, a_n, b_n, c_n, and d_n are fitting parameters for sensor n. By using fitting curves, it is possible to calculate $\frac{dR}{dT}$ which represents the sensitivity of each T-mapping sensor. An Allen-Bradley resistor value is about 12kΩ at 1.6K, $\frac{dR}{dT}$ is approximately 30Ω/mK; and $\frac{dR}{dT}$ is about 10Ω/mK at 2K.

Noise comes from the environment and the electronic system. Increasing measurement sampling number is an effective way to reduce noise from the electronic system. The PIXI controller can sample the sensor voltages at a 500 KHz rate, and average readings for 2^N samples. Figure 2 (b) shows the standard deviation of resistance decreasing with increasing sampling number. The dash line in the plot is a theoretical curve which is the standard deviation versus $\sqrt{1/2^N}$. The standard deviation is reduced to about 2Ω, when N is set to 14, corresponding to a sampling number of about 16000. We don't choose a higher N value because higher N will significantly extend scan time. The noise from the electronic system is about 200μK in a 2K helium bath; and 67μK in 1.6K helium. The total scan time is about 100s.

Thermal conductivity of grease as well as press-force of sensor against cavity-wall affects T-map noise level as well. Figure 3 is a lateral view of the subtraction between two T-map scans without applying RF field in 2K Helium bath. The total noise of the T-map system is about 1mK which achieved our initial goal.



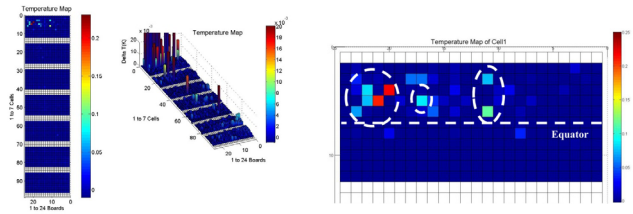


Figure 3: 3-sigma noise level of T-map system. The one sigma noise is only about 0.2mK.

Testing Results of T-map

The 9-cell cavity A9 was tested in a 2K helium bath and quenched at 21MV/m in pi-mode. The T-mapping boards covered the middle 7 cells of the cavity. Temperature-map data was taken at an accelerating gradient very close to quench. Figure 4 (a) depicts the temperature-rise (ΔT) map.

(a) (b)

Figure 4: (a) Map of temperature increase for 7-cells of an ILC cavity, (b) Detail T-map view of the dominantly heated Cell 1.

Most heating-spots were found on the top cell which is the top second cell of the 9-cell cavity. The highest ΔT is about 0.2K.

Figure 5 is the summary of ΔT versus H^2 curves; the axis on the right is the Q_0 of the cavity. Equation (5) depicts the ΔT and H^2 relationship of the sensor n. Here R_{sn} is the surface resistance close to the sensor n, $\vec{H}_n$ is the surface magnetic field at the sensor n, as the T-map sensors only cover the high magnetic-field region of each cell, thus $\vec{H}_n \approx H_{peak}$.

$$\Delta T_n = \frac{1}{2C} R_{s\,n} \vec{H}_n^{\,2} \qquad (5)$$

Copyright © 2013 CC-BY-3.0 and by the respective authors

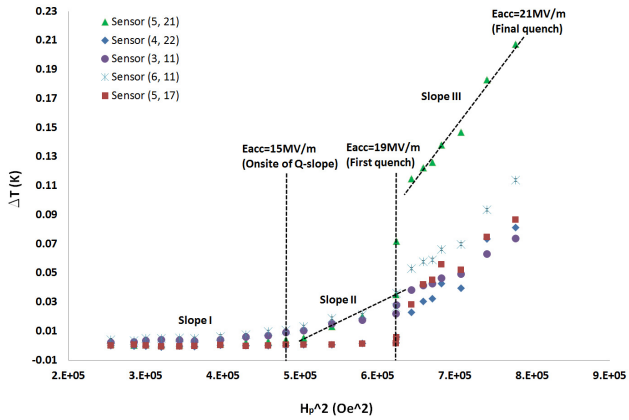

Figure 5: ΔT vs. H^2 curve.

The slopes of ΔT versus H^2 curves indicate R_s at the sensors from equation (5). Three slopes were observed. The slope I started from an acceleration gradient from 0 to 15MV/m. The surface resistance was consisted by BCS resistance and residual resistance. The slope II started at an accelerating gradient (E_{acc}) 15MV/m where the onset of Q-slope is. The surface resistance was increased due to the Q-slope. The heating increased dramatically around 19MV/m at the Multipacting barrier of the TESLA-shape cavity. The Multipacting triggered the first quench and processing of the cavity. After the Multipacting had been processed out, the heating increased with H^2 by the slope III until hard quench (21MV/m). The slope III indicates the surface resistance was increased further by flux trapping after the first quench.

Converting ΔT to Power Loss and Quality Factor

By summing the temperature rising of individual cells, we obtain power loss and quality factor of cavity and each cavity cell, shown in Figure 6 (a) and (b).

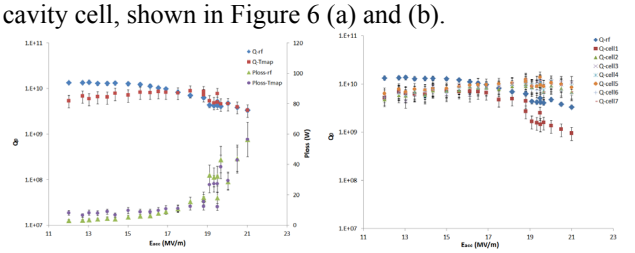

Figure 6 (a): Q_0, P_{loss} comparison between calculated from T-map and measured from RF. (b) The quality factor of individual cells compared to total Q_0.

The measurement curves match the calculated curve when the accelerating gradient is higher than 15MV/m where the heating started. Below 15MV/m, the heating from the cavity is too small to be detected accurately. The results from T-map indicate the measured cell 1 generated the most power loss on the surface, and degraded the total Q_0 starting from 15MV/m. The equation (3) suggests that the total Q_0 of the cavity is limited by the Q-value of the worst cell. The cavity test results also indicate that the Q-slope is possible to be a localized effect.

Surface Resistance Map

A surface resistance map is calculated from the ΔT of each thermometer, which is given by equation (6).

$$R_{s\,n} = \frac{2C\Delta T_n}{H_{peak}^{\ 2}} \qquad (6)$$

Figure 7 shows a surface resistance map when the cavity was at 21MV/m, close to quench.

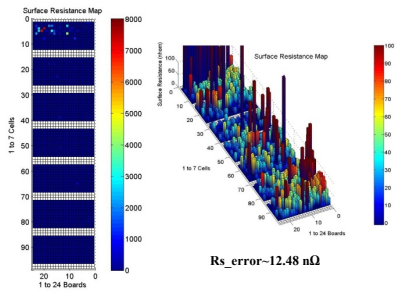

Figure 7: Map of the surface resistance R_s.

The maximum R_s value is close to 8000nΩ, and the average value of all R_s map is 74.26nΩ which agrees with the value (80.84nΩ) calculated from equation (1) by using the geometry factor and Q_0. The error of the surface resistance is about 16.8% calculated from the measurement error of ΔT, accelerating gradient (E_{acc}) and Q-value by uncertainty propagation formulas.

INVESTIGATION OF THE SURFACE RESISTIVITY OF SRF CAVITIES VIA THE HEAT AND SRIMP PROGRAM AS WELL AS THE MULTI-CELL T-MAP SYSTEM*

M. Ge#, F. Furuta, D. Gonnella, G.H. Hoffstaetter, M, Liepe, H. Padamsee,
Cornell University, Ithaca, NY, 14853, USA

Abstract

The thermal feedback model with the linear BCS resistance which were believed not strong enough to explain medium-field Q-slope (MFQS) is still valid. The HEAT and SRIMP program (H&S program) which adopted the SRIMP code for BCS resistance calculation allows inputting full material parameters, hence is able to simulate different cavity cases e.g. baked, unbaked, BCP'd, EP'd, and so on. The results agree with the measurement data from the low-field up to the hot-spots onset field. With the T-map data, it's a clear view that the localized hot-spots occur above MFQS region and caused high-field Q-slope.

INTRODUCTION

The surface resistance of superconductor under RF field is a critical topic, because it determines the Q-value of SRF cavity in accelerating fields. The thermal feedback model with the linear BCS resistance was developed for Medium-Field Q-Slope (MFQS) study [1]. However, the thermal feedback model was believed not strong enough to account for the observed MFQS [1, 2, and 3]. In this work, we explain the thermal feedback model with linear BCS model is still valid for MFQS and the localized hot-spots cause the Q-slope in high fields.

HEAT AND SRIMP PROGRAM

The surface resistance of superconductor under RF field includes two parts, one is BCS resistance (R_{BCS}) and the other is residual resistance (R_0), shown in equation (1). And equation (2) is the simplified R_{BCS} forms.

$$R_s = R_{BCS} + R_0 \quad (1)$$

$$R_{BCS} = A\left(\frac{1}{T}\right) f^2 \exp\left(-\frac{\Delta}{kT}\right) \quad (2)$$

Here, the factor A is a constant which determined by material property such as mean free path (l) *etc.*, Δ is the energy gap, f is the frequency.

The traditional HEAT program [4] uses Pippard approximation [5]:

$$R_{BCS}(T) = (2.78\times10^{-5}\Omega)\frac{\nu^2}{t}\left(\frac{148t}{\nu}\right)\exp\left[-\frac{1.81g(t)}{t}\right] \quad (3)$$

$$t = \frac{T}{T_c}, \quad \nu = \frac{f}{2.86GHz}, \quad g(t) = \left[\cos\left(\frac{\pi t^2}{2}\right)\right]^{1/2} \quad (4)$$

where f is the frequency of the RF field, T is the temperature. However in equation (3) and (4), it doesn't consider the Nb property. Comparison between baked and un-baked cases, the mean free path l is reduced by baking. Hence the factor A in equation (2) is changed and decreases the BCS resistance after baking. But equation (3) and (4) are unable to reflect the changes.

The improved HEAT program, HEAT and SRIMP code (H&S code), uses SRIMP [6, 7] to replace the equation (3) and (4). The SRIMP was written by Jurgen Halbritter for the BCS surface resistance calculation. The method of calculation incorporates the full BCS theory. Five material parameters are required to describe the superconductor:

- The superconducting transition temperature T_c;
- The energy gap (entered as Δ/kT);
- The London penetration depth, λ at T=0;
- The coherence length, ξ at T=0;
- The electron mean free path, l, at 4.2K.

MULTI-CELL T-MAP SYSTEM

The T-map system is known as a powerful tool for surface resistance research. It's able to detect tiny heating on exterior wall on cavities. Cornell University developed a multi-cell T-map system [8].

SURFACE RESISTANCE ANALYSIS

The EP'd and BCP'd Cavity Cases

Figure 1 is the comparison Q vs. E curves between H&S program calculation and RF measurement from 1.7 to 2K. The plot shows the calculation agrees with the measurement results well. The cavity is TELSA single-cell cavity NR1-3. The cavity was EP'd and 120°C baked. During the test, the cavity was FE and quench free.

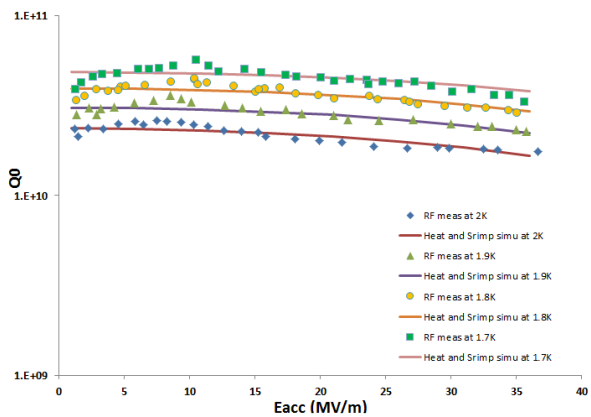

Figure 1: Comparison of H&S calculation and RF measurement at different temperatures for EP'd cavity.

The Q_0 versus Temperature data measured at low accelerating field was fitted by the SRIMP to obtain the material parameters described in previous section. In the fitting, we use surface RRR value to represent electron mean free path [9].

Here we selected the residual resistance, energy gap, and surface RRR as fitting parameters. The cavity was 120°C baked; therefore the surface RRR was reduced to 4.4. Converted the surface RRR to electron mean free path, the value is about 119 Angstrom. The detail of the conversion is discussed in the reference [9].The BCS resistance is minimum when mean free path is around 120 Angstrom [1].

Figure 2 shows the comparison of the BCP'd cavity case. The cavity is the 7-cell cavity ERL 7-4 for Cornell ERL project. The cavity was BCP'd more than 100μm; then the cavity was furnace treated under 650°C vacuum; after light-BCP, the cavity was 120°C baked in furnace followed by HR rinsed; and then the cavity was HPR'd and assembled in class 10 cleanroom.

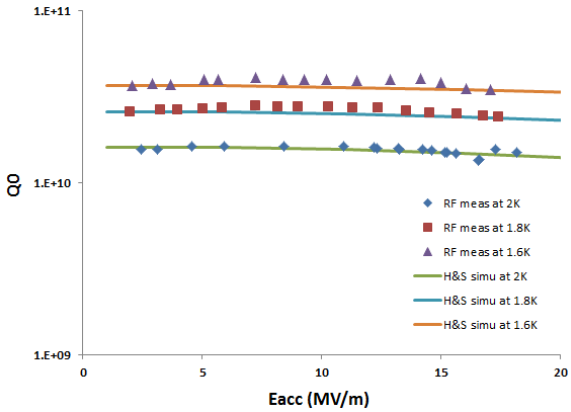

Figure 2: Comparison of H&S calculation and RF measurement at different temperatures for BCP'd cavity.

The SRIMP code fitting from the Q_0 versus temperature data indicates that the R_0 is about 5.6 $n\Omega$; the energy gap is 1.825; and the surface RRR is about 4.56. Using these parameters as the input of H&S program, the result agrees with the RF measurement very well at different temperatures.

The Baked and Unbaked Cavity Cases

In EP'd and BCP'd cavity cases, it suggests that 120°C baking plays an important role in reducing the BCS resistance to minimum. The H&S program is able to reflect the baking effect. In the Figure 3, there is the comparison between the cavity NR1-2 baked and un-baked cases. The NR1-2 cavity was EP'd about 30μm, and was tests before and after 120°C baking. Table 1 shows the material parameters comparison fitted by SRIMP. The surface RRR was reduced from 38 to 6.9, and energy gap was increased from 1.86 to 1.956. The changing of the parameters reduced BCS resistance from 13.78$n\Omega$ to 6.02$n\Omega$ at the accelerating gradient equalling 2MV/m; however the residual resistance was increased from 4.5 $n\Omega$ to 10.16 $n\Omega$; the total surface resistance was reduced from 18.27 $n\Omega$ to 16.18 $n\Omega$ at 2MV/m, which is shown in Table 2.

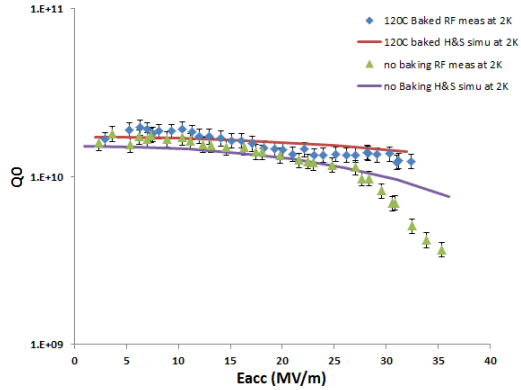

Figure 3: Comparison of H&S calculation and RF measurement between the baked and the un-baked cavity.

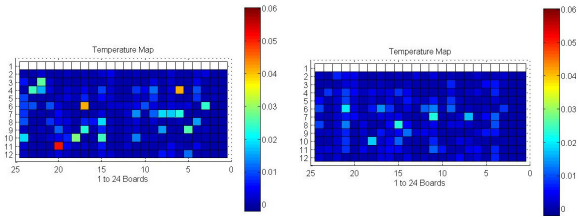
Table 1: Material Parameters Comparison of NR1-2

Parameters	Baked	Un-baked
T_c (K)	9.2	9.2
Energy gap	1.959	1.86
λ(A)	360	360
ξ(A)	640	640
Surface RRR	6.9	38
Residual resistance (R_0) ($n\Omega$)	10.16	4.5

Table 2: Surface Resistance Comparison of NR1-2

Parameters	Baked	Un-baked
BCS resistance at 2MV/m ($n\Omega$)	6.02	13.78
Residual resistance ($n\Omega$)	10.16	4.5
Surface resistance at 2MV/m ($n\Omega$)	16.18	18.27
Q_0 at 2MV/m	1.72×10^{10}	1.52×10^{10}

In the un-baked cavity case, the H&S program's calculation agrees with the measurement data up to 25MV/m above which the obvious discrepancy occurs. The cause of the discrepancy is the localized hot-spots based on the T-map data which will be shown in next section.



The Localized Hot-spots and High-field Q-slope

From the cavity NR1-2 measurement data (the un-baked case), we found that all the hot-spots present above the 25MV/m where the onset of the Q-slope is.

Figure 4 (a) is the temperature map of the cavity NR1-2 at 32MV/m, and (b) is the temperature map after the

Copyright © 2013 CC-BY-3.0 and by the respective authors

baking. By the contrast, we clearly see the hot-spots were suppressed by the baking, and the Q-value was recovered. Before the baking, the cavity was no quench; and the performance limited by RF power source. After the baking, the cavity limited by the hard quench at 32MV/m.

(a) Before the baking, (b) After the baking

Figure 4: Temperature map comparison of NR1-2 before and after the baking at 32MV/m.

The sensor in 11th row and 20th column shows the highest temperature increase in the Figure 4 (a), and the value is closed to 0.11K. The Figure 5 shows the heating versus accelerating gradient (E_{acc}) of the sensors (11, 20), (4, 6), (6, 17), (3, 22). The comparison curve from the sensor (3, 3) was selected because the sensor located in non-heating region.

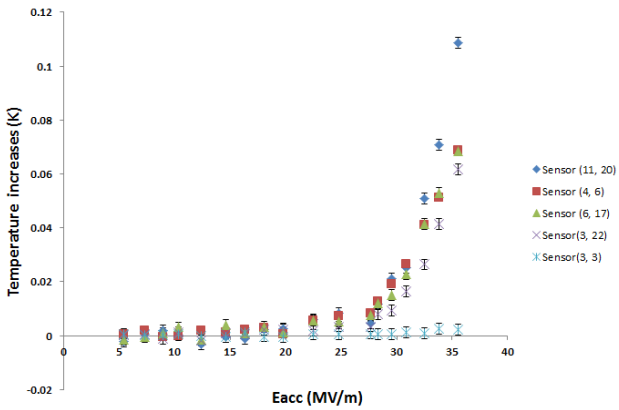


Figure 5: The temperature increases vs. accelerating gradient.

The H&S program is able to calculate the surface resistance of the hot-spots based on the T-map data. The program treats the residual resistance within one sensor coverage area as uniformed; in other words, the program utilizes the average residual resistance value within one sensor. To obtain the power loss on one hot-spot, the program gradually increases residual resistance thus increase the heating on exterior wall. The calculation ceases when the heating on exterior wall matches the T-map data. The power loss in none hot-spots region is mainly caused by BCS heating. Summing the power loss on each sensor region, the cavity Q_0 is obtained. The Figure 6 depicts the calculated Q_0 of NR1-2 compared with the RF measurement data. The scattering of the calculated result depends on the quality of the T-map data, e.g. the quantity of the broken sensors which misses the hot-spots detection.

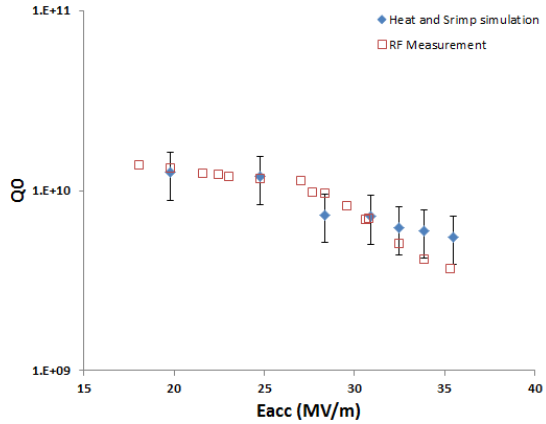

Figure 6: The Power loss on the Hot-spots comparison between H&S program and RF measurement.

CONCLUSION

The thermal feedback model with linear BCS resistance is valid for the medium-field Q-slope analysis. The H&S program's calculation indicates that the residual resistance is field-independent below the hot-spots onset field (25MV/m for NR1-2), and the residual resistance became field-dependent after the onset.

The distribution of the residual resistance isn't homogeneous. The high residual resistance region formed the hot-spots which degraded the Q-value in high-field.

The H&S program's calculations match up the measurement data perfectly. In this paper we checked the BCP and EP case as well as baked and un-baked case. It can be used to estimate the best performance of SRF cavities.

Abstract

In preparation for building an energy-recovery linac (ERL) based synchrotron-light facility at Cornell University which can provide greatly improved X-ray beams due to the high electron-beam quality that is available from a linac, a phase 1 R&D program was launched, addressing critical challenges in the design. One of them being a full linac cryo-module, housing 6 superconducting cavities operated at 1.8 K in continuous wave mode, 7 HOM absorbers and 1 magnet/ BPM section. The final design will be presented and a report on the fabrication status that started in late 2012 will be given.

INTRODUCTION

An NSF funded R&D program for the 5-GeV superconducting energy-recovery linac (ERL) [1] at Cornell University includes the design, build and thoroughly test all aspects of a complete cryomodule.

The almost 10 m long module (see Fig. 1) houses 6 superconducting cavities, operated in CW mode at 1.8 K. These 7-cells, 1.3 GHz cavities with an envisaged Q of $2*10^{10}$ will provide an energy gain of 16 MV/m. Each cavity is fed by a 5 kW power coupler. The Higher Order Modes (HOMs) absorbers are placed next to each cavity to obtain an efficient damping for the high beam current and short bunch operation. The series linac module will have a quadrupole/ steerer section which is omitted in the prototype as it technically does not present a challenge.

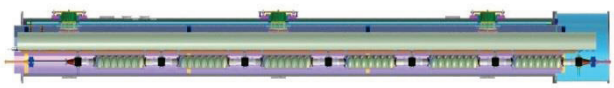

Figure 1: Cryomodule prototype.

COLD MASS SUPPORT SYSTEM

The beam-line string is suspended under the Helium Gas Return Pipe (HGRP) which acts as the beam-line backbone and is supported by three support posts to the vacuum vessel (see Fig. 2). The support system provides precision alignment and thermal insulation of the beamline string.

The HGRP is made of a Grade 2 Titanium pipe, with an outer diameter of 280 mm. With a 1 ton weight force of the beamline string, the maximum vertical displacement of the HGRP is estimated to be 0.1 mm and the natural frequency would be 88 Hz, indicating that a 3-posts support system is well suited to ensure an acceptable vertical displacement and vibration characteristics.

#r.eichhorn@cornell.edu

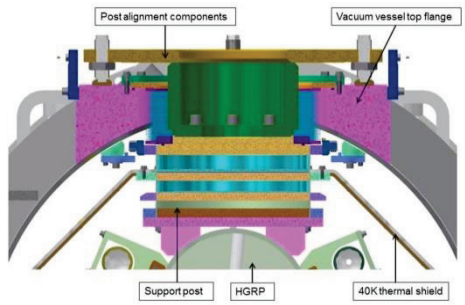

Figure 2: Cold mass support system.

The post has a same design as those used in the TTF cryomodule, which is an assembly of a low thermal conduction composite material pipe (G10 fiberglass pipe) and four stages of shrink-fit metal discs and rings. The two stainless steel disc/ring sets are connected respectively to the room temperature and to the 2 K cold mass environments. The two aluminum disc/ring sets provide thermal intercepts at 40 K and 5 K, with the 40 K set also providing structural support to the 40 K thermal shield. The heat load through conduction of each post (see Fig. 3) is estimated to be 8.58W to 40K, 0.54W to 5K and 0.05 W to 1.8K, respectively.

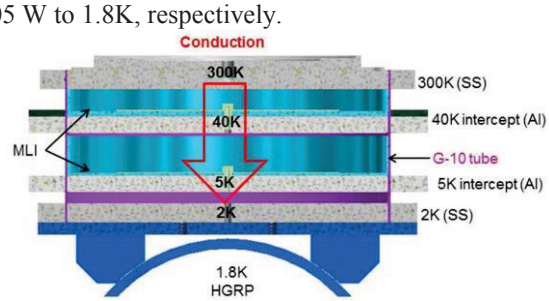

Figure 3: Support post.

The vacuum vessel is 965.2 mm in diameter, with a vessel cylinder made of carbon steel (A516 GR70) and stainless steel flanges that use O-ring seals. For the prototype the interior of the carbon steel portion will be painted with a low vapor pressure vacuum compatible epoxy, while the exterior will be painted with a marine paint product.

CYOGENIC PIPING SYSTEM

The cavities will be cooled by liquid helium sub-cooled to 1.8 K. Due to the fact that the half linac will be 350 m long, a big aperture (280 mm diameter) for the HGRP was chosen to provide the low flow impedance needed without excessive pressure drop. Connected to the HGRP at a single point in each module is a 100 mm diameter 2-phase helium manifold, show in Fig. 4. The purpose of this large 2-phase tube is to allow adequate surface area

Copyright © 2013 CC-BY-3.0 and by the respective authors

for evaporation and a sufficiently large cross-section for gas flow through it to the HGRP to avoid generation of waves on the liquid surface which could result in pressure fluctuations affecting frequency tuning of the cavities [2].

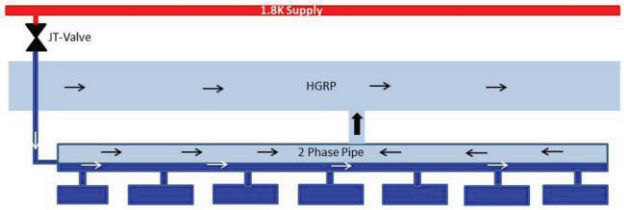

Figure 4: 1.8K flowchart.

A 5 K-6.5 K loop is used to cool the intercept all transitions to warmer temperatures in order to assure a minimal heat transfer to the 1.8 K system. A 40-80 K loop provides cooling for the coupler intercepts, cools the thermal radiation shield of the module and removes the heat generated in the Higher Order Mode (HOM) absorbers.

As show in Fig. 5, six lines of 50mm diameter run through the entire half-linac. In each module, local manifolds of smaller diameters deliver the cryogens via four valves (1.8 K, pre-cool, 4.5 K, and 40 K) which manage the flow division amongst the modules. The location and stiffness of piping supports were considered in the design to make sure the resonant frequencies are higher than 60 Hz (see Fig. 6 for details).

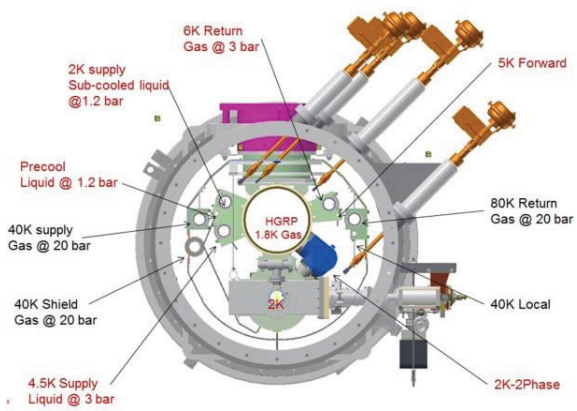

Figure 5: Piping system inside the cryomodule.

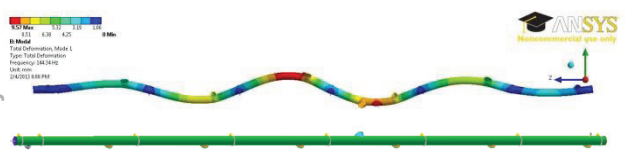

Figure 6: Natural frequency of the 1st mode of 2-phase pipe and the model showing the supports.

THERMAL SHIELD AND COOL DOWN

The radiation and convection heat loads are reduced by operating the shield at 40K and wrapping it with 30 layer multilayer insulation (MLI) blankets, in a vacuum environment. The magnetic shield, which is made of 0.5 mm Mu-metal sheets, will be mounted to the exterior of the 40K thermal shield to screen the Earth's field and any other stray magnetic field from the cavities.

The thermal shield is made from aluminum AL 1100-H14 sheets, with the upper section being thicker to support the weight. The sheets as shown in Fig. 7 are connected with fasteners as a rigid assembly with a good thermal contact. Reinforcement rings are attached to increase the mechanical stability.

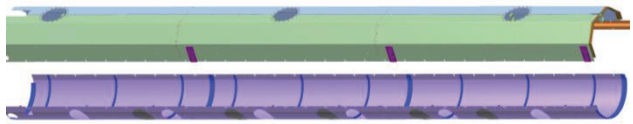

Figure 7: Upper and lower sections of the thermal shield.

To avoid excessive stress due to asymmetric cooling during the cool-down process, some slots (Fig. 8) are machined at the upper-lower section to unload the force.

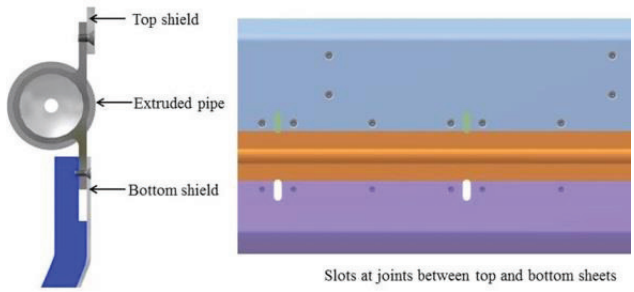

Figure 8: Joints between top and bottom sheets.

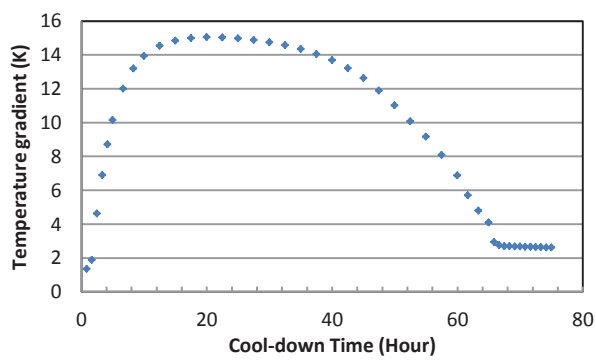
The thermal shield will be cooled by the 40 K delivery line which is connected to one side. As a result, the cool-down process will be asymmetric requiring a more detailed analysis.

Static heat loads includes conduction through the support post and radiation from room temperature vacuum vessel. With 30 MLI blankets covered on the shield, the radiation heat fluxes from room temperature are assumed to be 1.25 W/m^2. In the extruded pipe for the 40 K helium gas delivery, a convective heat transfer coefficient of 0.11 W/cm^2-K was estimated. The simulated results indicated that with a slow cooling rate of 4 K/hour, the temperature gradient reaches a maximum of 15 K on the entire shield, occurring 20 hours after the start of the cool down. Results are given in Fig. 9). Once



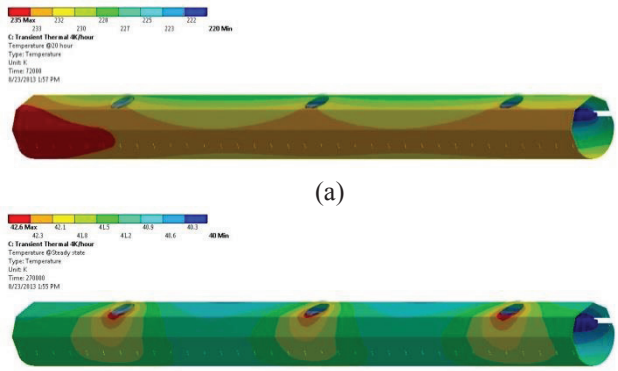


Figure 9: Temperature gradient on 40 K shield as a function of time during cool-down.

Copyright © 2013 CC-BY-3.0 and by the respective authors

fully cooled down, the steady state maximum temperature gradient will be only 2.6 K. At the worst scenario when the temperature gradient over the shield reaches the maximum, the thermal shield will be bent with a maximum relative deformation of 4.6 mm (Fig. 10), and the maximum stress will be about 60 MPa occurring at the corner of the slots.

(a)

(b)

Figure 10: Temperature distribution on the shield (a) at 20 hours after cool-down started and (b) at steady state.

ALIGNMENT AND ASSEMBLING

The HGRP defines the reference for the precision alignment of the beam-line string. Relative vertical alignment is ensured by precision machining on the interfacing surfaces of the supports, with a single machine tool setup at the final stage after all welding is done and a vibration stress relief is performed. The transverse and longitudinal alignment is obtained by the alignment pins on the support plates. The alignment key or a flexible cavity support allows the beam-line components to slide longitudinally relative to the HGRP during thermal cycling.

To accommodate the HGRP thermal contraction at cold relative to the vacuum vessel, the two side posts are slidable over the top flanges while the central post is locked in position. Details of the design are shown in Fig. 11. The central position of the side posts are pre-shifted at room temperature and will be concentric to the vacuum vessel flange at cold.

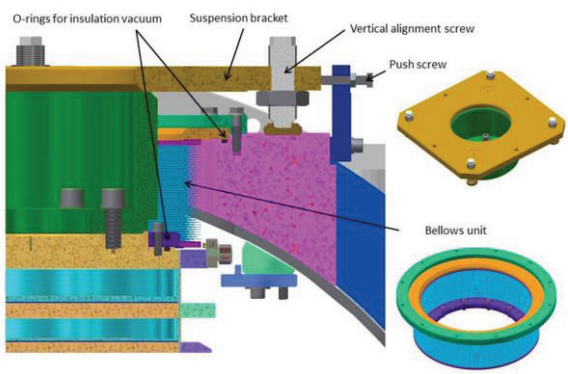

Figure 11: Post alignment components.

The prototype design foresees that it could be a spare module in the series linac that the final welding or connection for the cryogenic pipes will be made in-situ. In addition, the design also allows easy dismounting the whole assembly for replacing some components. The assembly sequence is that the beam-line string will be assembled in the clean room, and then attached to the HGRP. Once the cold mass is assembled, it will be rolled into the vacuum vessel on its rail system (see Fig 12).

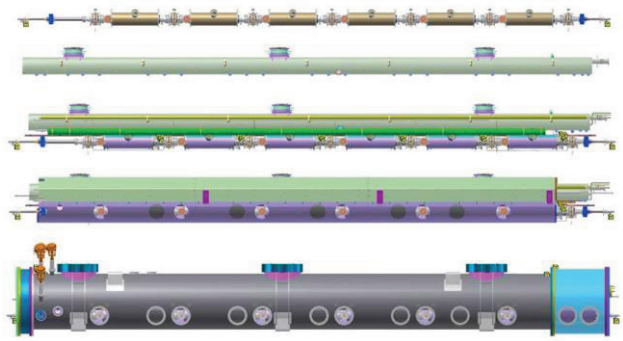

Figure 12: Prototype assembly sequence.

STATUS AND OUTLOOK

The major components of the cryomodule prototype are under fabrication. We anticipate starting the assembly process in November 2013, and have it completed and ready for test by the end of 2014.

ACKNOWLEDGMENTS

This design and construction work involves many people at CLASSE, which the authors gratefully acknowledge. Furthermore, we would like to thank Tom Peterson, Serge Claudet and John Weisend II for their help and their review during the design phase. This work has been supported by NSF awards PHY-0969959 and DMR-0807731 and DOE award DOE/SC00008431.

Abstract

The SIS structure—a thin superconducting film on a bulk superconductor separated by a thin insulating film—was propsed as a method to protect alternative SRF materials from flux penetration by enhancing the first critical field B_{c1}. In this work, we calculate the gibbs free energy of a vortex in a superconductor, and we show that an isolated thin film can enhance B_{c1}, but when it is placed in a SIS structure, due to the gradient in field across the film, we show that in fact B_{c1} = 0. We argue that the SIS structure is not beneficial for SRF cavities, but it may be useful in DC and low frequency applications. However, due to recent experiments showing low-surface-resistance performance above B_{c1} in cavities made of superconductors with small coherence lengths, we argue that enhancement of B_{c1} is not necessary, and that bulk films of alternative materials show great promise.

INTRODUCTION

SRF researchers have begun a significant effort to develop alternative materials to niobium, superconductors that could offer higher accelerating gradients E_{acc} and/or lower surface resistances R_s at a given temperature. There are several promising candidates, but most of them suffer from two potential liabilities. First, they have relatively small first critical fields B_{c1}, the magnetic field at which it becomes energetically favorable for a vortex to be inside the superconductor. Second, they have relatively small coherence lengths ξ. Vortex penetration is prevented at fields significantly above B_{c1} by an energy barrier, but surface defects on the order of ξ can reduce this barrier. These materials have ξ on the order of a few nm, compared to tens of nm for niobium, making even very small defects a potential vulnerability. As a result, there has been significant concern in the SRF community over whether vortex dissipation will occur if these materials are exposed to fields that bring them into the metastable state between B_{c1} and B_{sh}, the superheating field at which the energy barrier is reduced to zero for an ideal surface.

A. Gurevich proposed [1] a method to avoid the potentially vulnerable metastable state altogether. Pointing to the enhancement of parallel B_{c1} in films with thickness d smaller than the penetration depth λ, he suggested coating a niobium cavity with alternating layers of insulator (I) and thin film superconductor (S). With such a SIS structure, he proposed it might be possible to take advantage of the high B_{sh} and low R_s of the alternative superconductors used in the thin films without the disadvantage of their small B_{c1}. SRF researchers have been putting significant effort into developing SIS multilayers, and they are producing excellent work [2, 3, 4, 5, 6, 7, 8].

CALCULATING BC1

Tinkham [9] defines B_{c1} as the field at which "the Gibbs free energy [has] the same value whether the first vortex is in or out of the sample." For a SIS, the sample under consideration should be the full structure [10]. Stejic et al. [11] calculate the Gibbs free energy of a vortex in a thin film superconductor immersed in a parallel external field. They show that B_{c1} of the film is enhanced relative to the bulk value, according to

$$B_{c1} = \frac{2\phi_0}{\pi d^2}\left(\ln\frac{d}{\xi} + \gamma\right) \quad (1)$$

where ϕ_0 is the flux quantum, $\gamma = -0.07$ and $d << \lambda$. However, if a SIS structure is used to screen Nb SRF cavities, the geometry is quite different than that of an isolated film. How does Stejic's expression for B_{c1} change when the film is screening a bulk superconductor? In this case, it will have a B-field gradient across it, which will affect the free energy. We can use the same formalism as Stejic to calculate the Gibbs free energy for this case, and use it to find B_{c1} and B_{sh}[12].

Consider a single layer SIS structure, as shown in Fig. 1. A strongly type II superconducting film of thickness d, penetration depth λ_f, and coherence length ξ_f is separated from a bulk superconductor with with penetration depth λ_b by an insulating film of thickness δ. The superconducting film is screening the bulk from a parallel magnetic field with amplitude B_0. The screened field inside the bulk region has amplitude B_i. In our geometry, the x-axis is perpendicular to the film, pointing into it, with origin at the interface with the exterior. The z-axis is aligned with the magnetic field.

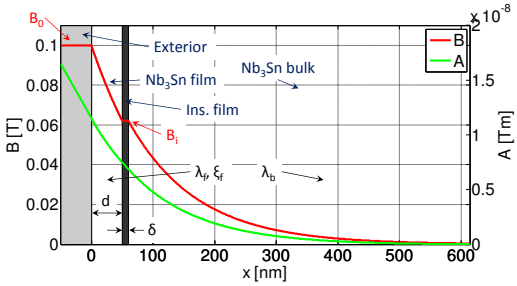

Figure 1: Geometry of the structure under consideration. The amplitudes of the magnetic field and the vector potential are plotted as a function of distance into the structure.

Stejic shows that the Gibbs free energy of a vortex in a superconductor can be determined from the value of two magnetic fields evaluated at the vortex location r_0: the Meissner-screened external field B_M and the field generated by the vortex in the film B_V.

$$\mathcal{G} = \frac{\phi_0}{\mu_0}\left(B_V(r_0)/2 + B_M(r_0)\right) \tag{2}$$

B_M can be found by minimizing the free energy in the structure when no vortex is present. This procedure gives:

$$B_M = \frac{B_0 + B_i}{2}\frac{\cosh\frac{x}{\lambda_f}}{\cosh\frac{d}{2\lambda_f}} - \frac{B_0 - B_i}{2}\frac{\sinh\frac{x}{\lambda_f}}{\sinh\frac{d}{2\lambda_f}} \tag{3}$$

where B_i is given by

$$B_i = B_0\left[\frac{\delta+\lambda_b}{\lambda_f}\sinh\frac{d}{\lambda_f} + \cosh\frac{d}{\lambda_f}\right]^{-1} \tag{4}$$

Stejic gives a relatively simple expression for B_V for the case when $d << \lambda$, but this would restrict us to very thin films. To study the full range of thicknesses, we turn to the more general expression from Shmidt [13] (this expression assumes $r_0 = (x_0, 0)$), which agrees with Stejic's expression for very small films:

$$B_V = \frac{2\phi_0}{\lambda^2 d}\sum_{n=1}^{\infty}\int_{-\infty}^{\infty}\frac{dk}{2\pi}e^{iky}\frac{\sin(\pi n x/d)\sin(\pi n x_0/d)}{k^2 + (\pi n x_0/d)^2 + 1/\lambda^2} \tag{5}$$

We can check our procedure by choosing $d >> \lambda$, such that the film behaves as a bulk supercondcutor. This calculation is shown in the top plot of Fig. 2. $B = B_{c1}$ when the free energy outside the superconductor is equal to that when a vortex is deep in the bulk. $B = B_{sh}$ when the barrier to flux penetration is reduced to zero (this plot is very similar to the one from Bean and Livingston's 1963 paper [14]).

We can study a single thin film (not in a SIS structure) by setting $B_i = 0$ in Eq. 3. This calculation is shown in the center plot of Fig. 2 (the free energy outside the film is

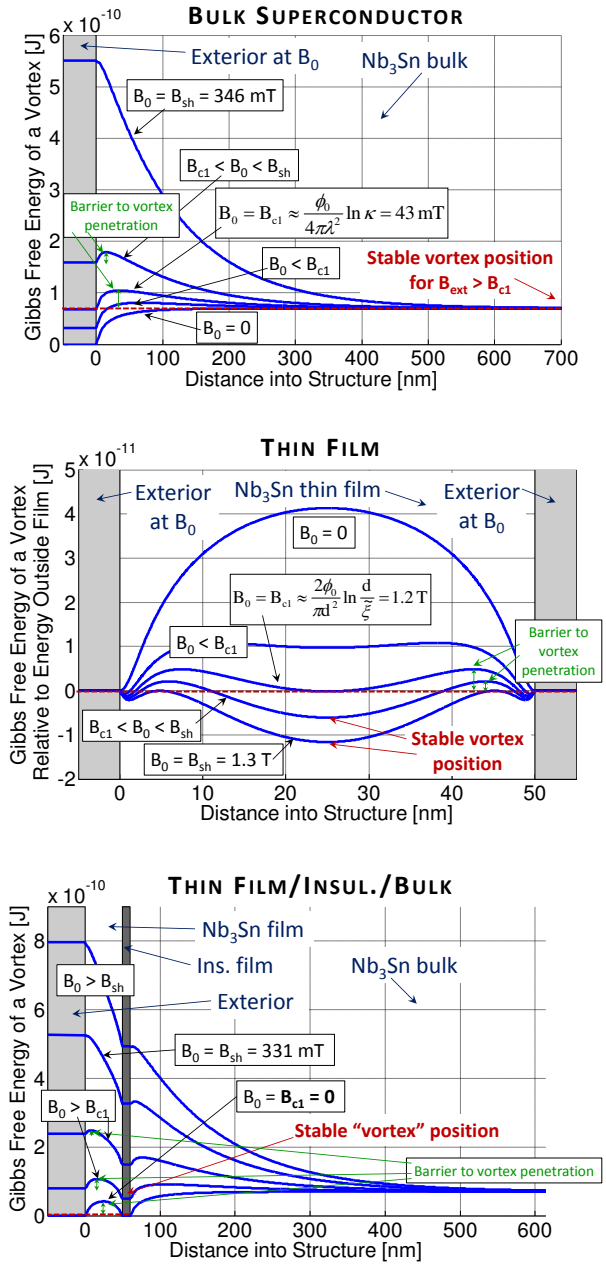

Figure 2: Gibbs free energy at various fields for a single vortex in (top) bulk Nb_3Sn, (center) a 50 nm Nb_3Sn thin film, and (bottom) a SIS structure with a 50 nm Nb_3Sn film on a Nb_3Sn bulk. B_{c1} is the smallest field at which there is a position inside the structure where the free energy for a vortex is smaller than the value outside. B_{sh} is the field at which the energy barrier to vortex penetration disappears. The top and center plots show the B_{c1} enhancement for a thin film compared to a bulk. The bottom plot shows that for a SIS structure $B_{c1} = 0$. The expression for the thin film B_{c1} is not valid for the SIS structure because it assumes that the first stable vortex position will be at the center of the film. However, for the SIS structure, the first stable vortex position occurs on the side of the film adjacent to the insulating layer.

Copyright © 2013 CC-BY-3.0 and by the respective authors

subracted from each of the plots for clarity). In this case, there is no bulk, so the first location at which the free energy drops below the external value at high fields is in the center of the film. This would be the stable position for a single vortex above B_{c1}. Both B_{c1} and B_{sh} are much higher for the film than the bulk.

Finally, we plot the free energy of vortex in a single SIS structure in the bottom plot of Fig. 2. In contrast to the previous case, only one side of the thin film is exposed to the external magnetic field. The field at the other side is smaller due to screening by film. Since $B_V = 0$ at the edges of the film, Eq. 2 shows that the free energy in the insulating layer is lower than the free energy outside. The film provides screening at any finite B_0 below the second critical field, so for $B_0 > 0$, the energetically favorable configuration is for flux to be trapped in the insulating layer. As we explain below, this implies that in practice for the SIS structure, B_{c1} is zero.

Why is Eq. 1 describing the enhancement of B_{c1} in a lone thin film not applicable for the SIS structure? This expression assumes that the first stable vortex position will occur in the center of the film. It predicts when the free energy at the center of the film will dip below the value of the free energy in the exterior. However, for the SIS structure, the free energy at the insulator side of the film will dip below the exterior value at fields much smaller than this.

DISCUSSION AND CONCLUSIONS

In this paper, we have shown that contrary to suggestions that SIS structures enhance B_{c1}, in fact they reduce it to zero. In [15], it is also shown that the B_{sh} of an SIS structure is only marginally larger than the bulk value and only for a small parameter space, and that using a multilayer only decreases B_{sh} of the film. In addition, [15] shows that SIS structures exhibit unmanageable levels of heating above B_{sh} at high frequencies. Therefore, it seems that SIS structures are not beneficial for SRF applications. However, they may be useful in DC and low frequency applications, where it should be possible to set up a gradient in the phase of the order parameter in the thin films, allowing them to screen very large fields.

Based on the results of this study, the authors of this paper recommend that SRF researchers developing alternative materials concentrate their efforts on bulk films. Bulk films are quite simple to fabricate compared to SIS films, but they offer a similar ideal SRF performance. And although we have shown that it is not possible to augment B_{c1} with SIS structures, there is still great promise for alternative materials. Because of recent experiments showing that low-surface-resistance operation above B_{c1} is possible with cavities made from short coherence lengths superconductors [16] [17], we now know that the potential of bulk films has not yet been realized.

Abstract

The phase 1 R&D program launched in preparation to building a 5 GeV Energy Recovery Linac (ERL) at Cornell, a full main linac cryomodule is currently built, housing six 7-cell cavities. In order to control the beam break-up limit, the shape of the cavity was highly optimized and stringent tolerances on the cavity production were targeted. We will report on the details of the cavity production, the accuracy of the cups forming the individual cells, the trimming procedure for the dumbbells, the cavity tuning and final accuracy of the cavity concerning field flatness, resonant frequency and overall length within this small series production.

INTRODUCTION

Six Cornell ERL 7-cell cavities will be connected in each cryomodule in the full LINAC. Between each cavity there are bellows and HOM absorbers. Therefore a tight tolerance of +/- 0.5mm must be applied to the length of each cavity (see Table 1). Unfortunately, due to space restrictions in Cornell's electron-beam welder, the beam tubes must be welded to the cavity before the final equator weld, which does not allow the cavity to be trimmed to its final length. Therefore, the cavity length must be controlled through other means.

Table 1: Length and Frequency Tolerances

Length (mm)	1160	+/- 1
Frequency (MHz)	1298.985	+/- 0.100

The first series production of three unstiffened ERL cavities at Cornell was completed some time ago. Each of the cavities did not meet the length or frequency tolerance. The results of the production can be seen in (Table 2). Each cavity was long, as well as low in frequency. Adjusting the frequency through the use of tuning served only to lengthen the cavities even further. In an effort to avoid a situation such as this in the second production series of three stiffened cavities, the previous production steps were analysed and a new strategy was formed.

Table 2: Length and Frequency of Production Cavities

Pre-Tuning

	Length (mm)	Frequency (MHz)
ERL7-002	1161	1298.46
ERL7-003	1161.5	1298.459
ERL7-004	1160.7	1298.498

Post-Tuning

	Length (mm)	Frequency (MHz)
ERL7-002	1165.9	1297.462
ERL7-003	1163.9	1297.504
ERL7-004	1162.1	1297.541

RF AND MECHANICAL TOLERANCES AND GRADIENTS

The half-cell contour was designed using FEM to calculate the correct resonant frequency at 1.8 K under vacuum. The room temperature frequency at STP is then extrapolated from this calculation.

The half-cell contour, when combined with the end-groups, drives the overall cavity length. However, several manufacturing and processing steps can have an effect on either length, frequency, or both. For example, etching the cavity will drive the frequency of the cavity down, but has no consequence on the overall length. However, field flatness tuning can be used to adjust the frequency of the cavity while simultaneously changing the overall length of the cavity.

It is important to know how each process will affect both the frequency and length of a cavity. To do so, each process' "gradient" must be known. For example, the tuning gradient is 430 kHz/mm. This means tuning the cavity will change its frequency by 430 kHz for every on millimetre. Other gradients are shown in Table 3.

The trimming gradient is, perhaps, the most salient variable during production. This gradient was calculated

Table 3: Various Manufacturing Gradients

Dumbbell Trimming	5	kHz/µm
Etching	10	kHz/µm
Tuning	430	kHz/mm

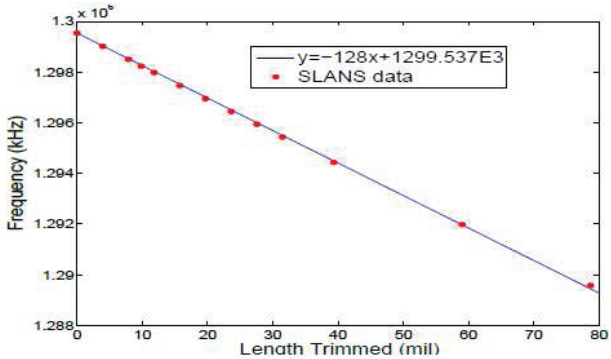

Figure 1: Calculated trimming gradient using the SLANS Code.

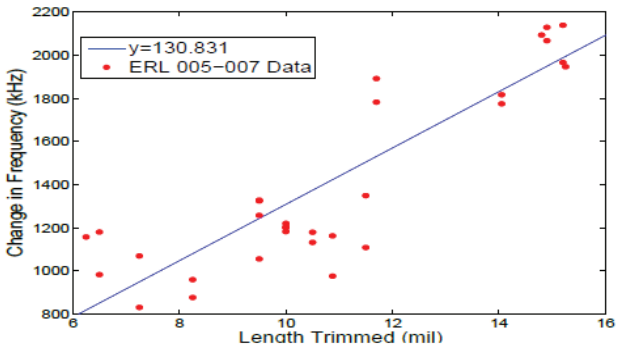

Figure 2: Measured trimming gradient using the newly designed dumbbell apparatus.

using SLANS and was found to be very linear (Fig. 1). Experimental trims of various dumbbells at various lengths confirmed this value (Fig. 2). The experimental trimming gradient is approximately 5.2 kHz/μm. This is within 1.5% of the theoretical value, giving good agreement between theory and experiment. The good agreement is partially due to the improved design for the RF measurement of the dumbbells which now ensures that the dumbbell does not deform under the load (see below).

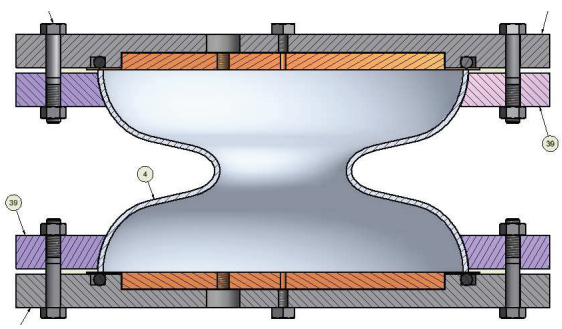

Figure 3: Improved dumbbell apparatus.

ROOT CAUSE OF FREQUENCY AND LENGTH DISCREPANCY

Before attempting to develop a protocol for frequency and length control during production, an effort to find the root cause of the discrepancy between the target cavity frequency and the manufactured cavity frequency was made. After many tests, it was determined that the fixture used to measure the resonant frequency of dumbbells reported an incorrect result. The original fixture, based on the JLab design [1,2], ensures adequate RF contact by pressing the dumbbell between two copper plates using a power screw. The middle of the dumbbell is unsupported. This can lead to a deformation of the dumbbell and subsequent shift in resonant frequency. To combat this problem, a new fixture was designed and constructed.

The revamped RF measurement fixture design was based off of the DESY design used for tesla cavities [3]. Figure 3 shows the new apparatus as built. Two aluminium plates are placed on the ends of the dumbbell. Inside these plates are copper RF contact plates. Aluminium plates are placed on the outer contour of the half-cells of each dumbbell. These plates are bolted to the equator plates for a good RF contact.

The middle plates in this fixture serve to brace the half-cells of the dumbbell so that adequate force may be applied to obtain a sufficient quality factor for measurement, while avoiding deformation of the half-cells.

LENGTH AND FREQUENCY CONTROL DURING THE SECOND SERIES PRODUCTION

During the second series of stiffened cavity production, the following quality control steps were applied:

- Coordinate measurement (CMM) of all half-cells in both untrimmed and trimmed states.
- CMM of untrimmed welded dumbbells.
- Frequency measurement of all dumbbells in the untrimmed state.
- CMM and RF measurement of all dumbbells after trimming.

Steps 1 & 2 were performed to verify all half-cell contours were within acceptable limits. Steps 3 & 4 were used to derive the cavities length and frequency.

To insure the cavity being produced would fall within both the frequency and length tolerances, the following algorithm was used:

$$\Delta L = d_{Trim} + d_{Tune} \ ,$$

$$\Delta F = d_{Trim} \times \Delta_{Trim} + d_{Tune} \times \Delta_{Tune} \ ,$$

where, d_{Trim} and d_{Tune} are the change in length due to trimming the dumbbells and tune the cavity, respectively. Δ_{Trim} and Δ_{Tune} are the trimming gradient and tuning gradient, respectively. Using these two equations, it is possible to find a solution that will yield the correct cavity length after frequency and length after trimming and tuning.

SECOND SERIES PRODUCTION OF STIFFENED CAVITIES

Six dumbbells were selected for a prototype fabrication in the second series of cavity production (ERL7-005). These dumbbells are listed, along with their pre- and post-trimmed lengths in Table 4. (Note: weld shrinkage has been accounted for in the overall length calculation.) At the target frequency of 1298.985 MHz, each these dumbbells would be shorter than the target dumbbells length, adding up to a cavity that was too short, but at the right frequency. Figure 4 shows the variance in both frequency and length of the six selected dumbbells before and after trimming. The pre-trim dumbbells have some variance in both length and frequency, but this is to be expected, as no frequency control protocols have been applied yet. The post-trim dumbbells, however, are very close in frequency relative to one another, while varying in length by approximately 0.5 mm.

The dumbbells' target frequency was changed to 1298.635 MHz in an effort to correct the lack of length at the correct frequency. By leaving an extra 0.7 mm per half-cell on each dumbbell after trimming, the resonant frequency of the cavity would be too low by 350 kHz, but the length would only be -+1.1 mm. It is assumed that, tuning the cavity by 350 kHz to the correct pi-mode frequency would lengthen the cavity by approximately 0.8mm, bring the finished cavity to the tolerable length, and correct frequency. (Note: The target length has been changed from 1160 mm to 1159 mm for this production series.)

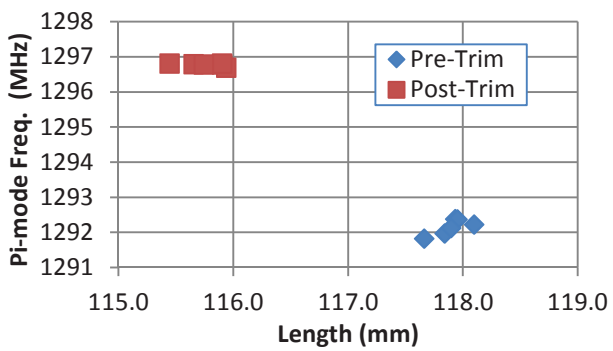

Figure 4: Variance of dumbbell frequency before and after trimming.

CONCLUSION

Cavity ERL7-005 has just recently come off of the production line. ERL7-005's length is 1157.1mm and its' pi-mode frequency is 1298.259 MHz with 79% field flatness. This results differs from the predicted above. ERL7-005 is approximately 1.1mm too short in length (1157.1mm overall) and 400 kHz (1298.259 MHz) too low in frequency. The cause of this is still under investigation.

STUDIES OF THE SUPERCONDUCTING TRAVELLING WAVE CAVITY FOR HIGH GRADIENT LINAC*

Pavel Avrakhov#, Roman Kostin, Alexei Kanareykin (Euclid TechLabs, LLC, Solon, Ohio), Nikolay Solyak, Vyacheslav P. Yakovlev (Fermilab, Batavia)

Abstract

Use of a travelling wave (TW) accelerating structure with a small phase advance per cell instead of standing wave may provide a significant increase of accelerating gradient in a superconducting linear accelerator. The TW section achieves an accelerating gradient 1.2-1.4 larger than TESLA-shaped standing wave cavities for the same surface electric and magnetic fields [1]. Recent tests of an L-band single-cell cavity with a waveguide feedback [2] demonstrated an accelerating gradient comparable to the gradient in a single-cell ILC-type cavity from the same manufacturer. This article presents the next stage of the 3-cell TW resonance ring development which will be tested in the travelling wave regime. The main simulation results of the microphonics and Lorentz Force Detuning (LFD) are also considered.

INTRODUCTION

The primary advantage of a superconducting travelling wave accelerating (STWA) structure is an increased accelerating gradient up to a factor 1.24 for the same surface magnetic and electric field ratios E_{peak}/E_{acc} and B_{peak}/E_{acc} as for re-entrant [3] standing wave (SW) ILC [4] cavity. However, the TW regime for a high gradient linac requires too high level of RF power flux in the accelerating structure. Typical pulse power for L-band TW linac is a few hundred MW which is 10^3 times more than feeding power for superconducting SW cavities. Concept of the traveling wave resonator with a superconducting TW structure allows to keep pulse power on a reasonable low level

Figure 1 presents the first developed and tested 1.3 GHz prototype of a travelling wave SC resonator which consists of a single-cell cavity and a waveguide (WG) feedback [2]. The 1-cell model has the same shape as a regular full-sized cavity, which helped to understand the problems with mechanical manufacturing, assembly, and welding of this geometry as well as the surface processing issues.

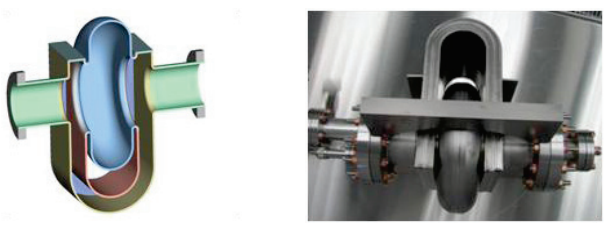

Figure 1: The single-cell model of a travelling wave cavity with waveguide loop.

*Work supported by US Department of Energy
p.avrakhov@euclidtechlabs.com

Two single cell resonators were manufactured at Advanced Energy System, Inc. (AES) and processed in Argonne and Fermi National Labs. Despite the fact that the STWR processing was without electropolishing, high gradient tests showed that the surface electric and magnetic fields reached the same values as 31 MV/m of TESLA-shaped cavity with no field emission. There were problems with the waveguide processing such as high pressure rinsing. But these problems did not lead to quenching in the waveguide because the surface electric and magnetic field amplitudes in the feedback loop were 2-3 times less than in the accelerating cavity. It should be noted the 1-cell STWR model could be tested only in SW regime.

The next step in SC TW cavity studies will be developing and manufacturing a multicell cavity and testing it in the travelling wave regime.

A NEW 3-CELL SC TW RESONATOR DESIGN STUDIES

According to plan, a new 3-cell TW cavity design (schematically depicted in Figure 2) was developed [5] and now is prepared for fabrication. In spite of the fact that the 3-cell structure has only one regular cell (in the middle of the cavity), it retains the same field distribution as for the full-sized 1 meter, 15-cell pattern.

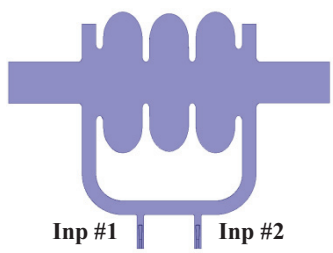

Figure 2: Traveling wave resonator with 3-cell TWaccelerating structure and two coaxial couplers.

As a standard for SC accelerating structure research it is testing on vertical test stand (VTS). Low level RF source of about 200-300 W at VTS requires the use of superconducting cavities with a high loaded quality factor Q_{load} of about 10^8. Well known problems for the SC high Q_{load} resonators are microphonics and Lorentz force detuning at the high gradient testing. But the TW structure detuning has specific feature when compared with the SW cavity - the degradation of the travelling wave regime. Unfortunately, TW operation cannot be restored only by frequency tuning as in the superconducting SW structure. Figure 3 illustrates

Copyright © 2013 CC-BY-3.0 and by the respective authors

forward and backward waves in the 3-cell superconducting travelling wave resonator (STWR) with 2.8 mm niobium walls deformed by external pressure. It is evident that a ±0.1 mbar pressure jump completely ruins the travelling wave regime in the non-reinforced STWR.

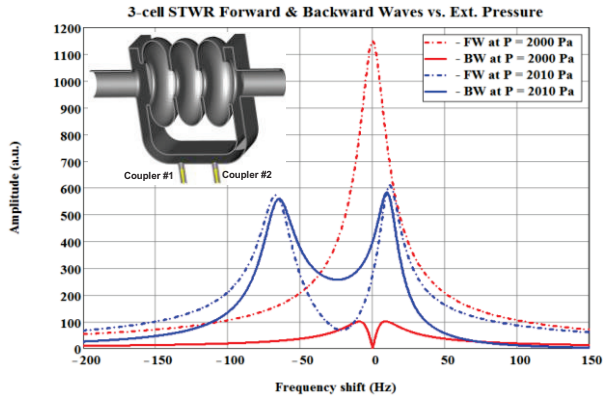

Figure 3: Microphonics detuning of the perfectly matched 3-cell superconducting travelling wave resonator with 2.8 mm niobium walls (pressure jump 10 Pa from 20 mbar to 20.1 mbar).

There are many ways to reinforce a low profile 160mm × 20mm rectangular WG, the most pressure-sensitive part of the STWR, but those involve other technical requirements for SC TW ring like the thermal conductivity of the WG wall and the capability for precise tuning. It imposes restrictions on the wall thickness and the WG loop shape. For instance, a WG loop with walls, more than 4 mm thick, could be overheated in CW regime. The most appropriate design, in our view, it is a waveguide with stiffening ribs on wide, or on both wide and narrow sides. Niobium ribs are a well-known way to reinforce large superconducting cavities such as 325 MHz SSR1, or low frequency 650 MHz 5-cell cavity for Project-X [6].

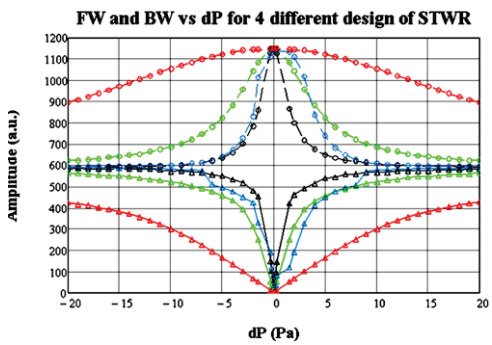

Figure 4: Amplitudes of forward (dash) and backward (solid) waves vs external pressure for 4 different designs of the 3-cell STWR: black curves - the non-reinforced model (all walls 2.8mm); blue curves – the model with cavity ribs only (thickness 4mm); green curves – the model with waveguide ribs only (4mm×10mm and 20mm between ribs); red curves - the most stiffened model with the cavity and waveguide ribs.

Figure 4 presents our efforts to reinforce the 3-cell STWR model to reduce the influence of microphonics. Stiffening ribs on the WG loop and on the cavity part dramatically improves the TW regime. Measured through the critical parameter $d\varphi/dP$, where $d\varphi$ is the phase shift caused by a pressure deviation dP, the last design has as a 57 and 12.6 times reduction (compared with the base design) of the microphonics sensitivity for waveguide loop and cavity part respectively.

It should be noted that the presented above results were obtained for fixed amplitudes and phases of the input signals: $P_{inp1} = P_{inp2}$, and a 90° phase difference between inputs. However, these parameters are fully controllable, and can considerably expand the acceptable external pressure variation. Figure 5 shows an example with suppression of microphonics detuning in the most stiffened STWR model only by adjustments of the inputs amplitude and phase. In this case the backward wave at a new operation frequency was completely suppressed, but the forward wave amplitude was kept almost the same (~94%). A 12% increase in power is required to obtain the nominal value of the forward wave amplitude.

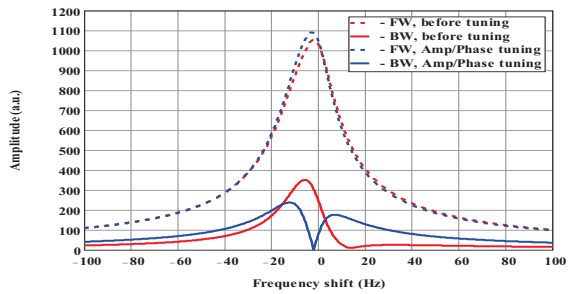

Figure 5: Forward and backward waves (FW & BW) under a 10 Pa external pressure variation in the TW resonator with stiffening ribs on the WG and the cavity parts: red curves – no tuning P_{inp1}/P_{inp2} = 1/1, $\Delta\varphi_{between_inp1\&inp2}$ = 90°; blue curves – after tuning P_{inp1}/P_{inp2} = 1.52/0.48, $\Delta\varphi_{between\ inp1\&inp2}$ = 96.3°

High gradient tests of the 1-cell STWR model have shown strong Lorentz forces in SW mode. Figure 6 demonstrates a comparison between the experimental results and the ANSYS simulation of the LFD in the real 1-cell cavity TW1AES002 (see Figure 1). 3-cell model simulations give similar cavity detuning behaviour.

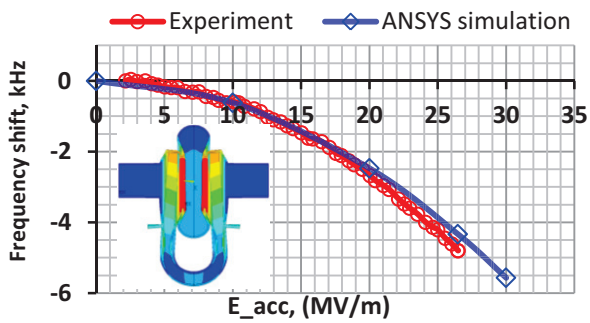

Figure 6: Lorentz force detuning data for 1-cell STWR cavity TW1AES002: experiment and simulation.

Copyright © 2013 CC-BY-3.0 and by the respective authors

The next series of graphs in Figure 7 illustrate simulations of a fine tuning procedure under strong LFD (E_{acc} = 31 MV/m, ring circulating power 631 MW) for the stiffened 3-cell STWR design. The frequency shift for this 3-cell model was -774 Hz and the TW regime was completely destroyed by LFD (Fig. 7-b).

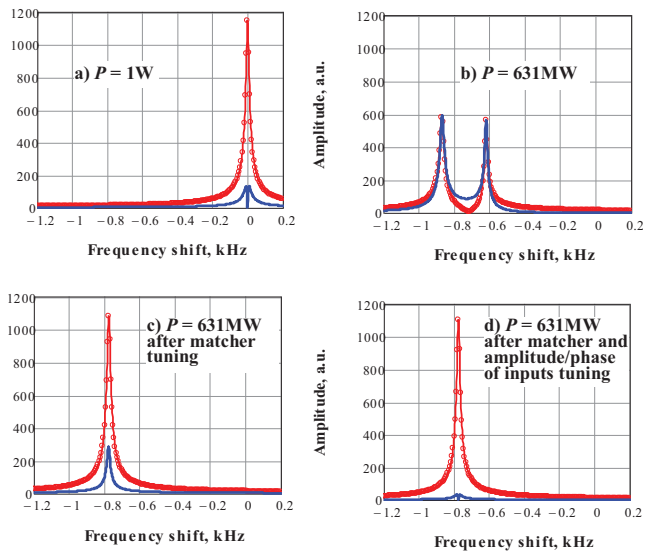

Figure 7: Tuning of the stiffened 3-cell STWR model after strong LFD: a) perfectly matched STWR before LFD; b) strong LFD under circulating power 631 MW; c) tuning by waveguide matcher deformation (+0.61 μm); d) the next stage of tuning is two inputs signal adjusting ($P_{inp1}/P_{inp2} \approx 1.245/0.755$, $\Delta\varphi_{between_inp1\&inp2} = 115°$, TW mode frequency shift is Δf_{TW} = -774.4 Hz)

This example of a strong LFD (about thirty STWR bandwidth) shows two needed stages of tuning – walls shape deformation by a special device named "matcher" (see in Figure 8) and more precise tuning by the redistribution of feeding power in the RF inputs. The first stage is stronger and might adjust both the TW mode and the STWR frequency. The input amplitude and phase control cannot change the cavity frequency and has a narrower acceptable range for detuned parameters. But according to our simulations (see Fig. 5) the fine tuning of RF inputs signals could be enough to withstand microphonics detuning in the stiffened STWR.

NEW 3-CELL DESIGN OF THE SUPERCONDUCTING TW CAVITY

The present design of the 3-cell STWR based on the obtained simulation results matched with the Fermilab VTS parameters. As SW superconducting accelerating structures the TW cavity has stiffening rings on accelerating cells and, in addition, stiffening ribs on the WG loop (see Figure 8). A new element for a VTS tested prototype will be waveguide matcher which will be used to maintain TW mode in the STWR. This will be achieved through one lever construction with two stepper motors and a movable pushing element. The first stepper motor (not seen in Fig. 8) is for WG shape deformations, which push or pull the pushing element. The second stepper motor is for moving the pushing element along the feedback waveguide in a specially designed cage. These stepper motors can provide up to a 10 nm displacement because of their gear ratios of up to 10^5 and their 1 mm shaft thread. Necessary matcher requirements obtained through the 3-cell model simulation are range and minimal step for shape deformation ±90μm / 20nm, and the longitudinal position ±4mm / 0.5μm, respectively.

There are five sleeves with conflate flanges for mounting pick-up antennas: three on the WG bend for calibration and TW directivity measurements, and two on the WG loop bottom side for power feeding.

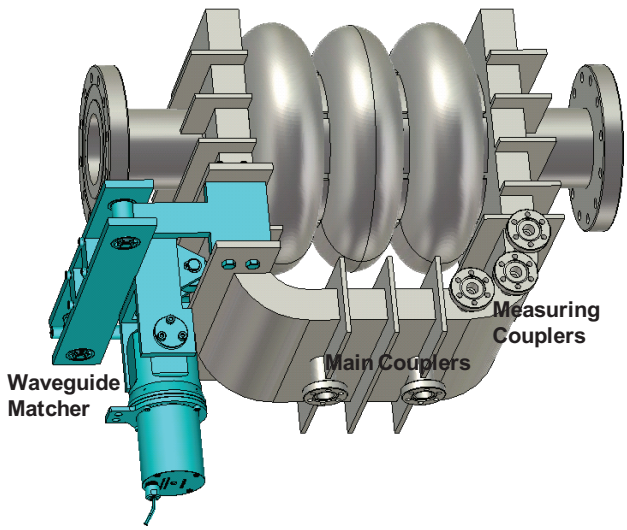

Figure 8: The 3-cell STWR assembly.

CONCLUSION

The results obtained in the STWR model simulation gave an understanding of the way to build a new 3-cell TW cavity design. Power limitation, strong microphonics, and Lorentz force detuning lead to reinforced niobium cavity, and a new tuning device in the new 3-cell design. Methods to create and support the travelling wave regime in this structure were discussed.

STUDY ON PARTICULATE RETENTION ON POLISHED NIOBIUM SURFACES AFTER BCP ETCHING*

I. Malloch#, C. Compton, L. Popielarski, Facility for Rare Isotope Beams (FRIB), Michigan State University, East Lansing, MI 48824, USA

Abstract

Niobium surface defects and inclusions can be introduced during the manufacturing processes used in the production of SRF cavities. Bulk removal methods (sanding, polishing, etc...) are frequently utilized to remove or smooth away these defects on the surface of the niobium metal. It is hypothesized that these mechanical removal methods are capable of trapping performance-degrading particulates, which are then exposed during subsequent chemical processing, potentially contaminating the cavity prior to RF testing. This paper summarizes results of a series of surface roughness and etching experiments performed to determine the relationship between the extent of polishing and trapped particulate, and to determine a method for mitigating this particulate contamination through BCP etching. The relationship between these experiments and RF cavity performance will be explored as well.

INTRODUCTION

The construction of the Facility for Rare Isotope Beams (FRIB) driver linac will require more than 350 niobium superconducting radio frequency (SRF) cavities. Four types of cavities will be used in the linac: 80.5 MHz β = 0.041 and β = 0.085 quarter-wave resonators, and 322 MHz β = 0.29 and β = 0.53 half wave resonators. Each of these cavities must be fabricated with utmost precision to ensure proper functionality of the cavities during RF testing and during the operation of the completed accelerator. Of the many critical aspects of these RF cavities, the surface finish of the niobium exposed to RF fields is paramount to the proper functionality of these cavities during testing. Unfortunately, despite the best of intentions and the most well-defined procedures and quality assurance protocols, issues can arise that compromise these niobium surfaces. Weld spatter deposited on the niobium during electron-beam welding of cavity components, foreign debris and inclusions imbedded in the niobium during sheet rolling or part stamping, and gouges or scratches occurring due to mishandling or machining errors can all impact the quality of the cavity surface [1]. Fortunately, these defects can frequently be fixed by means of mechanical abrasion. While these repairs are necessary, unfortunately, the use of abrasive media to repair the niobium surface can cause lasting degradation of the surface finish, and, as a result, potential degradation of cavity performance due to particulate contamination on the cavity surface. This study seeks to examine the lasting impact of these repairs, and to determine a method for mitigating the consequences by means of processing and analyzing a series of niobium samples.

EXPERIMENTAL

Two lots of niobium samples were used in this experiment. Each lot consisted of a series of small grain, high-RRR (>250), 3 mm thick sheet stock samples, shear-cut to approximately 2.5 cm square. Each sample was stamped with a serial number, photographed, degreased with acetone, ultrasonic cleaned, and precision measured for thickness (±0.0025 mm) with an NDT Systems Model TG900 ultrasonic thickness gauge.

As is typically performed with RF cavities, following cleaning, the samples were chemically etched with a standard solution of buffered chemical polish (BCP). The BCP mixture used at FRIB is a 1:1:2 mixture of concentrated hydrofluoric (49% w/w), nitric (70% w/w), and phosphoric (85% w/w) acids. The first lot of samples was divided into eight sub-lots. The sub-lots were each submerged in BCP and etched for between 60 and 480 minutes, removing up to 300 microns of niobium from the surface of the samples. Upon completion of the etching, the samples were thoroughly rinsed with ultrapure water (UPW) and set to dry in an ISO 5 cleanroom. Once dry, the surface roughness (both R_a and R_z) at six different locations on each sample was measured with a Fowler 54-410-500 X-Pro Portable Surface Roughness Tester.

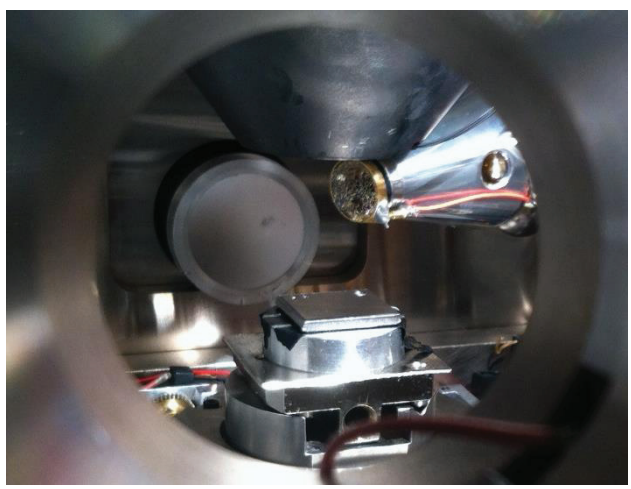

Figure 1: A niobium sample on the microscope stage as seen through the SEM's vacuum viewport.

To simulate a portion of an RF cavity repaired with an abrasive media, the second lot of samples was "polished"

for five seconds per sample with a pneumatic Dyno-File tool equipped with a medium-grit aluminium oxide conditioning belt. Ultrasonic thickness measurements showed that the abrasion did not remove an appreciable amount of material from the sample surface. Following the abrasion of the samples, they were divided into sub-lots, and ultrasonic cleaned once more. Once clean, the abraded samples were etched in the same manner as the as-received samples, then were rinsed and dried in the cleanroom and measured for surface roughness.

Once the surface roughness characterization of the samples had been performed, a representative set of samples were analyzed with a CamScan 44FE Field Emission Gun Scanning Electron Microscope to allow the topography and particulate retention of the samples to be observed in great detail (Fig. 1).

DISCUSSION

The development of the surface roughness for the as-received samples followed the same well-defined pattern that had been reported previously for chemically polished niobium surfaces [2, 3]. The surface roughness, R_z, prior to etching was very small, though it steadily increased for the first ~100 microns of etch removal. At this point, it began to plateau, and stayed relatively constant for the remainder of the etching procedure. The more surprising outcome was the evolution of the surface roughness for the abraded samples. Not surprisingly, the initial surface roughness of the abraded samples was significantly higher than was observed on the as-received samples (Fig. 2).

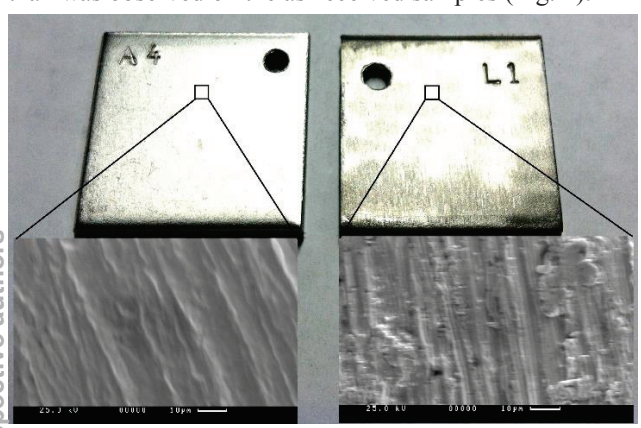

Figure 2: As-received niobium sample (left) compared to an abraded sample (right). Note the difference in surface roughness, both in the picture and in the SEM scans.

Once etching was commenced, the surface roughness fell sharply during the first 50 microns of removal, at which point the roughness began to climb, then plateau in a manner consistent with the as-received samples. The surprising finding was that the surface roughness of the abraded samples never converged with the as-received samples (Fig. 3). A similar pattern was observed with R_a measurements. The implication here is that under the conditions explored in this experiment, once a niobium surface has been abraded, the surface roughness will not return to a state consistent with a surface that has not been altered with an abrasive media. As can be seen in Figure 4, while the samples look very similar to one another with the naked eye, microscopy shows that they are not. Note the difference in the overall surface finish, and observe the valley that runs through the center of the image. These crevasses were seen in several locations on the abraded samples up until at least 100 microns of niobium had been removed from the surface. This has the potential to have serious consequences on RF cavity performance [4], since the increased surface area of a rougher material allows more room for particulates to become trapped on the surface, potentially resulting in field-emission and cavity quenching during operation.

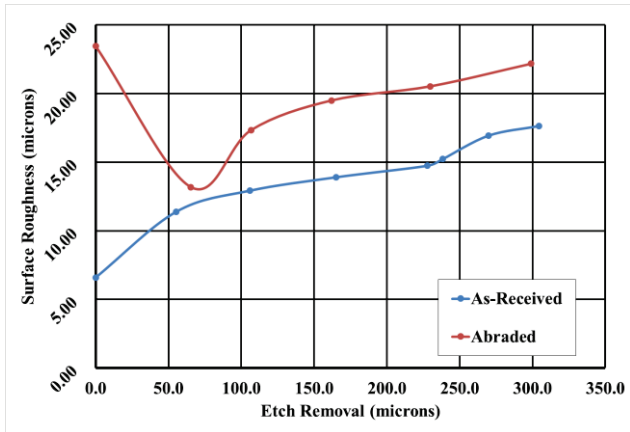

Figure 3: Plot of etch removal vs. surface roughness for the as-received and abraded niobium samples for different etch removal amounts.

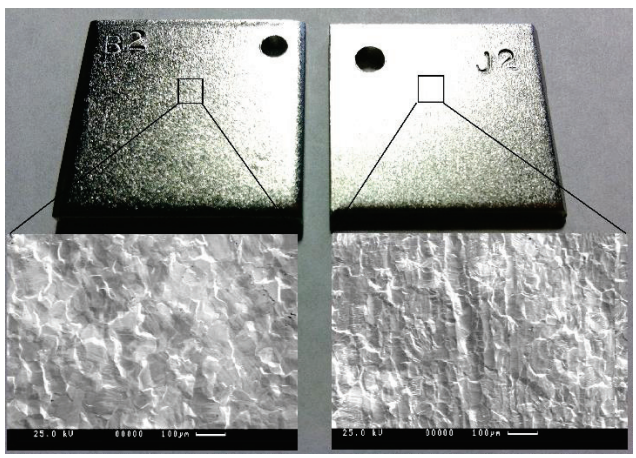

Figure 4: As-received niobium sample (left) compared to an abraded sample (right) following 70 microns of etching. Abraded sample has visibly worse surface finish under the microscope.

In addition to the concerns about the roughness of the niobium surface, there was also evidence to suggest that on top of the passive role that abrading can play in particulate retention, particulate was actively being ground into the surface of the niobium. These particulate were only exposed after significant amounts of etching had been performed (Fig. 5). While these particulate are not necessarily a *guarantee* of a bad cavity test, they are

Copyright © 2013 CC-BY-3.0 and by the respective authors

certainly not preferable, and can contribute to less than optimal cavity performance, especially at high-field.

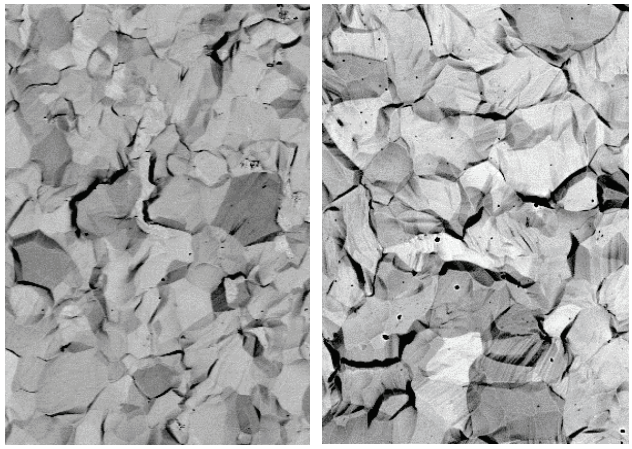

Figure 5: SEM scans of an as-received sample (left) and an abraded sample (right) after more than 100 microns of etching. Note the unusually high concentration of black particulate spots on the abraded sample.

SRF Cavity Repair: A Case Study

A β=0.085 quarter-wave resonator intended for use in the ReA3 coldmass was recently processed in the FRIB chemical etching and cleanroom facility. Once assembled and pumped down, the cavity demonstrated a large weld leak between the helium vessel and RF space along one of the cavity's flanges. At this point, the cavity was sent for repair at an electron-beam welding facility. During welding, suspected contamination in the weld area caused a significant amount of weld spatter to be deposited on the RF surfaces inside of the cavity.

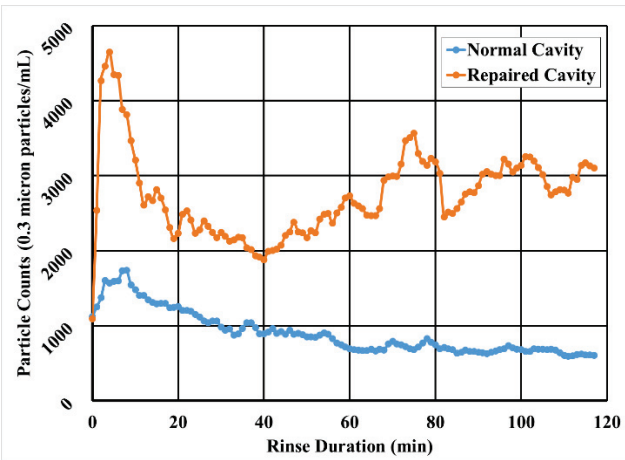

Figure 6: Liquid particle count comparison between a normal and repaired cavity during high-pressure rinsing.

The same abrasion method used in this experiment was used to remove the spatter and smooth out the resulting imperfections on the cavity surface prior to a chemical etch and high-pressure rinse (HPR) being performed. Liquid particle counts taken during the HPR were more than five times higher than were historically observed for a cavity of this type (Fig. 6). HPR was continued for an additional two hours, at which point the particle counts began to fall back to an acceptable range. Unfortunately, the subsequent cavity assembly and leak check revealed another leak requiring additional repair, so no comparison between cavity test results could be established. Despite the fact that no test results were gathered for this repaired cavity, data gathered over the course of many cavity processes indicates a correlation between low particle counts during HPR and superior cavity performance.

CONCLUSION

While the repair of surface defects on SRF cavities is often a necessity, careful consideration should be given to the methods and materials used. If abrasives must be used, as small of a surface area as possible should be affected. Care should also be taken to adjust processing procedures following these repairs to ensure the highest quality product possible. At a minimum, extended etching and high-pressure rinse cycles are recommended prior to assembly for RF testing. The necessity of repairs should be considered as well. Frequently, damage or inclusions on welded surfaces can cause defective welds; these must be repaired. However, if these issues are seen on other cavity surfaces, chemical polishing alone can often mitigate the damage without causing long-term impacts to the quality of the cavity surface. These less aggressive repair solutions should be pursued whenever possible.

ACKNOWLEDGMENTS

The authors would like to thank all the members of the NSCL & FRIB staff whose dedicated effort has made a significant contribution to this experiment. In particular, Ryan Brunk, Kyle Elliott, Doug Miller, Daniel Victory, Andrew Wisniowiecki, Ken Witgen, and Joseph Whaley. We would also like to extend our sincere gratitude to Di Kang for his assistance in gathering profilometry and microscopy data for this experiment.

SRF CAVITY ETCHING DEVELOPMENTS FOR FRIB CAVITY PROCESSING*

K. Elliott#, I. Malloch, L. Popielarski, N. Putman, Facility for Rare Isotope Beams (FRIB), Michigan State University, East Lansing, MI 48824, USA

Abstract

Updates to the FRIB beta=0.53 half wave resonator (HWR) design have provided an opportunity to test new buffered chemical polish (BCP) flow control techniques. New processing fixtures have been fabricated and used to process the FRIB beta=0.53 HWR. This paper will present details of the fixture mechanical design iterations, the resulting BCP flow simulations, a qualitative evaluation of the agreement between simulations and measured results, and developments in process validation techniques.

INTRODUCTION

Buffered chemical polish (BCP) processing techniques continue to progress with the FRIB β=0.53 half wave resonator (HWR) cavity. With the updated cavity design we were able to use new fixturing concepts and take a variety of measurements to better understand the processing parameters. The new β=0.53 HWR cavity has an internal volume of 76 L, and an internal surface area of 1.4 m^2.

The objectives for the design of the new chemistry fixtures were to reduce fixture complexity, reduce fixture installation time, and increase the etch uniformity.

FIXTURE DESIGN

Twelve different configurations were analyzed to determine the best concept for achieving uniform etch removal. Seven of the configurations were a derivative of the directional quill injection system used on the previous β=0.53 HWR cavity [1]. The other five configurations consisted of a single directional quill. Ultimately the single directional quill was chosen. The analysis of the single directional quill, and the four injection quill design, can be seen in Figure 1.

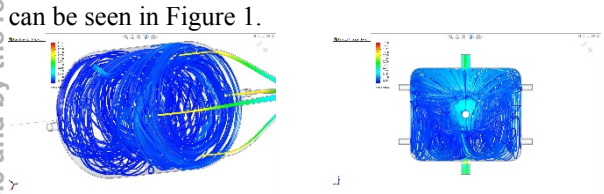

Figure 1: Left, analysis of four quill injection system. Right, analysis of single quill injection system.

* This material is based upon work supported by the U.S. Department of Energy Office of Science under Cooperative Agreement DE-SC0000661

#Elliott@FRIB.MSU.EDU

The single quill configuration shown in Figure 2 was chosen because it appeared to deliver equivalent mixing of the BCP compared to the four quill configuration, while reducing the complexity of the BCP delivery plumbing. The quality of the BCP mixing is determined qualitatively by choosing the fixture concept which produces the least velocity variation across the superconducting surface of the cavity.

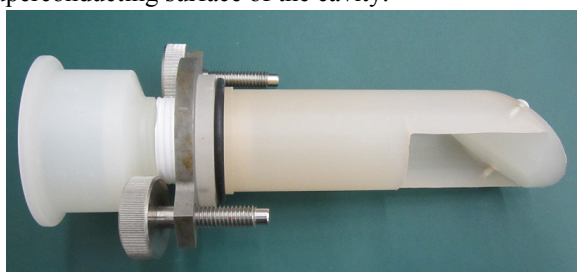

Figure 2: Single injection quill used for FRIB β=0.53 HWR cavity BCP processing.

One of the stated goals of this fixture iteration was to reduce installation time. This was done in two ways. First, the force needed to make the o-ring seal on each flange was carefully examined and revised. Second, we attempted to eliminate the need for tools during the fixture installation.

Past chemistry flanges were designed with a hole pattern to match the mating flange on the cavity. For example, one of the 2.75" ConFlat flanges of the prototype β=0.53 HWR cavity had six ¼" clearance holes (See Figure 3). Once the fasteners are were tightened there was nearly 12,000 lbs of force on the flange, though it is not known what portion of that force was transmitted to the o-ring.

O-ring Analysis

The Parker Hannifin o-ring handbook [2] indicates that only 20-30% compression is necessary to make a static o-ring seal. Given the o-ring hardness, thickness, and desired percent compression, the Parker Hannifin o-ring handbook indicates that 10-20 lbs of force per linear inch of o-ring is required to make a reliable seal. This means that only 300 lbs of force is needed for this seal.

A stainless steel backing plate was added to each flange to ensure that the tension from the fasteners was evenly distributed to the o-ring and, the number of fasteners was reduce from six to two. Because a well lubricated 1/4" fastener requires only 7.5 in*lbs of torque to produce 150 lbs of tension (half of the required 300 lbs), thumb screws

Copyright © 2013 CC-BY-3.0 and by the respective authors

were used in place of hex head cap screws. This eliminated the need for hand tools, and reduced the total BCP processing flange installation time from ~30 minutes to ~5 minutes.

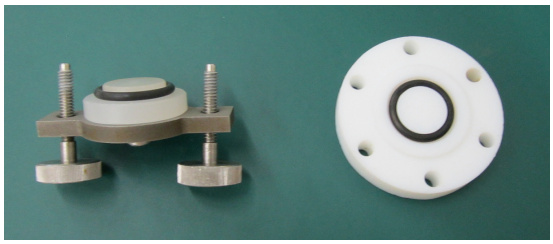

Figure 3: Left, new BCP blank flange design. Right, old BCP blank flange design.

EVALUATION OF SIMULATION

Ultrasonic thickness measurements (USTM) were taken on the new HWR cavity before and after each bulk etch step. The bulk etch removal for this cavity was taken in steps of 45 µm, 55 µm, and 30 µm respectively. The ultrasonic thickness measurements show strong correlation between the predicted flow path and the resulting etch patterns. Notice the high etch region which begins below the cavity beam port and broadens as the BCP impinges on the cavity surface. The black triangles in Figure 4 highlight this behavior. The new fixtures provided a more uniform etch in most locations on the cavity. One exception to this uniformity is the area near the radio frequency (RF) antenna ports indicated by the arrow in figure 4. The weld bead around this port allowed a gas bubble to form, reducing the local etch rate.

Figure 4: Left, Predicted flow pattern. Right, resulting etch removal measured by USTM.

PROCESS VALIDATION

Three different techniques were used to measure the amount of etching done to the cavity's RF surface. Those techniques were, ultrasonic thickness measurements, mass change analysis, and heat production analysis.

Ultrasonic Thickness Measurements

This method requires the user to take ultrasonic thickness measurements at numerous locations on the outside of the cavity before etching, and then repeat those measurements after etching. The thickness of material removed can then be calculated at each measurement location. This method is useful for determining locations of high etch removal, but it is also time consuming. If the removal has been calculated for the majority of the cavity's surface area all data points can be averaged to yield an accurate overall etch removal.

Mass Change Analysis

Unlike USTM's, this method does not provide information about removal rates in specific locations on the cavity. It is a useful way to quickly determine the overall etch removal. This method requires a mass measurement be taken before and after etching. Equation 1 below is used to calculate the average material removal from the cavity.

$$Removal = \frac{m_i - m_f}{\rho_{Nb} \times S.A.} \quad (1)$$

Where m is mass, ρ_{Nb} is the density of niobium, and S.A. is the surface area of the cavity.

Application of this method can be challenging because it requires a very accurate measurement of mass to yield accurate etch removal measurements.

Heat Production Analysis

Because the reaction between BCP and Niobium is very exothermic [3] a measurement of heat produced during the etching process can be used to determine the amount of niobium removed from the cavity's internal surface. The change in temperature of the flowing BCP is used to determine the amount of heat produced during the cavity etch. Equation 2 (below) is used to calculate the amount of heat which is put into the BCP.

$$Q(t) = \dot{V}(t) \times \rho_{BCP} \times c_{p,BCP} \times \Delta T(t) \quad (2)$$

Where $\dot{V}$ is the volumetric flow rate of the BCP, ρ_{BCP} is the density of the BCP, $c_{p,BCP}$ is the heat capacity of the BCP, and $\Delta T(t)$ is the temperature as a function of time. Now that the heat production known equation 3 (below) can be used to determine the amount of niobium removed from the cavity surface.

$$Removal = \frac{\int_{t_0}^{t_f} Q(t)dt}{M(Nb) \times \rho_{Nb} \times h_{RXN} \times S.A.} \quad (3)$$

Where M(Nb) is the molar mass of niobium, and h_{RXN} is the heat of the reaction.

One advantage of this method is that it can be applied during the etching process to determine when the cavity has received the desired amount of etching, and the resulting measurement is not affected by localized etch patterns.

Measurement Method Comparison

As mentioned earlier, this cavity was etched in three steps of 45, 55, and 30 micrometers respectively. Each measurement technique was used at every stage of the

Copyright © 2013 CC-BY-3.0 and by the respective authors

etching process. The result of each measurement technique are summarized in Figure 5 below.

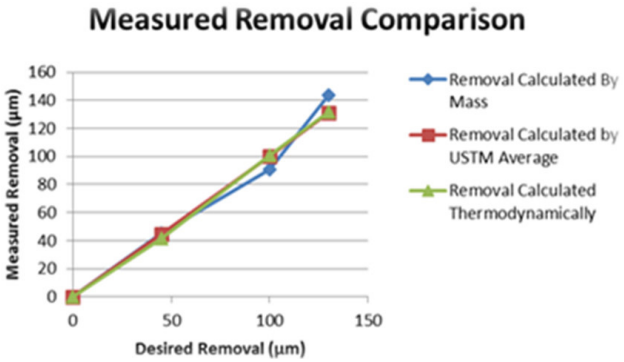

Figure 5: Comparison of measurement techniques for each stage of β=0.53 cavity bulk etch.

USTM is the most accurate technique at this time. The results of heat production analysis are in close agreement with the USTM method, as seen in Fig. 5. Measurements taken for the mass change analysis were done with a scale which had a resolution of .2 lbs., this can lead to measurement error of 7.5 µm.

CONCLUSION

Fluid flow simulations have proven to be effective in qualitatively predicting localized etch rates. Understanding predicted flow patterns will lead to accurate modeling of etch removal across the cavity's internal surface. After the removal patterns are understood the use of USTM's is no longer necessary. Instead mass change analysis or heat production analysis can be used to quickly and accurately verify etch removal.

MAGNETIC SHIELD OPTIMIZATION FOR THE FRIB SUPERCONDUCTING QUARTER-WAVE RESONATOR CRYOMODULE*

Y. Xu#, A. Fox, M. Johnson, M. Leitner, S. Miller, K. Saito, FRIB, East Lansing, MI 48824, USA

Abstract

The Facility for Rare Isotope Beams (FRIB) required 49 cryomodules containing 330 superconducting low-beta resonators, which have to be shielded from the earth magnetic field. Comprehensive magnetic shielding simulations have been conducted for 80.5 MHz β=0.085 cryomodules exposed to earth fields of 0.5 Gauss in different coordinate directions. The magnetic shield has to attenuate the earth magnetic field by a minimum factor of 33 (to less than 15 milli Gauss) in order to limit flux trapping in the resonators during cool-down. In the reported optimization studies, permeability of the magnetic shielding material, shield thickness, and number of magnetic shield layers have been varied. Different design concepts including global and local magnetic shielding have been evaluated. In addition, the design concepts are compared based on the cost of material, fabrication and assembly, the design complexity and compatibility with the overall cryomodule design to obtain an optimum solution.

INTRODUCTION

There are 49 cryomodules that will be built in FRIB: three 80.5 MHz β=0.041 cryomodules, eleven 80.5 MHz β=0.085 cryomodules, two 80.5 MHz β=0.085 matching cryomodules, twelve 322 MHz β=0.29 cryomodules, two 322 MHz β=0.29 matching cryomodules, eighteen 322 MHz β=0.53 cryomodules, and one 322 MHz β=0.53 matching cryomodule.

All cryomodules have to be shielded to attenuate the earth magnetic field in order to limit flux trapping in the cavities during cool-down to less than 15 milli Gauss. Two main different design concepts, room temperature global and low temperature local magnetic shielding as shown in Figure 1, have been compared on 80.5 MHz β=0.085 cryomodule from the attenuation ability, cost of material, fabrication and assembly, to the design and assembly complexity. The global magnetic shield locates between the vacuum vessel and the thermal shield and encompasses the entirety of cold mass, while the local magnetic shield is assembled around the resonators. Two local magnetic shielding designs are compared. One is to shield each resonator with individual shield, the other is to group the nearby resonators as much as possible.

ANSYS Magnetostatic is implemented to study the effects of permeability of material, size of magnetic shield, and the contribution from steel vacuum vessel. The magnetic flux on resonators is obtained to validate the effectiveness of the magnetic shield designs. Finally, Quality Function Deployment (QFD) is applied to compare different design concepts.

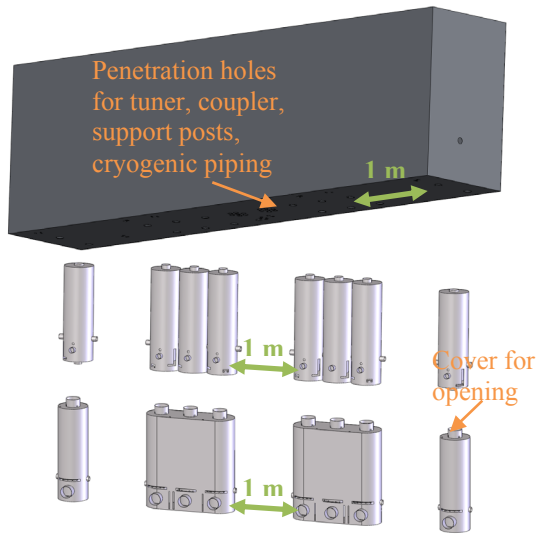

Figure 1: Global shield (top) and local single shield (middle) and local multi shield (bottom).

PERMEABILITY STUDY

The design of the magnetic shield starts with the proper material selection. Magnetic shielding materials should be chosen for their characteristic, usually in respect to permeability and saturation.

Manufacture Data

Amuneal Manufacturing Corporation compares the permeability of two products, Cryoperm 10 and Amumetal, as a function of ambient temperature shown in Figure 2 [1]. Amumetal has the maximum permeability at room temperature and is degraded at cryogenic temperature. Therefore, it is appropriate for the room temperature global magnetic shield. The permeability of Cryoperm 10 reaches its maximum at very low temperature (around 30 K) but is degraded at room temperature. Hence, it is proper for the low temperature local magnetic shield.

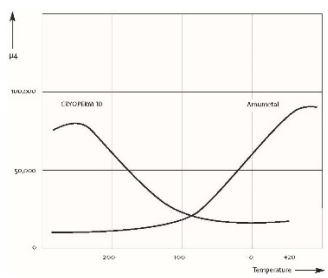

Figure 2: Permeability of Amumetal and Cryoperm 10 versus ambient temperature.

Recently, Amuneal developed a new shielding material Amuneal 4K (A4K) for cryogenic applications. A4K is

Copyright © 2013 CC-BY-3.0 and by the respective authors

claimed to have higher permeability than Cryoperm 10. Therefore, A4K will be employed in FRIB local magnetic shield design. However, Cryoperm 10 permeability will be utilized in the simulation for the sake of conservativeness.

Table 1 lists the permeability and saturation values of Amumetal and Cryoperm 10. Since a saturated shield is a poor attenuator, the selection of magnetic shield material must have adequate saturation characteristics.

Table 1: Permeability and Saturation

Material	Saturation (Gauss)	Permeability	
		μ Max	μ 40
Amumetal	8,000	400,000	60,000
Cryoperm 10	9,000	250,000	65,000

Measured and Simulation Data

It should be noted that the permeability provided above is the data obtained in the laboratory and has the optimum performance. However, the actual permeability of the shielding material depends on the heat treatment, fabrication and handling process of the material. Studies from CEA show that the actual performance of Cryoperm at low temperature is not as good as the one provided by manufacture. Therefore, simulations on FRIB Cryoperm magnetic shield are conducted at different permeability and compared with the measurement from other labs to determine a practical value of permeability. The comparison is made at the same shield thickness 1 mm.

Simulation of attenuation from FRIB local magnetic shield at different permeability with and without the vacuum vessel, 17500, 32500 and 65000, are displayed in Figure 3. It shows that the attenuation increases as the increase of the permeability. The measurement of CEA provides the attenuation from magnetic shield be 25 and that from both the magnetic shield and vacuum vessel be 100 [2]. In addition, the measurement of FNAL shows that the attenuation from both magnetic shield and vacuum vessel in their cryomodule is 120 [2].

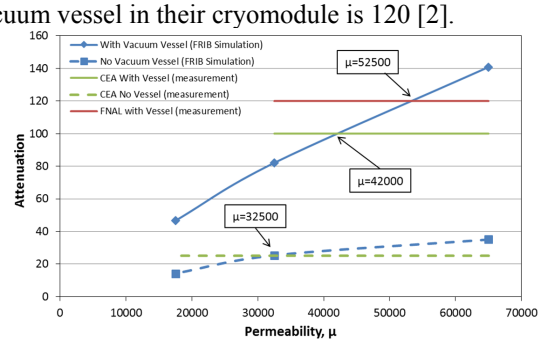

Figure 3: Permeability study.

The length of CEA test magnetic shield is 1.3 m, which is about the same as that of FRIB (1.25 m). Therefore, the performance of CEA and FRIB magnetic shields are similar. Although the permeability is not measured directly, it is reasonable to apply 32500 in the simulation to make direct comparison with the measurement of CEA. The length of FNAL 1.3 GHz cryomodule magnetic shield is 1 m, which is smaller than that of FRIB. Hence, higher attenuation is expected since the smaller the size the better the performance (also explained by Figure 4).

EFFECT OF MAGNETIC SHIELD LENGTH AND THICKNESS

Attenuation simulations on global magnetic shield with full, half, one third and quarter length are conducted and displayed in Figure 4. The shorter the magnetic shield length, the smaller the effective radius of the shield, hence the better its performance. Simulations on thickness 1.6 mm and 3.2 mm shields show that the attenuation increases 1.5 times as the shield thickness doubles. The theoretical study demonstrates that as the decrease of the effective radius of the shield, the attenuation ratio converges to 2 as the shield thickness doubles. For an infinitely large shield, the attenuation converges to 1 and is not affected by the shield thickness and material permeability. Therefore, the attenuation ratio is expected to be between 1 and 2 as the shield thickness doubles.

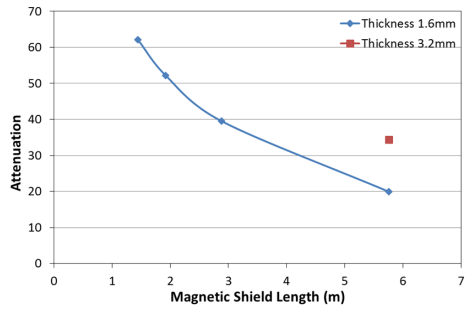

Figure 4: Effect of magnetic shield length and thickness.

STEEL VACUUM VESSEL

The contribution of steel vacuum vessel on the attenuation is displayed in Figure 3. Similar to the magnetic shield, the performance of vacuum vessel also depends on the material permeability, thickness and the vessel size. It can be observed from both the FRIB simulation and the CEA measurement that the contribution from the vacuum vessel is remarkable, especially with thick vessel wall (19 mm for FRIB).

GLOBAL MAGNETIC SHIELD

In the global magnetic shield design, no covers is implemented because of the relative small penetrations. The earth field is 0.5 Gauss in magnitude and varies in different directions for a thorough study. It is found out that the attenuation is the worst when earth field is -30° from the horizontal plane, which is the earth field direction at the FRIB location.

Global magnetic shield simulations are conducted on 1.6 mm, 3.2 mm and two layers of 1.6 mm shields with the contribution of vacuum vessel and the attenuation is 24, 34 and 34, respectively. Two layers of 1.6 mm shield is supposed to have better performance than one layer 3.2 mm shield. However, because of the space limit between the vacuum vessel and thermal shield in FRIB design, the spacing between two layers is very limited. Therefore, the enhancement on performance is not observed.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Since the requirement for magnetic shield is the ability to attenuate the earth field by a minimum factor of 33, single layer of 1.6 mm shield is not appropriate for FRIB QWR cryomodule. The magnetic flux density profile on x-y plane with 3.2 mm magnetic shield is displayed in Figure **5**. Dark blue represents the ***B*** field below 15 milli Gauss. Therefore, 3.2 mm Amumetal global magnetic shield is able to meet the FRIB design requirement.

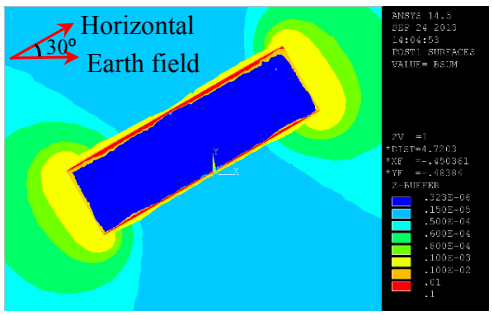

Figure 5: Magnetic flux density with global shield.

LOCAL MAGNETIC SHIELD

The same as the global magnetic shield simulation, the earth field is -30° from the horizontal plane and has magnitude of 0.5 Gauss in both local single shield and combined shield simulations. Tubular covers are necessary for the openings of power coupler, cryogenic supply, beam port and resonator supporting rail penetrations. The height of the cover is proportional to the diameter of the opening since magnetic fields can travel into an opening a distance equal to five times the diameter of the opening.

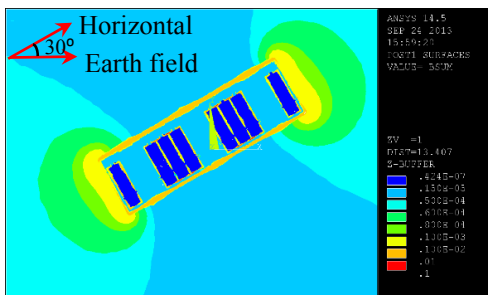

Figure 6: Magnetic flux density with local single shield.

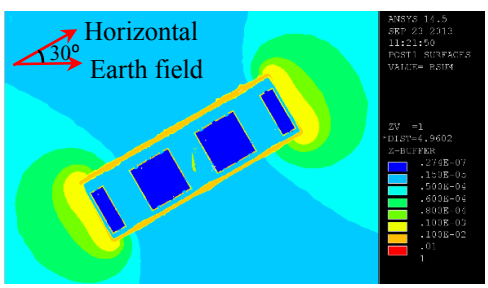

Figure 7: Magnetic flux density with local multi shield.

Simulations on local single shield and local combined shield indicate that the magnetic fields on resonator surfaces in both cases are less than 15 milli gauss (shown in dark blue in Figure 6 and Figure 7).

QFD

Quality function deployment (QFD) is a "method to transform user demands into design quality, to deploy the functions forming quality, and to deploy methods for achieving the design quality into subsystems and component parts, and ultimately to specific elements of the manufacturing process." [3] as described by Dr. Yoji Akao, who originally developed QFD in Japan in 1966.

The most important criteria is the inducted field less than 15 milli Gauss at resonator surface. It is shown in Figure 8 that all the designs meet the requirement but with different efforts. Global magnetic shield design requires more effort hence "bad relationship" is specified.

Other important factors include: design, assembly and fabrication complexity; compatibility with design of other systems such as bottom up design, cold mass, thermal shield, vacuum vessel, and cryogenic system; cost including material, fabrication and assembly cost. For example, the cost of 0.125" Amumetal global shield is the highest because of the highest material cost. In addition, the 2 layer 0.062" Amumetal global shield has the lowest compatibility with bottom up design, minimum spacing requirement and post-assembly accessibility to power coupler. In summary, the local A4K magnetic shield is the best design concept, especially with the multi-resonator configuration.

Max Relationship Value in Row		Relative Weight	Weight / Importance	Quality Characteristics (a.k.a. "Functional Requirements" or "Hows") / Demanded Quality (a.k.a. "Customer Requirements" or "Whats")	0.125" Mu-Metal global shield	Single Resonator A4K Shield	Multi-Resonator A4K Shield	2x .062" Mu-Metal shields	0.062" Mu-Metal global shield + A4K local shield

TUNING PROCESS OF SSR1 CAVITY FOR PROJECT X AT FNAL*

P. Berrutti, M. Awida, T. Khabiboulline, D. Passarelli, L. Ristori, V. Yakovlev
Fermilab, Batavia, IL 60510, USA

Abstract

SSR1 is a family of single spoke resonators to be used in Project X at Fermi National Laboratory. These cavities operate in CW regime having nominal frequency of 325 MHz and optimal beta of 0.22. SSR1 cavities will accelerate H- ions after the Half Wave Resonator (HWR) section from 9 MeV to 32 MeV. In the near future this cavity will be used in Project X Injector Experiment (PXIE), which contains the ion source, the LEBT, the MEBT, the RFQ of Project X, and a cryogenic temperature section, having one HWR and one SSR1 cryomodule. SSR1 cavities have been built and tested at FNAL, the preparation of these resonators includes RF tuning which is the main focus of this paper. The frequency of the cavity is carefully chosen prior to the vertical test, and it is adjusted before welding the helium vessel to obtain 325 MHz nominal frequency for the dressed cavity in operating conditions. Several SSR1 cavities have been tuned at FNAL, the procedure, the hardware and the data are presented.

INTRODUCTION

SSR1 cavities have been built and tested at Fermilab [1] [2]. During cavity production it is necessary to set frequency goals throughout the entire process, to match the final target frequency of 325 MHz for a cold jacketed SSR1. After assembling and welding of the niobium, the cavity arrives at Fermilab and undergoes several quality control steps: visual inspection, CMM measurements, RF QC and leak check. The frequency is monitored throughout the entire cavity processing; when the cavity is received from the vendor several measurements are taken: fundamental frequency, high order modes frequencies, and field flatness. SSR1 cavity processing includes baking at high and low temperature and chemical polishing, bulk and light BCP. The leak check and the chemical processing are two main causes of frequency shifts. During the first vacuum check the cavity geometry is deformed by the atmospheric pressure, which shrinks the structure inducing permanent plastic deformations, even though very small. The average Δf for SSR1 due to the leak check is -80 kHz. The bulk BCP removes 150 µm in average from the cavity surface, while the light chemical processing results in 30 µm material removal. The Δf produced by the bulk BCP has been averaged over 10 cavities and it is 150 kHz, while the one due to light BCP is 30 kHz. Transition ring [3] and helium vessel welding makes the frequency change as well; the two processes have been recently started at FNAL. All these are causes of frequency deviations; in order to control and compensate for these shifts it is necessary to tune the cavities with a proper fixture.

*Work supported by D.O.E. Contract No. DE-AC02-07CH11359
#berrutti@fnal.gov

SSR1 BARE CAVITY TUNING

The first tuning step of SSR1 comes for the preparation to the vertical test, the frequency is adjusted to 324.6 MHz in order to reach approximately 325 MHz once the cavity is cooled down to 2 K in the test dewar. Usually the cavity received from the vendor has a resonant frequency of 325.6 (±0.2) MHz, after the leak check, first bake and bulk chemistry it is usually higher by 70 kHz. The total frequency shift to apply is approximately 1 MHz, taking into account the cavity sensitivity 540 kHz/mm (simulated) [4] and the spring constant 21 kN/mm, the tuning requires a robust fixture capable of delivering forces of several tens of kN. Figure 1 shows the tuning machine for SSR1 cavities, it consists in a box equipped with two rods which allow pushing or pulling on the cavity beam pipes. Two load cells measure the forces applied on each rod, four displacement gauges give reading of the deformations the cavity is subject to, and they are mounted between the beam pipes and the coupler ports. A set of antennae is mounted on the coupler ports to allow recording the frequency step by step with a network analyser.

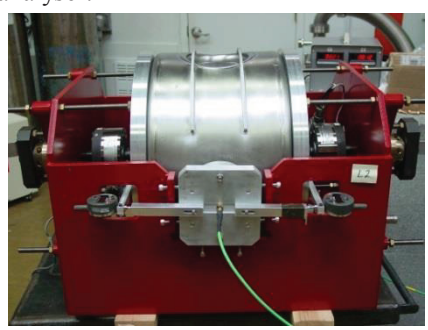

Figure 1: SSR1 tuning machine with a cavity in it.

To understand how the frequency changes when the tuning machine acts on the resonator, let us keep in mind Slater's rule:

$$\frac{\Delta f}{f_0} = \frac{1}{4W}\int_{V_i}^{V_f}(\varepsilon_0 E^2 - \mu_0 H^2)dV. \quad (1)$$

W is the stored energy in the cavity in initial conditions, V_i is the volume before tuning and V_f is the volume after deformations are applied. Since the rods are acting on the beam pipes the high electric field area is modified, consequently the change in frequency will have the same sign of the change in cavity volume: bigger volume means higher frequency.

Tuning Procedure

Before starting tuning the cavity, it has to be installed in the machine, which means have it fit centred in

Copyright © 2013 CC-BY-3.0 and by the respective authors

between the two rods to avoid any asymmetric deformation of the cavity structure. The tuning consists in applying a force on the cavity and then release it coming back to relaxed position. This is done in several steps, gradually, to avoid any abrupt change in the cavity geometry; RF measurements are taken for the stressed and relaxed conditions at each cycle. This process is repeated until the target frequency is achieved. Figure 2 shows the frequency of SSR1-112 during the tuning, one can see how for small forces applied the process is reversible and the frequency in the relaxed state is equal to the one before pushing or pulling. When the force overcomes the elastic limit of the material the cavity starts yielding, and as result the frequency for the relaxed cavity changes.

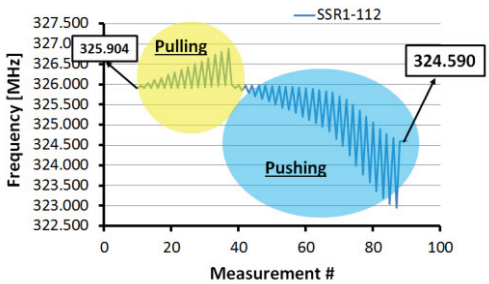

Figure 2: SSR1-112 frequency during tuning.

Frequency of the relaxed cavity is represented by the lower values for the pulling and higher values for the pushing. Despite the desired negative frequency shift, the first part of the tuning involves pulling which makes the frequency become higher. The reason why the tuning starts with pulling is to harden the material by stretching it; the frequency is not modified significantly usually a shift ranging from +80 to +100 kHz is sufficient. After the first pulling the real tuning by pushing starts, many cycle are usually required and the total force required can reach over 7000 lb_f.

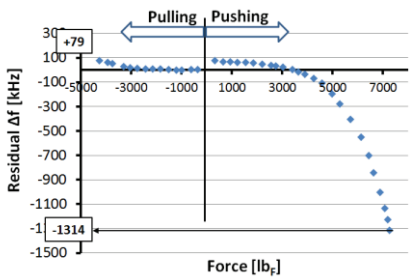

Figure 3: relaxed cavity frequency shift vs. force.

The figure above shows the Δf due to plastic deformation of the cavity, the pulling required almost 4300 lb_f while the pushing is over 7200 lb_f, the non-linearity of the last part of the plot is due to the yield of the material. When the value of frequency for the relaxed cavity is approaching the target, it is extremely important to increase the force by small steps since the material is yielding, and the frequency changes are much faster with the applied force. During the tuning it is possible to measure physical quantities related to cavity displacements, force applied and frequency shifts, in general it is interesting to look at frequency sensitivity as a function of the displacement and cavity spring constant. The frequency sensitivity $\frac{\Delta f}{l}$ measured in kHz/mm can be calculated from the plot of the frequency as a function of the average displacement, reported in figure 4. One can see two lines, one for the relaxed, one for the loaded cavity. The average of the parameter $\frac{\Delta f}{l}$ for all the cavities tuned is 460.7 kHz/mm, which is lower than the one predicted by simulations (540 kHz/mm). This mismatch is partly due to the residual asymmetry in the deformation induced by the rods; the error in evaluating the displacements is also not negligible, in addition the simulated sensitivity may differ from the real value.

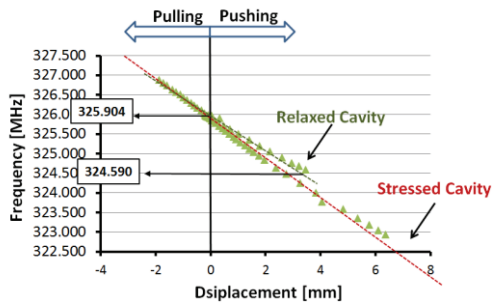

Figure 4: SSR1-112 frequency vs. average displacement.

Figure 5 shows the average displacement as a function of the force applied, from this plot it is possible to extract the spring constant value of the cavity evaluated as $\frac{\Delta F}{\Delta l}$, where ΔF is the difference in force applied; it is expressed in kN/mm, its average value is 22.2 kN/mm.

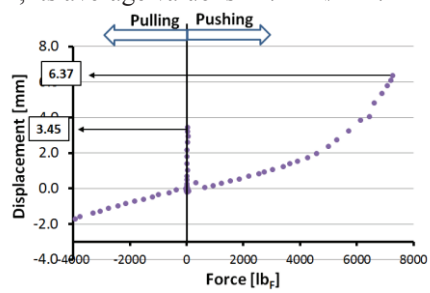

Figure 5: average displacement vs. force.

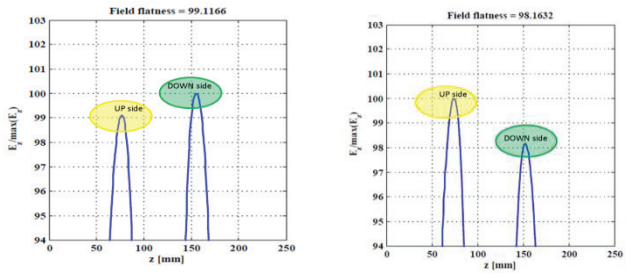
Tuning After Transition Ring Weld



In the latest design of SSR1 helium vessel [4] a transition ring is used to attach the niobium cavity to the stainless steel vessel [3]. The ring is attached to the cavity by electron beam welding, see figure 6, this operation is done after the resonator qualifies from the VTS. Recently Fermilab received two SSR1 cavities which had the transition ring welded, SSR1-107 and SSR1-108. The expected frequency shift was initially thought to be very small, while it turned out to be around 500 kHz. The cause of this shift is the contraction of the beam pipe area on the transition ring side; the weld induces the material to shrink while it cools down, pushing the beam pipe in and consequently reducing the resonant frequency.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Figure 6: SSR1 cavity with transition ring.

To prove this, bead pull measurements were taken on SSR1-108 before and after the weld, the normalized field amplitude plots are presented in figure 7, up side refers to the side of welding. Looking at figure 7(a) the maximum of the accelerating field is on the down side, opposite to the weld side, while for figure 7(b) the higher point appears on the transition ring side. Higher field means shorter gap, so this is an evidence of the shrinkage due to the weld.

(a) (b)

Figure 7: SSR1-108 field flatness before (a) and after (b) transition ring weld.

SSR1-107 has been tuned to compensate for the effects of the transition ring weld, following the procedure described in the previous paragraph but applying asymmetric forces to bring the gap length back to original value.

SSR1 DRESSED CAVITY

Fermilab recently received the first SSR1 cavity with helium vessel, in order to monitor the resonant frequency measurements have been taken during the entire welding process. Figure 8 shows the frequency history of SSR1-107 during the welding of the stainless steel helium vessel; the main steps are highlighted on the graph. The most critical procedure is the welding of the beam pipes to the vessel which brings up the resonator frequency significantly. The welds on the outer helium vessel shell do not induce significant shift, while the two ports (coupler and vacuum) may interfere with the helium vessel parts and put stress on the cavity: the lower peak in the yellow part of the graph is due to the ports pressing against the vessel parts, they have been machined during the welding procedure to solve this issue. The first cavity ended up having a total frequency shift of 264 kHz during the dressing process, the procedure and the design of the helium vessel parts will be revised in order to obtain lower shrinkage effect on the cavity geometry.

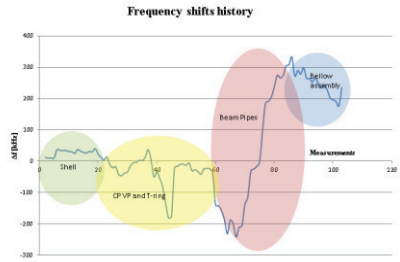


Figure 8: frequency shifts induced by helium vessel welding.

Once the resonator has been dressed it does not fit in the tuning machine anymore. A new fixture has been created to adjust the dressed SSR1 frequency: it consists in two stainless steel bars connected to the helium vessel on the tuner supports. Figure 9 shows the dummy tuner that will be used to adjust the frequency of the jacketed cavities; the device will allow tuning by pushing and pulling, unlike the real tuner device which will be able to compress the cavity only [4]. One rod is installed on each bar to allow tuning on the cavity wall, only on the side opposite to the transition ring, which has been connected to a bellow to allow movement.

Figure 9: SSR1-107 dummy tuner assembly.

CONCLUSIONS

Over ten SSR1 bare cavities have been tuned successfully at Fermilab, a new helium vessel design has been introduced and the first prototype has been built. The tuning procedure has been described and all the issues have been addressed. Currently tests and measurements are in progress on SSR1-107, to characterize all the features of the jacketed cavity; tuning will be done using the dummy tuner fixture, to assure that the target 325 MHz frequency is achieved.

SINGLE SPOKE RESONATOR INNER ELECTRODE OPTIMIZATION DRIVEN BY REDUCTION OF MULTIPOLES*

P. Berrutti#, T. Khabiboulline, L. Ristori, N. Solyak, V. Yakovlev,
Fermilab, Batavia, IL 60510, USA

Abstract

Accelerating cavities based on coaxial resonators, half wave and spoke resonators for example, do not have azimuthal symmetry. This lack of symmetry introduces a transverse field perturbation which affects negatively the beam dynamic, since the particles traveling through the structure are crossing two accelerating gaps separated by the inner electrode. The field asymmetry induces an asymmetric transverse momentum gain which, once expanded in multipoles, appears to be due to a quadrupole perturbation. Depending on the cavity geometry and particle velocity, the influence of electric and magnetic fields may vary quite significantly. One solution to obtain symmetric transverse fields in spoke resonators consists in modifying the inner electrode shape from a pole to amore elaborated structure resembling an X or a Y letter shape. The application of these changes symmetrizes both electric and magnetic fields and reduces the multipoles amplitudes to negligible values. This paper presents the study aimed at reducing the multi-pole amplitudes for SSR2 cavity for Project X; the presented procedure, in general, is valid for any spoke cavity.

INTRODUCTION

Coaxial resonators are widely used for low-beta applications At Fermilab one family of half wave resonators (HWR) and two families of single spoke resonators (SSR) will be used in Project X. The geometry of both HWR and SSR is obtained from a coaxial line approximately half of a wave length long. The accelerating gaps of these cavities are formed by the inner and outer conductors of the coaxial resonator. Particles are travel along an axis perpendicular to the inner electrode. Let us assume that the particles are traveling through the gaps along the z axis, the lack of azimuthal symmetry leads to a different transverse momentum gain on x and y axes, acting as a quadrupole on the beam [1]. This issue has already been examined at Fermilab [1], [2] and a solution has been implemented to overcome HWR field asymmetry [3]: the central part of the inner electrode was modified using a radially symmetric circular shape. Such modification allows to obtain regular transverse electric field reducing asymmetric effects on the beam envelope. When the same approach was used on SSR2, the second family of spoke resonators for Project X, results were quite unexpected: the field asymmetry was even higher than before. This was caused by the magnetic transverse fields, which are not negligible in SSR2 cavities.

TRANSVERSE FIELD ASYMMETRY

Half wave and spoke resonators accelerating mode is quasi-TEM mode, that has non-zero transverse components on paths slightly off the ideal electric axis of the cavity. Considering the z axis as the longitudinal direction, electric and magnetic fields will be present in x and y. In figure 1 transverse field components of SSR2 cavity are plotted along z, for an offset of ten millimetres on the x-y plane: along x axis E_x and H_y are present, while for an offset on y direction E_y and H_x.

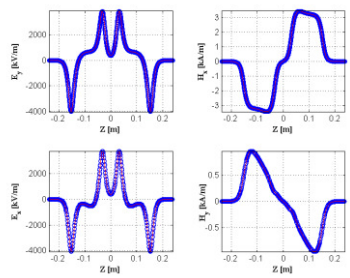

Figure 1: SSR2 electric and magnetic transverse fields.

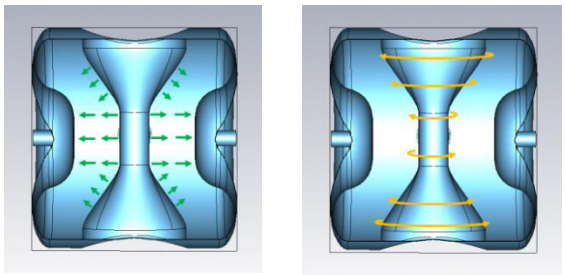
A particle traveling with a radial offset r will experience a transverse kick due to the electric and magnetic fields:



$$\Delta p_x(r,\alpha)c = \int_{z_i}^{z_f}\left(\frac{E_{x(r,\alpha)}}{\beta} - i\boldsymbol{Z}_0 H_y(r,\alpha)\right)e^{i\frac{kz}{\beta}}dz \quad (1)$$

$$\Delta p_y(r,\alpha)c = \int_{z_i}^{z_f}\left(\frac{E_{y(r,\alpha)}}{\beta} + i\boldsymbol{Z}_0 H_x(r,\alpha)\right)e^{i\frac{kz}{\beta}}dz. \quad (2)$$

Where $\boldsymbol{Z}_0$is the impedance of free space, $\beta = v/c$ and α is an angle, taken with respect to the x axis: α=0 corresponds to x axis and α=π/2 refers to y axis. The momentum gain can be calculated in the whole beta range for the accelerated particles, and its components can be evaluated separately to highlight the difference between electric and magnetic contribution. The electric field line are directed from the spoke to the outer walls, while the magnetic field lines spin around the inner post, hence the magnetic field component orthogonal to the electrode will be higher than the one parallel to it. Figure 2 shows SSR2 single spoke geometry, the green arrows on the left (a) represent a sketch of the electric field lines while the orange circles on the right (b) show the magnetic field spinning around the electrode.

(a) (b)

Figure 2: field line sketch of a spoke resonator (a) electric and (b) magnetic [1].

Assuming that the inner post lies along y, the magnetic field component orthogonal to the spoke will be H_x and the parallel one will be H_y; see plots in fig. 1 for comparison. All the transverse momentum gain components have been plotted in figure 3, the entire energy range of SSR2 cavity in Project X has been analysed (approximately from 40 MeV to 160 MeV). The left plot shows the electric field contribution; on the right the magnetic momentum gain is shown. Looking at fig. 3, it is immediately clear that the magnetic asymmetry is not negligible, especially for the higher beta region.

(a) (b)

Figure 3: (a) electric and (b) magnetic transverse momentum gain [1].

As a figure of merit for field asymmetry the following parameter Q can be used:

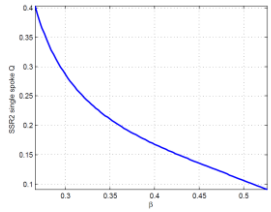
$$Q = \frac{\Delta p_x(r,0)c - \Delta p_y(r,\pi/2)c}{(\Delta p_x(r,0)c + \Delta p_y(r,\pi/2)c)/2}. \quad (3)$$

This parameter, evaluated on the full particle energy domain of SSR2, has been plotted in figure 4; its value is independent from the gradient or peak field because it is normalized over the sum of the two components: $\Delta p_x(r,0)c$ and $\Delta p_y(r,\pi/2)c$.

Calculating a multipole expansion of the transverse kick, it is possible to show that the asymmetry parameter is a measure of the quadrupole amplitude over the monopole.

ELECTRODE DESIGNS SHOWING NEGLIGIBLE FIELD ASYMMETRY

In order to bring symmetry to the cavity geometry it is necessary to re-design the inner electrode of the coaxial resonator. This modification consists in replicating half of the electrode with periodicity in the x-y plane, so the result will be an electrode resembling the shape of a letter Y or X. These two designs show very weak transverse field asymmetry for both electric and magnetic components. In the following subsections each design and its fields are described.



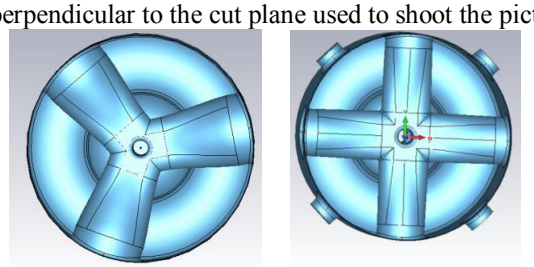


Figure 4: SSR2 single spoke asymmetry parameter vs. particle beta

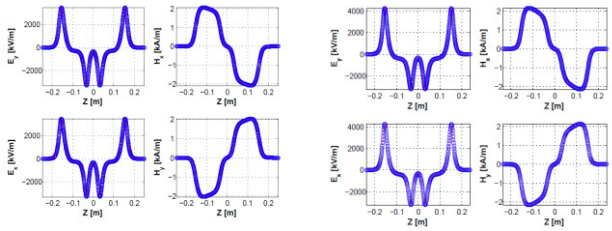
Y-Shaped Spoke

The Y-shaped spoke, see fig. 5(a), consists of an inner electrode replicated and equally spaced at 120 degrees in the x-y plane. In figure 5(a) the x-y cross section of the Y-spoke design is shown, particles travel along z axis which is perpendicular to the cut plane used to shoot the picture.

(a) (b)

Figure 5: (a) Y-spoke design cross section, (b) X-spoke x-y section.



The transverse electric and magnetic fields benefit from the modified electrode. Transverse fields on a 10 mm offset are plotted in figure 6(a), electric on the left magnetic on the right. The x and y components of the two fields are in separate plots because an overlapping will not allow distinguishing one from the other, since they are almost identical. In figure 7 (a) the asymmetry parameter Q has been plotted versus the particle beta in the energy range of Project X, its maximum value is just ≈ 3% of the maximum Q for the single spoke. Figure 8 shows the magnetic (b) and the electric (a) transverse momentum gain on a 10 mm offset from the centre of the beam tube, the magnetic components (on the right) show some residual asymmetry.

X-Shaped Spoke

The X-spoke design has been made by intersecting two single spoke electrodes rotated by 90 degrees from each other; figure 5(b) shows the x-y cross section of the cavity geometry. Transverse field components and the transverse kicks are almost identical; this design does not have noticeable field asymmetry. Figure 9 shows the transverse momentum gain calculated for the full beta range, electric components are plotted on the left (a) and magnetic on the right (b). Since $\Delta p_x c$ and $\Delta p_y c$ electric and magnetic are identical in the plots, it is worth looking at the parameter

MULTIPOLE ANALYSYS

A more complete approach to the problem of transverse field asymmetry involves the expansion of $\Delta p_R c$ (the radial component of the transverse kick) in multipoles. One should to start by calculating the transverse kick at a given radial value, for all the angles on the x-y plane. Subsequently it is possible to decompose $\Delta p_R c(r, \alpha)$ in harmonics to evaluate the dipole, quadrupole, sextupole and octupole amplitudes. Figure 10(a) shows the angular dependence of $\Delta p_R c(r,\alpha)$ for all the three different designs of SSR2, calculated at r=10 mm for a synchronous particle (beta = 0.47) longitudinal energy gain of 4.5 MeV.

(a) (b)

Figure 10: (a) $\Delta p_R c$ as a function of the angle α, (b) Fourier sum of the radial kick, constant component excluded.

Figure 10(b) shows the Fourier series of $\Delta p_R c$, the plot does not include the constant radial component, included in 10(a) instead. In 10(b) the amplitudes of X and Y-spoke have been multiplied by a factor 100. Table 1 reports the values of the multipoles amplitudes, up to octupole; it confirms how beneficial the modification to the inner electrode is, quadrupole amplitude is highlighted.

Table 1: Multipoles Amplitudes Calculated at r=10 mm and 4.5 MeV Synchronous Particle Energy Gain

Amplitudes	Single spoke	Y-spoke	X-spoke
1st[keV]	5.812e-14	2.57E-01	6.31E-14
2nd[keV/mm]	3.391	1.76E-03	0.000717
3rd[keV/mm^2]	4.331e-16	2.43E-03	2.77E-16

5th[keV/mm^4]	4.957e-18	3.58E-07	5.58E-18
6th[keV/mm^5]	2.338e-08	1.53E-07	2.89E-08
7th[keV/mm^6]	1.367e-19	4.31E-09	2.91E-20
8th[keV/mm^7]	2.719e-10	3.49E-10	6.35E-10

CONCLUSIONS

Alternative designs for a spoke resonator have been presented; the work has been driven by reduction of the field asymmetry which leads to a quadrupole perturbation on beam dynamic. Quadrupole amplitude has been reduced significantly and the X and Y-spoke designs have symmetric transverse fields (electric and magnetic). The approach to cavity design presented in this paper can be used for any spoke resonator which shows transverse field asymmetry.

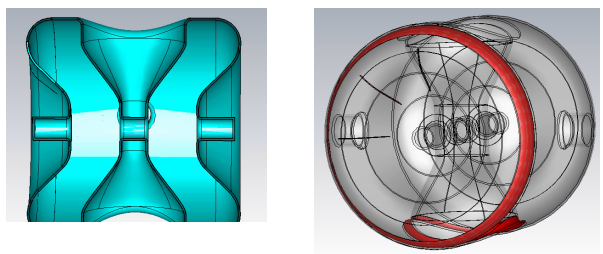
MULTIPACTING SIMULATIONS OF SSR2 CAVITY AT FNAL*

P. Berrutti#, T. Khabiboulline, L. Ristori, G. Romanov, A. Sukhanov, V. Yakovlev,
Fermilab, Batavia, IL 60510, USA

Abstract



SSR2 is the second family of single spoke resonator under development at Fermi National Accelerator Laboratory (FNAL). These cavities will be placed in Project X front-end after SSR1 spoke resonators, which have already been built and tested and FNAL. Spoke cavities are affected by multipacting and the nature of their 3D geometry does not allow simulating the multipactor process using 2D tools. 3D tracking simulations, of electrons inside the cavity volume, have been carried out using CST Particle Studio. Different Secondary Emission Coefficients have been applied to the cavity walls in order to understand how strongly the multipacting depends on material properties. The power levels used in simulations cover the whole operating gradient range of SSR2 cavity. Results of these simulations are compared to the one given by SSR1 model, which demonstrated good agreement with experimental data. The purposes of this paper are to present the results gotten from the tracking solver, to give a prediction of what will be the multipacting scenario for SSR2 cavity and if there will be any dangerous zone for operation.

INTRODUCTION

Multipacting affects SRF cavities from high energy elliptical cavities to coaxial resonators for low-beta application. This work is focused on multipacting in low-beta structures; the main aim is to present the results of SSR2 cavity for Project X. SSR2 is a spoke resonator in development for Project X at Fermilab [1], it operates at 325 MHz and its optimal beta is 0.51. The design has been finalized recently it was necessary to understand at what level this resonator is affected by multipacting (MP), what the critical gradients are and where the MP develops in the cavity geometry. The software used for MP simulations is CST Particle Studio which provides a particle tracking solver that uses the field from the eigen-mode solver of Microwave Studio. The figure of merit chosen as a final result of tracking simulations is the growth rate, which gives information on how fast the number of particles increase with time. Simulation of MP in SSR2 cavity have been run for three different niobium secondary emission yields (SEY): in CST environment the highest emission for niobium is given by the wet treated material, a bake out model gives the intermediate one and the lowest yield is given by the discharge cleaned niobium. The growth rate has been calculated in a wide range of gradients and the MP locations have been identified for the major MP barriers. The experience of Fermilab with MP in low-beta structure started with SSR1, which is the lower optimal beta spoke resonator for Project X, operating at 325 MHz as well. Multipacting in SSR1 cavity has been simulated, using the same approach as for SSR2, and these results have been compared with experimental data from multipacting barriers found during the vertical test of SSR1 cavity [2], [3]. All this has been done in order to compare SSR1 and SSR2 multipacting simulations, and to understand how reliable and accurate the results of these simulations are.

SIMULATION SET UP

In order to simulate multipacting using CST particle studio it is necessary to create a shell all around the cavity volume to have an emitting material. The outer layer has been grown from the outside of the vacuum volume of the cavity, without interfering with the inner ideal surface. Figure 1(a) shows the geometry of SSR2 used for multipacting simulations in the x-y cut plane view. Once created the emitter shell the primary particle sources needed to be built. They were placed on the geometry taking advantage of the symmetry of the spoke resonator. Figure 1(b) shows the particle sources chosen for SSR2 MP simulations; red surfaces indicate sources of primary electrons. This set up has been used for SSR1 simulations as well; it has been previously described in [4] when the first multipacting simulations of SSR1 cavity were done.

(a) (b)

Figure 1: (a) outer shell built around SSR2 geometry x-y plane view, (b) particle sources are highlighted by red surfaces.

Primary particles were launched from the sources with an initial energy ranging from 2 to 6 eV, the angle was chosen randomly by the solver to get an isotropic electron emission. When simulating multipacting it is extremely important to have the mesh dense enough in the locations where the MP happens, the multipacting spatial scale is much smaller than the cavity dimensions. Multipacting occurs in regions where the electric field is not high, compared to the accelerating field, and the magnetic field bends the trajectories in a way that they satisfy the resonant condition. Electron trajectories could be very small compared to the cavity radius or length especially for complicated shapes like spoke resonators; thus a very fine mesh is required to get accurate EM field calculation

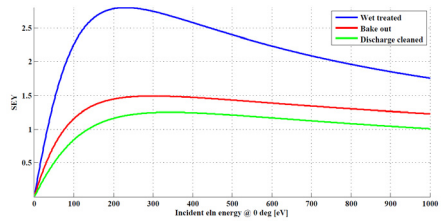
and reliable particle tracking in the multipacting regions. The emission model used is by Particle Studio is the Furman probabilistic model, which takes into account elastic backscattered, re-diffused and true electrons. The last ones are the responsible for electron growth since the backscattered and the re-diffused do not produce secondary particles. The available settings of secondary emission yield for niobium are three and all of them have been used in simulations, to understand how strongly the multipacting depends on the material property. Figure 2 compares the three SEY curves used, the plot is meant for a primary particle hitting the material perpendicularly to the surface.



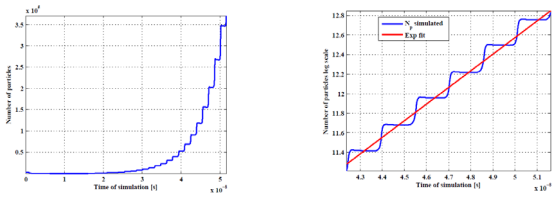


Figure 2: SEY of Nb as a function of the incident electron energy.

GROWTH RATE CALCULATION

A typical output from a multipacting simulation consists in a plot of the number of particles versus time of simulation. When multipacting occurs this curve can be approximated using an exponential function of time, the growth rate (GR) is the exponential coefficient that multiplies the time; after the MP is started the number of particles can be expressed by: $N(t) = N_0 e^{\alpha(t-t_0)}$. Where α is the growth rate, usually expressed in ns^{-1}, and N_0 is the number of particles at $t = t_0$, the time at which the MP process starts.

(a) (b)

Figure 3: (a) exponential particle growth vs. time, (b) last 3 RF periods of simulation time, particle number and its exponential fit.

Figure 3(a) shows the growth of particle with simulation time, usually the multipacting does not start immediately but it needs few RF periods to be engaged. Figure 3(b) shows the particle number and its approximation, y axis has been put in logarithmic scale; the figure shows the last 3 RF periods of simulation time, the one used to evaluate the growth rate value. From figure 3(b) it is clear that the resonant condition has been reached since the number of particles is increasing every half RF period, six steps appear over a simulation time of 3 RF cycles. The optimal number of RF periods to use for growth rate calculation has been chosen by looking at the GR values dependence on the RF cycles used for interpolation. Figure 4 shows the GR for number of RF periods going from 1 to 5, the optimal amount is considered to be around 3.

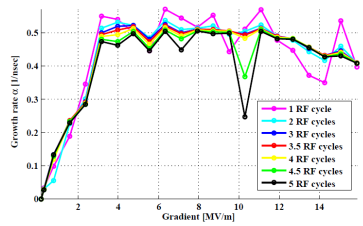

Figure 4: GR dependence on RF cycles used for the exponential fit.

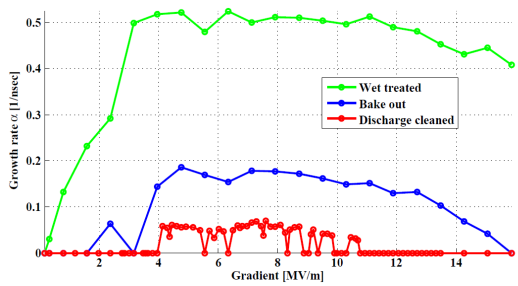
The definition of gradient used in this paper is in agreement with the one used in Project X documents and it is based on a definition of effective length of the cavity expressed by $L_{eff} = \beta_{opt}\lambda$; the gradient is therefore $E_{acc} = \Delta W_{max}/L_{eff}$, where ΔW_{max} is the energy gain for a particle traveling at optimal beta through the cavity with zero synchronous phase.

SSR2 MP SIMULATIONS

SSR2 growth rate has been calculated for E_{acc} ranging from approximately 1 to 15 MV/m; the maximum energy gain for the cavity in Project X lattice is currently 5 MeV, which corresponds to $E_{acc} \simeq 10.6$ MV/m [5]. The growth rate summary plot is presented in figure 5, it includes all three different material used in simulations.



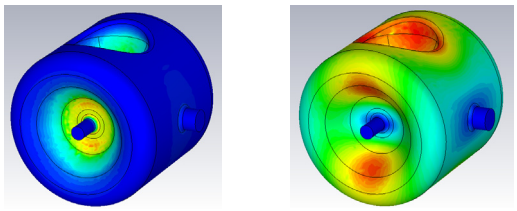


Figure 5: SSR2 GR vs. gradient summary.

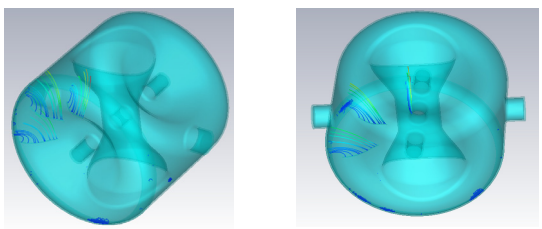
The wet treated emission model has been allowing multipacting throughout the whole gradient range, so it did not give any information about particular barriers proper of the cavity geometry. Bake out SEY has helped in reducing the high number of secondary electrons generated, lowering the overall growth rate and some low gradient MP disappeared. The discharge cleaned material has allowed seeing different MP barriers in the medium-high gradient range, low and high power multipacting have not been observed. The number of points on the red curve has been increased to enhance its resolution and not to miss small barriers. Multipacting locations have been observed looking at the particle trajectory plots, in order to understand why and how the MP locations move from one spot to another it is fundamental to know the field distribution in the cavity. To increase the gradient means to increase the fields, electric and magnetic, the electrons move accordingly with field amplitude which can satisfy



Copyright © 2013 CC-BY-3.0 and by the respective authors

the resonant condition. When the gradient is increasing linearly, MP moves to lower field areas to find the same field levels as for lower gradients. Figure 6 shows the field distribution is SSR2 (a) electric and (b) magnetic. Looking at fig. 7, which shows MP locations at different E_{acc} values, it seems that MP affects SSR2 cavity in the corners of the outer cavity wall. The MP spots move from the spoke vertical position, at low E_{acc}, to almost horizontal position on the corners, at higher gradients.

(a) (b)

Figure 6: SSR2 field distribution, (a) electric and (b) magnetic.

(a) $E_{acc} = 4.4$ MV/m (b) $E_{acc} = 6.6$ MV/m

(c) $E_{acc} = 8.7$ MV/m (d) $E_{acc} = 10.4$ MV/m

Figure 7: multipacting locations at different gradients.

SSR1 MP SIMULATIONS

Since several SSR1 resonators have been tested and multipacting barriers have been experimentally observed; the results of multipacting simulations of SSR1 have been compared with the data collected during the vertical tests of the cavities. Comparing the simulation results with the experimental data helps in understanding how accurate the simulations are, and how far from reality the model is. SSR1 simulations have been compared with experimental data and then with SSR2 MP, to see if the new cavity will have multipacting barriers whether softer or harder than the one observed during the tests of SSR1. The growth rate values of SSR1 and SSR2 are plotted in figure 8, the graph shows the data related to the lowest SEY model, since it is the only one the allows to see different MP barriers. SSR2 cavity shows harder multipacting barrier having higher growth rate values, the MP seems to occur for a wider power range as well. SSR1 has two main MP barriers according to simulations: the first ranges from 4 MV/m to 6 MV/m, the higher barrier starts at 6 MV/m and ends around 8 MV/m.

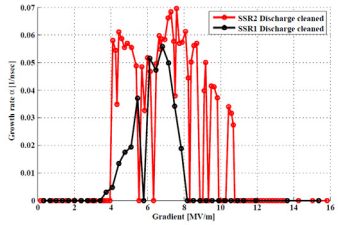


Figure 8: SSR1 and SSR2 GR comparison, discharge cleaned material.

The cold test data of all the SSR1 cavities is compared to the simulated growth rate in figure 9, which shows the time spent on each barrier for processing: around 4.5 and 6.5 MV/m all the cavities tested needed several hours for the MP to be processed, the black line in the plot represents the sum, on all cavities, of the time spent for processing. The simulations predict the two main barriers which all the tested cavities are showing during cold tests. The multipacting in SSR1 needs several hours to be processed and overcome; since SSR2 MP simulations showed an even worse scenario, the cavity may be subject to geometry changes to mitigate this phenomenon.

Figure 9: SSR1 MP processing time and growth rate.

CONCLUSIONS

MP has been simulated in SSR2 and SSR1 cavities for Project X, the results of SSR1 simulations have been compared with experimental data and the agreement seems good. SSR2 shows MP barriers harder and wider than SSR1, in the future SSR2 design may be slightly adjusted to mitigate the multipacting. Since the MP locations have been found the modification would involve slightly rearrangements of the outer wall corner.

New Helium Vessel and Lever Tuner for the 650 Mhz Cavities for Project X*

I. Gonin#, M. Awida, E. Borissov, M. Foley, C. Grimm, T. Khabiboulline, M. Merio, Y. Pischalnikov, L.Ristori, V. Yakovlev, FNAL, Batavia, IL 60510, USA

Abstract

The proposed design of the 3 GeV Project X Superconducting Linac employs two families of 650 MHz 5-cell elliptical cavities with different β. The β_G =0.61 will cover the 177-467 MeV range. To cover the range between 467-3000 MeV two versions of 650 MHz 5-cell elliptical cavities with β_G =0.9 and β_G =0.92 has been proposed. The low beam current for CW operation of the Project X requires cavities to operate at a high loaded Q and thus, narrow bandwidth. Therefore it requires the optimal mechanical design of cavities to minimize the sensitivity to microphonics.

INTRODUCTION

Fermilab is currently developing a multi-MW proton source, Project-X (PX) [1], which will provide intense muon, kaon, neutrino and nuclei beams for broad and diverse program at the intensity frontier of particle physics. Possible future upgrades of Project-X may require operating linac in a regime of a high beam current, when an average beam current is 5 mA or even 10 mA. The design of 5-cell elliptical 650 MHz β_G =0.9 is under development at Fermilab. An alternative design of elliptical cavity with a larger aperture (59 mm) and β_G=0.92 is suggested for HE 650 MHz section in order to comply with various upgrade scenarios of the Project X linac [2]. The design of a dressed cavity (both β_G =0.9 and β_G =0.92) has been mechanically optimized by minimizing df/dP, the sensitivity to microphonics detuning due to fluctuations in helium pressure. The results for β_G =0.9 version has been presented at IPAC 2013 [3]. In this paper we will present the results of COMSOL simulations of df/dP, mechanical resonances and cavity tunability of an alternative β_G =0.92 cavity. We will also present the mechanical design of tuners and ANSYS analysis of their properties. The tuner system will be identical for both versions of cavities design.

HELIUM VESSEL DESIGN

The helium vessel assembly is constructed from a single 5 mm thick sheet of grade 2 titanium that is rolled and seam welded into a tube with an inside diameter of 441 mm and a length of 930 mm. Two helium fill ports are featured to allow for an even cool-down of the cavity. The helium vessel assembly is shown in Figure 1. The weld joint designs on the helium vessel satisfy the ASME Boiler & Pressure Vessel Code Section VIII Division 2. It is important to note that the 5 mm wall thickness for the helium vessel specification was not because of the ASME code, but rather to help in reducing *df/dP* by using the helium vessel to help stiffen the cavity.

gonin@fnal.gov

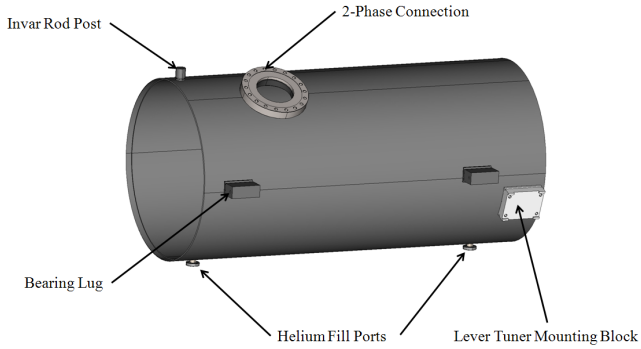

Figure 1: He vessel assembly.

The main coupler end and the field probe end of the helium vessel have slightly different joint designs due to the cavity installation sequence and variations in cavity lengths. The main coupler end of the vessel is considered a fixed position relative to the main coupler port of the cavity, and consistency between these key features for dressed cavities is maintained. Figure 2 shows the titanium-to-titanium TIG weld connection between the cavity and the helium vessel at the main coupler end. This joint design utilizes a backing ring and satisfies the ASME code.

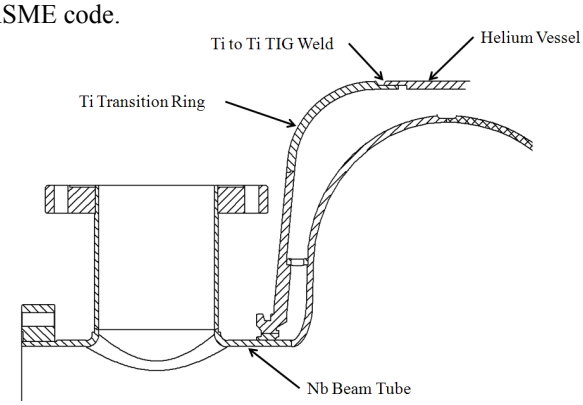

Figure 2: He vessel to cavity fixed joint design.

To allow for variations in the lengths of the manufactured cavities, the field probe end required a sliding joint design that would allow for cavity insertion from the field probe end to the main coupler end. As shown in Figure 3, cavities that vary by ±10 mm in length will not have any effect on the vessel design. This joint also satisfies the ASME code.

Copyright © 2013 CC-BY-3.0 and by the respective authors

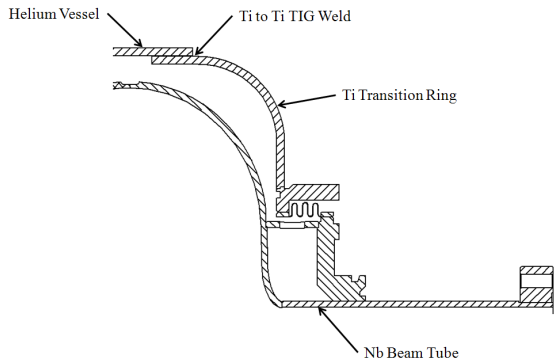

Figure 3: He vessel to cavity sliding joint design.

Dressed Cavity Pressure Boundary

Where practical, the overall cavity design must adhere to the ASME Boiler and Pressure Vessel Code. The pressure boundary will consist of the cavity walls, the connecting flanges, conical disks, and the helium vessel shell. This is outlined in Figure 4.

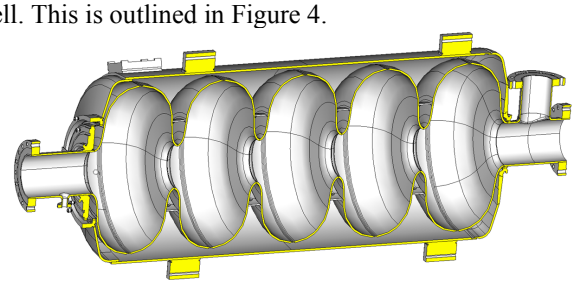

Figure 4: Pressure boundary of dressed cavity shown in yellow.

All electron-beam (EB) welds within the pressure boundary defined above are required to have a fully consumed joint: i.e. duel pass with full overlap or full penetration.

TUNER SYSTEM DESIGN

A compact fast/slow tuner for both versions of cavities has been developed for final tuning of the resonance frequency of the cavity after cooling down and to compensate frequency detuning due to the microphonics.

As shown in Figure 5, one end of the cavity is equipped with a lever tuner. The lever tuner was designed

- to tune cavity in the range of 200kHz.
- able to deliver up to 20kN forces on the cavity.
- fast tuning range up to 1kHz.

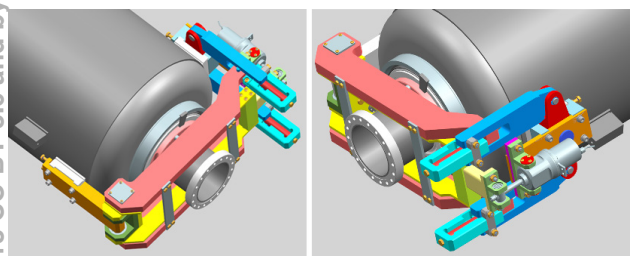

Figure 5: Lever tuner installed on dressed 5 cell cavity.

MECHANICAL ANALYSIS

The mechanical analysis of the β_G =0.92 650 MHz 5-cell elliptical cavity has been performed using the COMSOL and ANSYS FEA software. Figure 6 details a cross-section of the mechanical assembly including the niobium cavity shell and HV. Table 1 lists the material properties for 2K operating temperature used in the simulations. This assembly has different end groups – the left end group incorporates the slow and fast tuning systems and the right end group incorporates the main coupler.

The mechanical design of the cavity includes the following:

- Optimization of the df/dP, the sensitivity to microphonics detuning from fluctuations in helium pressure.
- Cavity tunability analysis.
- Incorporate the slow (stepper motor) and fast (piezo actuator) tuner designs. The slow tuner should be compact, reliable and provide the required tuning range, (about 200 kHz) keeping the cavity deformation below the yield limit.
- Simulations of cavity sensitivity to microphonics due to mechanical resonances and LFD.

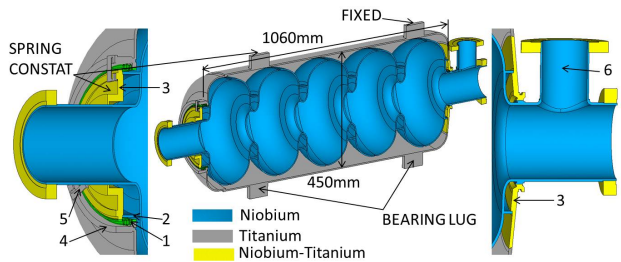

Figure 6: COMSOL model of mechanical assembly used in simulations. 1–bellows, 2–stiffening ring between end half-cell and conical flange, 3–conical flange, 4–bellows ring, 5–support brackets, 6–main coupler. Left – tuner end group. Right – main coupler end group.

Table 1: Mechanical Properties of Materials at 2K

	Young's modulus, GPa	Poisson's ratio	Density kg/m^3
Niobium	118	0.38	8700
Titanium	117	0.37	4540
Niobium-Titanium	68	0.33	5700

Optimization of df/dP

Initially the goal was to minimize df/dP as much as possible so we chose a middle stiffening ring radius of 134 mm (A) that resulted in df/dP < 5 Hz/mbar, however the cavity becomes quite stiff ~18 kN/mm at this ring radius. Room temperature RF tuning of the cavity was questionable. Afterwards, for an alternative β_G =0.92 cavity design we made a decision to sacrifice df/dP for the sake of making the cavity more tuneable and less stiff in order to avoid complicating the tuner design. A smaller

Copyright © 2013 CC-BY-3.0 and by the respective authors

diameter of bellows was proposed in order to help reduce df/dP of the dressed cavity.

COMSOL multiphysics 3D simulations of df/dP in the model presented in Fig. 6 has been done**.** The RF volume deformation induced by internal pressure determines the frequency shift. Boundary conditions used in calculations are:

- fixed displacement one of the bearing lug of Vessel.
- tuner stiffness is simulated by applying the spring constant K_{tuner}.

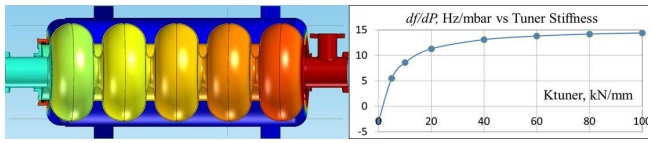

Figure 7: Total displacement for 1 bar internal pressure (K_{tuner} =20 kN/mm) and df/dP vs. stiffness of the tuner.

Fig. 7 shows the total displacements for an internal pressure of 1 bar with a 20 kN/mm tuner stiffness and dependence of df/dP vs. tuner stiffness. Modern cryogenic systems achieve rms pressure stabilities of ~0.2 mbar. It means, that even in case of infinite tuner stiffness, one can expect the maximum frequency deviation due to pressure fluctuation will be <4 Hz.

Mechanical Resonances

Mechanical resonances of cavities in a cryomodule can be excited by external vibrations. Fig. 8 represents the displacement plots of 10 lowest mechanical modes (7 of them are transverse T#1-T#7 and 3 longitudinal L#1-L#3). Boundary conditions used in the calculations are similar to the calculations described in the previous section. Fig. 8 shows the dependencies of the 3 lowest longitudinal modes vs. tuner stiffness.

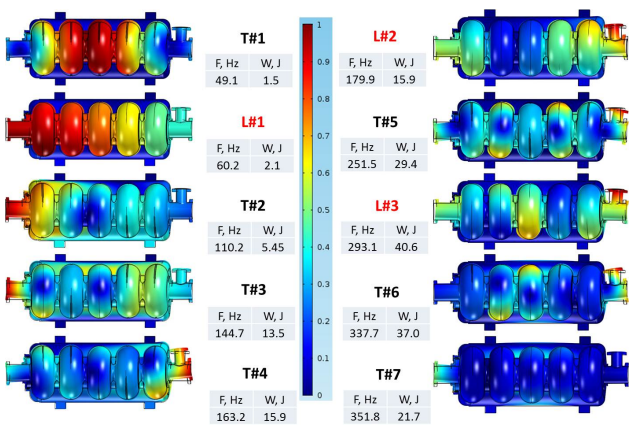

Figure 8: Frequencies, total energy, and COMSOL plots of normalized displacements of 10 lowest mechanical modes. Normalization is 1 mm maximum displacement.

ALLOWABLE WORKING PRESSURE

The dressed cavity has to be rated for a Maximum Allowable Working Pressure (MAWP) of 2 bar at Room Temperature (RT) and 4 bar at Cryogenic Temperature (CT). Preliminary structural analyses have been performed to verify that this requirement can be met. Different loading conditions have been studied; these are a combination of He pressure, dead weight, cooldown and tuner displacement. For each analysis, the Equivalent Stress is computed with finite element code and compared to the yield limit of the materials used (see Table 2). The results show that the MAWP required can be achieved under all the loading conditions.

Table 2: Yield Limit of the Materials Used for the Dressed Cavity

	Niobium	**Nb-45Ti**	**Titanium, grade 2**
RT (300 K)	38 MPa	475 MPa	275 MPa
CT (2 K)	317 MPa	544 MPa	834 MPa

Figure 9 shows the Von Mises Stress distribution for the cavity cooled down at 2 K and with a He pressure of 4 bar. The Equivalent Stress is below the yield of each material.

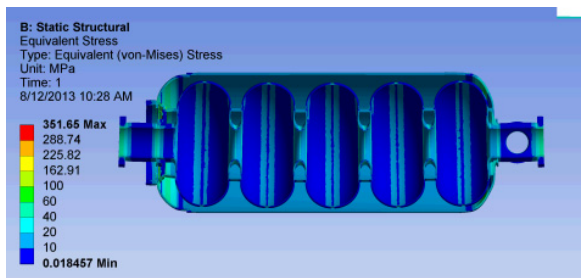

Figure 9: Equivalent Stress distribution at 2 K with 4 bar pressure applied.

Preliminary linear mechanical analyses have been done and show that the MAWP of 2 bar at RT and 4 bar at CT can be achieved. In the future, a set of linear, elastic plastic and local analyses will be performed to ensure that the dressed cavity complies with ASME Boiler and Pressure Vessel Code requirements.

CM2, SECOND 1.3 GHZ CRYOMODULE FABRICATION AT FERMILAB*

T. Arkan#, M. Awida, P. Berrutti, E. Borissov, C. Ginsburg, C. Grimm, E. Harms, A. Hocker, T. Khabiboulline, Y. Orlov, T. Peterson, R. Pilipenko, Y. Pischalnikov, K. Premo, L. Ristori, W. Schappert, V. Yakovlev, FNAL, Batavia, IL 60510, USA

Abstract

CM2 is the second 1.3GHz Cryomodule assembled at the Cryomodule Assembly Facility (CAF) in Fermi National Accelerator Laboratory. The string has a corrector coil magnet, a beam position monitor and eight cavities. All cavities are qualified at >= 33 MV/m gradient at the Horizontal Test Facility (HTS) before assembly. The dressed cavities were outfitted with magnetic shielding, blade tuner. The cold mass was assembled based on the Tesla TTF Type III+ cryomodule design. CM2 is currently being installed into the test stand in NML where it will be cooled down and high power tested. CM2 will also be the first cryomodule to be tested with an electron beam at the NML facility. This paper describes the assembly steps, the quality assurance methods and the challenges experienced during assembly and qualification at CAF.

INTRODUCTION

Fermilab's second 1.3 GHz cryomodule (aka CM2 or RFCA002) was assembled between July 2011 and March 2012. During the installation of this module at NML test facility, a vacuum leak was discovered in the 2-phase helium circuit. The module was brought back to CAF in June 2012 and was partially disassembled to find the location of the leak and to repair it. The module was then reassembled and transported to NML in April 2013. The module is currently being installed on the test stand. The cool-down and high power radio frequency (RF) test of the module is planned to start in September 2013.

CAVITIES AND COLD MASS COMPONENTS

All eight cavities manufactured by industrial vendors were specifically selected to be likely to achieve the ILC design goal based on their performance in individual RF tests [1]. The cavities were first tested "bare" in a vertical liquid helium dewar using low-power continuous-wave RF. Cavities which met the ILC vertical test specification ($E_{acc} \geq 35$ MV/m, $Q_0 \geq 0.8 \times 10^{10}$) were then welded into individual helium jackets at CAF and outfitted with a high-power input coupler. The high power couplers were purchased from CPI. The couplers were cleaned and high power conditioned at SLAC. These "dressed" cavities were then tested in the HTS using high-power pulsed RF. Qualified cavities along with a corrector coil magnet outfitted with XFEL style helium jacket and a button style beam position monitor (BPM) were all assembled into a cavity string in the CAF cleanroom. INFN design blade tuners [2] were purchased from Incodema. The tuner motors and gears were purchased from Phytron and Harmonic Drive Inc. The magnetic shielding parts were designed by Fermilab and were purchased from Amuneal. The vacuum vessel, gas return helium pipe (GRHP) assembly and cold mass support posts were procured from Zanon in Italy.

CRYOMODULE ASSEMBLY

Cavity String Assembly

The assembly of the cavity string was done in the CAF cleanroom situated in the CAF-MP9 building. Eight qualified cavities, a magnet, a BPM and two gate valves were interconnected using bellows in the Class 10 cleanroom. The assembly of the cavity string is the most important step throughout the cryomodule assembly to ensure that the measured gradient of the qualified cavities is preserved. Particulate-free-flange-assembly techniques were developed and optimized throughout the years at various institutions working on SRF R&D. CAF cleanroom technicians have over 7 year experience in particulate free ultra-high vacuum applications. CM2 cavity string (See Figure 1) was assembled while following the assembly travelers and working with strict adherence to the CAF cleanroom working protocols.

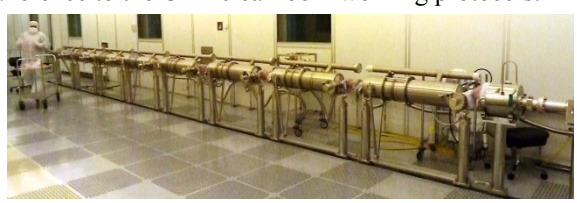

Figure 1: CM2 cavity string in the cleanroom.

Cold Mass and Final Assembly

After the string assembly was completed, the string was rolled out of the cleanroom into the cold mass assembly area at CAF-MP9 using the assembly rail. The 2-phase pipes of the cavities were interconnected using titanium (Ti) bellows welded using an automated orbital welding machine conforming to the ASME piping code. The cavities were then outfitted with magnetic shielding and blade tuner components. The cavity string was then lifted from the assembly fixtures and married to the GRHP assembly forming the cold mass assembly. The cold mass assembly was then transported to CAF-ICB building (See Figure 2). The X-Y axis alignment of the cavities to 250 microns was done using a laser tracker instrument. The cold mass was then transferred to the Big Bertha

Copyright © 2013 CC-BY-3.0 and by the respective authors

cantilever fixture for the welding of heat shields and multi-layer insulation (MLI) installation. (See Figure 3) The cold mass was then moved to the final assembly area in CAF-ICB where the warm end high power couplers and waveguides were assembled.

Figure 2: CM2 cold mass transport.

Throughout the cold mass assembly, several temperature sensors were installed on the critical components; RF measurements of the cavities were done several times and various vacuum leaks and pressure tests were conducted. After the final quality assurance checks, the fully assembled cryomodule was transported to the NML test area (see Figure 4).

Figure 3: CM2 cold mass on the Big Bertha fixture.

Figure 4: CM2 transport to NML.

CHALLENGES EXPERIENCED

Tuner Motor and Harmonic Drive Reliability

First tuner prototypes were designed and built at INFN and delivered to Fermilab. 50 blade tuners were later fabricated in U.S. industry. The Phytron brand tuner motor and the Harmonic Drive gearbox used for CM2 tuners were also used on most tuners worldwide. (See Figure 5)

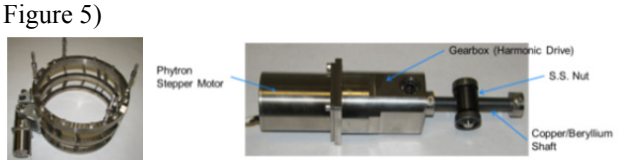

Figure 5: Blade tuner, motor, gearbox.

During the qualification and testing of the tuner components prior to the assembly of CM2 cavities, several mechanical problems were encountered:

1. Harmonic drive wave generator connection to the motor shaft: (See Figure 6)

- Phytron motor shaft has no provisions for a mechanical hard stop
- Dog-point set screws may lose grip on the shaft causing the wave generator to slip

Corrective Action – the motor shaft was cross-drilled and pointed set-screws were inserted with cryogenic grade Loctite.

Figure 6: Harmonic drive wave generator connection to the motor shaft.

2. Harmonic drive flex gear connection to copper/beryllium shaft: (See Figure 7)

- Screws may loosen causing gear to disengage from shaft causing gears to bind

Corrective Action – Internal lock washers were added under the screws and cryogenic grade Loctite was added.

Figure 7: Harmonic drive flex gear connection to copper/beryllium shaft.

Addressing CM2 coarse tuner reliability issues one tuner was tested at warm condition on the bench test. An automatic program ran actuator for 6 million steps to simulate real operating conditions. RF measurements were taken during the process to validate tuning progress. After test decision was made that "6millions steps at warm condition test" is too harsh to the shaft/nut coating. Instead all the eight CM2 motors installed on the cavities during cold mass assembly were subjected to 400-ksteps (~1% of the lifecycle).

In parallel with the warm testing, there was an opportunity to perform a cold full lifecycle test with a prototype cavity in HTS. The goal was to test the motor over a 10 day period to reach 30 million steps. The 30 million steps represents about 15-20 years of thermal cycling and cryomodule operation. This part of the test was completed successfully with the tuner/motor still functioning as predicted. Decisions were made to continue the cold test until a failure occurred or the system reached 60-million steps. At 31-million steps, the system suffered a failure. (See Figure 8) An autopsy was performed on the motor assembly and it was determined that the harmonic drive gear stripped and the wave generator got stuck in the spline gear.

Copyright © 2013 CC-BY-3.0 and by the respective authors

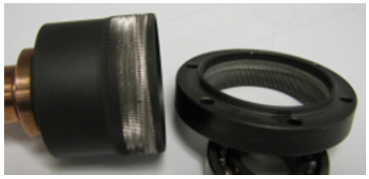

Figure 8: Harmonic drive gear failure.

Cavity HOM Antenna Shorts

During the electrical quality assurance checks of CM2 cryomodule, electrical shorts were found in three cavities at the high order mode (HOM) feedthrough connectors. An investigation of component dimensional tolerance stack up was undertaken to determine the cause. As it can be seen from Figure 9, the design distance between the antenna tip and the formteil is 0.5 mm. Taking into account that the antenna is assembled on the connector with a press-fit method in the cleanroom prior to the assembly of the feedthrough flange to the cavity, a tolerance stack up due to out of spec dimensions of individual components might cause an electrical short when the tip of the antenna touches the formteil.

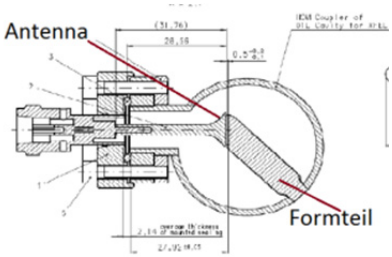

Figure 9: HOM Antenna assembly to the HOM coupler.

It was deemed that this problem will not be a critical issue for CM2 operations. However, all components in inventory were measured and the antenna tips were trimmed appropriately. It was also decided to conduct capacitance measurements on feedthrough flanges after these are assembled on the cavity in the cleanroom to ensure that there are no shorts.

Vacuum Leak on the 2-phase Circuit

During the vacuum leak checks of CM2 at NML testing facility, a vacuum leak was observed on the 2-phase helium circuit pipe. Initial leak checks at NML showed that the leak was in the vicinity of the Ti bellows between Cavity #8 and the magnet. (See Figure 10) The module was then transported back to CAF for partial disassembly and repair. The vacuum vessel, MLI and lower heat shields were disassembled in order to access the 2-phase pipe. After disassembly, it was observed that the magnet moved approximately 14 mm towards Cavity #8. Further investigation showed that the invar rod clamp designed to hold the spacing between the magnet and the cavity failed to restrain the magnet during vacuum pump down due to vacuum forces exerted on the clamp. After the magnet was moved back to its design distance, new clamps were designed and installed for the magnet and the cavities. We then started the leak check efforts and surprisingly no vacuum leaks were observed. Various leak checks, pressure tests in different configurations were done throughout a 3-month period to replicate the leak that was observed at NML.

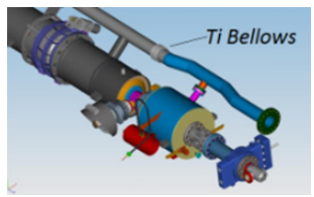

Figure 10: Ti bellows between magnet and cavity #8.

After several months of effort, a leak was observed. The leak appeared while checking the 2-phase helium circuit with the cold mass fully bagged and filled with helium. Further leak checks in the same morning without the bag showed a leak (mid 10^{-7} mbar x l/s) on the same Ti bellows that we observed a similar range leak at NML. Without changing the setup, the leak check inspector tried to confirm the leak in the afternoon. Surprisingly, the leak disappeared. We decided to replace the questionable Ti bellows with a new one. CM2 was then re-assembled. Further investigation was done on the removed Ti bellows to understand the strange leak behaviour. The bellows was sent out to an x-ray vendor but the analysis did not produce any useful results. Eventually, we were able to replicate the leak at Fermilab. First the bellows were cleaned and handled with UHV standards. The bellows were then pumped down and leak checked. The same range leak was observed on the seam weld of the bellows. If the technician touched the leak even with gloved fingers, the leak disappeared. Wiping with lint free cloths and using cleaning agents were not successful to open the leak. The bellows needed to be cleaned again with UHV standards in order to replicate the leak. It was deemed that the leak is so small that airborne dust particles, any residue from gloves might clog the leak and make it disappear. No further study was done on this bellows. Action items for future Ti bellows are to clean the bellows with UHV standards before incoming leak checks and always handle the UHV components with gloves and extreme care.

SUMMARY

The lessons learned during the fabrication of CM2 will be applied for future module assemblies at CAF.

ACKNOWLEDMENT

Special thanks to all the support (QC, RF, electrical, alignment & metrology, material handling) groups who helped CAF team during the CM2 fabrication.

WAKEFIELD LOSS ANALYSIS OF THE ELLIPTICAL 3.9 GHZ THIRD HARMONIC CAVITY*

M. Awida#, P. Berrutti, A. Saini, T. Khabiboulline, and V. Yakovlev, Fermilab, Batavia, IL 60510, USA

Abstract

Third harmonic 3.9 GHz elliptical cavities are planned to be used in many particle accelerator projects such as XFEL, NGLS, and ASTA. In this paper, the wakefield losses due to bunches from 8 mm down to ultra short bunches of 10 μm are analysed. Both the loss and kick factors are numerically calculated for bunches of relatively long length (>1 mm) using CST wakefield solver. The data is then used to asymptotically extrapolate the values for ultra-short bunches by finding the wake functions. These calculations are essential to estimate the cryogenic losses in cryomodules and for beam dynamic analysis.

INTRODUCTION

Third harmonic cavities are commonly used in the particle accelerators of light sources to improve the bunch stability and compensate for the distortion that could happen between the sinusoidal accelerating field and the relatively long beam bunches [1-6].

Third harmonic 3.9 GHz cavities are currently under production for several projects. For instance, DESY's XFEL and FNAL's ASTA. Other future light sources (like NGLS) are also planning to use the third harmonic cavities.

In collaboration with DESY, Fermilab constructed a third harmonic cryomodule for the Free electron LASer in Hamburg (FLASH) facility [1-4]. Each cryomodule contains four superconducting radio frequency (SRF) cavities operating at 3.9 GHz. The third harmonic 9-cell cavities are designed to operate at 2 K in the TM_{010} π-mode at an accelerating gradient of 14 MV/m, summing up to a total energy gain of 20 MeV per cryomodule. These cavities operate in a decelerating phase of 179º relative to the beam phase, and are optimized for 9 mA of beam current.

In addition, another cryomodule will be fabricated for Fermilab Advanced Superconducting Test Accelerator (ASTA). ASTA plans to deliver 50 MeV beam for a broad range of beam-based experiments to push limits of particle-beam generation, acceleration and manipulation. ASTA plans to employ Superconducting 3.9 GHz cavities for bunch linearization.

Before accelerating beam with third harmonic cavities, it is imperative to estimate the cryogneic losses by analysing the wakefield losses. This paper reports on an extensive wakefield analysis, carried out on these third harmonic cavities, including the simulated loss and kick factors for sub cm beam bunches. Based on the simulated data and using an asymptotic approximation, we estimate the loss and kick factors for sub mm beam bunches.

WAKEFIELD SIMULATION FOR SUB CM BEAM BUNCHES

Figure 1 shows the geometry of the third harmonic 3.9 GHz 9-cells elliptical cavity. In different to the wakefield analysis in [5], we resorted to CST microwave studio to compute the wakefields inside a single cavity due to relatively long bunches, where the structure is excited by a longitudinal line current [7]. The line current is placed on the beam axis for the loss factor calculations, while the line is displaced off axis for the kick factor calculations. In both cases, the line current representing the beam is formed with a longitudinal, Gaussian shaped charge distribution.

Accuracy of the analysis was checked versus the mesh size. Typically, the ratio between the bunch sigma (standard deviation of the Gaussian distribution) to the mesh step size in the longitudinal direction *Sigma/h* is used to check the accuracy of the analysis with conventionally using *Sigma/h* of 20 as a satisfactory level of mesh refinement. In this analysis, we have used a *Sigma/h* of 30, as shown in Fig. 2. Mesh size of approximately 70 million elements (per quarter of cavity) was needed for the relatively short RMS bunch length of 2 mm, as shown in Fig. 2.

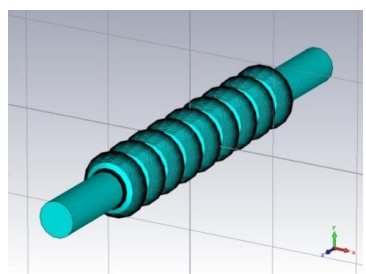

Figure 1: Geometry of the third harmonic 3.9 GHz cavity.

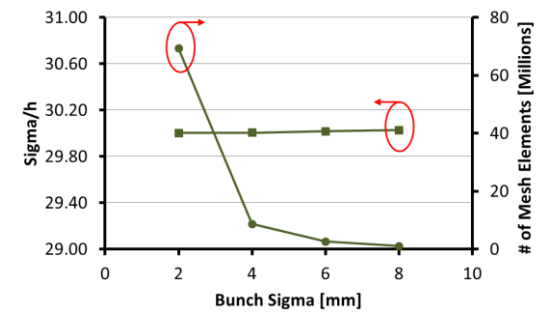

Figure 2: Sigma/h and number of mesh elements vs. bunch sigma.

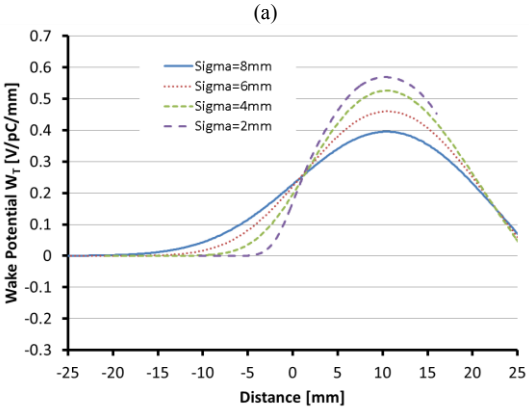
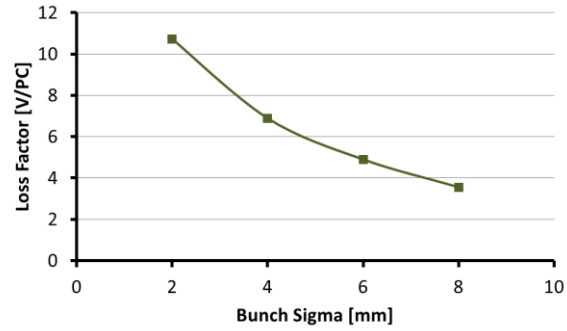
Figure 3 shows the wake potential both in longitudinal and transverse directions for various RMS bunch lengths ranging from 8 mm to 2 mm. As expected, the peak absolute value of the wake potential increases as the RMS bunch length decreases. The longitudinal wake potential increases from 5 V/pC to 16 V/pC as the RMS bunch length decreases from 8 mm to 2 mm. On the other hand, the transverse wake potential increases from 0.4 V/pC/mm to 0.6 V/pC/mm as the RMS bunch length decreases from 8 mm to 2 mm. The peak of the longitudinal wake potential happens at approximately 2 mm distance for all bunch RMS lengths, while the peak transverse wake potential happens at approximately12 mm distance.



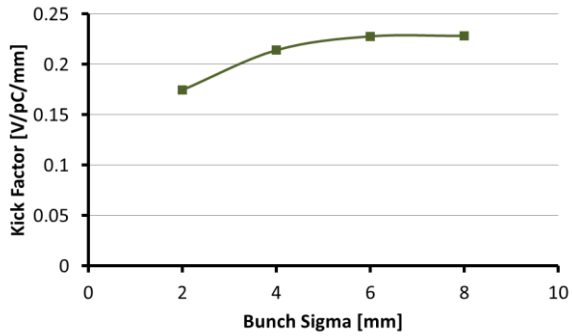
The loss and kick factors are shown in Fig. 4 (a) and (b), respectively. The loss factor varies from 3.5 V/pC to 10.5 V/pC as the RMS bunch length decreases from 8 mm to 2 mm, as shown in Fig. 4(a). On the other hand, the kick factor decreases from 0.22 V/pC/mm to 0.17 V/pC/mm over the same range.

ASYMPOTITIC APPROXIMATION FOR SUB MM BEAM BUNCHES

Computing the wakefield losses for ultra-short bunches is not possible using CST because of the mesh size limitation (for sub mm bunches, the mesh size would be in microns). In such case of ultra-short bunches, asymptotic approximation is typically used, where we could approximate the loss and kick factors by [8]



(a)



(b)

Figure 3: Wake potential for various bunch lengths. (a) Longitudinal. (b) Transverse.

(a)

(b)

Figure 4: Wakefield simulation results (a) Loss factor. (b) Kick factor.

$$L_{long} \cong \langle W^0_{long} \rangle = \frac{1}{Q}\int_{-\infty}^{\infty} W^0_{long}(s)q(s)ds$$

$$= \frac{1}{Q^2}\int_{-\infty}^{\infty}\int_{-\infty}^{s} w^0_{long}(s-s')q(s')q(s)ds'\,ds \quad (1)$$

$$L_{trans} \cong \langle W^1_{trans} \rangle = \frac{1}{Q}\int_{-\infty}^{\infty} W^1_{trans}(s)q(s)ds$$

$$= \frac{1}{Q^2}\int_{-\infty}^{\infty}\int_{-\infty}^{s} w^1_{trans}(s-s')q(s')q(s)ds'\,ds \quad (2)$$

where Q is the bunch charge, $q(s)$ is the longitudinal bunch distribution, W is the wake potential, and w is the wake function. However, the longitudinal and transverse wake functions at short distance s could be approximately related as [8]

$$w^1_{trans}(s) \cong \frac{2}{a^2}\int_0^s w^0_{long}(z)dz \quad (3)$$

where a is the iris radius

In the periodic structure the short range wake can be approximated as [8]

$$w_{long}(s) = A\frac{Z_0 c}{\pi^2 a}\exp\left(-\sqrt{s/s_0}\right) \quad (4)$$

$$w_{trans}(s) = \frac{2}{a^2}A\frac{Z_0 c}{\pi^2 a}2s_1\left(1-\left(1+\sqrt{s/s_1}\right)\exp\left(-\sqrt{s/s_0}\right)\right) \quad (5)$$

Upon substituting for the wake potential in the loss factor and kick factor equation and assuming Gaussian charge we could reach

$$L_{long} = \frac{A_1}{\sigma^2}\int_{-\infty}^{\infty}\int_{-\infty}^{s}\exp\left(-\sqrt{(s-s')/s_0}\right)\exp\left(-\frac{s'^2}{2\sigma^2}\right)\exp\left(-\frac{s^2}{2\sigma^2}\right)ds'\,ds \quad (6)$$

$$L_{trans} = \frac{4S_1}{a^2}\frac{A_1}{\sigma^2}\int_{-\infty}^{\infty}\int_{-\infty}^{s}\left(1-\left(1+\sqrt{(s-s')/s_1}\right)\exp\left(-\sqrt{(s-s')/s_0}\right)\right)\exp\left(-\frac{s'^2}{2\sigma^2}\right)\exp\left(-\frac{s^2}{2\sigma^2}\right)ds'\,ds \quad (7)$$

Where A_1, S_0, S_1 are fit parameters.

Figure 5 shows the asymptotic approximation of the loss and kick factors based on the simulated data points calculated using CST microwave studio for relatively long bunches. In this perspective, the fit parameters for the loss factor are A_1=17 $V.mm^2/pC$ and S_0=0.5 mm, while the fit parameter for the kick factor is S_1=0.33 *mm* with an iris radius of a =15 mm.

Figure 5(a) demonstrates that the loss factor for a RMS bunch length of 50 µm is about 39.5 V/pC, increasing to 46 V/pC for a RMS bunch length of 10 µm. On the other hand, the kick factor decreases with decreasing the RMS bunch length as shown in Fig. 5(b), thus the kick factor is clearly not a concern for ultra-small bunches.

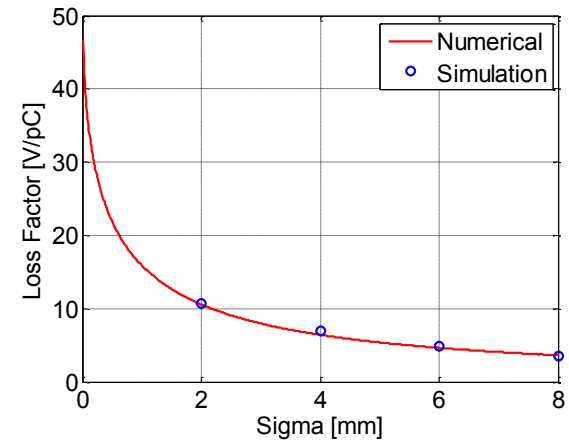

Figure 5: Asymptotic approximation (a) Loss factor. (b) Kick factor.

ESTIMATION OF CRYOGENIC LOSSES

Based on the aforementioned wakefield loss analysis, the cryogenic losses per cryomodule could be estimated as

$$L_{cyo} = nL_{long}QI$$

Where n is the number of cavities per cryomodule

For a particle beam of current 9 mA and charge 300 pC, the cryogenic losses of a four cavity cryomodule is listed in Table 1 for various bunch lengths.

Table 1: Cryogenic losses in W for a cryomodule of four cavities in case of beam current of 9 mA and beam charge of 300 pC.

Bunch RMS Length	Loss Factor [V/pC]	Cryogenic Losses [W]
8 mm	3.56	38.4
4 mm	6.89	74.4
2 mm	10.73	115.9
100 µm	35.1	379.1
50 µm	39.5	426.6
10 µm	46.5	502.2

CONCLUSION

Wakefield losses of the third harmonic 3.9 GHz elliptical cavity have been analysed. For relatively long bunches, the loss factor varies from 3.56 V/pC to 10.73 V/pC as the RMS bunch length decreases from 8 mm to 2 mm, while for ultra short bunches it reaches 46.5 V/pC for a RMS bunch length of 10 µm. The kick factor is not a concern for ultra-small bunches as it decreases with decreasing the RMS bunch length. The cryogenic losses for a cryomodule of four cavities would be 502.2 W for bunch RMS length of 10 µm, beam current of 9 mA and beam charge of 300 pC.

Abstract

We report the results of the recent 2.1 GHz superconducting rf (SRF) photonic band gap (PBG) resonator experiment in Los Alamos. The new SRF PBG cell was designed with the particular emphasis on changing the shape of PBG rods to reduce the peak magnetic fields and at the same time to preserve its effectiveness for suppression of the higher order modes (HOMs). The new PBG cells have great potential for outcoupling long-range wakefields in SRF accelerator structures without affecting the fundamental accelerating mode. Two 2.1 GHz PBG cells with elliptical rods were fabricated and tested with high power in a liquid helium bath at the temperature of 4 K and 2 K. The cells performed in accordance with simulation and the maximum achieved accelerating gradient was 18.3 MV/m.

INTRODUCTION

Superconducting radio frequency (SRF) cavities are the natural choice for the future generation of high-duty-factor accelerators for the high power free-electron lasers (FELs) where the heat produced in the accelerating structure must be effectively extracted [1]. Operating the accelerator at high frequency and low bunch charge reduces the risks of brightness degradation in electron beam transport. However, high frequencies become a disadvantage with respect to excitation of higher order mode (HOM) wakefields in the linac which get excited more easily and interact with the accelerated beam causing instabilities, energy spread and ultimately the beam breakup.

Photonic Band Gap [2] (PBG) cavities have the unique potential to filter out much of the HOM power and reduce the wakefields. A PBG resonator is capable of supporting the accelerating mode and not supporting any higher order modes which propagate towards the peripheries of the cavity and get filtered out with waveguides.

The first ever demonstration of acceleration in a PBG resonator was conducted at Massachusetts Institute of Technology (MIT) in 2005 [3]. Since then, the importance of PBG structures for accelerators has been recognized by many research institutions worldwide. In the experiment reported in [3], the 6-cell open copper PBG structure was employed to construct a room-temperature travelling-wave accelerator at 17.137 GHz with inherit ability to filter out wakefields.

#smirnova@lanl.gov

A project funded by the U.S. Department of Energy (DOE) Office of Science Early Career Research Program at Los Alamos National Laboratory has recently demonstrated fabrication and high power operation of single-cell SRF PBG resonators at 2.1 GHz [4]. Two resonators were fabricated in 2012 and demonstrated solid high gradient performance with the maximum achieved gradient of 15 MV/m limited by the magnetic quench.

We have initiated a project at LANL to push the high gradient limitations of the SRF PBG resonators and demonstrate the possibility of a resonator with significantly reduced peak surface magnetic field and still excellent performance with respect to filtering out higher order modes.

2.1 GHz SRF PBG RESONATORS WITH REDUCED SURFACE FIELDS

We have followed the idea of [5] and changed the shapes of the 6 inner rods of the PBG resonator from cylindrical to elliptical. This produced the desirable effect reducing the surface fields up to 40 per cent depending on the major radius of the elliptical rods [6]. The question however was if the new resonators with elliptical rods were as effective with respect to filtering out wakefields as resonators with round rods. To answer this question we used the time-domain solver of the CST Microwave Studio [7] and analyzed the confinement of HOMs and the fundamental mode in a PBG resonator with elliptical rods. We discovered that if the periodicity of the PBG structure is broken and the elliptical rods are moved slightly toward the center of the resonator, then the fundamental mode in this structure becomes better confined than in the structure with round rods. At the same time HOMs in this structure are confined worse and can be extracted more efficiently than in the structure with round rods [6].

The final dimensions and the accelerator characteristics of the structure with the shifted elliptical rods are summarized in Table 1. The cells were designed with 18 hollow cylindrical rods: 6 elliptical and 12 round. The maximum surface electric field in the PBG cell is reached on the blended edge of the beam pipe, as was in the case of the cavity with round cylindrical rods [4]. The maximum surface magnetic field is again reached on the rods of the PBG structure; however it is 40% lower than the maximum surface magnetic field in the cavity with round cylindrical rods operating at the same gradient.

Table 1: Dimensions and Accelerator Characteristics of the 2.1 GHz SRF PBG Accelerator Cell with Elliptical Rods

Spacing between the rods, p	56.57 mm
OD of the round rods, d	17.04 mm = 0.3*p
Shift of elliptical rods, Δp	0.89 mm
Major OD of the elliptical rod, a	24.94 mm = 0.5*p
Minor OD of the elliptical rod, b	9.80 mm
ID of the equator, D0	300 mm
Length of the cell, L	71.43 mm (λ/2)
Beam pipe ID, Rb	1.25 inches = 31.75 mm
Radius of the beam pipe blend, rb	1 inch = 25.4 mm
Q_0 (4K)	$1.8*10^8$
Q_0 (2K)	$6.2*10^9$
R/Q	150.7 Ohm
E_{peak}/E_{acc}	2.37
B_{peak}/E_{acc}	5.66 mT/(MV/m)

Two resonators were fabricated by Niowave, Inc from a combination of stamped sheet metal niobium with the residual resistance ratio RRR>250 and machined ingot niobium components with RRR>220. After the electron beam welding, a buffered chemical polish etch was performed to prepare the RF surface for testing. The temperature of the acid was carefully monitored during the etching. The photograph of resonators right after fabrication is shown in Figure 1.

Figure 1: Photograph of the 2.1 GHz PBG cavities with elliptical rods ready to be tested.

HIGH GRADIENT TESTING OF THE 2.1 GHz SRF PBG RESONATORS

The resonators underwent high gradient testing at LANL in Summer of 2013. Each cavity delivered from Niowave was opened in a class 100 clean room and a pickup coupler flange and a movable bellow with a matched power input coupler were attached at the ends of the beam pipes. The cavity was then sealed and taken out of the clean room, set on the vertical cryostat insert, pumped down and leak checked. The testing procedure was the same as described in [4].

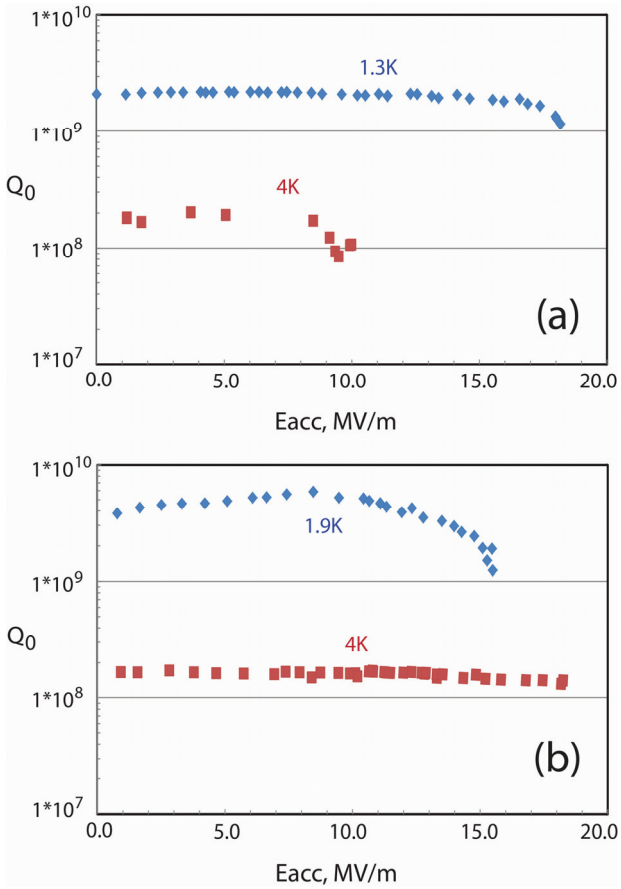

Figure 2: Unloaded Q (Q_0) as a function of accelerating gradient (E_{acc}) of the 2.1 GHz SRF PBG cavities with elliptical rods: (a) cavity #3 tested on 7/15/13, and (b) cavity #4 tested on 8/19/13.

Figure 2 shows the $Q_0 - E_{acc}$ curves at 4 K and 2 K for the two cavities with elliptical rods. Table 2 summarizes the test results. The cavities had somewhat longer beam pipes than the cavities with round rods, and Cavity #3 turned out to be undercoupled at 4 K even when the co-axial coupler was moved fully inwards. As a result, the 4 K measurements of this cavity were quite inaccurate. In addition, the magnetic field compensating coil was not turned on before the cool down, which explains the lower Q-values measured during the 2 K test. The cavity, however, performed excellent at 2 K and withstood a high 18.3 MV/m accelerating gradient. Cavity #4 was tested with a longer co-axial coupler probe. It performed excellent at 4 Kelvin and went up to 18.2 MV/m accelerating gradient and demonstrated high unloaded Qs. However, we observed a significant frequency shift in this cavity (300 kHz up vs. 30 kHz up in other three PBG cavities) when going from 4 Kelvin down to 2 Kelvin. Then during the testing at 2 K we observed a very strong

Copyright © 2013 CC-BY-3.0 and by the respective authors

Q-slope which was possibly due to field emission from a defect. The cavity quenched at 15.3 MV/m at 2 K.

Overall, the measurements totally confirmed the predicted improvement in the gradient performance of the cavities with elliptical rods as compared to the cavities with round rods.

Table 2: Measured Performance of Two 2.1 GHz SRF PBG Resonators with Elliptical Rods and Comparison to Theory

	Theory	Cavity #3	Cavity #4
Frequency	2.100 GHz	2.11524 GHz	2.11292 GHz
Q_0 (4K)	$1.8*10^8$	$1.6*10^8$	$1.6*10^8$
Q_0 (2K)	$6.2*10^9$	$2.2*10^9$	$3.9*10^9$
Maximum E_{acc} (4K)		10.0 MV/m	18.2 MV/m
Maximum E_{acc} (2K)		18.3 MV/m	15.3 MV/m
B_{peak} (4K)		57 mT	103 mT
B_{peak} (2K)		104 mT	87 mT

OBSERVATIONS OF THE FIRST SOUND GENERATED BY QUENCH

We have also attempted to put together a simplified quench diagnostics and installed 6 Buzzer Elements Piezo Benders 20 mm in diameter sensors, one next to each cooling hole of elliptical rods as shown in Figure 3. We observed ~10 kHz sound waves generated by quench at each road with the hope that the amplitude of the sound at each location could give us an indication of which of the six elliptical rods was experiencing quench.

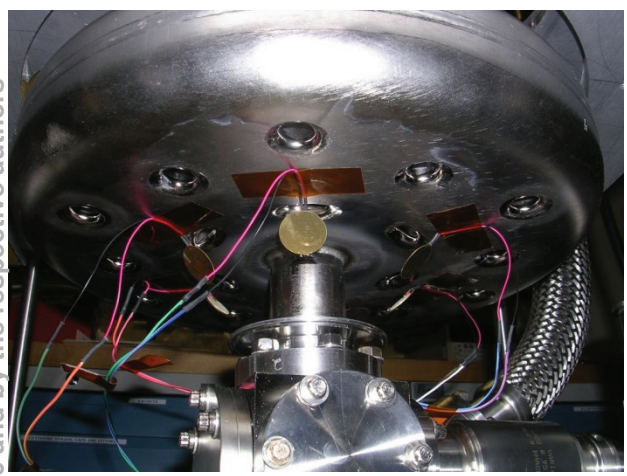

Figure 3: Piezoelectric sensors installed next to 6 hollow elliptical rods of the PBG structure.

The observed sound was similar in amplitude and timing at all six locations (Figure 4). This may suggest that quench occurred on the surface of the cavity outside of the rods, or that the sound mostly propagated through the metal body of the cavity instead of propagating through liquid helium. The detected sound traces looked very similar at both 4 K and 2 K.

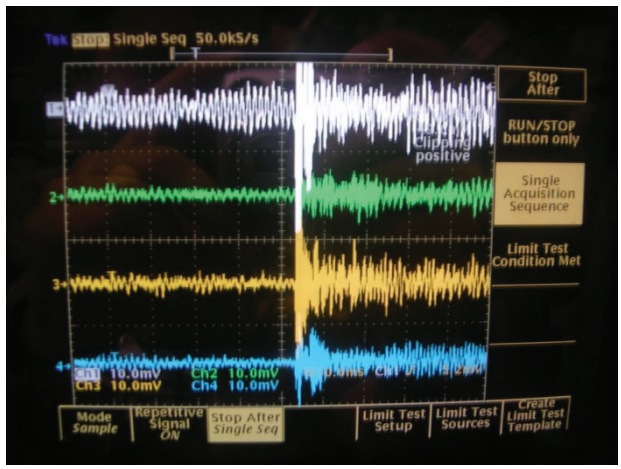

Figure 4: Sound traces from the piezoelectric sensors on an oscilloscope.

CONCLUSION

In summary, we have demonstrated the proof-of-principle fabrication and high gradient operation of superconducting photonic band gap cavities with elliptical rods. The cavities were tested at both 4K and 2K and performed quite well, demonstrating accelerating gradients as high as 18.3 MV/m. The two cavities with elliptical rods on average have performed 30 per cent better than the cavities with round rods tested earlier [4]. This is in perfect agreement with theoretical predictions. We believe that PBG technology will be successfully applied to design novel effective HOM couplers for high current SRF accelerators. As a result, it may significantly reduce the size the accelerators and allow increasing the brightness of the electron beam transport.

UPDATE ON THE DESIGN OF A FIVE-CELL SUPERCONDUCTING RF MODULE WITH A PBG COUPLER CELL*

Sergey A. Arsenyev#, Massachusetts Institute of Technology, Cambridge, MA 02139, USA
Evgenya I. Simakov, Los Alamos National Laboratory, Los Alamos, NM 87545, USA

Abstract

We present a complete design of the 5-cell superconducting accelerating module incorporating a Photonic Band Gap (PBG) cell with couplers. The purpose of the PBG cell is to achieve better Higher Order Mode (HOM) damping which is vital for preserving the quality of high-current electron beams in novel linear accelerators used, for example, for free electron lasers. We first discuss the aspects of incorporating a PBG cell in a superconducting PBG module. The main goal is to ensure the equal probability of quench in each of the five cells, which can be achieved with significant geometry modifications. We then present the simulation data on HOM damping. Particularly, we calculate the external quality factors for the 10 most dangerous HOMs for this particular structure. HOM coupler configurations and modifications to the PBG geometry are discussed.

INTRODUCTION

Superconducting radio frequency (SRF) cavities are the natural choice for the future generation of high energy linacs, especially for high-duty-factor machines where the heat produced in the accelerating structure cannot be effectively extracted [1]. Going to higher frequencies in SRF cavities is desirable because of the lower cost and higher achievable luminosity of an electron beam. However, higher order mode (HOM) wakefields excited by a beam scale as frequency cubed and can easily destroy the beam in a high-frequency machine. If we want to go to the frequencies as high as 2.1 GHz, we have to find an effective way to suppress or outcouple HOMs.

PBG cavities are of interest to the particle accelerator community because they have reduced higher-order modes that can degrade beam quality [2, 3].

Waveguide couplers are commonly used as an HOM suppression mechanism (see, for example, [4]). Usually the couplers are attached to the beam pipe. In contrast with a room-temperature PBG cell, the superconducting cell is made closed in the transverse plane and utilizes waveguide couplers to extract the HOMs. Low field at the periphery of the PBG cell allows us to attach the waveguide couplers directly to the outside wall of the cell. This is beneficial to HOM damping because the HOMs are extracted at the point where their field is higher than at the beampipe. We also use less waveguides and increase real estate gradient.

FIVE CELL MODULE DESIGN

We incorporate a PBG cell into a module of five accelerator cells by using it instead of one of the conventional cells. As an example of a conventional accelerating module we take a high-current FEL accelerating module from [4]. The middle cell of the module [4] was replaced with a PBG cell (Fig. 1). A module with an incorporated PBG cell should be designed with lower accelerating gradient in the PBG cell than in other cells [5]. This is due to the fact that for the same accelerating gradient, the surface magnetic field in a PBG cell is higher than in a conventional cell because of the more sophisticated geometry [6]. If the module was designed to have a flat field profile, performance of the entire accelerator would be limited by a single PBG cell due to the higher probability of quench. To make the non-flat gradient profile, we introduce small differences in the eigenfrequencies of the cells. Like in a system of connected pendulums, this leads to different amplitudes of the fields in different cells [5].

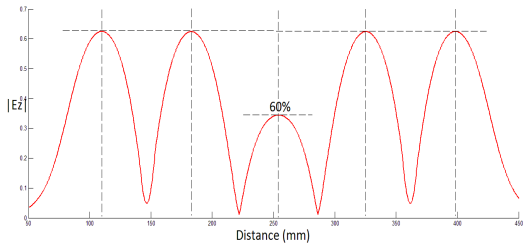

Figure 2: Electric field magnitude (accelerating gradient) along the central axis.

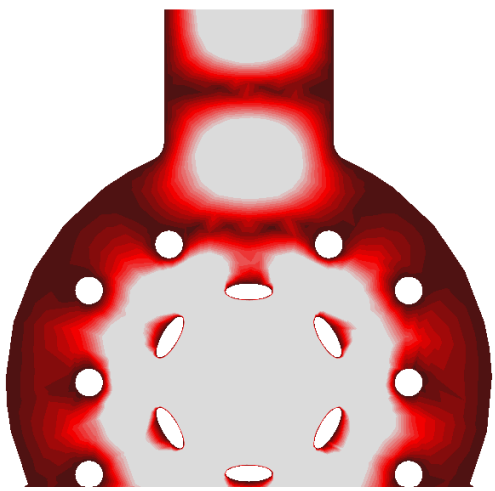

Figure 3: Magnitude of E-field in the fundamental mode coupled into the PBG structure thru the waveguide.

A conventional 2D PBG lattice has only rods with circular cross-section. The corresponding 5-cell module design was presented in [5]. However, it is beneficial to alter the shape of some rods to get better accelerating properties. In particular, the inner row of rods in the designed module is "squeezed" in radial direction and stretched in angular direction (Fig. 3) in order to produce lower ratio of the peak surface magnetic field to the accelerating gradient [7, 8]. Using elliptical rods allows us to push the gradient in the PBG cell higher, up to 60% of the gradient in the four conventional cells (Fig. 2). This is significantly better than we can do with a PBG cell which has only round rods (about 40%) [5]. Properties and dimensions of the accelerating module are listed in Table 1.

We are planning to use the Navy FEL beamline at LANL for the testing of the structure. The parameters of the experiment are listed in Table 2. The electron beam will be synchronous with the accelerating mode (beam on crest). Due to the negligible Ohmic losses almost all the power coupled to the module will go to the beam.

The fundamental mode coupler was designed to provide near critical coupling for the experiment with the electron beam (Fig. 3). Standard WR430 waveguide was used. One of the PBG rods was removed for coupling. The existing design can also be used for tests with the copper prototype and no beam – in that case Ohmic dissipation is approximately equal to the beam loading in the hot test and the coupling would still be close to critical. The beam tests will be conducted at much lower accelerating gradient (5 MV/m) than the cavity is capable to sustain. This ensures reliability of the structure.

Table 2: Parameters for the Planned Test

Charge per bunch	1 nC
Bunch repetition rate	100 MHz
Klystron power	200 kW
Average gradient	5.6 MV/m

HOM DAMPING

In order to understand what HOMs affect the beam the most, we performed a CST Particle Studio simulation with the beam displaced in either of the two transverse directions (X and Y). The computed wake impedance reflects the spectrum of the HOMs (Fig. 4). We used the areas underneath each peak as a criterion of whether or not the mode is dangerous. The area is related to a more commonly used quantity R/Q, which can be generalized for non-monopole modes. Each mode has two orthogonal polarizations, which are listed separately in Table 3. Generally we only have to look at the frequencies up to the beampipe cut-off, but one significant peak beyond the cut-off was examined as well (Table 3, modes 9 and 10). We then tried to minimize the quality factors for the most dangerous 10 HOMs. It was also verified that the frequencies of the monopole HOMs don't lie close enough to multiples of the beam frequency to allow the so-called "build-up" to happen.

There are dangerous HOMs with both the TE and the TM polarizations in the center cell. The HOM couplers should have cutoff below the frequencies of the modes with either polarization and therefore have customized dimensions (2.2in × 2.4in). The couplers and the PBG

Copyright © 2013 CC-BY-3.0 and by the respective authors

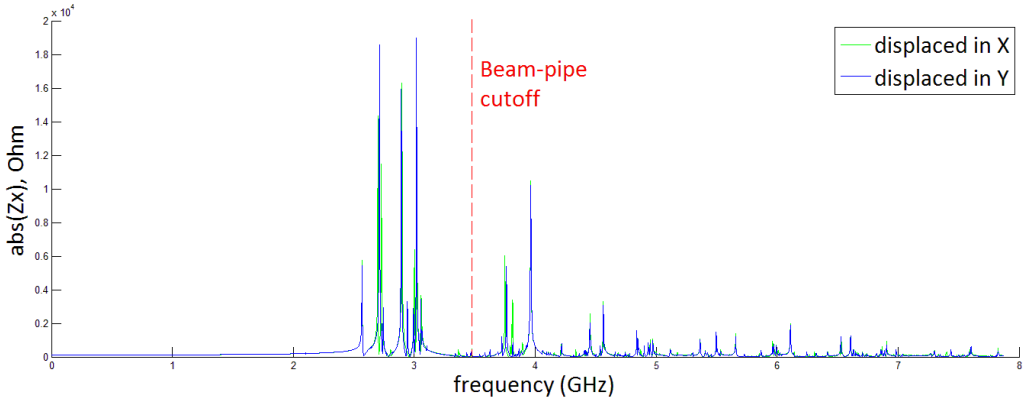

Figure 4: Transverse wake impedance profile for both X and Y beam displacements.

cell were optimized to provide sufficient dumping for all HOMs (Q less or about 1000). The final optimized Qs are listed in Table 3. The design also has advantage over the traditional solution of placing HOM couplers on the beam pipe because it utilizes only 3 couplers instead of 6.

Table 3: Quality Factors of the HOMs

Mode #	Peak area, Ohm/m*Hz	R/Q, Ohm	Frequency, GHz	Quality factor
1	27.1	32.4	2.556	1070
2	26.6	32.3	2.562	560
3	51.9	120.0	2.712	480
4	87.2	120.8	2.715	420
5	85.4	107.8	2.949	430
6	71.8	107.7	2.952	500
7	46.3	84.8	3.013	240
8	67.9	85.3	3.025	690
9*	73.9	79.0	3.943	200
10*	76.3	79.1	3.943	200

CONCLUSIONS

We designed a 5-cell SRF module with incorporated PBG cell and HOM couplers attached to the PBG cell. Using elliptical rods in the PBG structure enhanced the performance of the cavity (flatter gradient profile) relative to the round rods [5]. Fundamental mode coupler was designed to provide coupling close to critical for both hot-test and cold-test experiments. HOM couplers were designed to provide sufficient damping (Q less or about 1000) for the 10 most dangerous HOMs. We are planning to fabricate the copper prototype of the 5 cell structure first. It would let us measure quality factors of the HOMs and conduct a bead-pull test to determine the field profile. We then will fabricate the real superconducting module and mount it on the LANL Navy FEL beamline.

INITIAL STUDIES OF MULTIPACTOR SUPPRESSION VIA TE AND TM MODES*

S. Rice[1] and J. Verboncoeur[2], Michigan State University, East Lansing, MI 48824, USA

Abstract

The formation of multipactor is strongly dependent upon the secondary electron yield (SEY) of a surface, and the emission velocities of the emitted electrons, in addition to the electric field. Since the secondary electron yield (SEY) of a material is dependent upon the kinetic energy and impact angle of the incident electron, we investigate use TE and TM coaxial cavity modes to modify the impacting electron velocities to reduce the average SEY and suppress multipactor, which builds upon our previous work examining TEM modes.

INTRODUCTION

Multipactor [1, 2] is a resonant phenomenon in which an electromagnetic field causes stray electrons to impact a surface, liberating secondary electrons, in such a way that the process can sustain itself. This phenomenon is of considerable practical interest in the design and operation of microwave windows, waveguides, and radio frequency resonant structures.

The formation of multipactor is strongly dependent upon the secondary electron yield (SEY) of a surface contributing to multipactor, since in order to initiate and sustain multipactor, the average number of emitted secondary electrons must be greater than or equal to unity. Multipactor is also dependent upon the system geometry and field excitation, which must be conducive to accelerating electrons into the boundaries at the proper RF phase to enable re-acceleration of the emitted secondary electrons.

When an electron impacts a boundary, the average secondary electron yield (SEY) is determined by the kinetic energy of the incident electron. Figure 1 shows a representative SEY curve. The specific SEY curve used in this present research was generated using Vaughan's model [3] with parameters chosen to match the impact energy location (E_{max}) and peak value (δ_{max}) of Furman's SEY model for copper [4], and is used for all the results presented in this study.

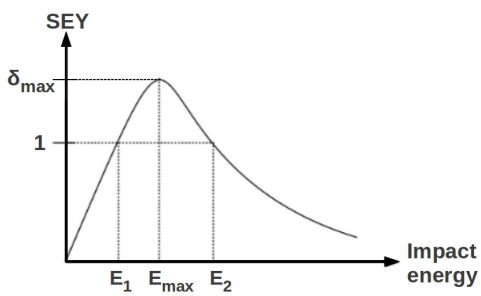

Figure 1: Typical SEY curve.

SIMULATION DESCRIPTION

Consider a coaxial cavity with conducting sidewalls, inner radius a, outer radius b, and longitudinal length L. The fundamental-mode TEM excitation at angular frequency ω can be parameterized by peak instantaneous voltage V_o and phase θ as $V_o \cdot \cos(\omega t+\theta) \cdot \sin(\pi z/L)$.

In our present research, we defined a=1 cm, b=5.65 cm, and L=1.86 m, and we used Vaughan's SEY model mentioned above. Unless otherwise noted, all secondary electron emission energies are set to zero to avoid the complication of the truly random (although typically low-energy) secondary emission energies. The selected geometrical values will allow a fundamental TEM mode to exist at 80.5 MHz, and the SEY model to yield maximum secondary electrons at $V_o \approx 1000$ V.

Electrons start from rest at the outer wall, and the net SEY is computed as the product of all the single-impact SEY values over 10 simulation steps, where each step is one fundamental mode period or boundary impact, whichever comes first. For each impact, a single simulated secondary electron is emitted and tracked. Only trajectories with at least two boundary impacts within ten fundamental-mode RF periods were considered to have net SEY > 0. The net SEY gives a proxy measure of the presence of the multipactor, since a net SEY < 1 would indicate that multipactor is not sustainable. Figure 2 shows the net SEY for the notional coaxial cavity for electrons starting at z values of 0.2L and 0.5L, where z=0 is defined to be the end of the cavity, and z=0.5L is halfway along the length of the cavity. The net SEY is displayed on a logarithmic scale, anything above 0 denotes a net increase in multipacting electrons. Note that to first order, the effect of changing z merely scales the multipactor voltage axis via the $\sin(\beta_z z)$ dependency.

MULTIPACTOR SUPPRESSION

Multipactor can only be sustained if the average SEY over the multipactor orbits is at least unity. This suggests a novel way to suppress multipactor, via the application of secondary excitation modes which result in the secondary electron impact energy being pushed away from the values where the SEY exceeds unity. Our previous work [5] explored multipactor suppression using an appropriately scaled and phase-referenced 3rd harmonic TEM mode, expressed mathematically as $-3V_o \cdot \cos(3\omega t+3\theta) \cdot \sin(3\pi z/L)$. The results are shown in Fig. 3, and it is apparent that the regions of sustainable multipactor have significantly decreased from the baseline case.

We now examine the use of TM and TE modes for the suppression of multipactor. This initial research examines the lowest order TM and TE modes, namely TM011 and TE011. The TM011 electric (E) and magnetic (H) field components are given by:

Copyright © 2013 CC-BY-3.0 and by the respective authors

$$E_\rho = \frac{j\beta_\rho\beta_z}{\omega\mu\epsilon}\left[A J'_0(\beta_\rho\rho) + B Y'_0(\beta_\rho\rho)\right]\sin(\beta_z z)$$
$$E_\phi = 0$$
$$E_z = \frac{-j\beta_\rho^2}{\omega\mu\epsilon}\left[A J_0(\beta_\rho\rho) + B Y_0(\beta_\rho\rho)\right]\cos(\beta_z z)$$
$$H_\rho = 0$$
$$H_\phi = \frac{-\beta_\rho}{\mu}\left[A J'_0(\beta_\rho\rho) + B Y'_0(\beta_\rho\rho)\right]\cos(\beta_z z)$$
$$H_z = 0$$

and the respective TE011 field components are given by:

$$E_\rho = 0$$
$$E_\phi = \frac{\beta_\rho}{\epsilon}\left[A J'_0(\beta_\rho\rho) + B Y'_0(\beta_\rho\rho)\right]\sin(\beta_z z)$$
$$E_z = 0$$
$$H_\rho = \frac{j\beta_\rho\beta_z}{\omega\mu\epsilon}\left[A J'_0(\beta_\rho\rho) + B Y'_0(\beta_\rho\rho)\right]\cos(\beta_z z)$$
$$H_\phi = 0$$
$$H_z = \frac{-j\beta_\rho^2}{\omega\mu\epsilon}\left[A J_0(\beta_\rho\rho) + B Y_0(\beta_\rho\rho)\right]\sin(\beta_z z)$$

where a cylindrical (ρ, φ, z) coordinate system is assumed, (βρ, βφ, βz) represent the respective wavenumber components, ω represents angular frequency, μ represents the magnetic permeability, ϵ represents the electric permittivity, J_0 and Y_0 respectively represent 0^{th}-order Bessel functions of the first and second kind, and primes denote derivatives. A and B are geometry-dependent constants which ensure that the tangential E-field goes to zero at the cavity boundaries. Since the electron speeds in our simulations are much less than the speed of light, the TM011 and TE011 magnetic field effect upon electron trajectory is negligible as compared to the electric field.

The plots in Fig. 4 show the net SEY for the same geometry and baseline excitation, but now with an additional mode of TM011 (top plots) or TE011 (bottom plots). The maximum field strength for each of these modes was set to 500 kV/m, which was somewhat arbitrarily chosen because this value is considered a strong but not unrealizable field strength. These modes were phase-referenced such that E_ρ started at zero phase at time=0 for the TM011 case, and E_φ started at zero phase at time=0 for the TE011 case. Additional phase shifts of 120º and 240º for the respective TM011 and TE011 fields were investigated. Although the specific multipactor-stable regions did exhibit some change, no qualitative difference was observed.

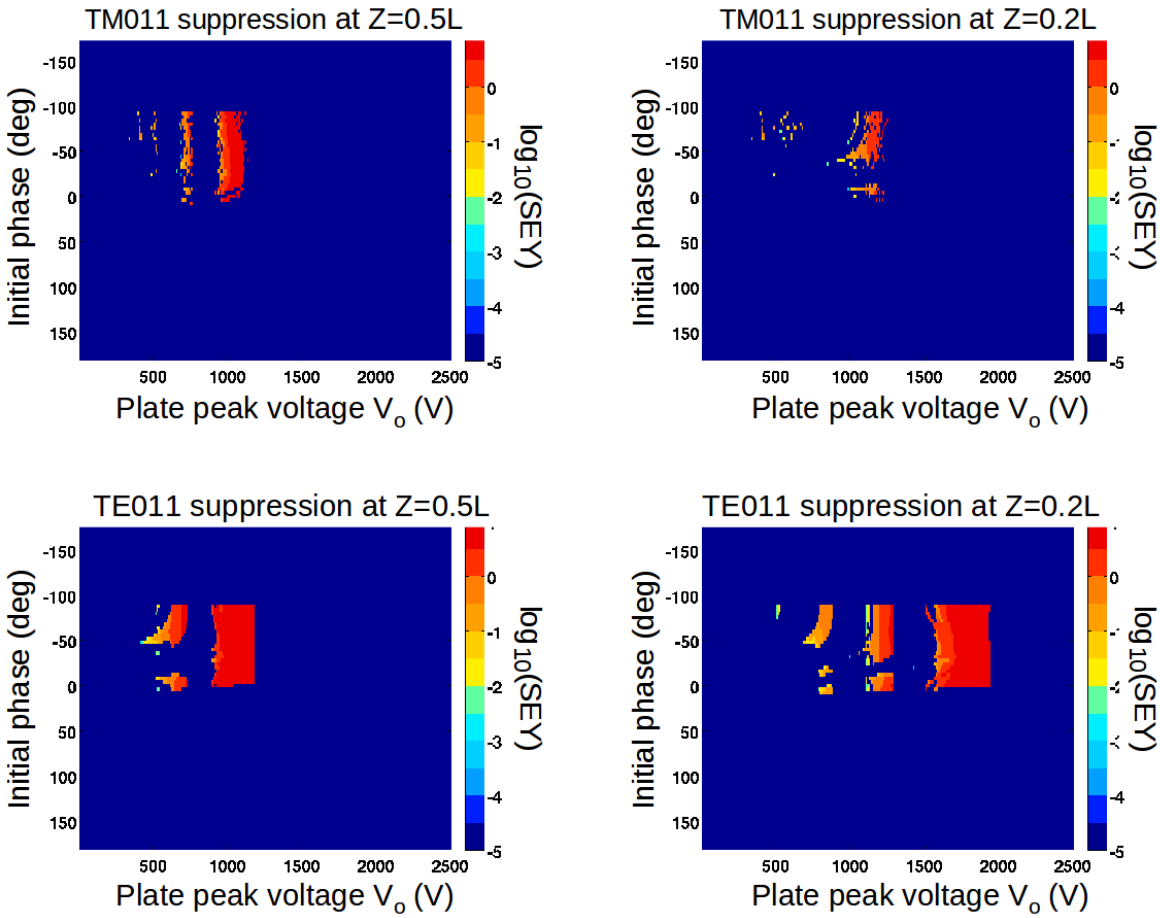

Figure 4: Multipactor sustainability with 500 kV/m TM011 (top) and TE011 (bottom) modes present, at z values of 0.5L (left) and 0.2L (right).

CONCLUSIONS AND FUTURE WORK

The TM011 and TE011 modes explored thus far do not suppress multipactor as much as the 3rd Harmonic TEM mode examined previously. [5] This is mainly attributable to the time scale of the different modes: the baseline TEM mode frequency is at 80.5 MHz, whereas the TE and TM modes considered here are at around 3.2 GHz, resulting in a small periodic perturbation to the overall trajectory of the particles. Additional work [6] presented in a poster at this conference also demonstrates the extreme sensitivity of multipactor simulation to the low-impact energy SEY and the secondary emission energies which are being neglected in the results presented above. Thus future work in this area will also take into account non-zero secondary emission energies.

Abstract

On the scheme of developing a medium energy electron-ion collider (MEIC) at Jefferson Lab, we have designed a compact superconducting rf dipole cavity at 750 MHz to crab both electron and ion bunches and increase luminosities at the interaction points (IP) of the machine. Following the design optimization and characterization of the electromagnetic properties such as peak surface fields and shunt impedance, along with field nonuniformities, multipole components content, higher order modes (HOM) and multipacting, a prototype cavity was built by Niowave Inc. The 750 MHz prototype crab cavity has been tested at 4 K and is ready for re-testing at 4 K and 2 K at Jefferson Lab. In this paper we present the detailed results of the rf tests performed on the 750 MHz crab cavity prototype.

INTRODUCTION

The rf dipole geometry has been studied as a compact and efficient design for an electron-ion crabbing scheme for electron-ion colliders [1]. Among some of the most attractive properties of this design are the lower balanced surface fields with higher net deflection, higher shunt impedance, the advantage of having the operating deflecting/crabbing mode as the lowest mode, and the simple dependency of the rf properties on just a few geometrical parameters [2]. It is for all these reasons that the designed 750 MHz crab cavity prototype shown in Fig. 1 built by Niowave Inc. [3] has been tested and characterized at its facilities and the Center for Accelerator Science at Old Dominion University (CASODU) to corroborate that the fields' symmetry, operation performance, conditioning to multipacting and external Q factor are in agreement with the designed values.

ROOM TEMPERATURE TESTS

Bead-Pull

In a TE_{11} deflector/crabber such as the rf dipole, the transverse kick has contributions from both the electric and the magnetic components of the fundamental mode, thus the symmetry of the field profiles is a key point in the fabrication of the cavity to avoid introducing higher-order nonlinear field effects on the beams.

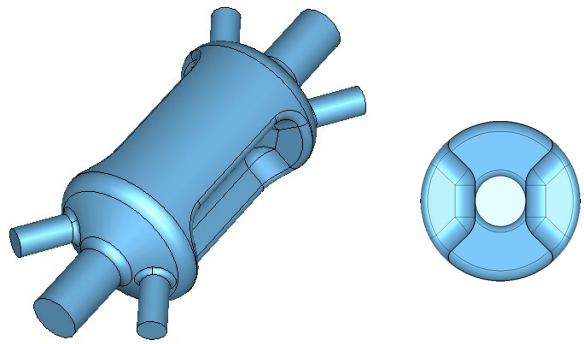

Figure 1: Rf dipole geometry and corresponding cross sections for the 750 MHz crab cavity design.

Table 1: Properties of the 750 MHz Crab Cavity

Parameter	750 MHz	Units
$\lambda/2$ of π mode	200.0	mm
Cavity length	341.2	mm
Cavity radius	93.7	mm
Aperture diameter d	60.0	mm
Deflecting voltage V_T^*	0.200	MV
Peak electric field E_P^*	4.45	MV/m
Peak magnetic field B_P^*	9.31	mT
B_P^*/E_P^*	2.09	mT/(MV/m)
Energy content U^*	0.068	J
Geometrical factor	131.4	Ω
$[R/Q]_T$	124.2	Ω
$R_T R_S$	1.65	$\times 10^4 \Omega^2$

At E_T^*= 1 MV/m

Once the electromagnetic design has been characterized using computer simulations, it is of utmost importance to characterize defects introduced during the fabrication and chemical treatment processes on the cavity, like assymmetries due to offsets on the load elements, perturbations induced by deformations on the volume, etc.

Different runs of bead-pull measurements were performed on the 750 MHz rf dipole crab cavity before and after e-welding using the automated bead-pull system set at CAS-ODU (see Fig. 2).

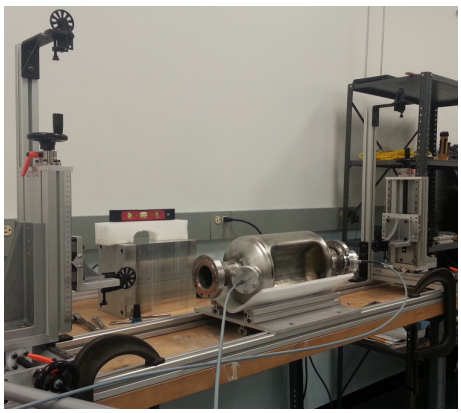

Figure 2: Bead-pull 750 MHz rf dipole set up at CAS-ODU.

The bead-pull results for both metallic and dielectric beads are presented in Figs. 3 and 4, compared with the calculations using the electric and magnetic fields for the crabbing mode found by simulations, showing a remarkable agreement at first order.

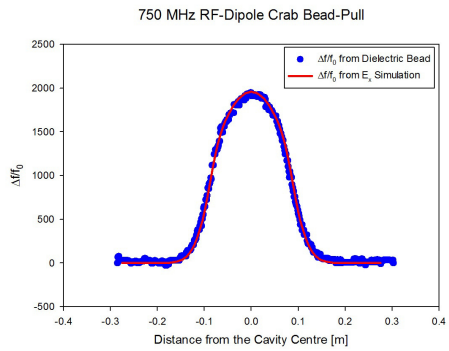

Figure 3: Frequency shift measured with a Teflon bead (blue) and calculated from the electric field by the simulations (red).

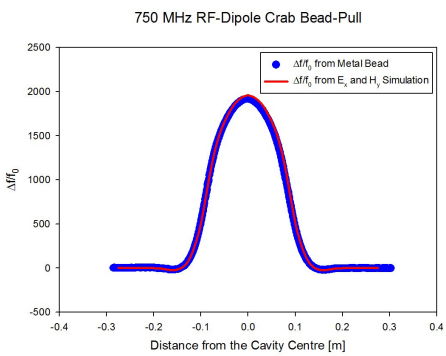

Figure 4: Frequency shift measured with a brass bead (blue) and calculated from the electric and magnetic field by the simulations (red).

Study of Losses at the Port Flanges

All the ports in the design are placed in the outer conductor regions with the lowest tangential surface magnetic fields, nevertheless these are not zero and there is still a fraction of them that can create currents on the nonsuperconducting flanges causing ohmic losses (see Fig. 5). The associated Q to these power dissipations can limit the final cavity Q_0 measured during operation or cryo-testing. For this reason a detailed numerical analysis was performed for the 750 MHz rf dipole crab cavity considering flanges both made of stainless steel and copper. The results are presented in Table 2.

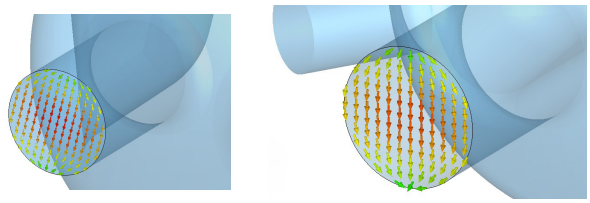

Figure 5: Visualization of the tangential magnetic field (H_y) obtained from CST Microwave Studio® simulations at the side-port flanges (left) and the beam-port flanges (right).

Table 2: Losses in the Port Flanges Due to Tangential Magnetic Field (H_y)

Copper			
Port	$\mathbf{P_{loss}}$ **[W]**	**Q**	**Total** $\mathbf{P_{loss}}$ **[W]**
2 Beam-ports	1.303×10^{-2}	3.61×10^{11}	
4 Side-ports	4.27×10^{-1}	1.102×10^{10}	
			$\mathbf{4.400 \times 10^{-1}}$
Stainless Steel			
2 Beam-ports	8.23×10^{-2}	5.713×10^{10}	
4 Side-ports	2.702	1.742×10^{9}	
			$\mathbf{27.844 \times 10^{-1}}$

Using for the flanges:

$$Q = \frac{\omega U}{P_{loss}}\,, \tag{1}$$

we have:

$$\begin{aligned} Q_{S.S.} &= 1.69 \times 10^{9}\,, \\ Q_{Cu} &= 1.07 \times 10^{10}\,. \end{aligned}$$

While for the cavity we have:

$$Q_0 = \frac{G}{R_s}\,. \tag{2}$$

And considering for 750 MHz: @4 K $R_s = 240\,n\Omega$ with $R_{BCS} = 20\,n\Omega$ and @2 K $R_s = 60\,n\Omega$, while from

Copyright © 2013 CC-BY-3.0 and by the respective authors

the simulations we obtained a $G = 131.4\,\Omega$. Then using Eqn. 2:

$$(Q_0)_{@4K} = 5.48 \times 10^8\,,$$
$$(Q_0)_{@2K} = 2.19 \times 10^9\,.$$

The results of this analysis showed us that the losses in stainless steel blanks and feed-throughs will not affect the measured Q_0 for the cavity on a test at 4 K, while in the case of 2 K we need to use Copper blank gaskets to minimize the losses at the flanges and reach the expected Q_0 values.

CRYOGENIC TESTS

For the performance test of the 750 MHz rf dipole crab cavity, the intrinsic quality factor (Q_0) achieved was measured as a function of the transverse voltage (V_T) at 4 K at the Niowave Inc. installations. During the testing a vertical dewar and a liquid He tank were used to cool the cavity down to 4.2 K while being driven by a 200 W amplifier (400-1000 MHz).

Among the important events during the testing to be noticed is that at low gradients a few multipacting barriers were present and conditioned without major problems and relatively quickly, this comes into agreement with the multipacting simulation results [4], even when no higher gradients were reached during this test. Due to that, the power dissipation on the cavity was enough to boil out the liquid He before we could move to higher gradients. No hard multipacting barriers or quenching occurred for the proof of principles cavity as can be appreciated in Fig. 6.

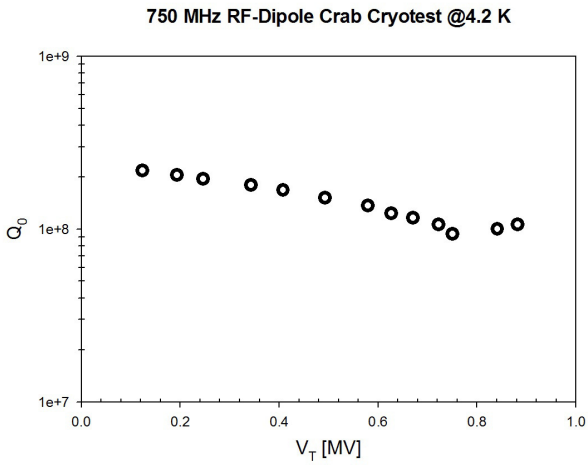

Figure 6: Q_0 curve obtained during the cryotesting of the cavity prototype up to ∼0.9 MV of transverse voltage.

Even when the curve describes a small slope it appears to be considerably flat around a value of $Q_0 \sim 1.5 \times 10^8$ (about a factor of 4 shorter with respect to the predicted value from the simulations). The region covered by the test corresponds to the region in which the multipacting barriers were expected to be present according to the analysis, having found no major problem to condition them without thermal breakdown or quenching. It can be observed around 0.8 MV of transverse voltage that the cavity presented a bigger multipacting conditioning, which was surpassed without further problem and the value of Q_0 reestablished.

All of the information compiled during the test supports that with the capability of keeping the temperatures, the cavity should reach the design specifications for the expected gradients without major problems. For this reason the cavity was shipped to ODU to be re-processed and retested at 4.2 K, and then at 2 K, when a leak on one of the brazings was detected and characterized. New parts have been purchased from Niowave Inc. and the cavity is scheduled to proceed with the corresponding cryotesting after repairing and re-processing at Jefferson Lab.

CONCLUSIONS

An rf crabber for both electron/ion bunches with designed values of $V_T = 1.6\,MV$, $E_p = 35.6\,\frac{MV}{m}$ and $B_p = 75.5\,mT$ per cavity was fabricated at Niowave Inc. After surface treatment [5] and high pressure rinsing, a thorough characterization of the rf properties and performance for the 750 MHz rf dipole prototype have been realized both at room temperature (low level rf) and at 4 K with satisfying results such as symmetry of the fields in agreement with the design simulations, capability of processing multipacting and absence of quenching at the reached gradients ($E_p = 20.0\,\frac{MV}{m}$, and $B_p = 41.9\,mT$) . Due to the success of this first test, a more detailed test at 4 K and 2 K to reach higher gradients was scheduled at the Jefferson Lab facilities, but having discovered a leak on one of the cavity brazings after shipping, the test has been rescheduled and the replacement of a new port by the cavity group at Jefferson Lab is currently undergoing.

AKNOWLEDGMENTS

We want to express our gratitude to the Niowave Inc. personnel, CAS-ODU members Subashini De Silva, Christopher Hopper and Kevin Mitchell as well as HyeKyoung Park and the cavity group at Jefferson Lab. This research used resources of the National Energy Research Scientific Center, which is supported by the Office of Science of the U.S. Department of Energy under contract No. DE-AC02-05CH11231.

MECHANICAL ANALYSIS OF THE 400 MHz RF-DIPOLE CRABBING CAVITY PROTOTYPE FOR LHC HIGH LUMINOSITY UPGRADE*

S. U. De Silva[1,2#], H. Park[2,1], J. R. Delayen[1,2], Z. Li[3]

Abstract

The proposed LHC high luminosity upgrade requires two crabbing systems in increasing the peak luminosity, operating both vertically and horizontally at two interaction points of IP_1 and IP_5. The required system has tight dimensional constraints and needs to achieve higher operational gradients. A proof-of-principle 400 MHz crabbing cavity design has been successfully tested and has proven to be an ideal candidate for the crabbing system. The cylindrical proof-of-principle rf-dipole design has been adapted in to a square shaped design to further meet the dimensional requirements. The new rf-dipole design has been optimized in meeting the requirements in rf-properties, higher order mode damping, and multipole components. A crabbing system in a cryomodule is expected to be tested on the SPS beam line prior to the test at LHC. The new prototype is required to achieve the mechanical and thermal specifications of the SPS test followed by the test at LHC. This paper discusses the detailed mechanical and thermal analysis in minimizing Lorentz force detuning and sensitivity to liquid He pressure fluctuations.

INTRODUCTION

The rf-dipole design is a favorable design for compact deflecting and crabbing applications especially at low operating frequencies [1]. The LHC high luminosity upgrade is one such current application that requires a crabbing cavity system with stringent dimensional constraints that will be operating at 400 MHz [2].

The rf-dipole cavity is one of proposed crabbing cavity designs. The design is proven to have improved rf-properties with low and balanced peak surface fields with high transverse deflection and high shunt impedance. The non-existence of lower order modes and widely separated higher order mode spectrum is an added advantage for this high current application of LHC.

An rf-dipole cavity with a cylindrical outer conductor has been designed and fabricated as a proof-of-principle cavity. The rf tests have been carried successfully [3]. The expected goal of 3.4 MV was exceeded and a transverse voltage of 7.0 MV was achieved. The major unknown in the rf-dipole geometry was the expected multipacting levels during operation. The conditions were simulated using the SLAC ACE3P code [4] and compared with rf results, show similar behavior. These multipacting levels were easily processed during the first cryogenic rf test and did not reoccur during the tests followed.

400 MHz CRABBING CAVITY PROTOTYPE

The transverse dimensions of the proof-of-principle cavity design exceed the dimensional specifications required by the LHC crabbing system. The cylindrical outer conductor restricts in reducing the cavity size as the operating frequency is directly related to the cavity frequency. The rf geometry is modified into a square shape outer conductor with similar loading elements, where the operating frequency is adjusted by rounding the edges of the cavity (Fig. 1) [5]. The rf properties of the prototype in comparison with the cylindrical cavity are shown in Table 1.

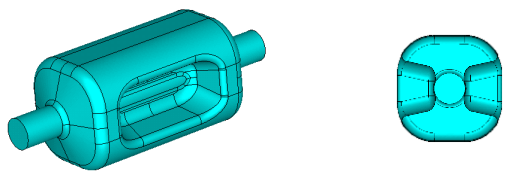

Figure 1: 400 MHz rf-dipole prototype with trapezoidal-shaped loading elements and the cross section.

Table 1: Properties of the Proof-of-principle and Prototype 400 MHz Rf-dipole Cavities

Parameter	Cylindrical shaped	Square shaped	Units
Cavity length	542.4	556.2	mm
Cavity diameter	339.9	281.0	mm
Aperture diameter (d)	84.0	84.0	mm
Bars length	350.3	293.0	mm
Bars inner height	80.0	117.5	mm
Angle	50.0	~12.0	deg
Deflecting voltage (V_T^*)	0.375	0.375	MV
Peak electric field (E_P^*)	4.02	3.65	MV/m
Peak magnetic field (B_P^*)	7.06	6.13	mT
B_P^* / E_P^*	1.76	1.68	
Energy content (U^*)	0.195	0.13	J
Geometrical factor	140.9	106.2	Ω
$[R/Q]_T$	287.0	429.2	Ω
$R_T R_S$	4.0×10^4	4.6×10^4	Ω^2

At $E_T^* = 1$ MV/m

The inner loading elements are curved to suppress the field non-uniformity across the beam aperture and to reduce the corresponding multipole components.

The complete cavity with fundamental power coupler and HOM couplers are shown in Fig. 2. The HOM couplers have been designed to achieve the transverse and longitudinal damping thresholds [5].

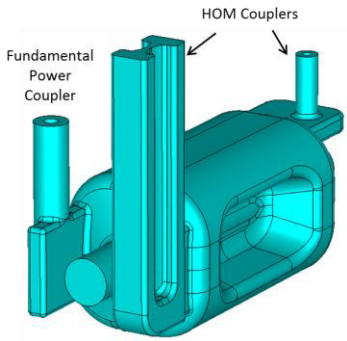

Figure 2: 400 MHz crabbing cavity proposed for LHC high luminosity upgrade.

The rf-dipole prototype design is finalized in terms of electromagnetic properties. The simulated multipacting conditions using the Tack3P in SLAC ACE3P suite [4] shows improved levels compared to the cylindrical proof-of-principle design [5].

MECHANICAL ANALYSIS

The 400 MHz crabbing cavity proposed for the LHC luminosity upgrade is expected to be tested at the SPS beam line prior to the tests at LHC. The SPS tests will include 1 or 2 cavities in a single cryomodule. Current work is focused in fabricating and testing of the first prototype, followed by the cryomodule assembly and testing at the SM18 test cryostat at CERN. The cavity will be beam tested at SPS beam line [2]. Prior to the cryostat assembly the cavity will be tested in a vertical test stand, preferably at the Jefferson Lab vertical test facility.

Stress Analysis

The rf cavity is expected to withstand different load conditions under different external pressures related to operational and safety conditions during vertical rf testing [6], cryomodule testing and beam line testing [7] as listed below:

- ❖ RF testing at the vertical test facility at Jefferson Lab
  - Testing condition – 1 atm external pressure at room temperature and during leak check
  - Operating condition – 1.1 atm external pressure and tuning force at 4 K. At 2 K the external pressure decreases to 0.03 atm
  - Safety condition – 1.4 atm external pressure at room temperature
- ❖ Cryomodule testing at the SM18 test cryostat at CERN
  - Maximum allowable pressure – 1.5 atm
  - Safety test pressure – 2.1 atm at room temperature
- ❖ Cryomodule testing in SPS at CERN
  - Maximum allowable pressure – 1.8 atm
  - Safety test pressure – 2.6 atm at room temperature

The rf dipole cavity fabricated with Nb sheets will experience stress levels under the different operating conditions. The estimated stress levels are required to be below the yield strength for Nb with material properties shown in Table 2.

Table 2: Material Properties of Nb at Room Temperature (RT) and Cryogenic Temperature of 4 K Used at CERN

Parameter	Value	Units
Density	8600	kg/m^3
Poisson's ratio	0.4	
Young's modulus at RT	1.0×10^{11}	Pa
Young's modulus at 4 K	1.23×10^{11}	Pa
Yield strength at RT	75	MPa
Max allowable stress at RT	70	MPa

The stresses analyzed using ANSYS [8] shows that the edges of the loading elements experience the highest stresses due to external pressure (Fig. 3), hence requires additional reinforcement to reduce the stresses below the yield strength.

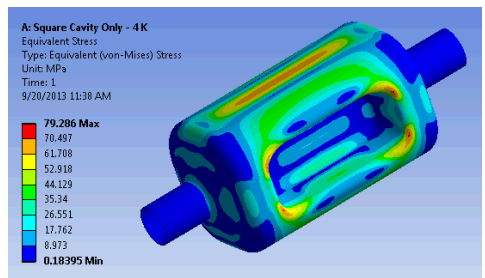

Figure 3: Stress distribution at 4 K and external pressure of 1 atm for a cavity with 3 mm uniform thickness.

Several options of cavity thicknesses with additional reinforcement were studied to achieve the design specifications for different operating conditions. Cavity with a uniform 3 mm thickness with stiffening plates added at the edges of the loading elements or a cavity with uniform thickness of 4 mm results similar stresses. The obtained stresses are below the yield strength for test conditions in a vertical test assembly, however does not meet the safety specifications for cryostat operation.

The cavity with uniform thickness of 4 mm is considered with additional 4 mm stiffening plates shown in Fig. 4, meets the operational and safety requirements for testing in a vertical test assembly as well as in a cryostat test.

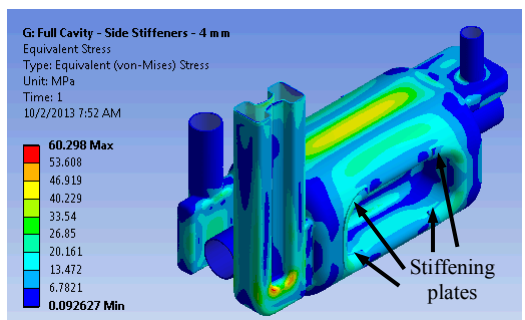

Figure 4: Stress distribution at 4 K and external pressure of 1.1 atm.

As shown in Fig. 5 at an external pressure of 2.1 atm the cavity body has a stress intensity below 70 MPa,

Copyright © 2013 CC-BY-3.0 and by the respective authors

which meets the specifications under cryostat operation. The higher stresses shown at the horizontal HOM coupler can be reduced with the fixed support by the addition of flange and helium tank mount.

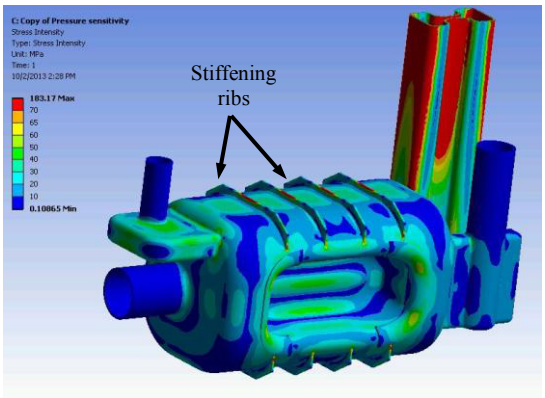

Figure 5: Stress intensity due to external pressure of 2.1 atm at room temperature.

Pressure Sensitivity

The flat surfaces at the top and bottom of the cavity experience the highest deformation due to external pressure. Table 3 shows the pressure sensitivity of the different cavity design options. The cavity with a 4 mm uniform thickness and stiffening ribs improved the sensitivity to pressure with a reduced ratio of -18.5 Hz/torr.

Table 3: Pressure Sensitivity for Different Cavity Designs

Cavity Design	***df/dP* [Hz/torr]**
Cavity with no coupler ports of 3 mm uniform thickness	-368.2
Cavity with coupler ports of:	
3 mm uniform thickness	-369.6
4 mm uniform thickness	-170.8
4 mm uniform thickness and stiffeners	-18.5

Lorentz Detuning

The Lorentz force detuning is an effect where the cavity is deformed by the radiation pressure. The magnetic field applies pressure and deforms the surface outward, while deformation due to electric field is inward as shown in Fig. 6. The curved loading elements around the beam aperture region reduce the deformation due to electric field while the outward deformation due to magnetic field counteracts the deformation due to external pressure to some extent.

The Lorentz coefficients (k_L) for different cavity designs:

- with 3 mm uniform thickness = -162.9 Hz/(MV/m)^2
- with 4 mm uniform thickness = -113.7 Hz/(MV/m)^2
- with 4 mm uniform thickness and stiffeners = -84.5 Hz/(MV/m)^2

The stiffeners were placed on the cavity to reduce the stresses for vertical testing, cryostat operation and safety conditions. The Lorentz coefficients can be improved with further reinforcement.

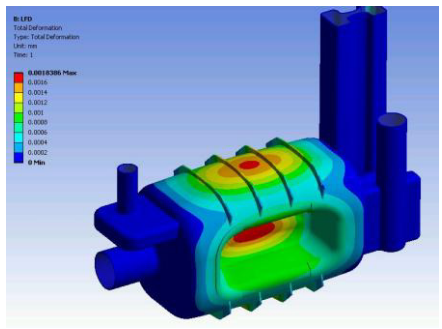

Figure 6: Deformation due to Lorentz force detuning.

CONCLUSION

The 400 MHz proof-of-principle cavity rf tests achieved a transverse voltage of 7.0 MV with high peak surface fields that gives the possibility of operating at a transverse voltage of 5.0 MV, which is above the expected goal of 3.4 MV. The preliminary mechanical analysis for the rf-dipole prototype cavity has been completed. Further analysis will be continued on reducing the pressure sensitivity and Lorentz detuning.

ACKNOWLEDGEMENTS

Abstract

The current requirements of higher gradients and strict dimensional constraints in the emerging applications have required the designing of compact deflecting and crabbing rf structures. The superconducting rf-dipole cavity is one of the first novel compact designs with attractive properties such as higher gradients, higher shunt impedance and widely separated higher order modes. The recent tests performed on proof-of-principle designs of the rf-dipole geometry at 4.2 K and 2.0 K in the vertical test area at Jefferson Lab have proven the designs to achieve higher gradients with higher intrinsic quality factors and easily processed multipacting conditions. The cavity characteristics, such as pressure sensitivity and Lorentz force detuning, were studied using ANSYS before the fabrication. These characteristics were measured during the cavity test. The comparison between the simulation and the measurement provides insight how the simulation can be used for design and fabrication of future cavities.

INTRODUCTION

The Jefferson Lab 12 GeV [1] upgrade is in need of an rf separator system that separates the maximum energy beam in to the 3 experimental halls simultaneously. Figure 1 shows the 12 GeV beam line schematic with the rf separator systems required for the energy upgrade.

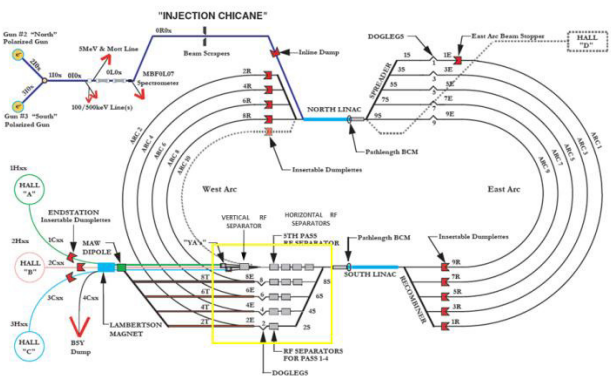

Figure 1: Jefferson Lab 12 GeV beam line.

The 6 GeV beam line has two separator systems for separating the beam horizontally and vertically. The horizontal separator system separates the beam that is recirculated into the linac from that sent to the experimental halls, where the vertical separator system separates the single beam into the 3 experimental halls. The existing rf separator system operates with a series of normal conducting rf separator cavities [2].

The 12 GeV energy upgrade requires a vertical rf separator system that operates at the increased beam energy. The superconducting rf-dipole cavity is one proposed options for the vertical separator system. Table 1 shows the optimized 499 MHz deflecting rf-dipole cavity [3]. The rf test results are shown in Figure 2.

Table 1: Properties of the 499 MHz Rf-dipole Deflecting Cavity

Parameter	Value	Units
Frequency	499.0	MHz
Cavity length	44	cm
Cavity diameter	25	cm
Aperture diameter (d)	40.0	mm
Deflecting voltage (V_T^*)	0.3	MV
Peak electric field (E_P^*)	2.86	MV/m
Peak magnetic field (B_P^*)	4.38	mT
Geometrical factor	105.9	Ω
$[R/Q]_T$	982.5	Ω
$R_T R_S$	1.0×10^5	Ω^2

At E_T^* = 1 MV/m

FABRICATION

The rf-dipole cavity was fabricated in parts consisting of two end caps and the center body sub-assemblies. The driving factors of the fabrication process at JLAB were the available expertise and time line. Instead of traditional stamping, machining a part of cavity was chosen due to its forming complexity and high stress identified during the study. Machining gave the freedom to increase the thickness where needed. The stiffeners were considered but not used in order to see the unstiffened cavity characteristics and performance.

Figure 3 shows the fabrication sequence. Before the electron beam welding, all parts were trimmed and chemically etched.

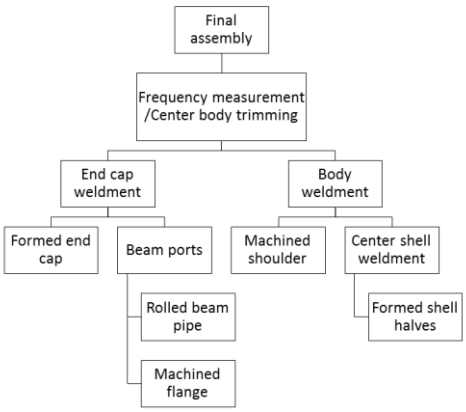

Figure 3: Fabrication sequence.

The end caps, center shell halves, and beam pipes were formed using the stamping dies. The center shell halves are open ended and they were conformed to the fixture during the longitudinal seam weld as shown in Figure 4. Figure 4 also shows the welded shell and the machined shoulder block.

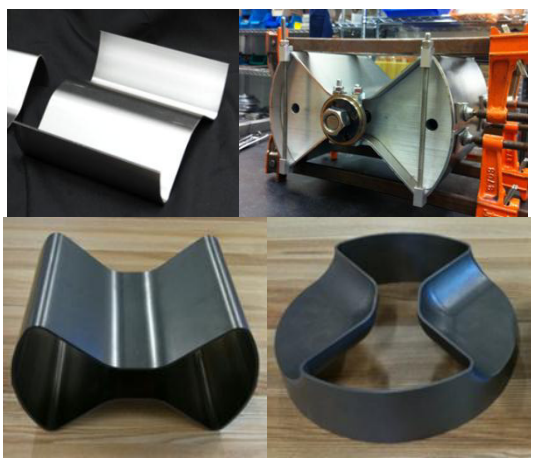

Figure 4: Formed shell halves and fixture assembly (top). Center shell weldment and shoulder block (bottom).

The sub-assemblies are then clamped tight and the frequency was measured (Figure 5). The frequency measurement and the center shell length trimming were repeated to achieve the target frequency.

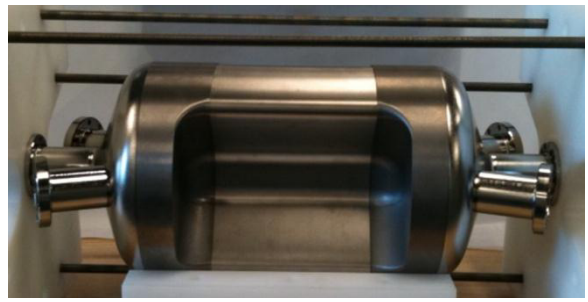

Figure 5: Clamped cavity for frequency measurement.

The next weld was to assemble the center shell body to the shoulder blocks. The center shell profile was slightly mismatched to the machined shoulder which would cause the stepped transition surface when it was welded. Therefore, the two profiles were constrained again with a collapsible fixture. This fixture was inserted between the center shell and the shoulder block as shown in Figure 6. Once it was tack welded in the electron beam welding machine, the fixture was taken out and inside and outside welds were performed.

Figure 6: Weld fixturing.

The final welds were the joints between the center body sub-assembly and end cap sub-assemblies. These joints required full penetration welds from outside.

COMPARISON

ANSYS was used for structural analyses under various conditions [4,5]. Additional analyses were conducted for predicting frequency change during the process, pressure sensitivity, Lorentz force detuning, and so on.

The target frequency of the cavity at room temperature before the final weld was calculated to be 497.8 MHz which would provide the operating frequency 499 MHz in the dewar.

Table 2 lists the cavity's frequency change along the process. The final trimming was done anticipating 498 MHz after final welding. However the welded cavity frequency was measured much lower. The investigation concluded that the deviations in the center shell weldment from the design profile the reason. During the trimming measurement (Figure 5) the center shell gap width was smaller due to the spring back. This resulted in higher capacitance and a higher frequency. Once the shell was conformed to the design profile during the weld the gap widened which lowered the frequency.

The total frequency shift from the welded cavity at room temperature to the cooled down evacuated cavity

Copyright © 2013 CC-BY-3.0 and by the respective authors

was calculated 0.97 MHz and the equivalent measurement was 1.01 MHz. The measurement and simulated frequency changes are in agreement.

Table 2: Frequency Changes of Cavity.

Process	Target/Simulation (MHz)	Measurement (MHz)
Before welding (clamped)	497.63	497.81
Welded cavity at room temperature	498.03	496.83
After bulk BCP	498.31	497.21
Evacuation and cool down to 4K*	499.00	497.84

* Simulation was separate but the measurements were made at the dewar simultaneously.

The rf tests on the 499 MHz rf-dipole cavity were performed at 2.0 K and 4.2 K. The results show high unloaded quality factor and low surface resistance [6].

The pressure sensitivity during the cool down process from 4.2 K to 2.0 K was measured to be -379.5 Hz/torr. As shown in Figure 7, the simulated results give a df/dP of -255.8 Hz/torr. The difference in the pressure sensitivity could be due to difference in material properties, and non-uniformity in the fabricated cavity. The higher sensitivity can be reduced by adding stiffeners at appropriate locations.

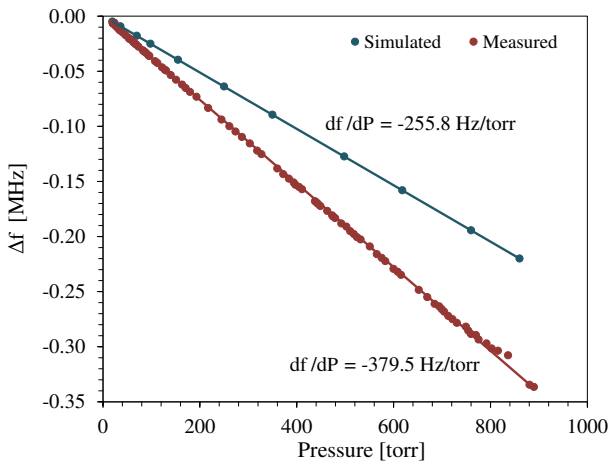

Figure 7: Pressure sensitivity of the 499 MHz rf-dipole cavity.

The Lorentz force detuning is an effect where the cavity is deformed by the radiation pressure. The magnetic field applies pressure and deforms the surface outward, while deformation due to electric field is inward. The change in cavity resonant frequency due to the deformation by Lorentz force was measured as shown in Figure 8. At 4.2 K and 2.0 K the Lorentz coefficients were calculated to be k_L = -57.7 and -53.7 Hz/(MV/m)^2, and the slight variation in the number is possibly due to ports calibration. The simulated coefficient is k_L = -52.4 Hz/(MV/m)^2 with a frequency shift of 5.2 kHz at a transverse voltage of 3.0 MV. This would also be reduced by adding stiffeners.

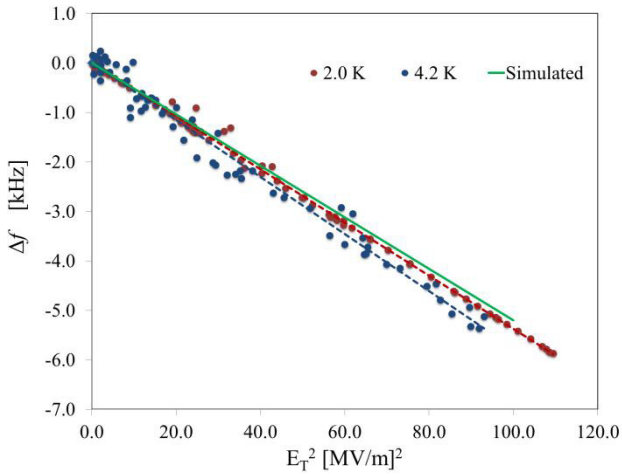

Figure 8: Lorentz force detuning at 4.2 K and 2.0 K rf tests.

CONCLUSION

The first rf test of the 499 MHz deflecting cavity was carried out and the test results were compared with the simulations. Differences between the simulation and the actual measurements are expected due to material and fabrication tolerances. The comparison of the 499 MHz rf dipole cavity case proves that these studies are useful to predict the behavior of the cavity and help to design to minimize the adverse effects of the cavity environment. In the case of the pressure sensitivity, further study is required to understand the deviation between simulation and measurement.

GEOMETRY EFFECTS ON MULTIPOLE COMPONENTS AND BEAM OPTICS IN HIGH-VELOCITY MULTI-SPOKE CAVITIES*

Abstract

Velocity-of-light, multi-spoke cavities are being proposed to accelerate electrons in a compact light-source [1]. There are strict requirements on the beam quality which require that the linac have only small non-uniformities in the accelerating field. Beam dynamics simulations have uncovered varying levels of focusing and defocusing in the proposed cavities, which are dependent on the geometry of the spoke in the vicinity of the beam path. Here we present the results for the influence different spoke geometries have on the multipole components of the accelerating field and how these components, in turn, impact the simulated beam properties.

INTRODUCTION

To address the varying levels of focusing and defocusing that beam dynamics simulations have shown exist, we first evaluate the higher order multipole components contained in the accelerating field to better understand what contributions could lead to the observed behavior. The design of the cavities, and the linac, are then evaluated using results generated by ASTRA particle tracking simulation code.

MULTIPOLE COMPONENTS

The higher order multipole components are analyzed using the method given in [2, 3]. Various cavities have been considered for fabrication, and the field non-uniformity for each of these cavities is shown in Fig. 2. The difference in the models essentially comes down to the shape of the spoke aperture region. A standard racetrack is preferred because of the rf properties, but a rounded square, ring [4], and elliptical aperture have also been studied, and are shown in Fig. 1.

These geometries have varying degrees of symmetry. The ring and racetrack apertures, for similar cavities, have been studied and presented elsewhere [3]. Additional optimization of apertures (c) and (d) is necessary. However, it is likely that some compromise would have to be made, in terms of increased peak surface fields, to decrease the multipole components. Figures 3 and 4 show the $E_z^{(2)}$ and $E_z^{(4)}$ components as a function of position. All the cavities have the same mesh, and similar $E_z^{(2)}$ components, however there is a clear difference in the $E_z^{(4)}$ components.

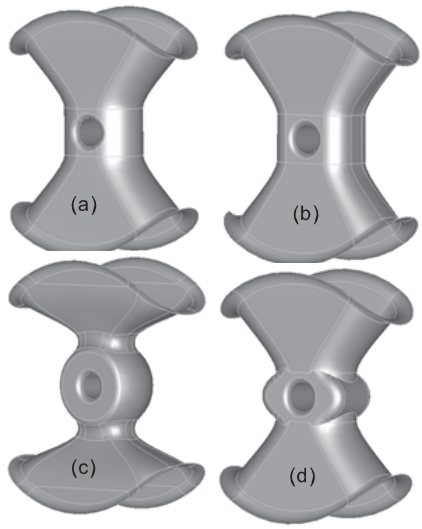

Figure 1: Various spoke aperture geometries studied. (a) racetrack, (b) rounded square, (c) ring, and (d) elliptical.

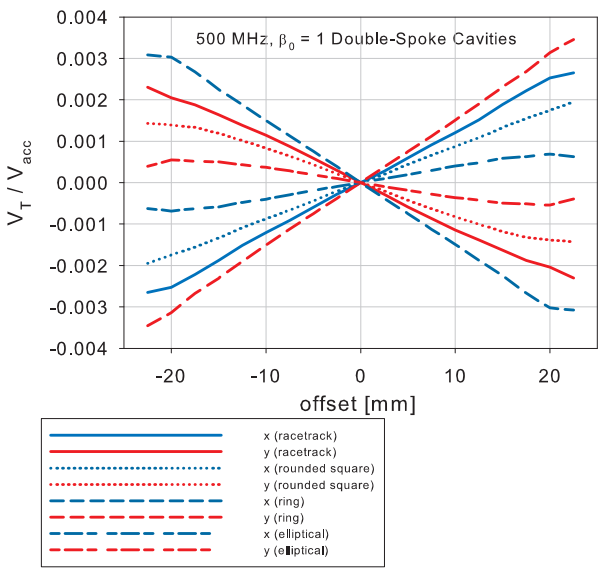

Figure 2: Dependence of transverse voltage (normalized to V_{acc}) on transverse offset for the aperture geometries presented in Fig. 1.

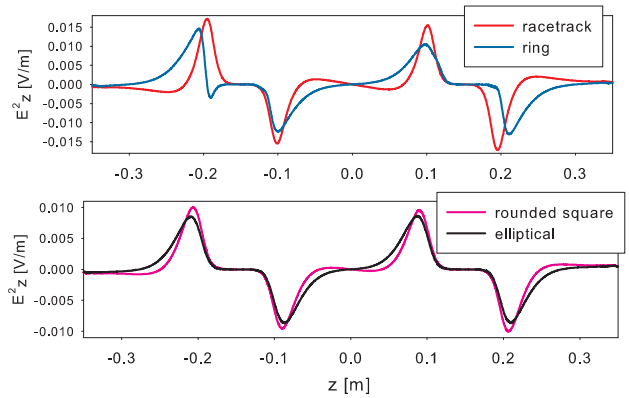

Figure 3: $E_z^{(2)}$ for various aperture geometries.

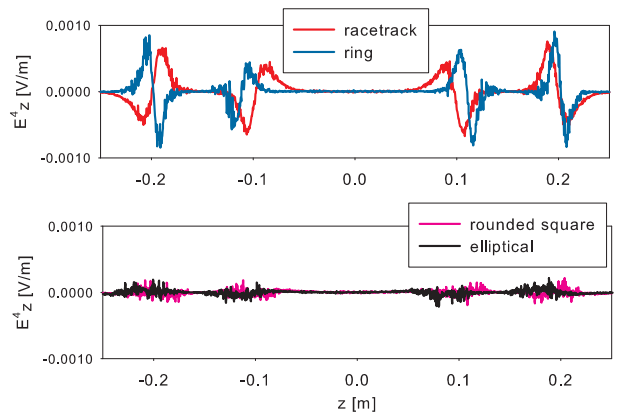

Figure 4: $E_z^{(4)}$ for various aperture geometries.

With the square and elliptical aperture, the octupole component is small enough to be obscured by noise.

While there are some similarities with the studies done by [4] and [5] on HWRs and single-spoke cavities, the geometry of the spokes presented here (other than the actual aperture region) is vastly different, which makes a direct comparison difficult.

BEAM DYNAMICS

The beam dynamics were simulated using the current cathode and gun specifications, detailed in [1]. After exiting the gun, the electron beam is defocusing in both transverse directions equally. The beam then gains 5.86 MeV in the initial double-spoke cavity. The optical parameters of the beam after a single cavity are presented in Tab. 2. As the spoke cavities are not symmetric with respect to the beam line, the transverse components are no longer equal, which is expected. However, the difference between the transverse components of either α or β differs between the four designs. With the least difference is the elliptical aperture, while the ring aperture has the most. Another noteworthy point is that after a single cavity, the β_x and β_y of the beam are diverging for the designs that are not the elliptical aperture.

Table 1: Multipole Components, 500 MHz, $\beta_0 = 1$

Aperture Geometry	$\mathbf{b}_2$ [mT]	$\mathbf{b}_4$ [mT/m^2]
Racetrack	0.37 + 0.006i	-3.9 + 720i
Rounded Square	0.25 - 0.001i	N/A
Ring	-0.45 - 0.07i	141 - 264i
Elliptical	-0.1 - 0.001i	N/A

At the exit of the cavity, a perfectly round beam would be such that $\beta_x = \beta_y$. After passing through a single cavity, the list of apertures in order of decreasing roundness is as follows: elliptical, rounded square, racetrack, and ring. This is also the order that would be obtained by listing apertures in order of increasing $|b_2|$. A comparison of the beam spots for the four designs with optimal configuration after one cavity is seen in Fig. 5.

The results become even more interesting when the electron beam passes through two cavities, shown in Tab. 3. The (-) entries correspond to an iris-to-iris distance of 0.619 m separating the two cavities, while (S) corresponds to a distance of 0.255 m. Entries with (R) correspond to the second cavity rotated 90° as in [1], so that the first spoke in the second cavity the beam traverses is orthogonal to the first spoke in the first cavity that the beam passes through. A few conclusions can be formed. Both the ring and elliptical apertures have β_x and β_y diverging, regardless of the separation or orientation of the second cavity. The racetrack and rounded square apertures diverge for either separation if the second cavity is unrotated, while the β_x and β_y converge for either separation if the second cavity is rotated.

More narrow observations can be made. For both distances, a rotated second cavity produces a rounder beam except for the (-) elliptical. Given that this technique works on the elliptical if there is a shorter separation distance, it may be that if a beam is round to the first order at the exit of an unrotated second cavity, rotating the second cavity decreases the roundness of the resulting beam. The beam behavior similar to a quadrupole is when the beam focuses in one direction while defocusing in the other, which corresponds to each transverse component of α having a different sign.

Since it has now become clear that the separation between the two cavities does have an impact that differs between designs, it is difficult to form any firm conclusions. It is possible to configure the racetrack and rounded square cavities to produce a converging beam for two cavities, while it is impossible to do so with the ring and elliptical designs, regardless of the distance between the two cavities. To develop further conclusions would require a systematic sweep over different separation distances and orientation of the second cavity for all four aperture designs. Though a worthwhile topic, it is beyond the scope of this paper.

As the quadrupole moment is significant in all four of the presented designs, it is difficult to discern the impact of

Table 2: Beam Properties After a Single Cavity

Aperture Geometry	α_x	α_y	β_x [m]	β_y [m]
Racetrack	-19.58	-12.34	55.31	45.67
Rounded Square	-20.21	-16.34	55.51	49.46
Ring	-4.687	-26.27	44.38	56.87
Elliptical	-16.90	-18.47	53.42	51.28

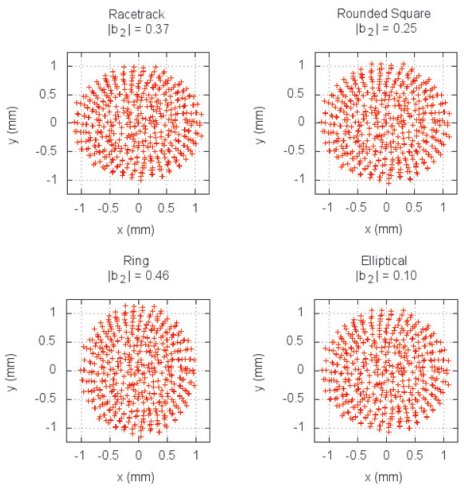

Figure 5: Beam spots of the different designs, with corresponding $|b_2|$ values, after a single cavitiy.

the octupole moment on the beam. Consequently, we are unable to form any conclusions about the relationship between $|b_4|$ and the behavior of the beam. A study of this aspect would require the quadrupole moment of the compared designs to be sufficiently constant. Additionally, it would also require a reliable method of accurately integrating $E_z^{(4)}$, which is difficult for the rounded square and elliptical apertures, as seen in Fig. 4.

To emphasize the connection between the beam behavior and $|b_2|$ for a given aperture design, this analysis begins with a single cavity. Once a second is added and it becomes clear that the separation between the two also has an impact, making it difficult to discern the consequences of separation and $|b_2|$ from the current set of results. Given a linac consisting of four cavities, separated as in [1], the optimum results are shown in Tab. 4. Optimal configurations for all designs except the elliptical are obtained by rotating the second and fourth cavity. For the elliptical, the optimum results are obtained by rotating only the third cavity.

CONCLUSION

The multipole components and beam optics have been studied for different spoke aperture geometries. A racetrack shaped aperture provides the most desirable rf properties, and with the proper orientation, an acceptable beam shape. The fabrication of this cavity is underway at Jefferson Lab.

STUDY OF CAVITY IMPERFECTION IMPACT ON RF-PARAMETERS AND MULTIPOLE COMPONENTS IN A SUPERCONDUCTING RF-DIPOLE CAVITY*

R. G. Olave, J. R. Delayen†, S. U. De Silva, Old Dominion University, Norfolk, VA, USA
Z. Li, SLAC National Accelerator Laboratory, Menlo Park, CA, USA

Abstract

The ODU/SLAC superconducting rf-dipole cavity is under consideration for the crab-crossing system in the upcoming LHC luminosity upgrade. While the proposed cavity complies well within the rf-parameters and multipolar component restrictions for the LHC system, cavity imperfections arising from cavity fabrication, welding and frequency tuning may have a significant effect in these parameters. We report on an initial study of the impact of deviation from the ideal shape on the cavity's performance in terms of rf-parameters and multipolar components.

INTRODUCTION

Due to transverse geometry constraints at the nominal operating rf frequency of 400 MHz, novel compact cavities are under consideration for the upcoming LHC High Luminosity upgrade. The ODU/SLAC superconducting rf-dipole cavity is a suitable candidate as it satisfies the requirements for high gradients, high shunt impedance, low surface fields, no lower order modes, and well-defined and widely-spaced higher order modes [1]-[3]. The cavity geometry, while compact, is not azimuthally symmetric and therefore it becomes important to identify any higher order multipolar components at the operating frequency, since these can lead to beam instabilities in the LHC system. The ODU/SLAC rf-dipole cavity satisfies all specifications for the LHC crab cavity system in terms of rf parameters and in terms of multipole contributions up to the octupole term [4]; Table 1 presents a list of the relevant rf parameters for the cavity. As we prepare for fabrication of a prototype cavity, we are analyzing the impact of individual imperfections or departures from the ideal cavity geometry, that may arise from fabrication or welding errors, while additional distortions would result from the tuning process. In this paper, we present an initial analysis on how such geometry imperfections, particularly those due to welding of the poles, would result in the introduction of undesired higher order multipole components.

IMPERFECTIONS IN THE POLES VS FIELD UNIFORMITY

The design optimization of the cavity showed quite clearly that the geometry of the aperture region of the poles near the beam axis is of vital importance in minimizing the contribution of the sextupole component, which results in a more uniform deflecting voltage across the beam aperture region. For this reason, we start by looking into imperfections in the shape or welding of the poles. Using CST Microwave Studio® 2012 (CST MWS) we have altered the optimized design near the beamline to introduce individual defects in the alignment or geometry of one of the poles, according to the following list:

Table 1: RF Parameters of the 400 MHz Rf-dipole Cavity (at E_T = 1 MV/m and Reference Length $\beta_0\lambda$)

Parameter		Units
Frequency	400.28	MHz
$(R/Q)_T$	412.7	Ω
$(R/Q)_T * (QR_s)$	4.43x10^4	Ω^2
E_p/E_T	3.66	
B_p/E_T	6.14	mT (MV/m)

- (A) Yaw (rotation about y-axis) of one pole.
- (B) Pitch (rotation about x-axis) of one pole.
- (C) Roll (rotation about z-axis) of one pole.
- (D) Horizontal displacement of one pole.
- (E) Vertical displacement of one pole.
- (F) Blending radius at the outer corner of one pole.
- (G) Blending radius of the feather-like structure near the beamline of one pole.
- (H) Aperture radius in one pole.

Figure 1 shows transverse and longitudinal views of the cavity, where the optimized pole geometry can clearly be seen, as well as the places where deformations have been added according to the previous list.

The robustness of the cavity design is such that none of the individual imperfections introduced so far produces drastic changes in the rf-parameters. For items (A), (F) and (G), the transverse voltages (normalized to the transverse voltage at the ideal cavity's beamline) barely change as function of transverse offset from the ideal beamline, from those of the ideal cavity geometry. This can be seen for example in Fig. 2, which includes a plots for different yaw (rotation about the y-axis) angles, as well as a plot (red) of the transverse voltage as a function of transverse offset of the ideal cavity for reference. As can be seen, there is field uniformity in a large region within the cavity's aperture, even for large yaw angles in one of the poles.

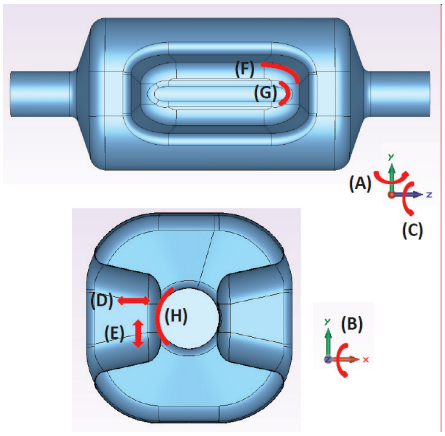

Figure 1: Longitudinal and transverse views of the optimized cavity, and individual imperfections that have been introduced in the geometry of the left pole.

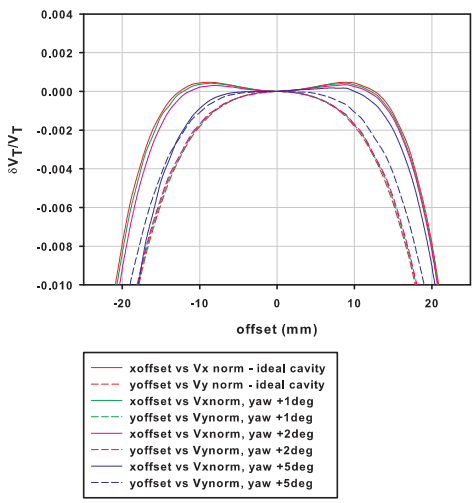

Figure 2: Effects of the yaw (rotation about the y-axis) of one pole on the normalized transverse voltages in the aperture region.

The introduction of a pitch angle results in changes similar to those of displacing a pole in the vertical direction, items (B) and (E). These result in an asymmetry in the horizontal (x-direction) voltage profile, accompanied by displacement of the electrical center of the cavity. This can clearly be seen in Fig. 3, which shows the effects of the pitch (rotation about the x-axis) of one of the poles on the normalized transverse voltage as a function of transverse offset.

The largest effects on the normalized transverse voltages seen so far are due to the roll (rotation about the z-axis) of one of the poles. These effects can be seen in Fig. 4 as a sharp asymmetry in the vertical (y-axis) voltage profile, as well as a displacement on the electrical center of the cavity.

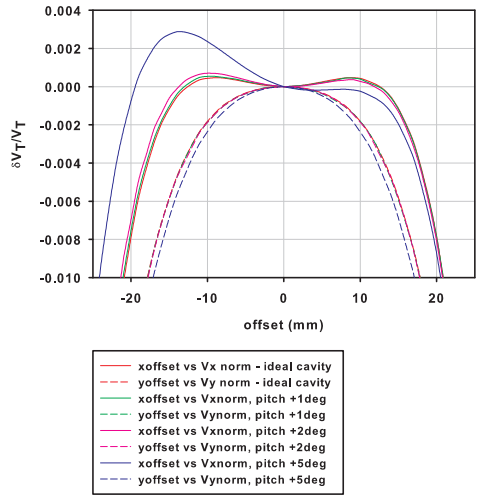

Figure 3: Effects of the pitch (rotation about the x-axis) of one pole on the normalized transverse voltages.

It is worthwhile to note that even for large imperfections, such as a roll angle of 5°, the change in the normalized transverse voltages is on the order of a few percent.

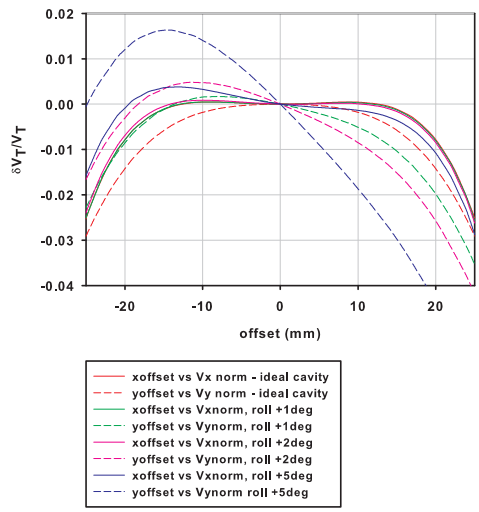

Figure 4: Effects of the roll (rotation about the z-axis) of one pole on the transverse voltages.

The effect of a horizontal displacement of one of the poles, item (D), is simply to shift the electrical center of the cavity. The effects of changing the aperture radius of one of the poles, item (H), is still under analysis.

IMPERFECTIONS OF THE POLES VS MULTIPOLE COMPONENTS

Following the procedure outlined in [5]-[8], from the interpolation of the electromagnetic fields on the surface of a virtual cylinder of radius R through the length of the cavity

Copyright © 2013 CC-BY-3.0 and by the respective authors

in a region free of charge, a general complete solution to the fields can be found. The accelerating electric field can then be expressed as:

$$E_z(r,\phi,z) = E_z e^{i\omega t} = \sum_{n=0}^{\infty} r^n \left(E_z^{(n)} cos(n\phi)\right) e^{i\omega t}, \quad (1)$$

where E_z is the electric field along the beamline direction z and ω is the rf frequency. If the field $E_z(R,\phi,z)$ is known, then the coefficients $E_z^{(n)}$ can be found via inverse Fourier integration of the surface fitted field.

Using the Panofsky-Wenzel theorem we may then calculate the transverse change in momentum (kick) of the particles as a series of multipolar RF kicks:

$$\Delta p_\perp = \left(\frac{e}{\omega}\right) \int_{-\infty}^{+\infty} (-i)\nabla_\perp E_z|_{t=z/v_z} dz \,. \quad (2)$$

Finally, we can express the transverse rf-kicks in the notation commonly used for the multipole magnetic kick strength for magnets. It is important to notice that in our case, the transverse rf-kicks are not static, but functions of time, and as such, they are complex numbers oscillating at the rf-frequency of interest (400 MHz).

$$B^{(n)}(z) = \frac{nj}{\omega} E_z^{(n)}(z), \quad b_n = \int_{-\infty}^{+\infty} B^{(n)}(z) dz \,. \quad (3)$$

Table 2 presents the multipolar components of the ideal cavity for reference. Because of the geometry of this cavity, all even b_n should be zero, so that gives us a reference for the degree of error in our calculations. Table 3 presents the multipole components for the cavities with the imperfections we have used as examples, namely for varying (A) yaw, (B) pitch, and (C) roll, normalized to V_T = 1 MV.

Table 2: RF Multipole Components, Normalized From Simulation Field Data to V_T = 1 MV, of the 400 MHz Rf-dipole Cavity

Multipole component		**Units**
V_T	1	MV

b_2	0.001	mT
b_3	37.4	mT/m
b_4	-1.8	mT/m^2
b_5	-1.94 x 10^5	mT/m^3

It can be seen that although higher order multipole components appear when the cavity is deformed, their contribution is not too significant (supported by the small percentage of variation in the transverse voltage profiles presented in the previous figures), and the cavity remains within the specifications required for the LHC crab cavity system.

CONCLUSION

We are analyzing the impact of imperfections in the shape of the cavity on rf-parameters and multipole components. So far there are no deformations that would make the cavity non-compliant with the requirements for the LHC crab system. However, the analysis is not complete, and there can be significant shifts in the electrical center of the cavity. Our future plans include a comparison of these parameters for cavities normalized to the electrical center of the cavities, as opposed to normalization with respect to the ideal cavity.

Abstract

A single-cell superconducting deflecting cavity operating at 2.815 GHz has been proposed and designed for the Short Pulse X-ray (SPX) project for the Advanced Photon Source (APS) upgrade. Each deflecting cavity is equipped with one fundamental power coupler (FPC), one lower order mode (LOM) coupler, and two higher order mode (HOM) couplers to achieve the stringent damping requirements for the unwanted modes. Using the electromagnetic simulation suite ACE3P, HOM damping was calculated for the cavity including the full engineering design waveguide configurations and rf windows. Trapped modes in the bellows located in the beampipes connecting the cavities in a two-cavity cryomodule were analyzed. Multipacting activities in the cavity and damping waveguides were simulated under the condition of field asymmetry due to a realistic cavity imperfection to assess possible problems during high power processing.

INTRODUCTION

The Advanced Photon Source (APS) can provide photon pulses of several tens to hundreds of picoseconds. There are growing requests from users to use shorter pulse X-rays (SPX) for the analysis of short time-scale physical processes. It has been proposed at APS [1,2] to utilize a pair of superconducting deflecting cavity modules to generate ~1ps X-ray pulses at one of the straight sections, without disrupting the regular X-ray pulse usage for other users. In the proposed scheme, the first set of cavities add a correlation between bunch longitudinal position and transverse momentum. X-Rays produced by this bunch will also have this correlation, and can be put through transverse slits to produce a much shorter X-Ray pulse. The second set of cavities are located a multiple of 180 degrees of phase advance to unchirp the beam, removing the effects of the first cavity set. A cryomodule of four such cavities on each side of the undulator will be needed to produce the required 2-MV deflecting voltage [3].

A two-cavity prototype cryomodule, Fig. 1, is currently under construction and to be tested before the full installation of the four-cavity cryomodules for the APS upgrade. Because of the added complicity of the multi-cavity system, understanding of potential trapped modes and multipacting issues in such a multi-cavity system is essential to validate the design concept. In addition to the planned test, detailed numerical analysis of the HOM damping and multipacting were carried out on the two-cavity prototype module. In this paper, we present the simulation results of HOM damping and multipacting analysis under realistic imperfection conditions.

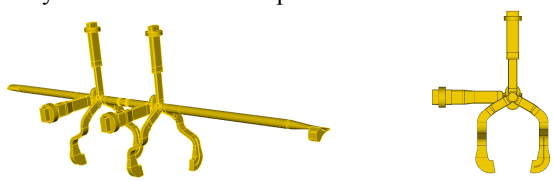

Figure 1: SPX two-cavity deflecting module, and the layout of the FPC and HOM/LOM damping couplers

TWO CAVITY PROTOTYPE MODULE

The layout of the two-cavity module, including the couplers, bellows, and extended beam pipes, is shown in Fig. 1. The cavity has a flattened oval shape and operates in the TM110 mode at 2.815 GHz, which has a strong magnetic field on the beam axis that produces transverse deflection. The RF power is fed from a fundamental power coupler (FPC) waveguide, the vertical waveguide in Fig. 1, which forms one of the legs of a ”Y”-end-group off-cell. The other two legs of the “Y”-end-group, the curved waveguide underneath the cavities, are for damping the higher-order modes. The cavity also supports a TM01 mode, which is at a lower frequency than the operating mode. An on-cell lower order mode (LOM) coupler, horizontal waveguide in Fig. 1, is directly attached to the cell at the cavity equator which offers a more compact geometry with enhanced LOM and HOM damping. Beampipe bellows are in between the two cavities for alignment flexibility.

We have used the parallel finite element EM code suite ACE3P [4] developed at SLAC to analyze the trapped mode damping and multipacting in the two-cavity cryomodule. Fig. 2 shows the finite element mesh around

the cavity and the bellows used by the ACE3P code. The electric field profile of the operating mode, which produces a vertical deflection, is also shown in Fig. 2.

TRAPPED MODES AND HOM DAMPING IN THE TWO-CAVITY MODULE

HOM Damping and Impedance

The HOMs up to 4.6 GHz were calculated using the Omega3P parallel eigensolver. The FPC, the LOM/HOM, and the beampipe ports are modelled with absorbing boundary conditions to evaluate the external Q_{ext}. Due to the geometry asymmetry, most of the HOMs are not centred at the geometric axis of the cavity. Because of this centre offset, a beam passing through the cavity centre will see multipole field components [5]. For example, a mode with a clear dipole mode pattern will have a finite monopole component when the centre is off the cavity axis. After the eigenmode calculations with Omega3P, the multipole components of each mode were calculated with respect to the beam centroid using a postprocessing tool. The impedances associate with the multipole field components of each mode were then calculated and are plotted in Fig. 3. The RF quantities plotted in Fig.3 are defined as the following, with "v" the voltage of the respective multipole component.

$$\left(\frac{R}{Q}\right)_T = \frac{|V_z(r_0)|^2}{\omega U (r_0\omega/c)^2} \qquad Z_T = \frac{\omega}{c}\left(\frac{R}{Q}\right)_T Q_{ext}$$

$$\left(\frac{R}{Q}\right)_L = \frac{|V_z(r_0)|^2}{\omega U} \qquad Z_L = \left(\frac{R}{Q}\right)_L Q_{ext}$$

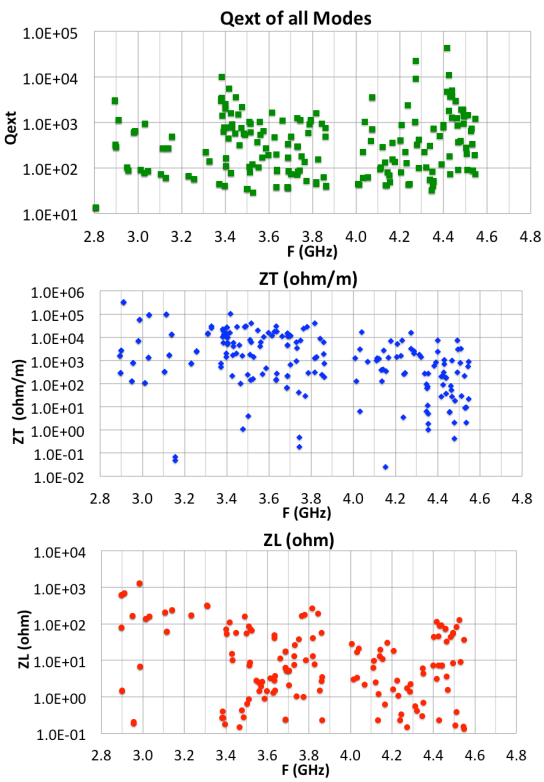

Figure 3: Q_{ext} and impedances of the HOMs in the two-cavity system.

Simulation results have shown that all the modes are well damped. There are no significant trapped modes found in the two-cavity system. Both transverse and longitudinal impedances met the requirements for beam stability [6].

HOMs in the Beam Pipe Bellows Region

There are a few modes above the beam pipe TM010 cutoff frequency of 4.41GHz that have longitudinal impedances of about 100 ohms. Two of these longitudinal modes are shown in Fig. 4. Both have relatively strong magnetic fields in the bellows region. These are the type of modes of concern in a multi-cavity module as they could produce RF heating to the bellows. Simulation results have showed that the two-cavity prototype module design can provide essential damping via the LOM and HOM couplers to these modes thus minimizes the beam coupling to the modes. As a result, the RF heating by these coupled modes does not seem to be of concern.

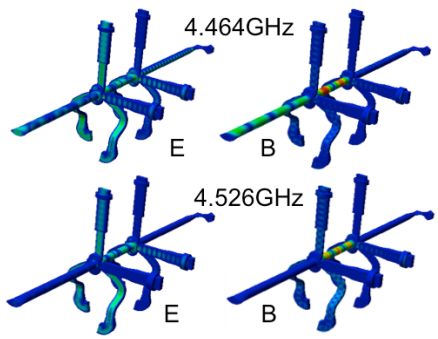

Figure 4: Monopole modes that have strong magnetic fields in the bellows region.

MULTIPACTING DUE TO FIELD ASYMMETRY

The rectangular LOM coupler has a TE10 mode cutoff frequency lower than the deflecting mode frequency. The rejection of the LOM coupler to the deflecting mode relies solely on the field symmetry. In an ideal case, the deflecting dipole mode can only couple to the TE20 mode of the LOM coupler which is cutoff at the operating dipole mode frequency. The asymmetric "Y"-end-group causes only a slight field asymmetry in the cavity which in turn induce negligible power leakage through the LOM coupler. However, the first horizontal test of a prototype cavity showed sharp heating at the LOM strongly correlated with a strong Q-switch and a significant power leakage through the LOM coupler [7]. This pointed to a field asymmetry caused by a shape imperfection and possible multipacting related to such a field that limited the cavity performance. Track3P multipacting simulation code was used to analyse multipacting resonances under a field asymmetry modeled with a simple "dent imperfection" on the cavity wall. The amount of "dent" induces an RF leakage that is comparable to the

Copyright © 2013 CC-BY-3.0 and by the respective authors

measurement. Fig. 5 shows the field leaking via the LOM coupler (horizontal) with the induced field asymmetry by a "dent". The multipacting map obtained for the "ideal" and "imperfect" cavities are shown in Fig. 6 for comparison.

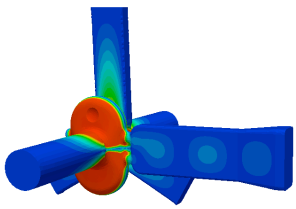

Figure 5: Power leakage through the LOM coupler in an imperfect geometry with a "dent", comparable to the leakage measured in the prototype cavity.

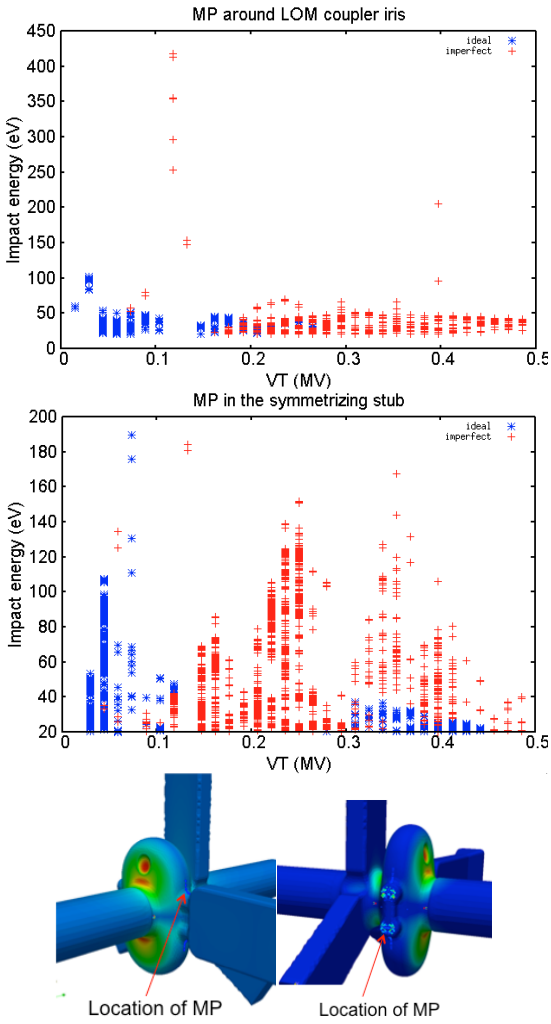

Figure 6: Effect of a field asymmetry on multipacting.

The multipacting band in the LOM coupling iris region is shifted to a higher field level in the case with the field asymmetry. The impact energies of the resonant trajectories in this band are mostly lower than 50 eV. The SEY for niobium at these energies are relatively low, and the multipacting bands in both "ideal" and "imperfect" cases are considered not strong barriers.

An enhanced multipacting band around 0.24 MV deflecting voltage was found in the symmetrizing dog-bone in the case with the field asymmetry. The energies of the resonant trajectories in this band are as high as 140 eV. The SEY of these trajectories is much higher than the ones around the LOM iris. Significant multipacting is possible in this region when a field asymmetry exists. This multipacting band was observed in the RF testing of the prototype cavity that has a imperfection asymmetry [6]. The multipacting band was eliminated in the RF test by tuning the LOM coupler to minimize the leakage and subsequently the field asymmetry, which agrees with the analogy of an ideal cavity.

SUMMARY

HOMs and trapped modes were calculated for the two-cavity prototype cryomodule using the parallel code Omega3P. No dangerous trapped modes were found in the two-cavity system. All modes were well damped. Both the transverse and logitudinal impedances are below the instability threshold. A few monopole modes above 4.41 GHz were found to have strong fields in the bellows region. These modes are well damped by the LOM/HOM couplers and are low in impedances. HOM heating of the bellows does not seem to be a significant issue. Multipacting in the cavity due to imperfection and asymmetry was analyzed using Track3P. An enhanced multipacting band in the symmetrizing stub was found when there is a finite RF power leakage through the LOM coupler due to a shape imperfection, which can be eliminated by tuning the LOM coupler. The simulation results are in good agreement with the RF test of a prototype cavity.

WAKEFIELD COMPUTATIONS FOR A CORRUGATED PIPE AS A BEAM DECHIRPER FOR FEL APPLICATIONS*

C.-K. Ng, K.L.F. Bane, SLAC, Menlo Park, USA

Abstract

A beam "dechirper" based on a corrugated, metallic vacuum chamber has been proposed recently to cancel residual energy chirp in a beam before it enters the undulator in a linac-based X-ray FEL. Rather than the round geometry that was originally proposed, we consider a pipe composed of two parallel plates with corrugations. The advantage is that the strength of the wake effect can be tuned by adjusting the separation of the plates. The separation of the plates is on the order of millimeters, and the corrugations are fractions of a millimeter in size. The dechirper needs to be meters long in order to provide sufficient longitudinal wakefield to cancel the beam chirp. Considerable computation resources are required to determine accurately the wakefield for such a long structure with small corrugation gaps. Combining the moving window technique and parallel computing using multiple processors, the time domain module in the parallel finite-element electromagnetic suite ACE3P allows efficient determination of the wakefield through convergence studies. In this paper, we will calculate the longitudinal, dipole and quadrupole wakefields for the dechirper and compare the results with those of analytical and field matching approaches.

INTRODUCTION

In order to cancel the residual energy chirp in a beam before it enters the undulator in a linac-based FEL, a beam dechirper whose design consisting of periodic corrugations on the chamber walls has been proposed [1]. Such a dechirper is a passive device as it uses the longitudinal wakefield generated by the beam transit to compensate for the energy difference within the beam. The dechirper can be installed in machines such as LCLS-II where a superconducting linac will be used for beam acceleration and the wakefields generated in the superconducting cavities are not strong enough to dechirp the beam.

The original dechirper proposed for the light source NGLS was a round corrugated metallic pipe. The wakefields for the round geometry have been calculated using an analytical approach and formulas are available. Later, a flat rectangular geometry with corrugations on two parallel metallic plates was adopted and a dechirper was built and tested [2] at the injector test facility (ITF) for the PAL-XFEL in Korea [3]. The rectangular geometry has the advantage that the separation of the plates can be adjusted for different machine operation conditions. Formulas for the wakefields obtained by the analytical approach have been worked out recently for the rectangular case [4, 5]. Furthermore, numerical method using field matching in the frequency domain has been developed [4], which is believed to be more accurate than the analytical method.

The analytical approach is a good approximation when the depth and period of the corrugation are small compared with the separation of the plates. The corrugations in the dechirper being tested at PAL are small with respect to the chamber dimensions, but it is desirable to perform direct simulation by 3D electromagnetic code to verify the validity of the analytical approximation. This work focuses on numerical simulation using the finite-element electromagnetic code suite ACE3P [6] to calculate the wakefields of the dechirper and compare them with the analytical and field matching approaches. In addition to determining the longitudinal wakefield that is used to cancel the energy chirp of the beam, the dipole and quadrupole wakefields that kick and defocus the beam and hence increase its emittance will also be evaluated.

THE DECHIRPER MODEL

A sketch of the geometry of the dechirper is shown in Fig. 1. The corrugation is defined by the period p, the gap g, and the depth h. These corrugation parameters are fractions of a millimeter in size. The corrugations are located at the top and the bottom of the rectangular chamber with half height a and half width w. In order to provide sufficient longitudinal wakefield, the height of the dechirper needs to be small enough (on the order of millimeters), which is small compared with the chamber width, and the length of the dechirper needs to be long enough (on the order of meters). The dimension parameters of the dechirper tested at PAL are a = 3 mm, p = 0.5 mm, g = 0.3 mm, and h = 0.6 mm. In practice, a is adjustable from $2a$ = 5 mm to 28 mm. The validity of the analytical approximation is when p, $h << a$ and the corrugation depth h is much larger than its period p. It can be seen that the corrugation dimensions are about an order of magnitude smaller than the dechirper height. A direct 3D numerical simulation is required for cross check of the analytical calculation.

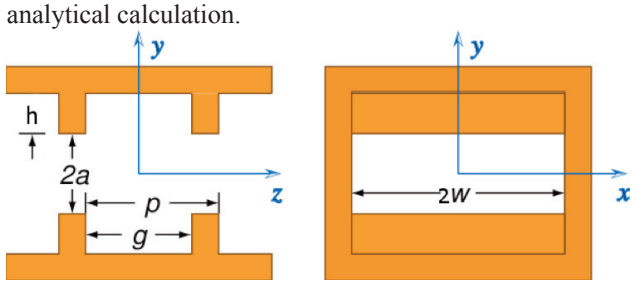

Figure 1: Sketch of the geometry of the dechirper.

NUMERICAL APPROACH

The 3D numerical simulation is performed using the time domain module T3P of the code suite ACE3P. The wakefield computation in T3P is facilitated by the following simulation capabilities. First, T3P runs on computers at NERSC computing facility, which provides massively parallel computation to achieve fast computing speed. Second, a moving window technique for unstructured grids implemented in T3P confines short-range wakefield computation to the region of the mesh around the moving beam, thus substantially enhancing the computation efficiency. It should be pointed out that while it is straightforward to implement the moving window technique in the FDTD method with regular rectangular grids, its implementation in the finite-element method using unstructured grids is rather non-trivial [7, 8]. It requires careful mapping of field quantities when transferring the solution from the current window to the next one, especially under the computation environment where multiple computer processors are used.

Despite the above-mentioned computational advantages, simulating the full dechirper of meters long and with large chamber *w/a* aspect ratio is still challenging, if not infeasible. Fortunately, the wakefield will reach steady state after a certain catch-up distance, and the reflection from the sides of the chamber will be negligible when *w/a* is larger than a certain value. Therefore, a reduced model with much smaller length and width than the actual device can be used to obtain accurately the wakefield per unit length of the dechirper. Because of symmetry, only a quarter of the reduced model as shown in Fig. 2 is needed for T3P calculation.

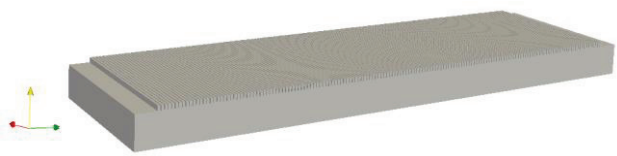

Figure 2: One quarter of the vacuum region of the dechirper model with corrugations situated on a half of the top plate used for T3P simulation. The full model is obtained by reflection with respect to the horizontal and vertical planes.

Figure 3 shows three snapshots of the beam transit in the dechirper with 160 corrugations. The computation at each time step in T3P is confined only in the colored region when the moving window technique is employed in following the transiting beam. Thus the computation domain is only a small fraction of the model, which drastically reduces the computation time.

Convergence studies have been performed by varying the number of corrugations and the width of the chamber, respectively. It was found that when the number of corrugations reaches 160, the longitudinal wakefield per unit length does not change. Fig. 4 shows the comparison of the longitudinal wakefields for a model with 144 and 160 periods. It can be seen that the two curves are almost the same. In a similar manner, when the chamber *w/a* aspect ratio is greater than about 2.5, the wakefield remains unchanged. In all the following numerical simulations, the dechirper model has 160 corrugations and *w/a* of the rectangular chamber is 3.

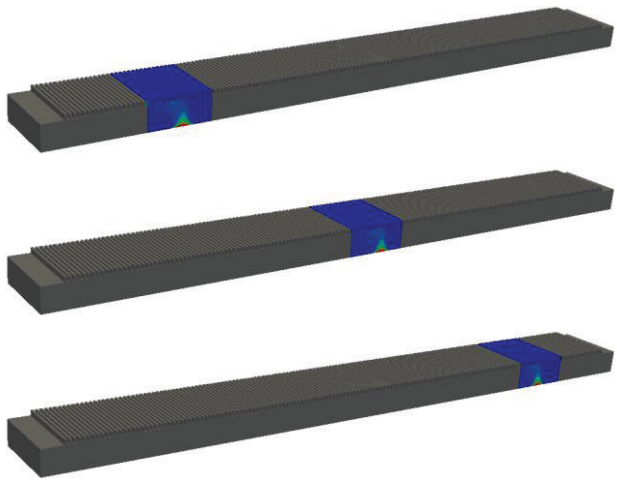

Figure 3: Snapshots of beam transit in the dechirper with 160 corrugation periods. The beam comes in from the left boundary at the origin (the lowest corner) and moves to the right. The colored region in each snapshot indicates the moving window at the corresponding time.

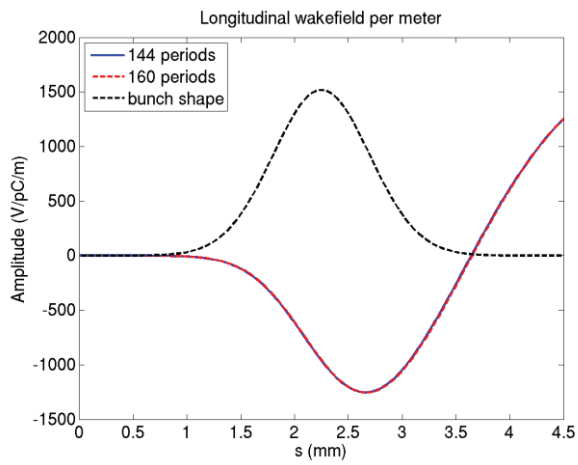

Figure 4: Longitudinal wakefield per unit length of the dechirper with 144 and 166 corrugations.

WAKEFIELDS OF DECHIRPER

The dimensions of the PAL dechirper have been listed in a previous section. To calculate the wakefields of the dechirper, a Gaussian bunch with σ = 0.45 mm is used, which corresponds to the rms beam size at the PAL test facility. Choosing appropriate boundary conditions at the symmetry planes in the quarter model shown in Fig. 2, one can determine the monopole and quadrupole wakefields with the beam transiting on the axis in a single T3P run, and the dipole wakefield with the beam transiting at an offset position in the vertical direction using different boundary conditions in another T3P run. The total transverse wakefield in the vertical direction is

Copyright © 2013 CC-BY-3.0 and by the respective authors

the sum of the dipole and quadrupole components and is given by

$$W_y = y_d W_{yd} + y_w W_{yq},$$

where W_{yd} and W_{yq} are the dipole and quadrupole wakefields, and y_d and y_w are the positions of the drive and witness particles, respectively. The wakefields are expressed in terms of per meter length so that the values for the actual dechirper can be readily obtained by multiplying with its length. In each of the monopole, dipole and quadrupole calculations, the T3P numerical results are compared with those evaluated by the analytical and field matching approaches.

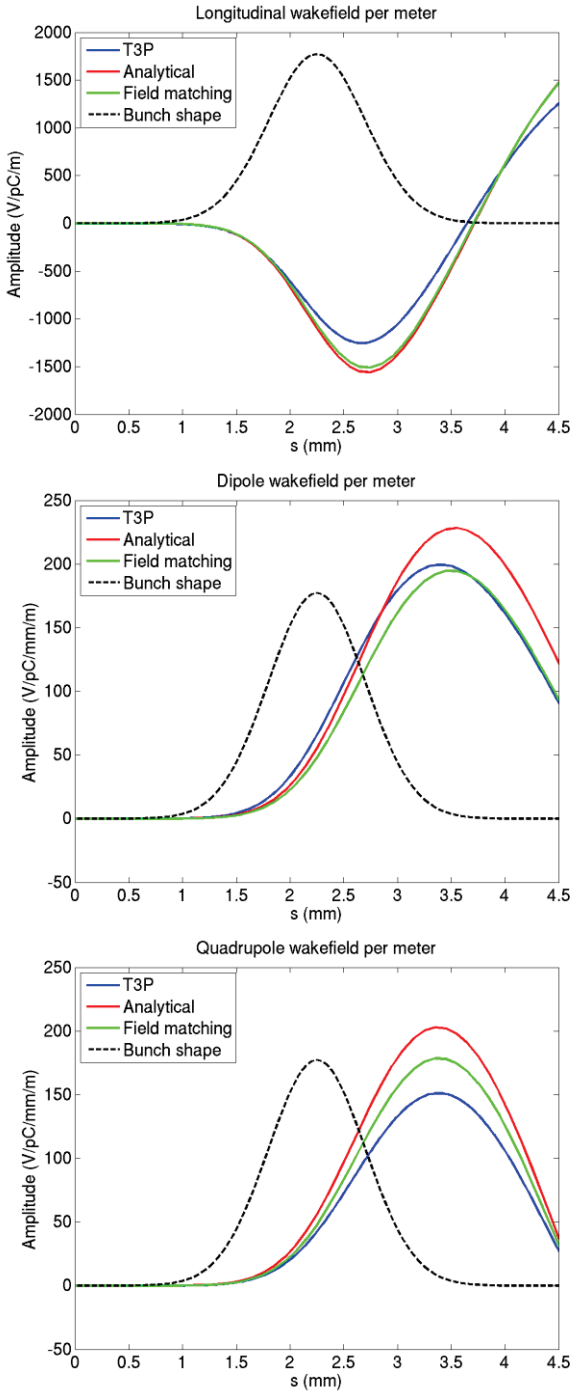

Figure 5: (Top) Longitudinal, (Middle) dipole, and (Bottom) quadrupole wakefield per meter length of the dechirper obtained by the analytical, field matching and numerical approaches.

Figure 5 shows the longitudinal, dipole and quadupole wakefields obtained by T3P numerical calculation, the analytical and field matching approaches. The loss factor obtained by numerical calculation is 821 V/pC/m, and the kick factors for the dipole and quadrupole components are 75 V/pC/mm/m and 52 V/pC/mm/m, respectively. In comparing the results of different approaches, Table 1 list the ratios of the loss or kick factors for any two of the approaches. In general, the analytical and field matching approaches agree with each other within 10%, while the numerical approach agrees either with the analytical approach or the field matching approach within 10-20%, depending on individual cases. This indicates that while analytical formulas render a fast means to determine the wakefields in a dechirper, in particular in exploring the parameter regime during the initial design phase, it is always desirable to further quantify the results with numerical methods for the final design.

Table 1: Comparison of the ratios of the loss factor or kick factors obtained by the analytical, field matching and numerical approaches.

Wake	FM/ Analytical	Numerical/ Analytical	Numerical/ FM
Monopole	0.97	0.84	0.87
Dipole	0.87	1.08	1.25
Quadrupole	0.86	0.73	0.85

MECHANICAL DESIGN OF A NEW INJECTOR CRYOMODULE 2-CELL CAVITY AT CEBAF*

G. Cheng#, J. Henry, J. Mammosser, R. A. Rimmer, H. Wang, M. Wiseman, S. Yang, JLAB, Newport News, VA 23606, USA

Abstract

As a part of Jefferson Lab's 12 GeV upgrade, a new injector superconducting RF cryomodule is required. This unit consists of a 2-cell and 7-cell cavity, with the latter being refurbished from an existing cavity. The new 2-cell cavity requires electromagnetic design and optimization followed by mechanical design analyses. The electromagnetic design is reported elsewhere. This paper aims to present the procedures and conclusions of the analyses on cavity tuning sensitivity, pressure sensitivity, upset condition pressure induced stresses, and structural vibration frequencies. The purposes of such analyses include: 1) provide reference data for cavity tuner design; 2) examine the structural integrity of the cavity; and 3) evaluate the 2-cell cavity's resistance to microphonics. Design issues such as the location of stiffening rings, effect of tuner stiffness on cavity stress, choice of cavity wall thickness, etc. are investigated by conducting extensive finite element analyses. Progress in fabrication of the 2-cell cavity is also reported.

CEBAF NEW INJECTOR CRYOMODULE CAVITIES

Presently in the injector section of CEBAF there is a "Quarter Cryomodule", which has two 5-cell cavities. With the upgrade of operating energy from 6 GeV to 12 GeV, a few options for the booster cavity layout have been studied [1] and the 2-cell plus 7-cell cavities layout is deemed desirable. The demanded field amplitude for the 7-cell cavity is around 13 MV/m. An economic decision is made to refurbish a low loss JLAB Renascence cryomodule [2] 7-cell cavity, which is capable to provide 17-21 MV/m accelerating field amplitude, to be used in the new Injector Cryomodule. The 2-cell cavity is a new design based on the low loss cavity shape and is expected to provide approximately 4.6 MV/m accelerating field.

2-CELL CAVITY MECHANICAL DESIGN

The 2-cell cavity is made of high RRR fine grain niobium. Basic mechanical properties used in all design analyses are listed in Table 1. Note that the 2-cell cavity niobium material is the same as SNS cavity material and the cavity will be baked at 600 ^{o}C for 10 hours. Although niobium is not a "code material", the ASME Boiler & Pressure Vessel Code (BPVC) rules are referenced during the pressure induced stress analysis for the 2-cell cavity. The allowable stresses are determined per BPVC rules, i.e. the allowable stress is the lesser of 2/3 of yield strength or 1/3.5 of the tensile strength.

Among the major cavity mechanical design considerations, the choice of cavity wall thickness is mainly dictated by the upset condition pressure induced stress. The wall thickness also affects the cavity stiffness, tuning and pressure sensitivities, as well as vibration natural frequency. Similar theory applies to the option of using ring shape stiffeners. All mechanical design analyses are performed in ANSYS®. The tuning and pressure sensitivity calculations involve electromagnetic to structural coupled field analysis technique. Each design topics is addressed in a bit more details in the following sections.

Table 1: High RRR Niobium Mechanical Properties [3-5]

Properties	Room Temperature	Cryogenic Temperature
Young's Modulus, psi	1.49e7	1.79e7
Poisson's Ratio	0.38	0.38
Density, lb/in^3	0.31	0.31
Yield Strength, ksi	9.5	83.7
Tensile Strength, ksi	26.3	118.8
Allowable Stress, ksi	6.33	33.9

2-CELL CAVITY STRUCTURAL STRESS

Three loading conditions are examined for the stress state in the 2-cell cavity: 1) 2.2 atm pressure at room temperature (R.T.) simulating pressurization during the cryomodule cool down process, 2) 5 atm pressure at cryogenic temperature (C.T.) simulating pressurization caused by upset conditions [6], and 3) 5 atm pressure with 300 μm tuning displacement. The pressure chamber surrounding the niobium cavity is formed by the interior of a helium vessel and the cavity external surfaces. The helium vessel for this 2-cell cavity is made of stainless steel and has one bellows to mitigate the thermal stress developed during cool down and caused by the mismatch of expansion coefficients between niobium and stainless. The bellows also permits tuning of the cavity without holding up against an otherwise stiff helium vessel. Outside the helium vessel, a scissor-jack tuner is mounted. The helium vessel bellows and tuner are simulated as springs in the cavity stress analysis model. The bellows' longitudinal spring constant is relatively small. The tuner's warm and cold stiffnesses are analysed separately on a preliminary tuner design model.

Two cavity wall thickness values are considered in the stress analyses: 3 mm and 4 mm. As to the stiffening rings, three design options, i.e. no rings, one ring between 2 cavity cells and 3 rings (2 added between the cells and helium vessels), are investigated. It is found that at least 3 rings are needed to reduce the pressure induced stress. The stiffening rings' radial locations are studied and it is found that large diameter rings would increase the cavity stiffness hence reduce the stresses, however, when the rings are too big, electron beam welding of these rings could affect the braze joint between niobium cavity and stainless steel helium vessel. In addition, if the cavity and helium vessel assembly is too stiff, tuning of the cavity will become difficult. The stiffening ring diameter is finally decided to be consistent with that for the 7-cell cavity. Table 2 shows the stress results for the 2-cell cavity with 3 stiffening rings and 3 mm or 4 mm wall thickness. Based on Table 2, the 4 mm cavity is selected. Note that the peak stresses typically occur at sharp corners where the stiffening rings are welded to the cavity. Such stresses are disregarded due to finite element model singularities that are incredible. The "body stress" is taken at "hotspots" that are away from the singularity points. Figure 1 shows the stress for the 4 mm thick cavity subjected to 2.2 atm pressure at R.T.

Table 2: Pressure Induced Stresses in Cavity with Different Wall Thicknesses

Cases	Tuner Stiffness (lbf/in)	Cavity stress (psi)	3 mm	Acceptable?	4 mm	Acceptable?
5 atms at C.T.	88,001	peak stress	22,036	-	18,656	-
		body stress	18,890	Yes	16,001	Yes
5 atms C.T. with 300 μm tuning	88,001	peak stress	24,756	-	23,104	-
		body stress	21,225	Yes	19,812	Yes
2.2 atms at R.T.	79,700	peak stress	9,177	-	7,850	-
		body stress	7,905	No!	6,172	Yes

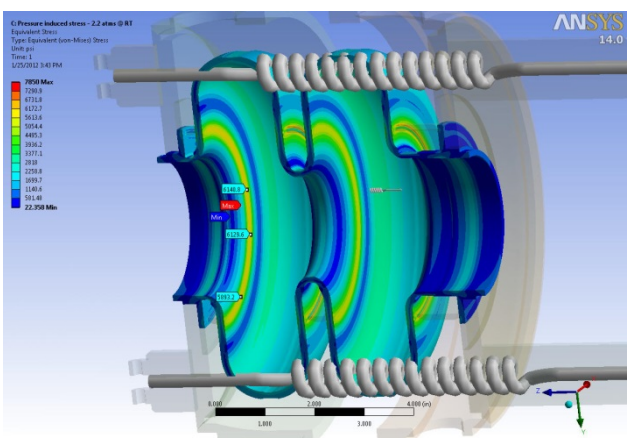

Figure 1: Stress in the 2-cell cavity (4 mm thick with 3 stiffening rings) subjected to 2.2 atm pressure at R.T.

2-CELL CAVITY TUNING AND PRESSURE SENSITIVITIES

The scissor-jack tuner exerts tuning force to the cavity through two pairs of tuner tabs that are mounted on the end plates of the helium vessel. The change of cavity electromagnetic frequency versus displacement between the pairs of tuner tabs is defined as the tuning sensitivity for the 2-cell cavity. Knowing the tuning sensitivity is important in tuner design as well as tuner operation.

Another important characteristic of the 2-cell cavity is its pressure sensitivity, that is, cavity electromagnetic frequency change with respect to helium vessel pressure fluctuation. Based on operational experiences, a ±0.1 torr pressure fluctuation is typical [7]. It is also learned from operational practices that such pressure fluctuation does not occur in a rapid manner. This means that the slow tuner can rectify the frequency shift in time. Ideally, one would want to control the pressure sensitivity to be a quite small number. This is affected by a number of factors, among which the size of the helium vessel bellows is crucial. The 2-cell cavity's helium vessel adopts a nominal 10″ diameter bellows design. This size of bellows is also used in Jefferson Lab's 12 GeV upgrade cryomodules (also called C100 cryomodules). It is expected that the pressure sensitivity of the 2-cell cavity to be at a similar level as C100 cryomodule cavities. Note that the stainless steel helium vessel and the 2-cell cavity (4 mm wall thickness and having 3 stiffening rings) itself are quite stiff, which helps in reducing the pressure sensitivity.

Coupled field analyses are carried out to solve for the tuning and pressure sensitivities. In principle, the model includes the vacuum volume that is enclosed by the niobium cavity. For tuning sensitivity analysis, the cavity and helium vessel are included in the model. For pressure sensitivity analysis, the tuner (simulated as a couple of equivalent springs) is also included. Frequency of the undeformed vacuum volume is calculated first. Then tuning displacement or pressure load is applied to the cavity and helium vessel. The niobium cavity deforms and the deformed shape of cavity is used to alter the vacuum volume. In the analysis model, the cavity and vacuum volumes share common interfaces so that nodal displacements at interfacial nodes can be conveniently transferred from the cavity to the vacuum. At last, the "deformed" vacuum is used to calculate a new frequency. The difference between the before and after structural deformation frequencies is then divided by the tuning distance or pressure applied to calculate the corresponding sensitivities.

For the 4 mm thick 2-cell cavity equipped with 3 stiffening rings, the tuning sensitivity is calculated to be 2.63 MHz/mm. Based on this, to achieve a coarse tuning range of 600 kHz, 228 μm tuning is needed. In the mechanical designs, this tuning distance is rounded up to 300 μm to be conservative. The cavity and helium vessel assembly's cold stiffness is estimated to be 8.93 N/μm.

Figure 2: Fabricated 2-cell cavity major components.

The pressure sensitivity of the 2-cell cavity is calculated to be 382 Hz/torr. For the C100 7-cell cavity (3mm wall thickness, no stiffening rings), the measured pressure sensitivity is around 320 Hz/torr. So, the new 2-cell cavity's pressure sensitivity is comparable to that of the C100 7-cell cavity.

CAVITY VIBRATION FREQUENCY

To mitigate the detrimental effects brought by microphonics, "one should push the mechanical resonance frequencies as high as possible…" [8] In the 2-cell cavity design, 4 mm wall thickness and 3 stiffening rings are selected not only for resistance to the pressure loads, but also for high vibration frequencies. The 2-cell cavity is hosted by a helium vessel, which is supported by eight Nitronic rods in the transverse direction and two Nitronic rods in the axial (parallel to beam axis) direction. All rods are mounted to a spaceframe, which is bolted to a vacuum vessel that is anchored to the ground. Vibration analysis is very sensitive to the boundary conditions employed. However, it is impractical to build a mathematical model that reflects a real cryomodule's conditions precisely. In the 2-cell cavity vibration model, the vacuum vessel, spaceframe and Nitronic rods are assumed to be stationary, although in reality they pass environmental vibrations to the helium vessel and niobium cavity. The point is to examine the cavity's natural resistance to vibrational resonance. Therefore, the boundary conditions are that at the helium vessel end where 4 transverse rods and 2 axial rods exist, fixed support boundary condition is applied. At the other end where only 4 transverse rods exist, the helium vessel is fixed in transverse directions only. Basically, the cavity vibration model has a set of fixed-guided boundary conditions. The lowest vibration mode of the 2-cell cavity is found to be an axial mode, i.e. parallel to beam axis extension/compression oscillation, with a frequency of 218 Hz, which is much higher than the design criteria of 100 Hz. The 2-cell cavity is thus deemed as being robust in terms of its resistance to low frequency vibration resonances.

CAVITY FABRICATION

Fabrication of the 2-cell cavity has started. As shown in Fig. 2, major components such as the fundamental power coupler endgroup, end half cells, dumbbell, HOM endgroup, etc. are made. Special tools to help in dumbbell trimming and stiffening ring electron beam welding were designed and made. The amount of trimming on these components are determined per RF measurements. The 2-cell cavity is aimed to be finished in the Fall of 2013 and qualification tests will follow.

NOISE REDUCTION USING FILTERS ON TURN-BY-TURN LHC ORBITS TO OBTAIN MAGNETIC ERRORS WITH THE ACTION AND PHASE JUMP ANALYSIS METHOD

A.C. García B., J.F. Cardona, Universidad Nacional de Colombia*, Bogotá, Colombia

Abstract

The Action and Phase Jump analysis had been successfully used to obtain magnetic errors in RHIC. Analyses in LHC encountered significant noise. In this paper, a dual band-pass filter on LHC simulated orbits to reduce the noise is discussed. Gaussian and Uniform noise are studied independently. Results show that the best filter has a bandwidth of 0.0174 around the two transverse tunes. A low-pass band filter was also used to get the closed-orbit.

INTRODUCTION

The measurement of magnetic errors in an accelerator is an important task during the commissioning. One of the methods used to localize, to measure, and to correct magnetic errors is the Action and Phase Jump (APJ) Analysis. It is based on the theoretical principle of preservation of the Action and Phase variables in absence of a magnetic error. This method had been successfully tested in RHIC using closed-orbit data from experiments [1] and its theoretical development is fully presented in [2].

Preliminary analyses on turn-by-turn (TBT) orbits at the LHC show promising results [3, 4], but with a certain levels of noise than for the RHIC case, due to a bigger bandwidth of the LHC BPMs. Efforts to reduce the noise, like taking advantage of the thousands of turns provided by the LHC BPMs system (in contrast with the few orbits used in RHIC) have been done.

In this paper we discuss the use of pass-band digital filters to reduce noise in LHC TBT orbits; supplemented by an initial change of the PYTHON APJ code. A simulation of the beam trajectory, using MAD-X, is made for the thin LHC injection optics (V.6.5), where normal and skew linear quadrupole errors A_1 and B_1 were included, at the IR quadrupole MQXA.3L5 of beam 1.

Noise originated from the distribution of particles in the beam and noise originated from the misaligments of the BPMs are simulated using a Gaussian distribution and an Uniform distribution, respectively. The BPMs gain is also taking into account by using these distributions. This type of distributions had been used in noise studies for the closed-orbit measurement [5].

A BAND-PASS FILTER FOR THE LHC

The BPMs are the devices that provides measurements of the beam position in the transverse plane around the accelerator. For a fixed longitudinal position, the transverse position is sampled every turn leading to:

$$z(n) = \sqrt{2J_z\beta_{z,BPM}}\sin\left(\psi_{z,BPM} + 2\pi Q_z n - \delta_z\right) \quad (1)$$

where $z = \{x, y\}$ is the transverse plane coordinate, J_z is the Action, $\beta_{z,BPM}$ and $\psi_{z,BPM}$ are the beam β_z-function and phase advance at the BPM longitudinal position, δ_z is the Phase, and Q_z is the accelerator tune, at the transverse plane $z = \{x, y\}$. In this study, the data simulated with MAD-X on the acelerator LHC beam 1, is used to created new trajectories with simulated noise.In one case, the noise corresponds to a Gaussian distribution of $\sigma_{Gauss} = 0.1$ mm, which is added randomly to the each BPM data, and in the other case a Uniform distribution up to 0.3 mm is used. Then the resulting signal is filtered to evaluate wheter the filter help to reduce the uncertainty on the determination of magnetic errors using APJ method.

In this study, the filter was implemented using directly PYTHON functions, although trials were also made with own built transfer functions. From the available filters, the band-pass filter was chose, because it reduces the noise without damaging the magnetic error recovery. A second order filter is implemented, with Butterworth coefficients and the double run function [6].
