LHC OPERATION AT HIGHER ENERGY AND LUMINOSITY

G. Papotti, CERN, Geneva, Switzerland

Abstract

The Large Hadron Collider (LHC) at CERN (Geneva) was commissioned and operated in the years 2009-2013 up to a beam energy of 4 TeV. A peak luminosity of $0.77 \cdot 10^{34}\,\mathrm{cm}^{-2}\mathrm{s}^{-1}$ was reached and an integrated luminosity of around 29 fb^{-1} was delivered to both ATLAS and CMS. This performance allowed the discovery of a scalar boson. The LHC is presently in a shutdown phase dedicated to consolidation and maintenance that will allow the restart of beam operation in early 2015 at an increased beam energy of 6.5 to 7 TeV. Maximum acceptable pileup, effectiveness of electron-cloud scrubbing, and fast loss events are some of the issues that will shape the choice of operational parameters, cycle setup, and the commissioning strategy. The baseline choices and options for the restart after the shutdown are presented. In addition the roadmap for future performance upgrades is sketched.

INTRODUCTION

The Large Hadron Collider (LHC) at CERN is a 27 km long circular accelerator and collider based on superconducting two-in-one magnets and designed for a beam energy of 7 TeV [1]. It features 8 straight sections: 4 Interaction Points (IPs) are reserved for accelerator equipment and 4 house particle physics experiments. IP3 and 7 are dedicated to the collimation system, IP4 houses the RF system and most of the beam instrumentation, IP6 the beam dump system. IP1 and 5 contain ATLAS and CMS, the high luminosity experiments, while IP2 and 8 accommodate ALICE and LHCb, together with beam injection.

Initial commissioning with beam was re-started at the end of 2009, and first collisions at 3.5 TeV were achieved on 30 March 2010. The decision to limit the energy to 3.5 TeV was taken in order to reduce the risk of repeating events similar to the 2008 incident, when a highly resistive splice combined with a non-continuity in the copper stabilizer caused localized over-heating and an accidental release of the 600 MJ that were stored in the sector. After two years of successful running at 3.5 TeV with no accidental beam-induced quench at high energy, the decision was taken to run at 4 TeV per beam (in 2012 and 2013) until the start of the first Long Shutdown (LS1) during which the machine is being consolidated to run safely at 7 TeV.

The few weeks in 2009 and the year 2010 were dedicated to gaining the first operational experience. Initially, operation was with "pilot" bunch intensity (few 10^9 ppb), to commission the first squeeze. In June 2010 the bunch intensity was increased to "nominal" ($\approx 10^{11}$ ppb) and the summer was a period of steady running at $\approx$1 MJ to gain experience with intense beams and Machine Protection. In September the injection of bunch trains was commissioned (150 ns bunch spacing) and by mid-October the yearly target of an instantaneous luminosity of $10^{32}\,\mathrm{cm}^{-2}\mathrm{s}^{-1}$ was achieved.

Operation in 2011 started with 75 ns beams, and 50 ns beams were used only after a scrubbing run. With 50 ns beams, the number of bunches was slowly increased to 1380, then luminosity production was improved by reducing the transverse emittance, by squeezing further (from beta star 1.5 m to 1 m) and finally by gently increasing the bunch intensity. Squeezing to 0.6 m in 2012 allowed the production rates to increase even further and the year culminated with the discovery of the Higgs boson on 4 July 2012. The main machine and beam parameters are recalled in Table 1 for 2010-2012 and for the Design Report [1] for comparison. Operation with lead ions was also very successful [2, 3], but is not discussed here.

LONG SHUTDOWN 1

In the morning of 16 February 2013 the last LHC beam of run 1 was dumped and the LS1 started. The duration of the LS1 is planned to be approximately 20 months, and first beam is supposed to be back in the LHC in early 2015. This is to be compared to the winter shutdowns of 2010, 2011, 2012, that were as short as a couple of months and during which only fundamental maintenance was carried out.

The LS1 [4] firstly addresses the need to consolidate the interconnections between the LHC main magnets (soldered joints of two superconducting cables, splices, stabilized by a copper bus bar) to allow the LHC to operate at the nominal centre-of-mass energy of 14 TeV. It additionally targets consolidation activities to guarantee reliable operation of the LHC and its injectors until the next long shutdown (presently foreseen for 2018). Quality controls are performed on the splices and, in case of failure, the splices are remade. Consolidation activities include also the installation of shunts to improve electrical continuity and insulation boxes that provide mechanical restraints in addition to dielectric strength.

At the time of writing, the shutdown activities are progressing well. The consolidation activities spread across most of the machine, with hte interconnections being opened in sectors 12 and 23 being opened, the electrical

pile-up μ	8	17	38	26	120	44

quality of the old splices being tested in sector 81, shunts and insulation boxes being installed in sectors 67 and 78. The activities in sector 56, the first to be opened, are completed apart from few non-conformities, and the first vacuum leak tests gave positive results.

The activities have so far accumulated a delay of 3 weeks with respect to the initial schedule. This can be traced back to a few causes: a few technical issues (which are being solved), the summer vacation period and the consequent slow down of activities, and the fact that more splices than expected are to be redone (15% was expected, while 30% failed the quality tests so far, on 40% of the machine). A few bad surprises were also discovered, e.g. damaged bellows in the cryogenic system and in the electrical feed boxes, for which the repair is under study.

PREPARATION FOR RESTART

At the end of the shutdown activities a number of tests are performed on a sector by sector basis: electrical quality assurance tests are performed at room temperature, followed by flushing and cool down to cryogenic temperatures, further electrical quality tests and a full campaign of powering tests.

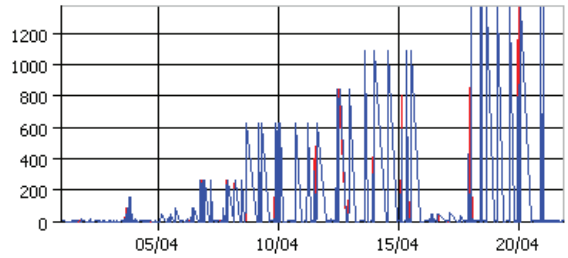
The hardware commissioning powering tests verify correct behaviour of the superconducting circuits and the associated protection systems, and are currently foreseen for the second half of 2014. All circuits but the main ones are tested up to the 7 TeV equivalent current values. Concerning the main circuits, the current baseline is to train them to 6.55 TeV (for which about 100 quenches are expected to be needed [5]), to allow to initially operate at 6.5 TeV beam energy.

In parallel to the powering campaigns, the other accelerator systems are also tested in "dry runs", so to verify the equipment control from the central control room (e.g. beam dump, RF, injection kickers, etc.). Also, in parallel to the end of the powering tests, a "sector test" with beam is foreseen for the end of 2014. It plans the injection of beam from point 8 to point 7 to the dump in point 6. It requires the readiness of sectors 67 and 78 and many other systems, and allows verifying system-wide integration and pre-commissioning many key procedures.

Finally, a global machine checkout takes place, in which the integration of all systems is verified, including interlocking functionality. The goal is to run the machine through the full cycle without beam.

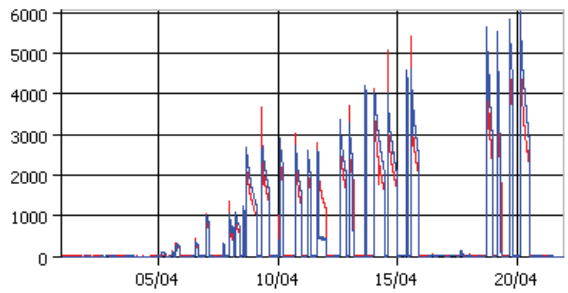
BEAM COMMISSIONING

The LHC commissioning with beam starts after a successful machine cold checkout. The breakdown of the beam commissioning into phases to build the nominal cycle is rather standard. Traditionally, the first injections are used to "thread" the beam around the machine: with the smallest intensity detectable by the beam position monitors, the trajectory is corrected one sector at a time, and the beam stopped on collimators. When a closed orbit is established, the setup of the RF system can start, allowing to capture the beam. Injection of a bunch of nominal intensity is used to record a flat orbit reference and setup primary collimators, beam instrumentation, transverse damper, etc.



The first energy ramp and beta star squeeze require the commissioning of orbit, tune and radial feedback, then optic measurements and corrections are also performed. Then, crossing and separation bumps are added throughout the cycle, allowing further measurements of aperture and beta star. Finally, collisions are established in all interaction points and RF cogging is performed to align the collision in the center of the experiments. Note that the protection by the collimators is verified by performing controlled tests of losses at injection, flat top, after squeeze and in collisions.

A total of about 2 months in the beginning of 2015 is required for completing these steps, including testing thoroughly all machine protection systems. While in this initial phase everything is performed with at most 2-3 nominal bunches in the machine, the injection of many bunches at a time (bunch trains) and the increase of intensity in the machine is performed in steps, i.e. "intensity ramp-up".



Intensity Ramp-up

The intensity increase from few nominal bunches to a full machine is staged in steps. Some fills with limited number of bunches allow verification of the nominal cy-

(a) Number of bunches per fill in April 2012.

(b) Luminosity per fill in April 2012 [10^{30} cm^{-2}s^{-1}].

Figure 1: Intensity ramp-up in April 2012.

cle and the procedures, e.g. scaling of losses. Fills with more bunches allow approaching intensity (or luminosity) related problems slowly, e.g. effects on vacuum or heating of machine components. This procedure took about one month in April 2012 and it was divided in 7 steps: 2-3 fills and 4-6 hours each with 48, 84, 264 and 624 bunches for cycle validation, and 3 fills for a total of at least 20 hours with 840, 1092, 1380 bunches for intensity-related problems. The resulting number of bunches and luminosity are shown in Figure 1.

For the restart in 2015, the uncertainty on the duration of the intensity ramp-up is dominated by the effectiveness of electron-cloud scrubbing.

OPEN QUESTIONS

Three effects that are expected to shape beam commissioning in 2015 are recalled next: electron cloud effects and their scrubbing, the so-called Unidentified Falling Objects (UFOs) and beam stability. Additionally the issue of radiation effects on electronic components is included.

Electron-cloud and Scrubbing

The operation of an accelerator with closely spaced proton bunches can give rise to local accumulations of electrons inside the vacuum chamber depending on beam structure and properties of the chamber (e.g. the Secondary Electron Yield, SEY). In particular if the SEY is higher than a threshold value, an avalanche effect can take place and cause vacuum pressure rise, increased heat load on the cryogenic system, increased beam emittance, and single and multi bunch instabilities.

Electron cloud effects were observed in the LHC as soon as bunch trains were injected, with 150, 75, 50 and 25 ns bunch spacing. Scrubbing runs took place in 2011 and 2012 as dedicated periods during which the electron cloud generation is enhanced so to "clean" the vacuum chamber walls, and thus decrease the SEY and effectively improve beam quality for physics operation. Additionally, Machine Development time was allocated for electron cloud studies for 25 ns beams. In particular, in December 2012, a short run was dedicated to study 25 ns beams to assess the evolution of the SEY and other possible differences compared to 50 ns beams [6]. After an initial improvement of heat load and beam lifetime, a sharp slow down of the scrubbing process was observed in the studies at 450 GeV (see Figure 2). This lead to the conclusion that, at restart in 2015, at least one week of scrubbing will be required for 50 ns running, an additional week for 25 ns running, and that coexistence with electron cloud will be probably inevitable in the first part of the physics run (so that physics will be performed with degraded beam parameters). The understanding of the observations and underlying physical phenomena is progressing well at the moment of writing, and this could impact positively on the above statements.

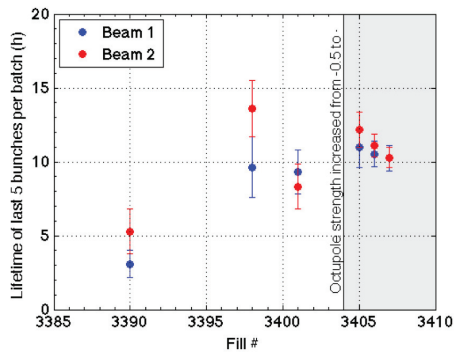

Figure 2: Single beam lifetime during the December 2012 scrubbing run.

Unidentified Falling Objects

UFOs are micrometer size dust particles that, when interacting with the beam, produce fast beam losses (approximate duration of about 10 turns). Such events were observed since 2010 and caused a non negligible number of beam aborts (about 5% of the total number of dumps above injection energy, or ≈20 dumps/year).

The occurrence of such events has been thoroughly studied [7]. There is evidence for a "scrubbing" effect over the course of 2011 and 2012, e.g. the rates in 2011 decreased from 10 to 2 events/hour. There is also evidence for deconditioning after periods without beam as technical stops, e.g. an increase of a factor 2.5 after the 2011-12 winter stop. Because of this, an increase in rates is expected after LS1. Additionally, during the 25 ns studies, UFO rates increased by a factor 10 at 4 TeV. This, combined with the

Copyright © 2013 CC-BY-3.0 and by the respective authors

energy dependence of UFOs, indicate that they might be a major source of beam dumps (extrapolations indicate over 100 dumps per year). In a very pessimistic scenario they might impose to start with 50 ns beams, or at a lower beam energy.

Beam Stability

Many instabilities were observed during run 1, in all phases of the operational cycle, and many different countermeasures have been deployed to cure them (see for example [8]). Transverse instabilities caused emittance blow up at injection (2010 and 2011) and were cured by increasing the octupole strength for increased Landau damping. "Dancing bunches" (longitudinal dipolar and quadrupolar motion) are observed at high energy for low longitudinal emittance, and are cured by controlled emittance blow up by phase noise since 2010. Lack of Landau damping was also observed in 2012 for beams colliding only in LHCb, and was solved by changing the filling scheme to have additional collisions in ATLAS and CMS for these bunches so to increase the tune spread by the beam-beam interaction. A transverse instability was reproducibly observed at the end of squeeze in 2012 and caused mostly emittance increase: it was not fully understood, but it could be mitigated by high chromaticity and high transverse damper gain.

Beam instabilities are expected also at 6.5-7 TeV and will shape many operational choices. The option to collide the beam already during the squeeze is being considered to profit from Landau damping by head-on beam-beam force. The amount of opening of collimator jaws is still under discussion as it compromises between cleaning efficiency and machine impedance. The high setting of chromaticity and transverse gain will be kept if needed, the efficiency of the octupoles might be limited by the available hardware current and the small emittance.

Radiation to Electronics

The Radiation To Electronics project (R2E) aims at limiting the Single Event Effects so to reduce the R2E induced beam dumps and the impact on machine availability [9]. A thorough analysis allows identifying which beam dumps are likely to be caused by radiation effects, correlate them with radiation levels in the tunnel and integrated luminosity. The systems that were the most sensitive in 2012 operation were the Quench Protection System and an auxiliary power supply of 600 A Power Converters, followed by cryogenics and vacuum equipment.

R2E mitigation actions consist of equipment relocation from critical to safer areas or addition of shielding to reduce the exposure to radiation, and equipment upgrades or redesign to improve radiation hardness. These measures already improved the number of dumps from 12 dumps/fb^{-1} in 2011 to 3 in 2012, and a major campaign during the LS1 aims at reducing the rate further to 0.5 dumps/fb^{-1}.

EXPECTED PEAK PERFORMANCE

The main machine and beam parameters for 2015 operation are shown in Table 1. With a baseline beta star of 40 cm, peak luminosities of 1.5 to 2 $\cdot$ 10^{34} are within reach with 25 ns and 50 ns beams. The excessive pile-up that characterizes the 50 ns beams makes 25 ns the preferred choice for having cleaner physics events. Electron cloud scrubbing might be slow or impose initial physics operation with degraded beam parameters, but would be an investment until LS2 (2018).

Conversely, 50 ns beams are the fallback plan in case in of insurmountable problems with 25 ns beams, e.g. electron cloud or UFOs. The higher brightness that can be provided by the LHC injectors for the 50 ns beams allows achieving higher luminosity with less stored energy in the machine, but would impose the need for luminosity leveling at ATLAS and CMS.

UPGRADES

The present LHC will reach the end of its usefulness in the early 2020s, when the running time necessary to halve the statistical error in the measurements will be more than 10 years, making a substantial increase in luminosity necessary to maintain scientific progress. At the same time, the triplet and cleaning insertion magnets will reach the end of their lifetime due to radiation, and the limit of cooling and cryogenics systems will be reached (at $\approx$ 1.75 $\cdot$ 10^{34} cm^{-2}s^{-1}. A novel machine configuration, called High Luminosity LHC (HL-LHC), will be installed during the LS3 to overcome these limitations.

High Luminosity LHC

The High Luminosity LHC (HL-LHC, [10]) is an approved project aiming at obtaining 3000 fb^{-1} within ten-twelve years of operation. This translates to the goal of an integrated luminosity of 250 fb^{-1} per year, i.e. about ten times the present LHC, which can achieved with peak luminosities of 5 $\cdot$ 10^{34} cm^{-2}s^{-1} , leveled down from higher, "virtual" luminosities.

These specifications require a number of equipment upgrades. Large aperture magnets are needed for the IP quadrupoles to accommodate for very low beta star. Crab cavities are also needed to profit from the small beta star despite the large crossing angle. Additional dispersion suppressor collimators remove cleaning bottlenecks, but require the use of high field dipoles to free up space longitudinally to allow their installation. Additional cryogenics plants for P1, P4, P5 will provide the same cooling power in all arcs. The use of new, super-conducting links (300-700 m long) allow power converters to be moved to surface, effectively reducing radiation-induced risks and increase availability (critical aspect when working with leveled luminosities). Additionally, an upgrade of the LHC Injector Chain is foreseen that will help both beam brightness and

Copyright © 2013 CC-BY-3.0 and by the respective authors

availability, and an upgrade of the high-luminosity experiments will allow them to cope with higher pile-up density (i.e. 140 events per crossing).

Options for the Farther Future

The HL-LHC will also reach the end of its lifetime after 10-12 years of operation, i.e. in the mid-2030's. For the LHC, the lead time was about 25 years, so that similarly the design phase of a new accelerator should start now for it to be operational few years after the end of HL-LHC. A number of new designs are being studied at present at CERN, to take advantage of the existing accelerator complex and infrastructure.

Studies aiming at very high field magnets (16-20 Tesla) are ongoing [11], and would allow a High Energy LHC [12] to be installed in the LHC tunnel, that could reach center of mass energies of 26-33 TeV. With similar, high field magnets, and a tunnel with larger circumference (84-104 km), a Very High Energy LHC could be installed with center of mass energies of 100 TeV (see for example [13]).

Similarly to the LEP/LHC experience, where the same tunnel was reused for two different machines, lepton-proton collisions could be explored in the LHC tunnel with LHeC [14], or e+e- in the 84-104 km tunnel with TLEP [15.

CONCLUSIONS

The LHC is presently in a shutdown phase and operation with beam resume in early 2015 at a higher beam energy, the present baseline is 6.5 TeV. The use of 25 ns beams is imposed by the need to limit the pile-up and provide clean physics events to the experiments, but might bring other important issues along, as degraded beam parameters due to electron cloud effects or impaired machine availability due to excessive UFO rates. Work is already ongoing to prepare the High Luminosity upgrade of the LHC, that is supposed to start operating in about 10 years, and studies are taking place to devise what the next circular accelerator might look like.

THE CLIC PROJECT - STATUS AND PROSPECTS*

E. Adli†, University of Oslo, Norway
On behalf of the CLIC/CTF3 collaboration

Abstract

Following the feasibility demonstration of the novel CLIC technology and the publication in 2012 of a CLIC Conceptual Design Report for a Multi-TeV Linear Collider to be built in stages, a new phase towards a technical design is being launched by a global collaboration of volunteer institutes. This paper reviews the status and plans of the CLIC study outlining the developments planned for the next project phase.

INTRODUCTION

The CLIC project is a study for a Multi-TeV e+ e- collider based on normal-conducting X band technology, and a Two-Beam Acceleration scheme in order to provide compressed rf pulses for the main accelerating structures with high efficiency. The compressed rf pulses allow the main charge to be accelerated at a very high loaded gradient of 100 MV/m, in short pulses of 156 ns. CLIC completed the CDR in 2012 [1] and the project is currently in a project preparation phase where further optimization, system tests and detailed design of the machine will take place. In addition, the CLIC project has started collaborations for the use of CLIC X band technology in compact free electron lasers and medical applications.

The CLIC project is linked to the European Strategy Particle Physics priorities related to the Energy Frontier. The LHC may discover Beyond Standard Model physics when operation starts at full energy in 2015, and, depending on the findings, higher-energy hadrons as part of LHC energy upgrades or a high energy e+ e- collider might be the best option to access the new physics. The CLIC work in this period is also integrated under the Linear Collider collaboration, where the ILC technology provides an option for an early exploration of the Higgs sector in particular, while CLIC remains the only option for a Multi-TeV e+ e- collider. Wherever possible, shared activities for ILC and CLIC are being coordinated.

This paper will discuss the main conclusions of the Conceptual Design Report and highlight key activities foreseen in the project period from 2012 to 2018, which we will refer to as the "next period".

CONCEPTUAL DESIGN REPORT

The CLIC conceptual design report (CDR) was completed in 2012, and documents a proof of principle of all aspects related to the Two-Beam Acceleration scheme, both by comprehensive simulation studies of all parts of the machine and by a detailed experimental program in the CLIC

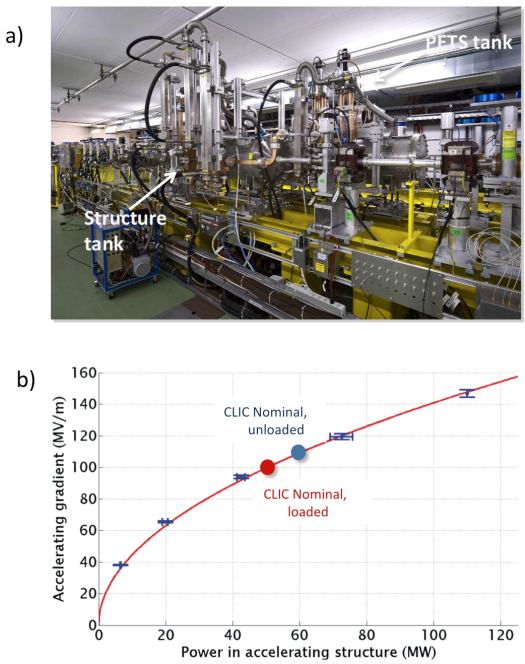

Figure 1: a) The Two-Beam Test Stand at the CLIC Test Facility. b) Experimental results of two-beam acceleration, up to and beyond the nominal CLIC gradient.

Test Facility 3 at CERN [2]. Figure 1 shows a) the CLIC Test Facility Two-Beam Test Stand and b) data points for the achieved two-beam accelerating gradient as function of input power to the X band accelerating structure. Drive beam generation has been verified and the achieved gradient is up to and beyond the CLIC target of 100 MV/m. Furthermore, ongoing rf based tests of the main linac structure gradient are close to or on target for all parameters (gradient, pulse length and breakdown rate), and Figure 2 shows a summary of the latest results. Uncertainty from beam loading will be tested in the current next period. Studies of the deceleration versus power production shows good consistency [3]. Concerning emittance generation, the CLIC damping ring has similar specification to an ambitious light source, and no show stoppers were identified for generation of the ultra low emittances. Concerning emittance preservation, the alignment system principle has been demonstrated, the stabilization system have been developed and benchmarked and integrated simulations of emittance preservation in the main linac meet or exceed the luminosity targets.

STAGING AND OPTIMIZATION

The Two-Beam Acceleration scheme is particularly suited for energy staging of the machine; once the drive

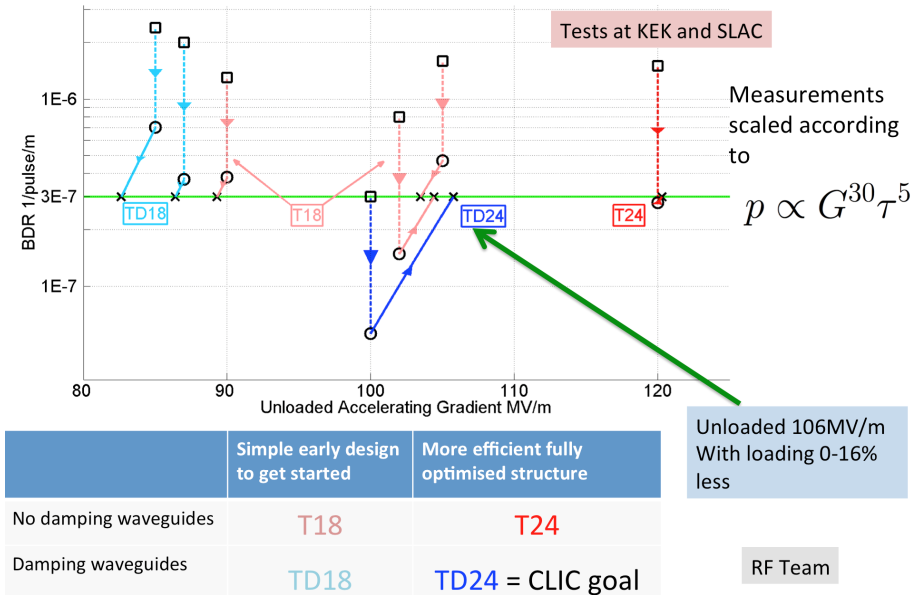

Figure 2: Structure test results, where gradients are scaled to the CLIC allowed breakdown rate of 3×10^{-7}. A fully optimized CLIC structure with damping waveguides have recently reached an unloaded gradient of 106 MV/m.

beam complex is constructed, rf power for additional lengths of the main linac can be provided simply by increasing the drive beam length in the drive beam accelerator. No upgrades are needed for the drive beam complex, and once the drive beam complex has been constructed, the addition cost per GeV of center of mass energy is favorable to klystron based alternatives. Furthermore, lower energy machines can run most of the time during the construction of the next stage. A consistent three stage implementation scenario has been defined. Schedules, cost and power are being developed, although the energies of the individual stages will be determined by LHC physics results. The minimum center of mass energy being considered is about 375 GeV, which will allow precision studies of the Higgs and the Top quark. Figure 3 illustrates an example of the various stages of a CLIC machine.

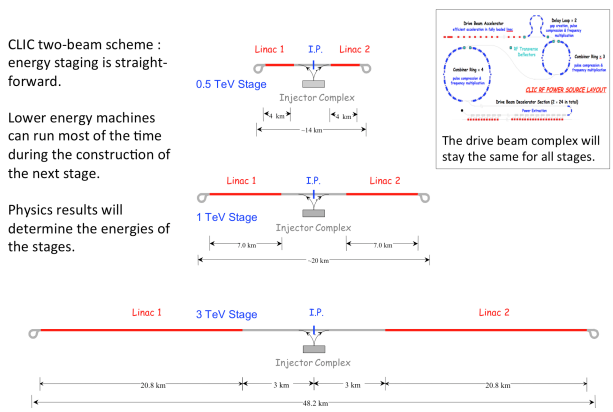

Figure 3: Example of CLIC energy stages. The center of mass energy can be increased without modifications to the drive beam accelerator complex. The actual energy of each stage will be guided by LHC physics results.

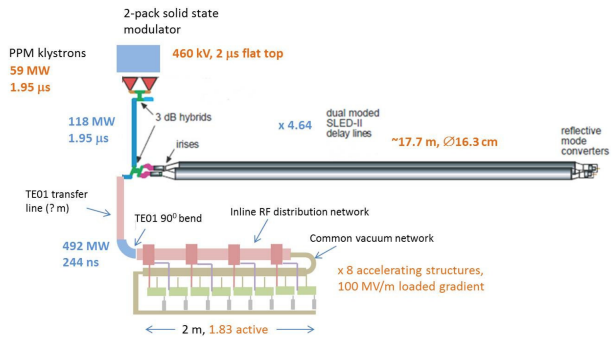

Figure 4: A rf unit for a klystron based CLIC. Two 60 MW klystrons can power 8 CLIC accelerating structures at a gradient of 100 MV/m.

The CLIC machine is currently being re-optimized for the lowest energy stage (375 GeV). The optimization includes overall design and system optimization, technical parameters for all systems, cost, power/energy optimization, scheduling and site studies. Examples of areas which can give increased machine power efficiency are the use of permanent magnets for the drive beam, and studies of high-efficiency L-band multi-beam klystrons for the drive beam acceleration. The goal is to push the tube efficiency towards 80%, and increase the drive beam klystron power output.

As part of the preparation for an optimal implementation strategy, a 500 GeV CLIC where the main linac are powered by klystrons (as opposed to a drive beam) has been studied in detail [4]. 4,400 klystrons would be required for a 500 GeV machine and a simple cost study indicated a comparable cost as for a drive beam-based CLIC linac. The luminosity is comparable to that of the drive-beam based design. The pulse length is the same as for the drive-beam

Copyright © 2013 CC-BY-3.0 and by the respective authors

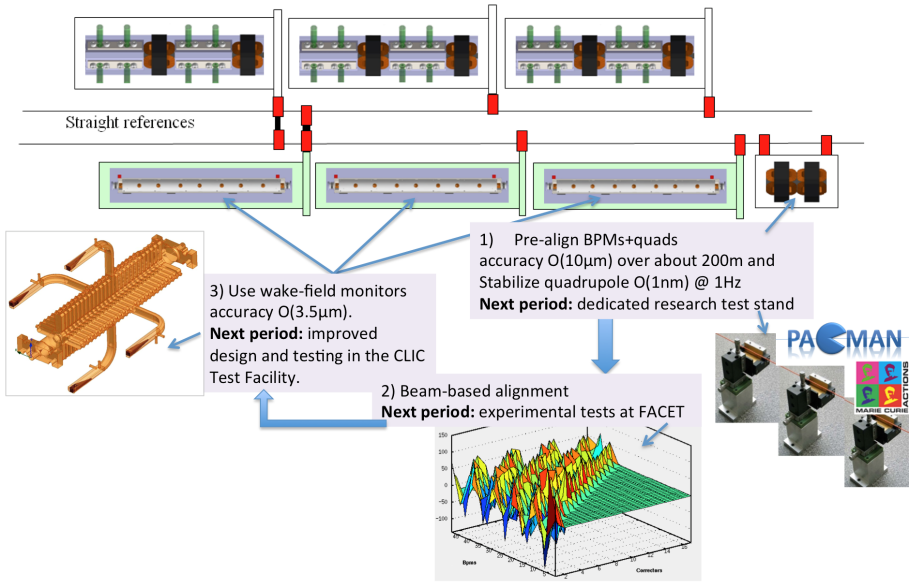

Figure 5: Three areas where main alignment and stabilization will be further studied in the next period: 1) development of an automatic alignment and stabilization test stand, 2) experimental tests of beam-based alignment at FACET, 3) experimental tests of wakefield monitors.

design. The drive beam design has the advantage of a comparably lower cost per additional GeV. Figure 4 shows one rf unit for a klystron-based CLIC, where a compressed rf pulse from two 60 MW klystrons powers 8 CLIC accelerating structures.

LUMINOSITY AND ALIGNMENT

In order to reach the target luminosity of 10^{34} $/\mathrm{cm}^2/\mathrm{s}$ CLIC requires a normalized vertical emittance of 20 nm at the interaction point, and a maximum emittance growth of 10 nm in the main linacs. Robust emittance preservation in the main linac is foreseen to be achieved using beam-based alignment and integrating wakefield monitors on the structures. In the next period, the two topics will be addressed experimentally. The 2 km FACET linac test facility at SLAC [5] now provides a unique opportunity to test beam-based alignment for linear colliders experimentally, and a proof of principle of the dispersion free correction algorithm as planned for CLIC has recently been experimentally demonstrated [6]. The experiments have shown that an automatic global correction scheme can successfully control the dispersion and reduce the emittance over 500 m of linac. Wakefield monitors are currently being developed, with the aim of providing the required resolution of 3.5 um with a robust and economical design. The monitors will be tested in CTF3 to ensure that the target precision can be reached [7]. Figure 5 illustrates the CLIC alignment techniques and some of the developments foreseen in the next period.

In addition, the machine components in the main linac and the beam delivery system must be pre-aligned at a 10 um level, and the final doublet quadrupoles must be stabilized to a sub nm level. Proof of principles of both pre-alignment and stabilization has been demonstrated with the CDR, and in the next period a sizable research project funding ten PhD student grants, "PACMAN", has been approved [8]. The technical goal of the program is to develop very high accuracy metrology and alignment tools and integrate them in a single automatic alignment test stand.

CLIC TEST FACILITY

The CLIC Test Facility 3 (CTF3) has demonstrated drive beam generation and two-beam acceleration in the CDR period. CTF3 is planned to be operated up to the end of 2016 to address further system tests and perform more detailed studies. The facility has recently demonstrated drive beam combination by a factor four with the nominal emittance of 150 um in both planes, and the current stability of the drive beam has earlier been demonstrated to better than the CLIC requirements of $\Delta I/I = 7.5 \times 10^{-4}$ [9]. The final step of a full demonstration of the CTF3 drive beam generation is stable factor 8 combination. The progress has been impeded the last year by technical problems with the traveling wave tubes required for the sub-harmonic bunching, required for delay loop operation. A fast phase feedforward system has been designed to correct the drive beam phase profile and jitter, with the aim of demonstrating the CLIC drive beam phase requirements [10]; the first kickers and amplifiers are to be installed in 2013. As a prototype of a CLIC injector, a 1 GHz klystron test stand to test a drive beam accelerating structure at full power is planned, including a gun and a sub-harmonic buncher [11].

In the two-beam test stand, new structures will be conditioned with drive beam rf and the breakdown rates measured. Kicks imparted to the beam during breakdown events will be measured and characterized, and the precision of the CLIC wakefield monitors will be measured. A dogleg halfway down the linac allows the drive beam to

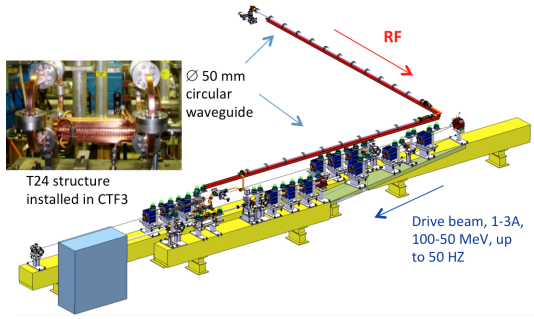

Figure 6: A new beam loading test facility: a 1 A CTF3 beam and X-band rf power will be simultaneously delivered to an accelerating structure.

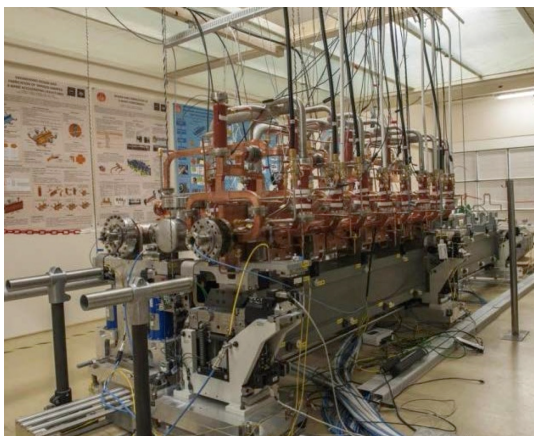

Figure 7: The first prototype of the CLIC two-beam module has been completed, and is undergoing thermo-mechanical validation.

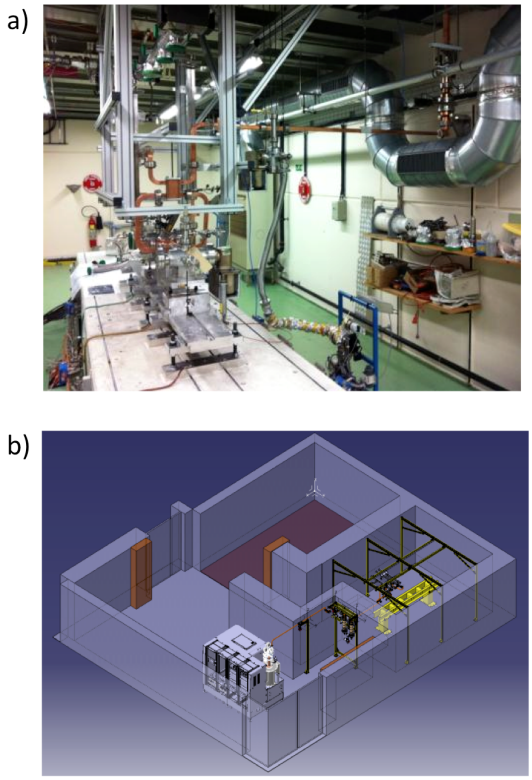

Figure 8: a) a new X-Band test facility, with a SLAC-provided 12 GHz klystron. b) Planned X-Band test facilities will include commercially acquired tubes from CPI and Toshiba. In total these facilities will provide X-band power for testing up to 8 accelerating structures simultaneously.

be directed to a test accelerating structure. Using this to deliver a 1 A beam from the linac, simultaneously as it is filled with the nominal X-band rf power [12], breakdown rates in the accelerating structure can be tested with beam loading and compared to operation without beam loading. Figure 6 shows the sketch of the planned beam loading test facility.

Finally, full prototypes of the CLIC two-beam modules are being constructed and tested [13]. Two modules will be build for laboratory system integration tests and thermo-mechanical validation. Figure 7 shows a picture of the first of the laboratory modules, completed and installed at CERN. The first tests results are promising and in line with simulations [14]. A similar two-beam module is currently under fabrication for installation in CTF3, fully equipped with X-band structures and components. The power extraction structures will provide the nominal power for the accelerating structures, thus giving a complete system test of a full CLIC main linac module with rf and beams.

X-BAND TECHNOLOGY

In the coming project period, the CLIC project will see a significant increase in X-band structure test capacity. One 12 GHz klystron based X-band test stand ("XBOX 1") has been operating at CERN for a year [12], allowing 12 GHz structure to be tested at 50 Hz. This test stand uses a scaled version of the XL4 klystron tube developed for the NLC, provided by SLAC. With the use of a SLED1-type pulse compressor output power of up to 100 MW can be provided in pulses of 250 ns, sufficient to power two CLIC accelerating structures at nominal power and pulse length. A second test area ("XBOX2") is under construction and planned to be commissioned by end 2014. A SLAC XL5-type tube will be commercially procured from CPI, and will provide XBOX2 similar capabilities as XBOX1. A cluster of four 6 MW tubes from Toshiba ("XBOX3") is planned to be commissioned by the end of 2015 and will give additional test capabilities. In total we estimate that more than 40 accelerating structures will be tested in these facilities by 2017. Figure 8 shows the XBOX test facilities.

The basic high gradient structure research will continue in the next period, including further development of the understanding of rf breakdown from first principles by theoretical studies, and multi-scale simulation studies. Modeling and simulations efforts for understanding the formation of vacuum arcs in breakdowns are being pursued [15], and the simulation results will be benchmarked against experiments at the DC spark test stand at CERN [16].

Two CLIC X-band technology application projects have recently been started. The first is use of CLIC X-band structures for compact FELs in the few GeV range. An

Copyright © 2013 CC-BY-3.0 and by the respective authors

early collaboration with Turkey has been followed by a recent initiative where countries or institutes can collaborate with CLIC on common CDR work for a FEL based on CLIC X-band technology [17]. Institutes from 5 different countries have already shown interest. Example parameters for an X-band FEL are an electron energy of 6 GeV and a charge of 250 pC, as proposed in [18], however, different institutes could pick different parameters. Collaborators may profit from the planned X-band test facilities at CERN, thus reducing the risk of starting a new project. For CLIC, development and eventually operation of GeV level e- linacs with high gradient X-band structures will provide an increased technology maturity for the X-band technology. A second project studies the potential for technology transfer of CLIC high-gradient research to 3 GHz high gradient structures for proton therapy, where a main goal is to increase the effective gradient in proton therapy linac structures to about 50 MV/m (a factor of two with respect to the state of the art).

CONCLUSIONS

The CLIC project has demonstrated the two-beam acceleration proof of principle, documented in the comprehensive Conceptual Design Report completed in 2012. In the next period up to 2018, the CLIC study will continue a number of technical studies on power and cost optimization, system tests including full CLIC module tests with rf and beam and experimental verifications of methods to preserve nm emittances. New X-band test facilities are being constructed and will greatly increase the capacity for 12 GHz rf testing. Finally, projects for the use of CLIC X-band technology in high-gradient FELs and CLIC high-gradient research technology transfer have been initiated with a potential outcome of increased technology maturity of a linear collider X-band technology.

ACKNOWLEDGMENTS

This paper is written based on input from the entire CLIC collaboration. In particular we acknowledge in-depth discussions with Walter Wuensch, Daniel Schulte, Igor Syratchev and Steinar Stapnes. This work is supported by the Research Council of Norway.

COLLIDERS – "QUO VADIS?" : PAST 20 YEARS, NEXT 20 YEARS, AND BEYOND*

V.Shiltsev#, Fermilab, Batavia, IL 60510, USA

Abstract

Particle colliders for high-energy physics have been in the forefront of scientific discoveries for more than half a century. The accelerator technology of the colliders has progressed immensely, while the beam energy, luminosity, facility size, and cost have grown by several orders of magnitude. The method of colliding beams has not fully exhausted its potential but has slowed down considerably in its progress. This paper briefly reviews the colliding beam method and the history of colliders, discusses the development of the method over the last two decades in detail, and examines near-term collider projects that are currently under development. The paper concludes with an attempt to look beyond the current horizon and to find what paradigm changes are necessary for breakthroughs in the field.

PAST AND PRESENT COLLIDERS

It is estimated that in the post-1938 era, accelerator science has influenced almost 1/3 of physicists and physics studies and on average contributed to physics Nobel Prize-winning research every 2.9 years [1]. Colliding beam facilities which produce high-energy collisions (interactions) between particles of approximately oppositely directed beams did pave the way for progress since the 1960's. Discussion in this section mainly follows recent publication [2].

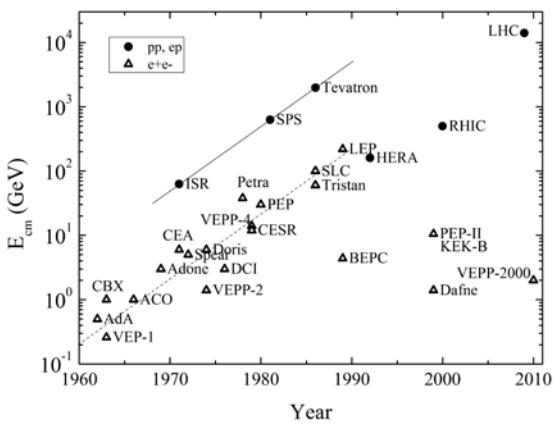

Figure 1: Colliders over the decades (after [2]).

Twenty nine colliders reached operational stage between the late 50's and now. The energy of colliders has been increasing over the years as demonstrated in Fig. 1. There, the triangles represent maximum CM energy and the start of operation for lepton (usually, *e+e-*) colliders and full circles are for hadron (protons, antiprotons, ions, proton-electron) colliders. One can see that until the early 1990's, the CM energy on average increased by a factor of 10 every decade and, notably, the hadron colliders were 10-20 times more powerful. Since then, following the demands of high energy physics, the paths of the colliders diverged to reach record high energies in the particle reaction. The Large Hadron Collider (LHC) was built at CERN, while new *e+e-* colliders called "particle factories" were focused on detail exploration of phenomena at much lower energies. Over the last 50 years, the luminosity of the colliders has improved by more than 6 orders of magnitude and reached record high values of over 10^{34}cm^{-2}s^{-1}. At such luminosity, one can expect to produce, e.g., 100 events over one year of operation (about 10^7 s) if the reaction cross section is 1 picobarn (pb)=10^{-39} cm^2.

Table 1: Past, Present and Possible Future Colliders; hadron colliders are in **bold**, lepton colliders in *Italic*, facilities under construction or in decisive design and planning stage are listed in parenthesis (…)

	early 1990's	early 2010's	2030's
Europe	**HERA, (LHC)** *LEP (Dafne)*	**LHC** (*Super-B,* **HL-LHC, LHeC,** *ENC*)	**HE-LHE** *CLIC?*
Russia	*VEPP2, VEPP4* (**UNK**, *VLEPP*)	*VEPP2000, VEPP-4M* (**NICA**, *Tau-C*)	**NICA** ? *Higgs Factory* ?
US	**Tevatron**, (**SSC**) *SLC, CESR,*(*PEPII*)	**RHIC** (*e***RHIC**, *ELIC*)	*Muon Collider* ? *PWLA/DLA* ?
Asia	*Tristan, BEPC* (*KEK-B*)	*BEPC* (*Super-KEKB*)	*ILC* ? *Higgs Factory* ?
Total	9 (7)	5 (9)	1 + ?

At the same time, the number of the facilities in operation has dropped from 9 to 5, as indicated in Table 1 which lists all operational colliders as of the early 1990's and now (early 2010's) and accounts for the projects under construction or under serious consideration at this time (in parenthesis).

NEXT TWO DECADES

There are several colliders currently under construction or at the design stage and which, therefore, have good prospects of becoming operational and deliver results in the next 20 years. Schematically they can be categorized by as follows:

Energy Frontier: the LHC luminosity upgrade project HL-LHC [3] to quintuple the performance of the energy frontier machine by mid-2020's to $5\cdot10^{34}$cm^{-2}s^{-1} with luminosity leveling at 14 TeV c.m. energy in proton-

proton collisions; the LHC energy upgrade to ~33 TeV cme will require development 20T dipoles [4].

Low-Energy Hadron Collders: like, e.g., Nuclotron-based Ion Collider fAcility (NICA) currently under construction at JINR (Dubna, Russia) [5] which will allow for the study of ion-ion (Au^{+79}) and ion-proton collisions in the energy range of 1-4.5 GeV/amu with average luminosity of 10^{27} cm^{-2} s^{-1} and also polarized proton-proton (5-12.6 GeV) and deuteron-deuteron (2-5.8 GeV/amu) collisions.

Electron-Hadron Colliders: such as LHeC [6], in which polarized electrons of 60 GeV to possibly 140 GeV collide with LHC protons of 7000 GeV with design luminosity of about 10^{33} cm^{-2}s^{-1}; eRHIC at BNL (polarized nuclear beam to 100 GeV/nucleon and polarized protons upto 250 GeV colliding with 20-30 GeV ERL-accelerated polarized electrons, the luminosity varies from 10^{33} cm^{-2}s^{-1} to 10^{34} cm^{-2}s^{-1}) [7] and Electron-Ion Collider (ELIC) at JLab (30-7 GeV polarized electrons and 30 to 150 GeV storage ring for ions, high luminosities of ~$5\cdot10^{33}$ cm^{-2}s^{-1} to 10^{35} cm^{-2}s^{-1} require continuous electron cooling) [8]; and electron-nucleon collider ENC at FAIR (GSI, Darmstadt, Germany) utilizing the 15 GeV antiproton high-energy storage ring HESR for polarized *p* and *d* beams, with the addition of a polarized *e*- 3.3 GeV storage ring with peak luminosities in the range of 10^{32} to 10^{33}cm^{-2}s^{-1} [9].

Electron-Positron Factories: such as asymmetric $e+e-$ Super-B factory in KEK [10] with beam energies of about 4 GeV and 7 GeV and with a design luminosity approaching 10^{36} cm^{-2} s^{-1}; and Tau-Charm factory in Novosibirsk [11] which calls for c.m. collision energy variable from 3 GeV to 4.5 GeV (from J/psi resonances to charm barions) and luminosity in excess of 10^{35} cm^{-2} s^{-1}.

Higgs Factories: *e+e-* coliders with an optimal $E_{cm} \sim m_H$ + (110±10) GeV ~250 GeV can be either ring-based as, e.g., TLEP [12] or be based on the ILC-type linear collider [13]; their issues and challenges are discussed in [14]. A possible alternative can be a $\mu+\mu-$ collider with factor of two lower c.m. energy $E_{cm}\sim m_H$ which would have advantageously large cross section some $(m_\mu/m_e)^2\sim$40,000 times higher than for *e+e-*, and significantly smaller c.m.e. spread $\delta E_{cm}/E_{cm}\sim$ 0.01-0.003% (compared to ~0.2% for the *e+e-* factories) [15].

Energy Frontier Lepton Colliders: if - as presently believed - a multi-TeV lepton collider will be needed to follow the LHC discoveries, then the most viable options currently under consideration are e+e− linear colliders ILC and CLIC [16] or μ+μ− Muon Collider [15] – see Table 2. Each of these options has its own advantages and issues [17].

FAR FUTURE COLLIDERS

The forecast on the far future of colliders beyond, say, the 2030's, will require several things: understanding of the available resources, the desired science reach, and on the possibilities. As of today, the world's particle physics research budget is some 3B$. Assuming that it will not change by much in the future (in todays' dollars) and that not more than 1/3 of the budget can be dedicated to construction of the next energy frontier collider, one can estimate the cost of an affordable future facility to be about or less then 10B$ (in current prices). Other desired features of such flagship could be: it ideally should not exceed 10 or few 10's of km in length, it should stay under *O*(100MW) of AC wall power consumption, and, of course, it would be great if its energy reach significantly (> ×10) exceeds that of the LHC.

Table 2: Comparison of Lepton Collider Alternatives

	ILC	CLIC	MC
c.m.e., TeV	0.5	3	1.5-4
dE/E, rms	~2%	>5%	~0.1%
L, cm^{-2}s^{-1}	$2\cdot10^{34}$	$2\cdot10^{34}$ *	$(1\text{-}4)\cdot10^{34}$
Feasibility	2007	2012	~2016
Techn.design	2013	2016	~2020
# elements	38,000	260,000	10,000
Σ length, km	36	~60	14-20
AC pwr,MW	230	580	~170-220

*peak luminosity within 1% c.m. energy spread

The cost estimates of the modern colliders are quite complicated, but an attempt to analyse known costs of 15 large accelerators (SSC, RHIC, VLHC, ILC, B-Factories, FNAL MI, NLC, SNS, LHC, XFEL, FAIR, ESS, CLIC, SPL, NuFactory) has resulted in a phenomenological cost model [18] that matches the actual costs (in terms of *TPC*, the Total Project Cost, widely used in the US DOE accounting) within approximately ±30% :

$$TPC = \alpha\left(\frac{L}{10km}\right)^{1/2} + \beta\left(\frac{E}{1TeV}\right)^{1/2} + \gamma\left(\frac{P}{100MW}\right)^{1/2}$$

where, *L* is the total length of the tunnel, *E* is cm energy, *P* is total site AC power for the facility; and technology dependent coefficients are α=2B$, β=1B$ for NC magnets, 3B$ for SC magnets, and ≈10B$ for NC/SC RF, γ=2B$ - see Fig.2.

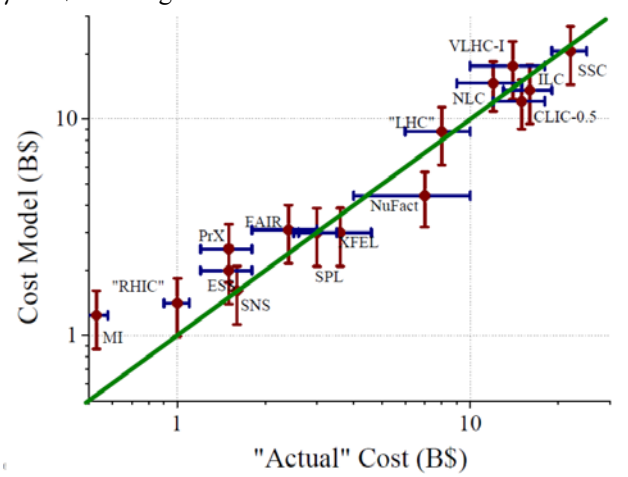

Figure 2: Phenomenological cost model vs actual cost for large accelerator facilities.

Copyright © 2013 CC-BY-3.0 and by the respective authors

The model predicts that if currently available technologies are employed, then only Higgs factories or a few-TeV Muon Collider can potentially meet the desired cost requirement. If the costs of civil construction and power infrastructure are not changed, i.e., α and γ are as of today, then future 100 TeV, 10 km and 100MW collider should be based on technology that guarantees cost of the accelerator components of about 6B$, i.e., the coefficient β< 0.6B$, that is two times cheaper than for modern NC magnets. Are there now or can we think of such technologies?

ARE THERE WAYS TO THE FUTURE?

To the date, the community thinking was more about fast acceleration to get to the energies of interest within a smaller footprint, rather than explicitly about the cost. The opportunities for high energy colliders under active discussion now are :

Acceleration in Dielectric Structures: direct beam excitation of wakefields in dielectric structures allows accelerating gradients of ~100 MV/m and ~1 GV/m at the microwave $O(10)$ GHz and THz ranges [19]. Conceptually, a DWA-based linear collider would consist of a large number of ~100 GeV modules (stages) with some ~0.3 GeV/m gradient each driven by a separate ~1 GeV high intensity electron beam. Even without going into difficulties associated with staging, cost and power considerations, it is hard to imagine that more than 3 TeV c.m. energy DWA facility can fit within in a 10 km site. Further increase of the gradient to ~1-3 GV/m is thought to be possible in μm scale dielectric structures driven by lasers operating in optical or near-infrared regime [20, 21].

Acceleration in Plasma: generation of the PWA gradients on the order of 30-100 GV/m by beams or lasers in plasma densities of n_0=10^{17}-10^{18} cm^{-3} have been already demonstrated in small scale (few cm to a meter) experiments [22, 23]. Laser-PWA collider would operate at relatively low densities n_0~10^{17}cm^{-3} and energy gain per ~2m stage of 10 GeV and average gradient ~5TeV/km, while a beam-PWA collider design needs a conventional high power 25 GeV electron drive beam accelerator and many (dozens to hundreds, depending on the final energy) 1-m long plasma cells with an average geometric accelerating gradient ~0.25 TeV/km. Without going into the luminosity considerations [24] and just projecting such gradients further one can think of an ultimate ~10 TeV e+e- collider within 10 km footprint.

More than an order of magnitude reduction of the cost of accelerator components in such colliders is predicted to be needed in order to fit under the expected TPC limit [18]. In addition, due to radiation in the focusing channel and beamstrahlung at IPs acceleration of electrons is limited to only few TeV. Heavier particles are required.

Acceleration in Crystal Channels: field gradients of upto 100 GeV/cm or 10 TV/m are possible in solids due to high density of charge carriers n_0~$10^{22\text{-}23}$ cm^{-3}. Muons, which do not interact with nuclei, would the particles of choice. X-ray lasers can efficiently excite solid plasma and accelerate muons inside a crystal channel waveguide [25], though ultimate acceleration gradients ~10TeV/m might require relativistic intensities, exceeding those conceivable for X-ray sources as of today. Side injection of powerful x-ray pulses into continuous fiber of 0.1 – 10 km long fiber allows to avoid multiple staging issues intrinsic to other methods and reach 10-1000 TeV collider energies – see Fig.3.

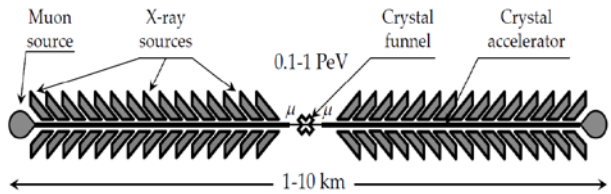

Figure 3: Layout of linear X-ray crystal muon collider [2].

It is not possible to even guess-timate the cost of such unproven acceleration method. One can only foresee that a quest for 100-1000 TeV energies will come at the price of the expected luminosities and will require at least three paradigm shifts [2]: 1) development of the new economical technology for ultrahigh acceleration gradients ~0.1-10 TeV/m in sub-nm structures (crystal fibers); 2) acceleration of heavier particles, preferably, muons; and 3) new approaches to HEP at such energies research with luminosities limited to ~$10^{30\text{-}32}$ cm^{-2}s^{-1}.

STATUS OF THE ELECTRON-POSITRON COLLIDER VEPP-2000 *

A. Romanov, D. Berkaev, A. Kasaev, I. Koop, A. Kyrpotin, A. Lysenko, E. Perevedentsev, V. Prosvetov, Yu. Rogovsky, A. Senchenko, P. Shatunov, Yu. Shatunov, D. Shwartz, A. Skrinsky, I. Zemlyansky, Yu. Zharinov
BINP SB RAS and Novosibirsk State University, Russia

Abstract

VEPP-2000 began high energy physics experiments in the end of 2010 and finished its third experimental season in July of 2013. The last season was dedicated to the energy range of 160-510 MeV per beam. Compton back-scattering based energy measurements were used for the regular energy calibration of the VEPP-2000 together with resonance depolarization and NMR based methods. The concept of the round colliding beams lattice along with the precise orbit and lattice correction yielded the high peak luminosity of $1.2\times10^{31}cm^{-2}s^{-1}$ at 505 MeV with average luminosity of $0.9 \times 10^{31}cm^{-2}s^{-1}$ per run. The total beam-beam tune shift up to 0.174 was achieved in the runs at 392.5 MeV. This corresponds to beam-beam parameter $\xi = 0.125$ per one interaction point. The injection system is currently being upgraded to allow for the injection of particles at the top energy of VEPP-2000 collider and to eliminate the present lack of positrons.

COLLIDER OVERVIEW

VEPP-2000 collider was designed for the refinement of the cross section of the e^+e^- annihilation to hadrons in the energy range $0.4 \div 2$ GeV [1]. The lattice design was aimed to fulfill the conditions of round colliding beams [2], which promised higher luminosity performance because of an additional integral of motion.

The main proposed collider parameters are given in Table 1. VEPP-2000 was designed for one-by-one bunch operation with two functional interaction points. The ring consists of four 90 degree achromatic bends with four straight sections (Fig. 1). Two of the straight sections are occupied by the CMD-3 and SND detectors along with final focus superconducting solenoids, the third is used for injection, and the RF cavity is placed in the fourth.

The focusing system consists of six quadrupole families, three focusing and three defocussing, and four final focus configurable solenoids. Three sextupole families are available for the chromaticity correction. All sextupoles have additional coils that form skew-quadrupole fields to correct the coupling. Due to dense element placement, the orbit steering fields are generated by additional coils in main dipoles and quadrupoles resulting in 20 horizontal and 16 vertical correctors.

The beam diagnostics system consists of 4 electrostatic pickups that are capable of taking turn-by-turn data; 16

Transverse emmitances, $cm \cdot rad$	ϵ_x, ϵ_y	$2.2 \cdot 10^{-5}$
Betatron tunes	ν_x, ν_y	4.1, 2.1
Twiss β at IP, cm	β_x, β_y	6.3
Particles/bunch	e^-, e^+	$1.0 \cdot 10^{11}$
Tune shifts	ξ_x, ξ_y	0.075
Luminosity/IP, $cm^{-2} \cdot s^{-1}$	L_{max}	$1.0 \cdot 10^{32}$

CCD cameras that take beam images using synchrotron light; two photomultipliers for bunch current measurements; one DCCT for measurements of full circulating current; two phi-dissectors [3] that give information about the longitudinal distributions of particles in both bunches.

The first beam was injected to the VEPP-2000 in the end of 2007 without final focus solenoids. This special "warm" configuration of lattice was used to test all vital systems of the collider. After installation of the final focus solenoids, the first luminosity runs were done in 2010. These runs were done only with SND detector, while the CMD-3 de-

tector and its solenoidal field were off. The CMD-3 field of 8-13 kGs breaks the lattice symmetry with greater influence at lower energies.

ENERGY CALIBRATION

The requirement for the precise measurement of the hadron creation cross sections applies strict constraints on the precision of the energy measurement tools. The relative uncertainty of the beam energy should be within $\Delta E/E \leq 10^{-4}$. VEPP-2000 has a number of tools to solve this complex task.

The most precise absolute method is based on resonant depolarization of the beam [4]. The series of spin resonances of the experimental ring leaves only several energy points that could be used for this method, also non-ideal orbit inside the final focus solenoids affects the measurements in unpredictable way. Therefore the main goal of the resonant depolarization method is to calibrate and test faster techniques using special lattice without solenoid fields. The other, even longer, absolute method of energy calibration is measuring the cross sections of the well-known resonances, for example, of ϕ and ω mesons.

The fastest and the least precise method is based on power supplies readings and a complex calibration model. It gives the precision of about 1 MeV and is used for the preliminary energy adjustments. Another fast method is based on readings from the NMR probes installed in each main dipole. The data from the NMR should be calibrated and combined with readings from steering magnets located inside the achromatic bends to give the energy measurement. These measurements have very low statistical jitter of about $0.2 \cdot 10^{-4}$ but the systematic errors are still quite big $\sim 10^{-3}$.

The main energy measurement tool is based on the Compton backscattering [5]. The laser beam interacts with the electron bunch inside the main dipole and the germanium calorimeter detects spectra of the reflected photons. The short interaction length results in lower flux in comparison to the regular configurations where the interaction occurs in the straight section, but it also produces a non-trivial energy distribution of these photons that is used to compensate low statistics. Figure 2 shows the typical edge of the backscattered photons.

In January 2013, a detailed comparison of Compton, NMR and depolarization methods of energy measurements was done. During these tests the precise calibration coefficients for NMR based method have been worked out (Fig. 3).

LATTICE AND CLOSED ORBIT CORRECTION

Fast and reliable closed orbit and lattice correction algorithms are extremely important for successful operation of the VEPP-2000 because of regular energy change in very wide range.

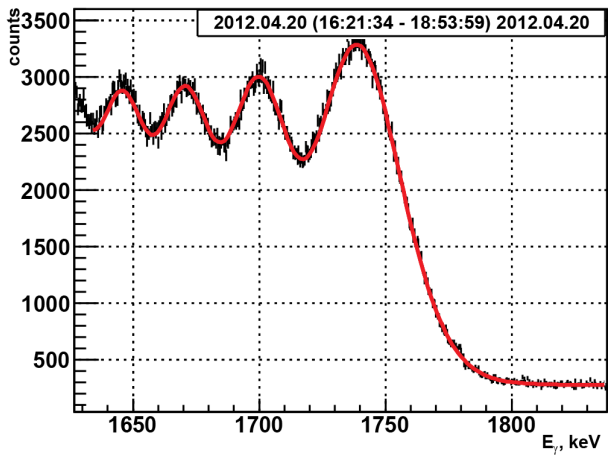

Figure 2: Compton backscattering spectrum at VEPP-2000. Reconstructed energy is $E = 993.662 \pm 0.016 MeV$.

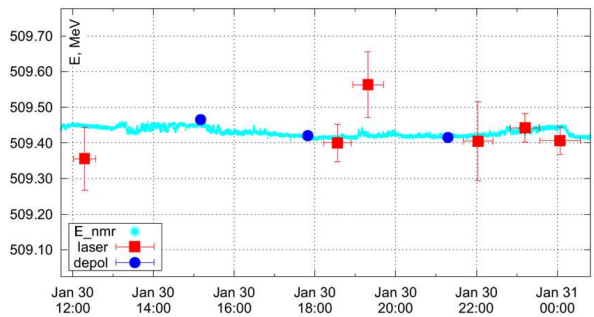

Figure 3: Comparison of three different method of energy measurements: blue circles – resonance depolarization; red squares Compton backscattering; light-blue curve – calibrated NMR.

The main task of the orbit correction in VEPP-2000 is to set the closed orbit as close to magnetic axes of elements as possible. After the best orbit is achieved, one can save and store ideal positions of the beam at locations of the BPMs and use them for future orbit corrections.

To correct the lattice of VEPP-2000, a program was written to implement expanded LOCO algorithms [6–8]. First, a model that best describes the experimental data is found. Second, based on this model, the corrections can be found that fix supposed distortions. The first task is usually performed by minimizing χ^2:

$$\chi^2 = \sum_i \frac{(M_{\mathrm{mod},i} - M_{\mathrm{mes},i})^2}{\sigma_i^2} = \sum_i V_i^2 \qquad (1)$$

where $M_{\mathrm{exp},i}$ and $M_{\mathrm{mod},i}$ are the experimental and theoretical sets of data points; σ_i is precision of corresponding measurement. If the model has the set of parameters p_j, then one can linearize the dependence $V_i(p_j)$:

$$\Delta V_i(\Delta p_j) \simeq \sum_j \frac{\partial V_i}{\partial p_j} \Delta p_j = -V_i, \qquad (2)$$

Copyright © 2013 CC-BY-3.0 and by the respective authors

Inverting the Eq. 2 with help of singular value decomposition (SVD) one can find the variation of the model parameters to reduce χ^2:

$$\Delta p_j = \sum_i \left(\frac{\partial V_i}{\partial p_j} \right) \Big|^{-1}_{SVD} (-V_i) \,. \qquad (3)$$

Several iteration are needed because of nonlinear dependence of the model on the parameters.

Before the last season, one of the main drawbacks of the full lattice correction procedure was required time of 2-3 hours. During the shutdown in the summer of 2012, the replacement of the old CCD cameras with the new ones was performed. Additionally, the image treating software was rewritten so the overall time required for the correction decreased to 40-50 minutes.

LUMINOSITY PERFORMANCE

Last season started with unexpectedly small dynamic aperture in the collider ring. Investigations revealed that it was reduced by strongly nonlinear dipole correctors. Due to dense element placement, most steering magnets are located in the quadrupoles and create significant sextupole fields. To fix huge initial distortion of the uncorrected closed orbit, the superconducting final focus solenoids were slightly moved. This hardware orbit correction in combination with of other tuning tools allowed to reach very good results during the last season.

VEPP-2000 team steadily increases the luminosity production rate over the whole running period. Recently the careful lattice tuning with and the bunch length control resulted in world largest beam-beam parameter $\xi = 0.125$ per one IP that corresponds to the observed tune difference between frequencies of the π and σ modes of $\Delta\nu = 0.174$. This outstanding result was obtained during regular runs in the strong-strong regime at the energy level of $E = 392.5$ MeV per bunch.

Figure 4 illustrates comparison of the predicted luminosity and the one obtained in the best runs. Blue dashed line illustrates the case of constant lattice scaling with energy:

$$\beta^* = const;\ \epsilon \propto \gamma^2;\ L \propto \gamma^4. \qquad (4)$$

The final focus solenoids could provide lower β^* at energies lower than 1000 MeV. Red dashed lines in Figure 4 represent the luminosity dependence in the case of variable final focus strength, so that:

$$\beta^* \propto \gamma;\ \epsilon \propto \gamma;\ L \propto \gamma^2. \qquad (5)$$

Finally, there is another trick to boost the luminosity at lower energies. The final focus solenoids have complex inner structure with longitudinal and radial sectioning. At lower energies, it is possible to switch the current supplies to move the effective center of the final focus closer to the interaction point. Three solid lines on Fig. 4 illustrate the predicted limit of luminosity for three different configurations of the final focus fields. The tests of this approach revealed a dramatic decrease of dynamic aperture, probably because of increased influence of the solenoid fringe fields.

During the last season, VEPP-2000 collected data at energies down to 160 MeV per beam that is the world record for modern electron-positron colliders.

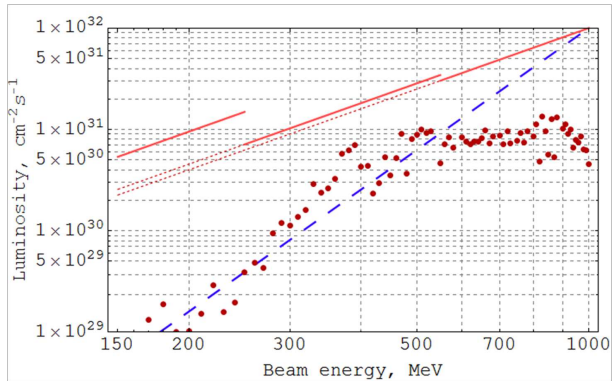

Figure 4: Luminosity dependence on energy. Lines – theoretical estimations; dots – performance in best runs over the entire VEPP-2000 operation time.

Figure 5 illustrates luminosity integrals in different energy ranges over the entire VEPP-2000 operation time. The last season was dedicated to the low energy range, but despite this the total integral is of the same order of magnitude as in the previous seasons aimed at higher energies.

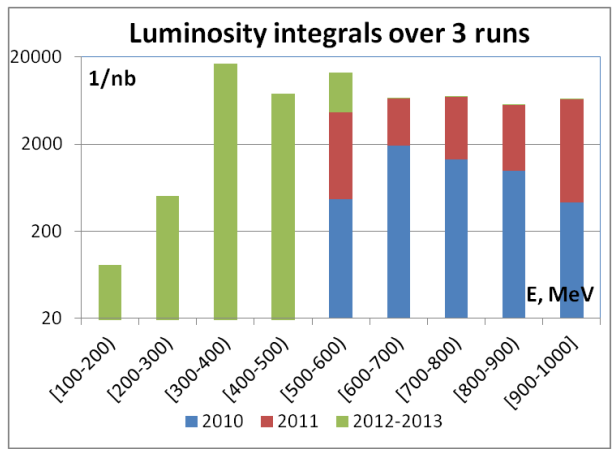

Figure 5: Luminosity integrals collected by SND in different energy ranges over the entire VEPP-2000 operation time.

LUMINOSITY MONITORING

There are a number of theoretical and empirical considerations regarding lattice configuration depending on the energy [8], but the last step of the final tuning is almost always unique and done manually. To optimixe the luminosity performance, the operator should fine tune parameters such as beta-functions at the IPs, closed orbit position, betatron tunes, chromaticity, betatron coupling and others.

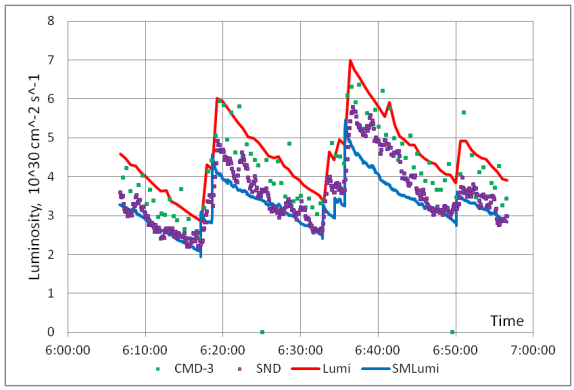

Figure 6: Comparison of the luminosity values from different measurements: green dots – CMD-3, purple dots – SND, red and blue lines – estimation methods.

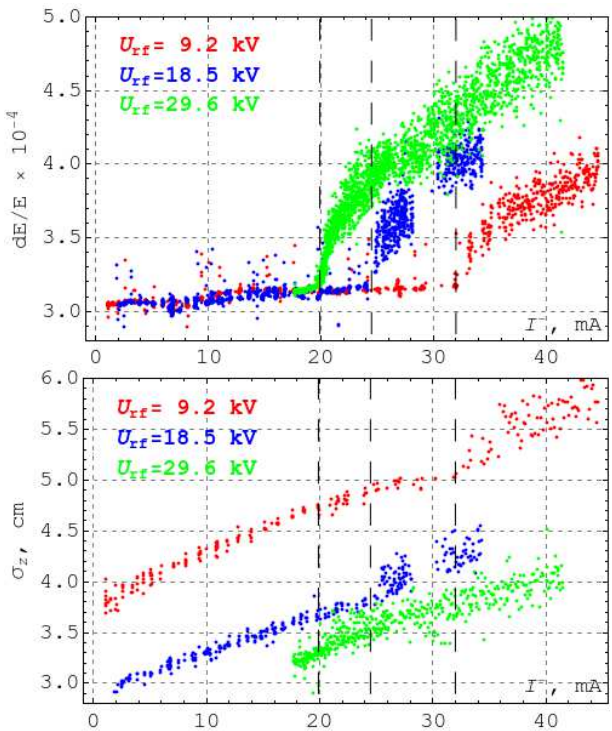

Figure 7: Correlation of the current dependence of the extracted energy spread and the measured bunch length.

To help the operator with this task both detectors provide luminosity measurements. Unfortunately, the time needed for one data point is too long and, in addition, at low energies statistics become to poor. To overcome these limitations, two luminosity estimation methods were developed based on machine diagnostics [9].

Both presented methods of luminosity estimation assume that the accurate optics model of the real accelerator ring is available. If there are no focusing perturbations in the lattice other than those caused by the collisions, and thus located at the IP, one can use known transport matrices to evaluate the beam sizes at the IPs from the beam size measurements by CCDs.

The first method was implemented in the software called "LumiMeter" and is based on the fitting of the emitances and effective beta functions for e^- and e^+ bunches and both IPs. The second method was implemented in Java code called "SMLumiMeter" and is based on fitting of the set of second moments for both bunches.

Bunch lengthening

At the end of the last experimental season, the e^- and e^+ phi-dissectors were installed at VEPP-2000, that can measure bunch length with the precision of about 2 mm [3]. The bunch length measurements combined with energy spread estimations produced by "SMLumiMeter" revealed the presence of microwave instability that could be controlled by RF voltage (Fig. 7).

UPGRADE STATUS

Starting from the first experimental season it became obvious that old injection complex strongly limits the operation of the VEPP-2000 at high energies. Last season also demonstrated insufficient positron production range at lower energies when the beam lifetime in the collider goes down.

To overcome the listed difficulties, a deep upgrade of the injection system was started in July 2013 at VEPP-2000. Booster BEP will be modified to be able to cover the full energy range of VEPP-2000. In the new configuration, particles will be transported to the BEP from the VEPP-5 injection system by about 200 meters channel. Table 2 shows comparison of the old and new injection systems. Figure 9 illustrates VEPP-2000 facility after upgrade.

Table 2: Comparison of the Old and New Injection Facilities

e^+ production rate, e^+/sec	2×10^7	3×10^8
e^- production rate	10^9	1×10^11
Max booster energy, MeV	825	1000
Booster accum. energy, MeV	125	500
Max pulses rate, Hz	0.7	12.5

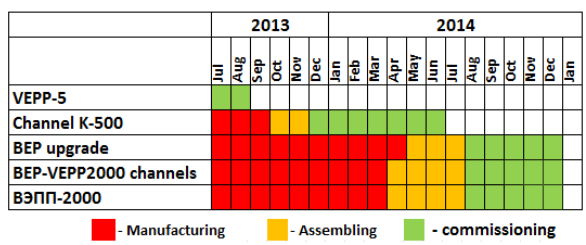

Figure 8: VEPP-2000 upgrade schedule.

In general, there are five major parts of the started upgrade. First of all VEPP-5 injection system should be fully commissioned and become a reliable source of high quality beams. Next, some elements of new channel K-500

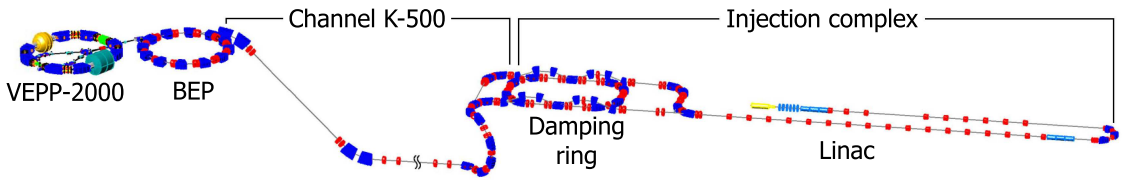

Figure 9: Layout of the facilities related to the VEPP-2000 collider after upgrade.

should be manufactured, installed and tested. The third part is aimed at booster BEP upgrade. Some subsystems of VEPP-2000 will be modified for better beam control. In addition, the old transport lines between BEP and VEPP-2000 were designed for the old BEP energy and, therefore, must be significantly modified. Figure 8 illustrates a timetable for the listed activities.

Due to funding limitations it was decided to upgrade the BEP booster rather than to build a completely new ring. The main dipoles and quadrupoles will be manufactured by reshaping existing yokes. The preserved bending radius and cross section of conductors apply extreme requirements to the design. At 1GeV, it will be possible to operate BEP only in rapid-cycling mode with fast ramping up and down with top guiding field almost 26 kGs. The first prototype of the upgraded main dipole was recently tested and demonstrated all necessary parameters (Fig. 10). Quadrupole prototype manufacturing is in progress. The vacuum chamber will be also re-shaped by compressing and milling the old one.

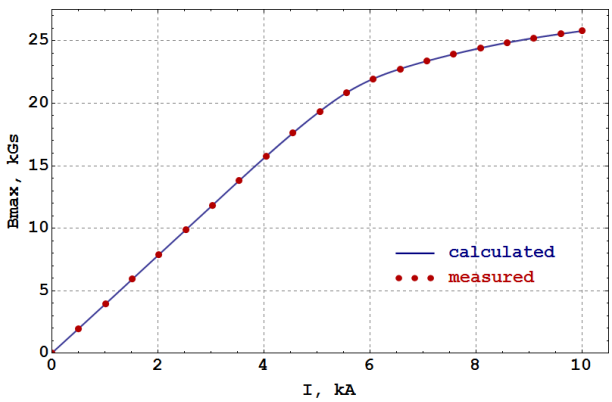

Figure 10: Comparison of the calculated and measured magnetic field vs current for the upgraded BEP dipole.

CONCLUSION

Correction techniques from precise magnet alignment to versatile beam-based algorithms, as well as bunch length adjustments and manual fine tuning, based on computer control, allowed to reach the limits of the VEPP-2000. It became obvious that main limitations come from the obsolete injection facility, therefore its upgrade will be necessary for the long term, high luminosity performance of the VEPP-2000. The long shutdown for the serious upgrade was stared in July of 2013.

Among the main VEPP-2000 achievements over the past years are:

- The total integral in the energy range $160 \div 1000$MeV is about $64pb^{-1}$.
- The world record of the beam-beam parameter $\xi = 0.125$ obtained during the regular run.
- Data collection in lowest energy range for the e^+e^- colliders down to 160 MeV per bunch.

PERSPECTIVES AND CHALLENGES FOR DIFFRACTION-LIMITED STORAGE RING LIGHT SOURCES*

R. Hettel, SLAC NAL, Menlo Park, CA 94025, USA
M. Borland, ANL, Argonne, IL 60439, USA

Abstract

This paper provides an overview of the scientific motivation for developing diffraction limited storage ring (DLSR) light sources, reviews the main R&D challenges associated with DLSR implementation and summarizes the worldwide effort presently in progress to build a new generation of very low emittance rings.

INTRODUCTION

Synchrotron radiation from storage rings is the dominant source of high brightness photons from the infrared to hard X-rays, serving a multitude of scientific applications. Recently X-ray free electron lasers (FELs) have emerged, offering orders-of-magnitude higher peak brightness in ultra-short pulses. FELs offer nearly complete transverse coherence and energy bandwidth that will approach the transform-limit with seeding. Both ring- and FEL-based sources will play a vital role as they offer complementary beam properties, with rings providing low peak brightness with high average brightness and pulse repetition rate, which does not over-excite or damage samples as FELs do [1]. Another complementary capability for some storage ring sources is the production of high repetition rate (MHz), picosecond pulses for probing materials dynamics on the >10 ps timescale.

There are scientific applications and experimental methods that would greatly benefit from ring-based sources having much higher average brightness and transverse coherence. These include nanometer imaging applications; X-ray correlation spectroscopy and spectroscopic nanoprobes; and diffraction microscopy, holography and ptychography [2]. These applications will benefit from X-ray sources with average spectral brightness exceeding ~10^{22} photons/s/mm^2/mrad^2/0.1% BW and significantly higher coherent photon flux than presently available. This can best be provided only by reducing the electron beam emittance well below the present-day standard of nanometer-radians, towards the diffraction limit for X-ray beams.

WHAT IS A DLSR?

Diffraction-Limited Photon Emittance

While diffraction is typically associated with the divergence of a photon beam as it passes through a limiting aperture, it can be shown by solving the electric field wave equation that diffraction also occurs for a transverse spatially restricted photon beam, such as a Gaussian laser beam [3]. The transverse size and divergence of the electric field are related by a Fourier transform and the observed radiation intensity pattern, proportional to the square of electric field strength, satisfies the following:

$$\sigma_r(\lambda)\,\sigma'_r(\lambda) = \frac{\lambda}{4\pi} = \varepsilon_r(\lambda) \qquad (1)$$

where $\sigma_r(\lambda)$ and $\sigma'_r(\lambda)$ are the rms size and divergence, respectively, and $\varepsilon_r(\lambda)$ is the diffraction-limited emittance for a Gaussian photon beam having wavelength λ.

Extensive calculations of the radiation emitted by an undulator having N periods and length L have been carried out by several authors [3,4]. They reveal transverse beam size and divergence profiles that are only approximately Gaussian, so that the transform-limited value for the radiation emittance in (1) does not hold exactly. The rms size and divergence associated with the Gaussian fits to the calculated patterns are [4]

$$\sigma_r(\lambda) \approx 1.9\frac{\sqrt{2\lambda L}}{4\pi} \qquad \sigma'_r(\lambda) \approx \sqrt{\frac{\lambda}{2L}} \qquad (2)$$

and thus

$$\sigma_r(\lambda)\,\sigma'_r(\lambda) \approx \frac{\lambda}{2\pi} = \varepsilon_r(\lambda)\ . \qquad (3)$$

It should be noted that the factor of 1.9 for $\sigma_r(\lambda)$ in (2) is missing in [3]. This is not a serious issue – in fact, several other values can be derived depending on calculation and fitting assumptions. For the remainder of this paper, $\lambda/4\pi$ will be used since that value is commonly used by the synchrotron radiation community.

Diffraction-Limited Electron Emittance

A hypothetical filament of electrons having essentially no transverse size or divergence ("single electron" dimensions) passing through an undulator would emit radiation having the dimensions and emittance given in (2) and (3). A real electron beam has transverse size and divergence, which must be convolved with the single-electron photon parameters to determine the photon beam properties. Assuming Gaussian profiles, total horizontal or vertical emittance $\Sigma_{x,y}$ is given by

$$\Sigma_{x,y}(\lambda) = \varepsilon_r(\lambda) \oplus \varepsilon_{x,y}(e-) = \sqrt{\sigma_r{}^2(\lambda) + \sigma_{x,y}{}^2(e-)}\sqrt{\sigma'_r{}^2(\lambda) + \sigma'_{x,y}{}^2(e-)} \qquad (4)$$

where $\oplus$ denotes convolution, and $\sigma_{x,y}(e-)$ and $\sigma'_{x,y}(e-)$ are electron size and divergence, respectively, given by

$$\sigma_{x,y}(e-) = \sqrt{\beta_{x,y}\varepsilon_{x,y}(e-)} \quad \sigma'_{x,y}(e-) = \sqrt{\varepsilon_{x,y}(e-)/\beta_{x,y}} \qquad (5)$$

at the waist of the electron beam (and assuming zero dispersion). Total emittance is minimized when photon

†Work supported in part by Department of Energy Contract DE-AC02-76SF00515 and Office of Basic Energy Sciences, Division of Chemical Sciences

Copyright © 2013 CC-BY-3.0 and by the respective authors

and electron phase space orientations are matched, i.e.

$$\sigma_{x,y}(e\text{-})/\sigma'_{x,y}(e\text{-}) = \sigma_r(\lambda)/\sigma'_r(\lambda) \Rightarrow \beta_{x,y} = L/2\pi \quad (6)$$

(Fig. 1). This result assumes $\varepsilon_r = \lambda/4\pi$ and imposes a demanding requirement, e.g., $\beta = 0.6$ m for $L = 4$ m, a difficult value to achieve in the horizontal plane when using accumulation-based injection. Relaxing β_x to ~10 m can increase effective emittance by a factor of ~2 for emittances near the diffraction limit. This condition is less difficult if actual $\varepsilon_r = \lambda/2\pi$; then $\beta_x = L/\pi$. An optimization of beta functions that depends on undulator and electron beam properties is required in real designs.

From the above it can be inferred that a diffraction-limited emittance is reached when $\varepsilon_{x,y}(e\text{-}) << \varepsilon_r(\lambda)$. However it is conventional to say a ring is diffraction-limited when $\varepsilon_{x,y}(e\text{-}) = \varepsilon_r(\lambda)$. The diffraction-limited emittance for 1-Å X-rays (~12 keV) is 8 pm-rad, far below the nm-rad horizontal emittances for present-day storage ring light sources. However, vertical emittances at or below this scale are routinely reached in present machines by reducing vertical dispersion and coupling.

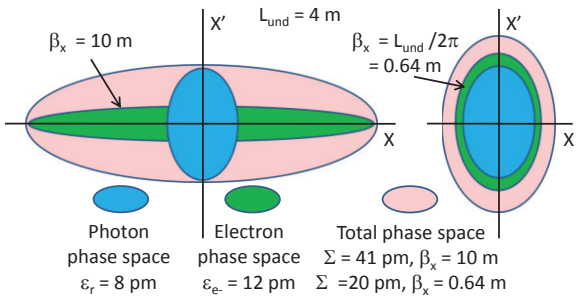

Figure 1: Total emittance (pink) is minimized when electron (green) and photon (blue) phase space ellipse orientations are matched. $\varepsilon_r = \lambda/4\pi$ is assumed.

Brightness and Coherence

The average brightness for a photon beam having wavelength λ is defined as the photon density in 6-dimensional phase space at that wavelength:

$$B(\lambda) = \frac{N_{ph}(\lambda)}{4\pi^2 \Sigma_x(\lambda)\cdot\Sigma_x(\lambda)\cdot(s\cdot\%\,BW)} \quad (7)$$

Closely related to brightness is the fraction f_{coh} of photons that are transversely coherent in each plane:

$$f_{coh-x,y}(\lambda) = \frac{\varepsilon_r(\lambda)}{\Sigma_{x,y}(\lambda)} \quad (8)$$

$$f_{coh-tot}(\lambda) = f_{coh-x}(\lambda)\cdot f_{coh-y}(\lambda)$$

When $e_x(e\text{-}) = e_r(\lambda)$, the horizontal coherence is 50%. If both horizontal and vertical electron emittances are at the diffraction limit, the total coherent fraction is 25%. Horizontal coherent fraction as a function of electron emittance for different wavelengths is shown in Fig. 2.

From (7) it is evident that brightness can be increased either by reducing emittance in the denominator, or by increasing photon flux ($N_{ph}(\lambda)/s$) in the numerator. The latter can be achieved by increasing the stored beam current and through the use of longer or higher-performance undulators. Nevertheless, while X-ray users are interested in high coherent flux, achieving it by increasing coherent fraction is more desirable since this reduces the amount of "unusable" incoherent flux and mitigates issues associated with high heat loads.

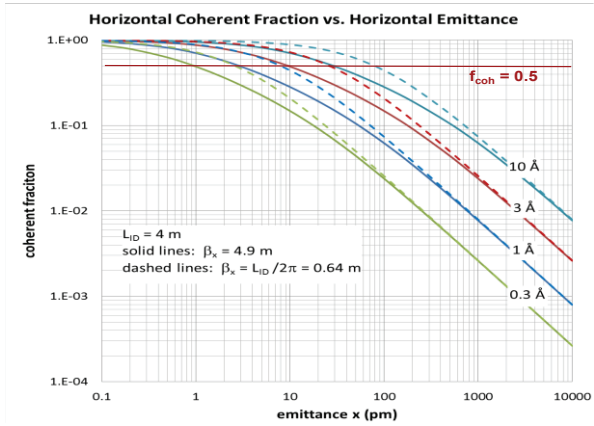

Figure 2: Horizontal coherent fraction versus emittance for various X-ray wavelengths. Dashed curves indicate the gain coherence for 4-m undulators when β_x is reduced from 4.9 m to 0.64 m (= $L/2\pi$).

The brightness and coherent fraction for various existing, imminent and potential future storage ring light sources are shown in Fig. 3. While these parameters will be increased ten-fold in the 0.1 to 10 keV range by sources now in construction, an even greater increase in that spectral range, and an enhancement of 2 or more orders of magnitude in the 10 to 100-keV range should be achieved by converting existing high energy rings (ESRF, SPring-8, APS) to lattices with emittances in the 60-150

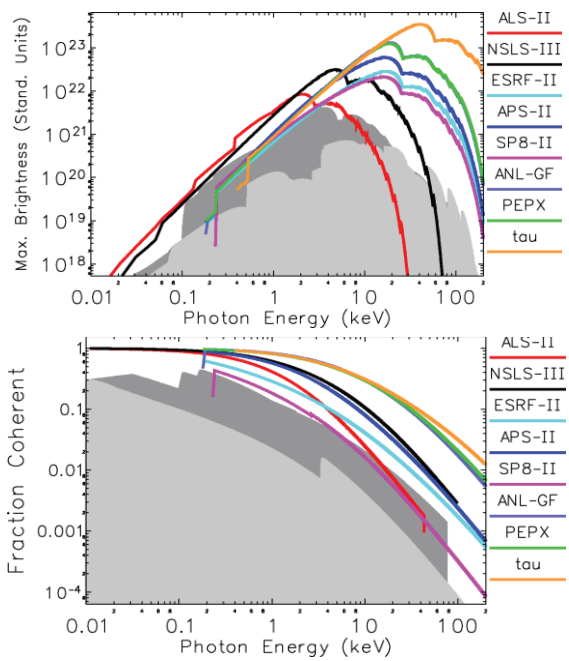

Figure 3: Brightness and coherence for present day storage rings (light gray), rings in construction (MAX-IV, NSLS-II, dark gray) and future rings (colored curves). Ring parameters given in Table 1.

Copyright © 2013 CC-BY-3.0 and by the respective authors

pm-rad range. Large circumference green-field machines having emittances of 1 to 10 pm-rad (e.g. PEP-X [5], TauUSR [6]) would approach maximal brightness and coherent fraction for hard X-rays.

Reducing Emittance

The natural electron emittance ε_0 is given by [7]

$$\varepsilon_0(e-) = F(\nu,\ cell)\frac{E^2}{(N_d N_s)^3} \propto \frac{E^2}{C^3} \qquad (9)$$

where F(ν,cell) is a function of the betatron tune and cell type, E is the electron beam energy, N_d is the number of dipoles in a given sector, N_s is the number of sectors (and straights) in the ring, and C is ring circumference. The C^{-3} scaling is valid only when the cell type is fixed. Stated simplistically, ring emittance for a given electron energy is reduced by increasing the total number of dipoles in the ring and by increasing focusing between dipoles to maintain low dispersion. Horizontal and vertical emittances are set by the coupling factor κ:

$$\varepsilon_x(e\text{-}) = \frac{1}{1+\kappa}\varepsilon_0(e-) \qquad \varepsilon_y(e\text{-}) = \frac{\kappa}{1+\kappa}\varepsilon_0(e-) \qquad (10)$$

Present-day rings have $\kappa < 0.1$. As ε_0 is reduced towards the diffraction limit, it is reasonable to set $\kappa = \sim 1$, enabling operation with a quasi-round beam that is beneficial to users. This increases Touschek lifetime and combats emittance growth caused by intra-beam scattering (IBS) in the very small electron bunch volumes.

Emittance can also be reduced by introducing more damping to combat radiation- and IBS-induced emittance growth. This can be accomplished using high-field damping wigglers (DW) and is effective if the energy loss per turn U_W in the wigglers is greater than the energy loss per turn U_0 in the dipole magnets, in which case

$$\frac{\varepsilon_W}{\varepsilon_0} \approx \frac{1}{1+U_W/U_0} \qquad (11)$$

The dipole field strength for large rings can be low (~0.5 T), making damping wigglers a practical way to reduce emittance by a factor of 2-3.

A third way to reduce horizontal emittance is to increase the horizontal damping partition J_x by a factor of two or so by passing the beam through magnets having a combination of positive dipole and defocusing gradient fields, e.g., gradient dipoles, Robinson wiggler [8], or by orbit offset in quadrupoles [9]. This method increases horizontal damping at the expense of longitudinal damping, reducing emittance while increasing the energy spread. Once gradient dipoles are used in the lattice, the other two methods do not add a significant benefit.

DLSR Properties

Given the discussion above, the properties of DLSRs can be summarized as follows:

- Brightness and coherence are as high as possible for a given beam current.
- Beam sizes and divergences are small in both transverse dimensions (microns and microradians).
- High coherence and small size allows beams to be focused to very small sizes – "nano-focusing" not achievable with present day sources, .
- High coherence preserves X-ray wavefront phase uniformity, enhancing coherent imaging techniques by providing high coherent flux with minimal need for aperturing slits, etc.
- "Round" beams are possible with the appropriate adjustment of coupling, betatron functions and vertical dispersion, enabling optimal use of H-V symmetric x-ray optics, circular zone plates, etc.
- Large circumference for multi-GeV rings allows reaching the diffraction limit for hard X-rays.
- Damping wigglers can be used to combat IBS, reduce emittance and increase lifetime.

As noted below the strong focusing lattices needed to reach a minimum emittance have small dynamic aperture (DA), potentially inadequate for normal beam accumulation using off-axis injection. In this case, an additional property for some designs is the need for on-axis "swap-out" injection [10] where stored electron bunches are completely replaced with new incoming bunches. Such lattice designs also tend to have a low momentum compaction factor, resulting 5-10 ps rms natural bunch lengths in some cases for rings having ~500-MHz RF systems, a factor of ~3 lower than present-day sources. In these cases, bunch lengthening RF cavities are needed to increase lifetime and reduce IBS.

CHALLENGES AND SOLUTIONS

The science case for high coherence storage rings has gained sufficient momentum to motivate existing facilities (e.g., ESRF, SPring-8, and APS) to develop plans to replace their lattices with ultra-low emittance designs. These lattices will increase brightness and coherent fraction by orders of magnitude, reaching diffraction limited horizontal emittances for few-keV X-rays. To reach the diffraction limit and maximal brightness for hard X-rays (<10 pm-rad), new machines with large circumference (~1.5 km for ~5-GeV electrons) will be required. The challenges and technological solutions related to these designs are discussed below.

Fundamental Challenges

The main path to reducing emittance in a storage ring is to increase the number of dipoles while limiting dispersive orbit amplitudes using many strong quadrupoles. These quadrupoles introduce chromatic aberrations that must be corrected with strong sextupoles, which in turn introduce higher order aberrations that must be corrected in order to achieve adequate dynamic and momentum aperture (MA). Without sufficient MA and DA, beam lifetime will be reduced, increasing beam loss, and off-axis injection becomes difficult, if not impossible.

The ~2-fold stronger quadrupoles and ~10-fold stronger sextupoles required by these rings, necessitates bore radii 2-3 times smaller than today's light sources. Small magnet bores imply small-aperture vacuum chambers in both transverse dimensions, reducing vacuum system

Copyright © 2013 CC-BY-3.0 and by the respective authors

conductance, and increasing issues with synchrotron radiation power absorption. Furthermore, the impedance from small aperture chambers exacerbates single- and mutli-bunch beam instabilities.

Challenges for DLSRs have been discussed in several workshops, including [11-13] and others.

DLSR Technology

Multi-bend achromat (MBA) lattices having more than 3 dipoles per sector has been envisioned as a way to increase the number of dipoles while providing many insertion device straight sections beginning with 4BAs in the early 1990s [14], an early 7BA lattice for the Swiss Light Source [15] and a 7BA, 3-GeV lattice reaching 0.5-nm-rad emittance with a 400-m circumference [16] (Fig. 4). Still, the challenges associated with compact magnets and small-bore vacuum chambers were daunting enough at the time to prohibit construction of such a machine.

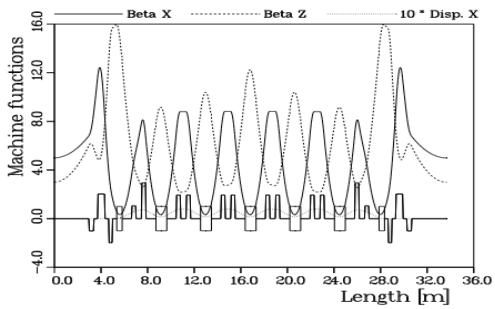

Figure 4: 7BA lattice [16].

Compact magnet and vacuum chamber technology for DLSRs has now been developed, primarily by MAX-Lab in Sweden, enabling construction of MAX-IV, the first 7BA light source [17]. MAX-IV will have a 2.6-cm diameter, primarily round copper vacuum chamber with shallow antechambers where needed to extract the X-ray beams (Fig. 5). To achieve sufficient vacuum pumping the chambers will be NEG-coated, using CERN technology already exploited in nearly 1/3 of the vacuum chambers at Soleil. NEG-coated chambers are now used routinely for small-gap insertion devices (IDs) in many light sources.

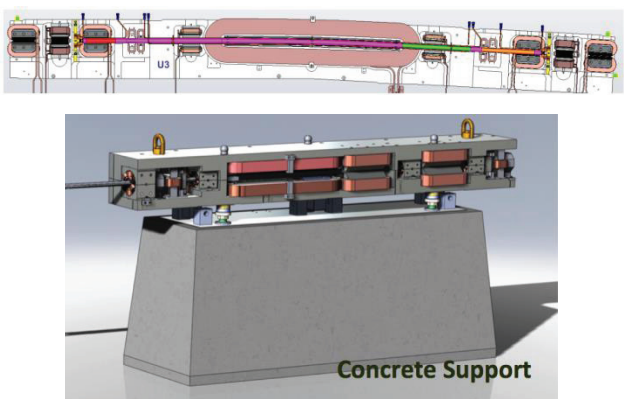

Figure 5: MAX-IV machined magnet block and vacuum chamber (top); a different style magnet block assembly on its concrete support (bottom).

MAX-IV magnets are machined from single blocks of iron, each containing a dipole and adjacent multipoles; the gradient dipole poles are machined directly from the block, while the highly precise multipole poles are machined separately and bolted in place, giving alignment precision on the order of 10 μm. The blocks are mounted on elevated concrete blocks, eliminating both support girders and individual magnet supports (Fig. 5). A magnet measurement system employing rotating coils, Hall probe sensors and precise alignment technology has been developed. The technology has been tested, first by constructing similar combined function magnets for the 700-MeV MAX-III ring in 2008, and then by testing the NEG-coated vacuum chamber system in one area in the 1.5-GeV MAX-II ring. Other DLSR designs use independent magnets having high alignment tolerances.

Accelerator physics methods and modeling tools for storage ring design have advanced appreciably over the last two decades, driven by the design of high-luminosity colliders, low-emittance damping rings, and enhanced light sources. Tools include symplectic tracking methods to accurately determine DA and MA, tracking-based lattice optimization codes and methods (e.g. multi-objective genetic algorithms, frequency map analysis, etc.) and analytical methods (e.g Lie algebra, amplitude dependent tune shift and resonance driving term minimization). These methods have been benchmarked on real machines with beam-based lattice calibration tools (e.g. LOCO [18]) and parameter measurement techniques.

Other relevant advances include: success of top-up injection in accommodating short beam lifetime; advances in electron and photon beam diagnostics, allowing precise characterization and correction of the ring, as well as stabilization of the beam to the sub-micron and sub-microradian level; development of fast high-voltage stripline kickers for the ILC effort, supporting on-axis injection with closely-spaced bunches; advances in electronics, from power supply stability to the speed of digital processors used for orbit feedback; development of highly stable solid state RF power sources; high performance undulator development (including superconducting); and coherence-preserving X-ray optics being developed for FELs.

DLSR Design Optimization

The optimization of parameters for any storage ring is a complex process that can only be briefly addressed here. In the case of DLSRs, the scientific community is likely to be a mixture of users seeking high brightness and coherence and those whose experiments are flux- rather than brightness-limited, leading to tension between reducing emittance and increasing stored current – an optimization that impacts facility cost since it is generally less expensive to increase current than it is to build an ultra-low emittance ring. As mentioned, it is possible to get high coherent flux with a high current, low coherent fraction ring. As seen in Fig. 2 there is a diminishing return in coherent fraction for decreasing emittance that must be weighed in the optimization.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Another consideration is the electron energy needed to fulfil spectral requirements. Higher energy, larger circumference rings (e.g. 6 GeV or more) will produce higher brightness hard X-rays, but competing brightness (within an order of magnitude) can be achieved with less expensive, lower energy, smaller circumference rings (e.g. 3-4 GeV) using harmonics from high performance undulators. Another factor is that ring energy can be optimized to minimize emittance growth due to IBS for a given beam current; for ~1-km rings, the optimal energy from this standpoint is ~4-5 GeV, while it is 5-6 GeV for 2-km rings. However the gain in hard X-ray emission at higher energy can lead to higher brightness, even if emittance is degraded. There is thus a trade-off between spectrum, emittance, circumference and cost.

A final comment on design optimization concerns the number, length and spacing of straight sections. Designers must decide whether long straight sections will be used for two IDs in a chicane, as opposed to providing more short straight sections holding single IDs. The spacing between straight sections, lattice bending radius, and thus the angle between adjacent photon beam lines, ultimately determines the length of X-ray beam lines and the amount of expensive experimental floor space needed for them. Experimental halls for very large rings can become overly expensive unless ID straights are spaced for efficient beam line alignment. In some cases this could lead to a hybrid lattice design for very large rings where beam line straight sections are consolidated in specific arcs having optimal spacing using one lattice type, while another minimal emittance lattice type is used elsewhere [19].

Table 1: Parameters for some low-emittance rings. (IC/IP/ID = in construction, planning, development; DW = damping wiggler.)

Facility	E(GeV) / I(A)	C (m)	ε_0 (pm)	Features

A summary of low emittance rings and future DLSRs being considered for the future is given in Table 1.

SUMMARY AND OUTLOOK

Storage ring light source technology has reached the stage where construction of a new generation of sub-nm-emittance rings is feasible. Machines having horizontal emittances as low as 0.25 nm-rad are now in construction, and several others having sub-100-pm emittances are in planning stages. Longer range plans envision rings having sub-10-pm emittances – machines whose technology will build on that developed for rings to be built in the next several years and which may require R&D in accelerator technology [12]. The longer range future for DLSRs might include enhanced capabilities, such as ring-based high repetition rate, low peak power FELs [20] and short bunch operation that offer beam properties complementary to linac-based FELs while serving a larger number of simultaneous users. The "MBA generation" is an exciting time for light source designers.

Abstract

Many synchrotron radiation facilities are studying lattice upgrades in order to lower the natural emittance and hence increase the radiation brilliance and transverse coherence. While large circumference rings are favoured for reaching ultra small emittance, recent advances in design and optimisation tools allow also medium size rings to reach emittances down to the some 100s of pm region, with workable lattices. Diamond is investigating a novel design whereby low emittance is conjugated with doubling of the capacity of the ring, based on a double-double bend achromat (DDBA) cell. Plans for the installation of one or more low emittance cells will be presented. This will serve as a prototype for a possible full phased upgrade of the storage ring in the longer term.

INTRODUCTION

The Diamond Light Source is actively pursuing a research programme for the development of an ultra-low emittance upgrade of the storage ring in order to achieve emittances in the range of 270 pm and below [1,2] which would improve the present emittance by a factor 10 or more. This emittance will allow the facility to remain competitive with the next generation high brightness light sources by substantially increasing the brilliance and the transverse coherence of the synchrotron radiation.

Accelerator physics studies have shown that lattices based on Multiple Bend Achromats (MBAs) can produce appealing emittance even with medium size rings such as the 561.6 m of the Diamond storage ring. The Diamond lattice upgrade is constrained by the requirement of maintaining the tunnel geometry and the position of the beamlines. The possibility of phasing the upgrade on a cell-by-cell basis to avoid long shutdowns was also considered in the studies. Reusing as much hardware as possible was considered, however it turned out that the magnets of the present lattice are not adequate for a reduced emittance lattice and so new magnet designs are now developed. Other technical subsystems are also under design, notably vacuum and diagnostics, while the RF system [3] and the power supplies will be reused. In this report we present the advances on the accelerator physics design.

MBAs have been proposed in the early '90s as a promising lattice design that allows reducing the emittance towards the diffraction limit [4] in the hard X-ray region. We therefore investigated the possibility of replacing our DBA lattice with an MBA. Various options were analysed starting with a very aggressive 7BA design with 45 pm emittance but with a very small dynamic aperture. More relaxed lattices 5BA and 4BA produced slightly larger emittance, 150 pm and 270 pm respectively. These values are in any case meeting the 10-fold emittance reduction target. In the analysis of the 4BA lattice it transpired that the 4BA cell can be split in two, inserting a new straight section in the middle of the cell. We later found that a similar concept was proposed in [5]. In this way the lattice strongly resembles again a DBA, despite the fact that the outer and inner dipoles in the cell have different lengths, and was therefore named "Double Double Bend Achromat" (DDBA). The additional straight section in the middle of the cell allows doubling the capacity of the present Diamond ring for Insertion Devices (IDs), while still maintaining a very small horizontal emittance.

The possibility of introducing an additional straight section has triggered the study of the installation of one or more such DDBA cells into the present Diamond lattice. The VMX [6] and the DIAD [7] beamlines have expressed strong interest in utilising a DDBA cell located in cell 2 and cell 11 respectively. A third modification of the lattice in cell 20 would allow the installation of a third harmonic cavity for bunch lengthening which will support the increase in the operational current to 500 mA and is in line with the potential phased upgrade of the full lattice.

The installation of the DDBA cells in the present lattice will provide the opportunity of testing many critical areas of a possible full upgrade of the machine. In particular it has kick-started the necessary R&D on several technical subsystems such as magnets, vacuum, diagnostics and the engineering integration of the subsystems.

MBA LATTICE STUDIES

The first options investigated to replace the existing DBA was a 7BA lattice, providing an emittance of 45 pm. The basic cell, shown in Fig. 1, is built on gradient dipoles with 0.45 T and 30 T/m quadrupole component and 90 cm length. The larger number of dipoles is accommodated by slightly reducing the lengths of straight sections. The natural chromaticity of this lattice is very high and requires strong sextupoles for correction. A dispersion bump is created between dipole 1 and 2 and symmetrically between dipole 6 and 7 to locate the chromatic sextupoles and reduce their required strength. The lack of a proper phase advance (π or 3π usually) between the chromatic sextupoles in the cell prevents the cancellation of the geometric driving terms. The phase advance was matched to complete 2π within one super period (4 cells). Most of the resonance driving terms (RDTs) can be cancelled in one super period in this way

Copyright © 2013 CC-BY-3.0 and by the respective authors

[8]. However, higher order terms are still large, difficult to compensate and the resulting dynamic aperture is only ± 1mm. With such a small dynamic aperture, off-axis injection is excluded and a major reconsideration of the injector system would be required. Furthermore the effect of intra-beam scattering quickly blows up the emittance for beam currents under consideration: at 300 mA in 900 bunches and 10% coupling, the emittance is double to 90 pm. Given the constraints on the geometry and layout of the beamlines, we do not have the flexibility to install damping wigglers to compensate for this effect. It was therefore decided not to pursue this option further for the moment.

A similar design based on a 5BA providing an emittance of 156 pm also showed similar, albeit mitigated, difficulties: the dynamic aperture is only ±3 mm. The layout of the optics function in the cell for these two options is shown in Fig. 1. The main parameters of the two lattices are reported in Tab. 1.

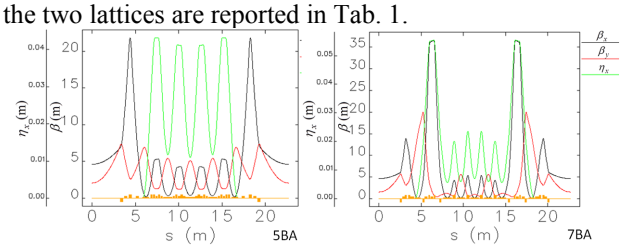

Figure 1: Optics functions for 5BA and 7BA lattices.

Table 1: Parameters for 5BA and 7BA Lattices

Parameters	5BA	7BA
Circumference [m]	561.6	561.6
Emittance [pm.rad]	156	45.7
Tune Point [Q_x / Q_y]	53.66/ 28.87	75.42/52.17
Chromaticity(ξ_x / ξ_y)	-130 / -50	-348/ -119
Length of straights [m]	9.5 / 6.5	8.0 / 5.0
Momentum compaction	1.30e-04	7.98e-05

THE DDBA LATTICE

Given the above difficulties, more relaxed optics were then considered. The usual 4BA cell, based on standard TME cells and matching cells, has been modified to accommodate an additional straight section in the middle of the cell, in the so called DDBA cell shown in Fig. 2. In this way the number of straight sections per cell is doubled. Table 2 reports the main parameters of the DDBA lattice and a comparison with the present lattice design.

The length of the additional middle straight section is a parameter of the optimisation and it turned out that a good matching can be achieved only up to 3.4 m. This length is sufficient to install one of the existing 2m in-vacuum ID and leaves sufficient space for flanges, BPMs, bellows and correctors. The excellent control of the optic functions in this straight allows the use of narrow gap ~5mm IDs without any detrimental effect on emittance and gas lifetime.

Table 2: Parameters for Existing DBA and DDBA Lattices

Parameters	Existing DBA	DDBA lattice
Energy [GeV]	3.0	3.0
Circumference [m]	561.6	561.0
Emittance [pm.rad]	2750	276
Tune Point [Q_x / Q_y]	27.20/ 13.37	50.76/18.36
Chromaticity(ξ_x / ξ_y)	-80.4 / -35.6	-128/ -94
Length of straights [m]	11.3 / 8.3	9.1- 6.7 / 3.4
Mom. compaction	1.66e-04	1.02e-04

The combined function dipoles play an important role in making the cell compact as almost all the vertical focussing is provided by the gradient in such dipoles. The maximum gradient of all quadrupoles and combined function dipoles was limited at 55 T/m and 15 T/m respectively. The dipole at the edge of the cell is shorter than the middle dipole by the factor of $3^{1/3}$ in order to minimise the contribution to the beam emittance and matching to zero dispersion in the straight section [9]. To achieve a more efficient chromaticity correction, we introduced a dispersion bump between dipoles 1 and 2 and dipoles 3 and 4. Chromatic sextupoles are introduced in these locations.

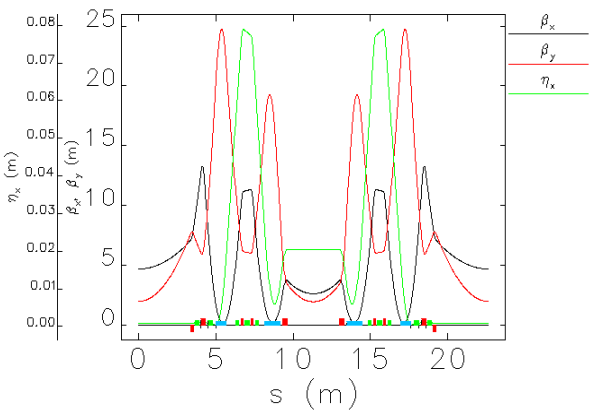

Figure 2: Optics functions for the DDBA cell.

The dynamic aperture and the momentum aperture were further optimised with a Multi-Objective Genetic Algorithm (MOGA) implemented in elegant [10], using the 10 sextupole families in the ring. The dynamic aperture is about ± 5 mm while the momentum aperture exceeds ±2 % everywhere in the ring and corresponds to a Touschek lifetime of 2.2 h. While the dynamic aperture is still too small for off-axis injection we believe that a more thorough search for the optimal phase advance per cell and using more sextupole families can improve the dynamic aperture to values compatible with our off axis-injection that currently produces a residual oscillation of 8.3 mm. This work will be the subject of forthcoming investigation. More details on the nonlinear dynamics optimisation can be found in ref. [1]. Alternative injection schemes in small dynamic apertures are under investigation [11].

IMPLEMENTATION OF ONE DDBA CELL

The DDBA cell opens the possibility of adding new straight sections to the ring and therefore accommodating new beamlines. This opportunity was used to modify the layout of the VMX beamline [6] by implementing one DDBA cell in the present cell 2 of the lattice. The VMX beamline was originally designed with two branches which were served by one in-vacuum ID and one short ex-vacuum ID respectively. With the DDBA cell, both branches can be served by 2m in-vacuum IDs with a considerably better performance. The modified lattice is shown in Fig. 3.

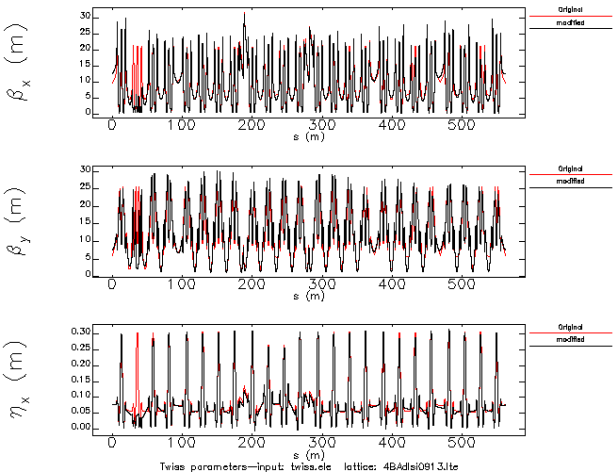

Figure 3: Optics functions with cell 2 upgraded to a DDBA cell.

The optimisation of the beam dynamics with MOGA showed that the insertion of the DDBA can be made almost transparent, as the dynamic aperture and Touschek lifetime of the ring are restored to the values of the original lattice. Figure 4 shows the DA of ±15 mm and the corresponding frequency map. The computed Touschek lifetime is 27h compared to the 29h of the original lattice.

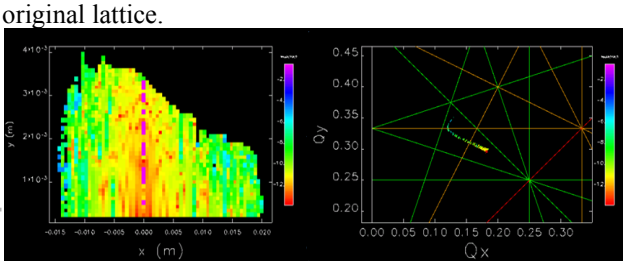

Figure 4: Dynamic aperture and frequency map for the Diamond lattice with one DDBA cell.

TWO AND MORE DDBA CELLS

In following studies, cell 11 was altered to a DDBA cell in correspondence of the DIAD beamline [7]. A new set of extensive numerical simulation was set up to optimize the dynamic aperture and the Touschek lifetime. Also in this case MOGA was used to set the values of ten existing sextupole families as parameters and the sextupoles in the new cell 11. A marginal readjustment of the sextupoles in the DDBA cell2 was required. The result presently achieved shows that the dynamic aperture is still about ±15 mm. The Touschek lifetime is 18h, that is a reduction to 62% of the existing value of the Touschek lifetime. We believe that, while already very promising, these values can still be improved to make also the second cell installation transparent to the operation of the existing ring.

Consequently we have started the analysis of a third DDBA cell. While this exercise is driven by the requirement to install a third harmonic cavity for bunch lengthening, it is also in line with the concept of a phased upgrade of the full ring and serves to prove the flexibility of our lattice. The lattice functions were matched as reported in Figure 5. The study of nonlinear beam dynamics will be carried out in the near future.

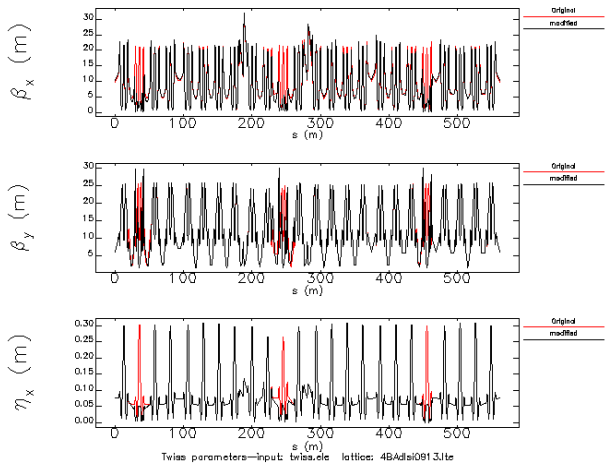

Figure 5: Optics functions with three cells upgraded to a DDBA (cell 2, cell 11 and cell 20).

CONCLUSION

Several MBA lattice options are considered for a possible low emittance upgrade of the Diamond storage ring. Lattices based on 7BA cells promise very small emittance, but their optimisation appears to be challenging. A modified 4BA lattice providing small beam emittance and doubling the number of beamlines appears to be a strong candidate for the upgrade of Diamond. The beam dynamics optimisation of one and two DDBA cells in the present lattice has shown that their installation will not compromise the operation of the ring, while providing substantial benefits for the corresponding beamlines. The implementation of a third DDBA cell is under investigation.

ANALYSIS OF TRANSVERSE INSTABILITIES OBSERVED AT J-PARC MR AND THEIR SUPPRESSION USING FEEDBACK SYSTEMS

Y. H. Chin, KEK/Sokendai, Tsukuba, Japan

Abstract

This paper presents an analysis of head-tail instabilities observed at the J-PARC MR (Main Ring) and their suppression using feedback systems. Instabilities were mainly observed at low energies. About 30% of particles are lost due to the instabilities if the feed-back system is turned off at the beam power of 120kW. Both horizontal and vertical instabilities were observed. Measurements of the horizontal oscillations initially suggested the excitation of higher-order head-tail modes during the injection. An analysis unveils that a dipole mode has a temporal appearance of higher-order head-tail modes if the chromaticity is sufficiently large. The development of instabilities in the presence of a large chromaticity should be considered for conditions beyond the Sacherer's text book case.

INTRODUCTION

J-PARC consists of three proton accelerators: a 400 MeV linear accelerator (currently operating at 180 MeV), a 3 GeV Rapid-Cycling Synchrotron (RCS) and a 50 GeV (currently 30 GeV) Main Ring (MR). The main parameters of the MR are summarized in Table 1.

Table 1: Main Parameters of the MR Ring

Circumference	1568 m
Injection Energy	3 GeV
Extraction Energy	30 GeV
Repetition Period	3 sec
RF Frequency	1.67-1.72 MHz
Number of bunches	8
Synchrotron tune	0.002-0.0001
Betatron tune	22.4, 20.77

In the normal operation mode, over 90% of the protons accelerated in the RCS are directed to the muon and neutron production targets in the Materials and Life Science Experimental Facility (MLF). The remaining protons are transported to the MR for further acceleration before being extracted via one of two (fast and slow) MR extraction ports.

The MR impedance is dominated by the transverse resistive-wall impedance of the stain-less steel chamber and the horizontal kicker impedance [1]. The kicker impedance has sharp peaks at about 1MHz and 10MHz. It is almost halved after four injection kickers were replaced by parasitic-impedance-free new models with HOM dampers (we still use five old-type kickers). The transverse resistive-wall impedance is exceptionally high, since the first betatron unstable line appears at around 40kHz on the vertical plane where the skin-depth is comparable to the wall thickness and the transverse impedance is proportional to the inverse of the frequency, not the square root of the frequency [2]. The beam instability evaluation before the commissioning of MR predicted that beam instabilities would start to hurt beam operation from the beam power of 100-200kW. Although the necessity of a damper system has been recognized, actual development has been delayed due to financial constraints. After the commissioning of MR started, the careful inventory of the existing hardware revealed that we already have some key components necessary to compose the damper system: several unused Stripline Position Monitors (SPM), and the exciters for tune measurements that can be exploited as damper kickers. It was found that only remaining component to be developed is a signal processing circuit to filter and process SPM data and then to produce kick signals. The whole project costs only less that 100k USD.

Figure 1 sketches the transverse (narrow-band) bunch-by-bunch feedback system. The beam position signals are sampled at an RF frequency times 64 rate (108.8MHz at 3GeV). The signal processing and digital filtering circuits consist of two LLRF4 boards with four 14-bit ADCs and two 14-bit DACs. They extract the betatron oscillation signals using 8-tap FIR filters. Its system integration and firmware development including EPICS interface was done by the Dimtel Inc. The kick signals are sent to the stripline damper kickers through the power amplifiers (two 500W/ 10kHz-250MHz ones for the horizontal plane and two 1kW/100kHz-8MHz ones for the vertical plane) to provide a single kick per bunch per passage for the both directions.

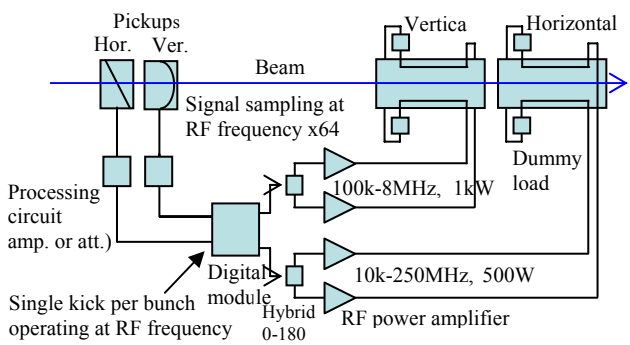

Figure 1: Schematic view of the transverse bunch-by-bunch feedback system (narrow-band).

Figures 2 (a) and (b) show the beam oscillation signals from the SPM recorded at a 500MHz sampling rate for the first 128ms period that covers the injection of the last batch of bunches from RCS (K4) and the onset of acceleration (P2) where all instabilities take place. The top figure (a) shows the signals with the feedback (FB) off, while the bottom figure (b) shows one with the FB on.

Copyright © 2013 CC-BY-3.0 and by the respective authors

The strong vertical oscillations are visible just after the onset of acceleration when the FB is turned off. The large horizontal oscillation can be also seen just after the injection of the last batch of bunches. They are strongly damped when the FB is tuned on. The DCCT monitor shows that the particle losses at the injection and at the onset of acceleration are about 500W and 4,800W, respectively, which are far larger than the collimator tolerance (400W). They are reduced to 100W and 25W, respectively, when the FB is turned on. Figures 3 (a) and (b) show the beam intensity measured by the DCCT monitors without and with FB, respectively. It can be seen that almost 30% of particles are lost due to the beam instabilities when FB is turned off. The FB is now indispensable in daily operation of MR.

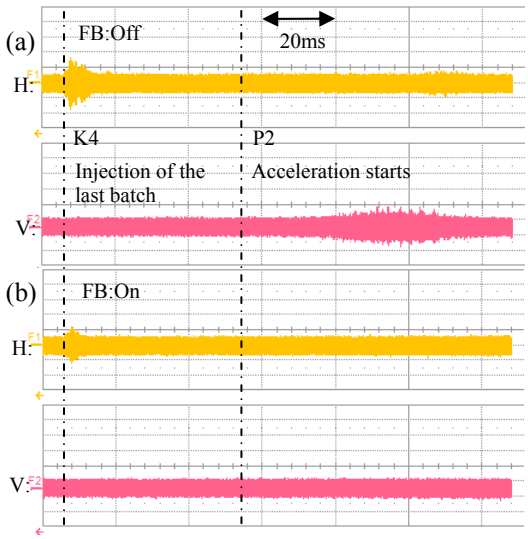

Figure 2: The beam oscillation signals from SPM for the first 128ms (a) when FB is turned off and (b) when FB is turned on.

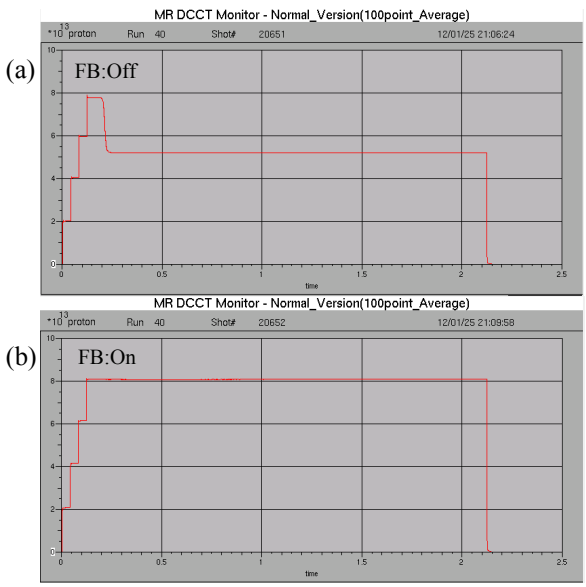

Figure 3: The beam intensity measured by the DCCT monitors (a) when FB is turned off and (b) when FB is turned on.

HEAD-TAIL INSTABILITY THEORY

Let us revisit the Sacherer's head-tail instability theory [3]. The chromaticity is defined by

$$\xi = \frac{d\omega_\beta}{\omega_\beta} / \delta \ , \tag{1}$$

where ω_β is the angular betatron frequency and $\delta = \Delta p / p$ is the relative momentum deviation. In other words, the betatron frequency depends on the momentum deviation as

$$\omega_\beta(\delta) = \omega_{\beta 0}(1 + \xi\delta) \cdot \tag{2}$$

When a particle moves along the ring, the accumulated betatron phase advance is given by

$$\phi_\beta(s) = \int \omega_\beta(\delta) \frac{ds}{\beta c} = \omega_{\beta 0}\left(\frac{s}{\beta c} - \frac{\xi}{\eta}\tau\right) , \tag{3}$$
$$\equiv \omega_{\beta 0} \frac{s}{\beta c} - \omega_\xi \tau$$

where τ is the arrival time difference of the particle at the position s (positive toward the head of bunch), βc is the velocity of the particle, and η is the slippage factor. Thus, the betatron phase advance varies linearly along the bunch and attains its minimum (maximum) at the head (tail) of the bunch.

To investigate how the difference of phase advance between the head and the tail of the bunch varies over one synchrotron oscillation period, we have developed the four particle model in the synchrotron phase space, as illustrated in Fig. 4. We assume that the arrival time is oscillating as

$$\tau = \hat{\tau} \cos(2\pi \nu_s k) \, , \tag{4}$$

where ν_s is the synchrotron oscillation tune and k is the revolution turn. We also assume that the chromaticity is negative and the ring is operated below the transition energy ($\eta < 0$). Thus particles move clockwise in synchrotron phase space.

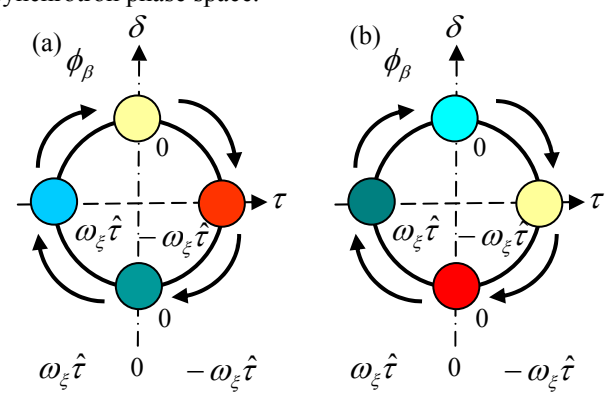

Figure 4: (a) The initial phase advance setting of the four particles. (b)The phase advance after a quarter period of the full synchrotron oscillation.

In principle, the betatron phase advance slows down (quickens up) by $\omega_\xi \hat{\tau}$ for every quarter period of synchrotron oscillation as the particle moves forward

Copyright © 2013 CC-BY-3.0 and by the respective authors

(backward) along the synchrotron orbit, respectively. As can be seen in Fig.4, the initial phase relationship along the bunch is preserved after the quarter period of synchrotron oscillation. One can quickly check that the phase pattern remains stationary over the full period of the synchrotron oscillation. In other words, the difference of the phase advance between the head and the tail of the bunch is constant, and we denote this constant as χ:

$$\chi = \phi_{\beta Tail} - \phi_{\beta Head} = 2\omega_\xi \hat{\tau} = 2\frac{\xi}{\eta}\omega_{\beta 0}\hat{\tau} = \text{constant}. \quad (5)$$

Let us assume that the dipole moment observed at a single point in the ring has the following standing wave pattern:

$$p_m(t) = \begin{cases} \cos(m+1)\pi\dfrac{t}{\tau_L} & m = 0,2,4,... \\ \sin(m+1)\pi\dfrac{t}{\tau_L} & m = 1,3,5,... \end{cases}, \quad (6)$$

where $\tau_L = 2\hat{\tau}$ is the total bunch length. The transverse pick-up signal observed at that point on the k-th revolution turn is given by

$$I_m(t) \propto p_m(t)\exp(i\omega_\xi t + i2\pi k\nu_{\beta 0}), \quad (7)$$

where $\nu_{\beta 0}$ is the betatron tune. The effect of the travelling-wave component $\exp(i\omega_\xi t + i2\pi k\nu_{\beta 0})$ over the standing-wave dipole moment $p_m(t)$ is to shift the bunch spectrum by ω_ξ. Figure 5 shows an example where the transverse resistive-wall impedance and the narrow-band kicker impedance are shown as impedance examples. The spectra are drawn for the head-tail modes 0 and 1 with positive phase difference χ. In this example, the mode 0 is stabilized, while the mode 1 becomes unstable by the transverse resistive-wall impedance at low frequency.

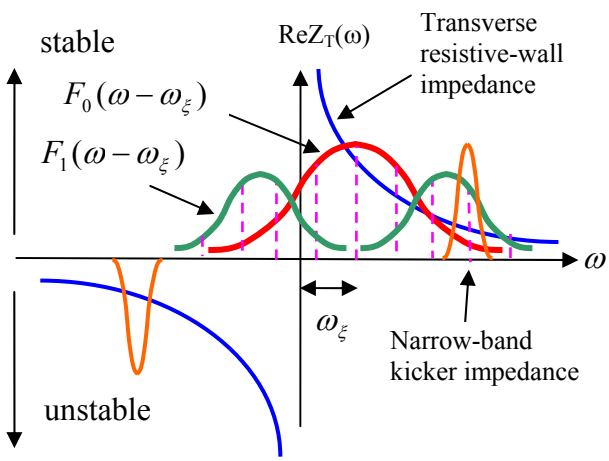

Figure 5: An example of the bunch spectrum shift by non-zero chromaticity.

The shift of the left peak of the bunch spectrum of the mode 1 means that a part of the mode now oscillates slowly. The head and the tail of the bunch will move almost in phase, not out of phase, to synchronize with the low frequency impedance. On the other hand, the shift of the right peak of the mode 1 bunch spectrum implies that this part of the mode now oscillates faster. In summary, the mode m=1 is degenerated at zero chromaticity, but it now splits to slower and faster oscillating parts by non-zero chromaticity. These split modes are equally excited due to the standing-wave condition of head-tail modes, and thus they always have a node at the centre just like the m=1 mode at zero chromaticity.

BEAM SIGNAL MEASUREMENT AT MR

We have made several beam studies to investigate beam oscillation signals from the SPM in more depth. The studies were done with 8 bunches with the beam power of 120-140kW. The typical chromaticity pattern is shown in Fig. 6.

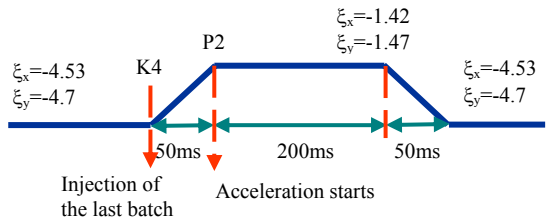

Figure 6: The typical chromaticity pattern.

Vertical Instability at the Onset of Acceleration

The vertical instability at the onset of acceleration (see Fig. 2(a)) is a text book case of the head-tail instability: it starts with a noise with the right phase relationship as shown in Fig.4 and then grows. Let us estimate head-tail modes that could be excited at the onset of acceleration by the MR transverse impedances. The phase difference χ is 4.4 for the chromaticity $\xi = -1.45$, the total bunch length of $\tau_L = 2\hat{\tau} = 150ns$ and the slippage factor of 0.058. That leads to the excitation of the m=0 or m=1 mode by the low frequency transverse resistive-wall impedance. The 10MHz kicker impedance can produce $\chi = 13.8$ and thus the m=3 mode is likely to be excited. Figures 7 show the maximum amplitude of the vertical oscillation when the FB is turned off (left) and is turned on (right), respectively.

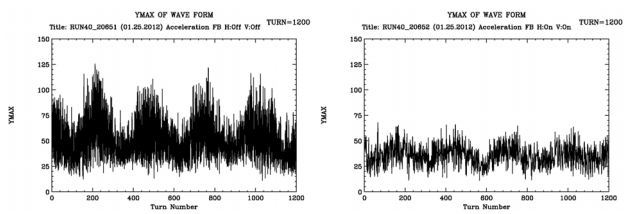

Figure 7: The time evolution of the maximum amplitude of vertical oscillation for the FB off (left) and on (right).

From these figures, the growth time can be estimated as about 1.2ms. The huge damping effect by the FB is recognizable in the right figure of Fig. 7. Figure 8 shows the vertical oscillation signals superimposed on 10 consecutive turns (when FB is tuned off). No node is visible, suggesting that the vertical oscillation is just a

Copyright © 2013 CC-BY-3.0 and by the respective authors

dipole mode. The BBU approach for the growth time estimate delivers the growth time of 1.5ms, in a reasonable agreement with the measurement of 1.2ms [4].

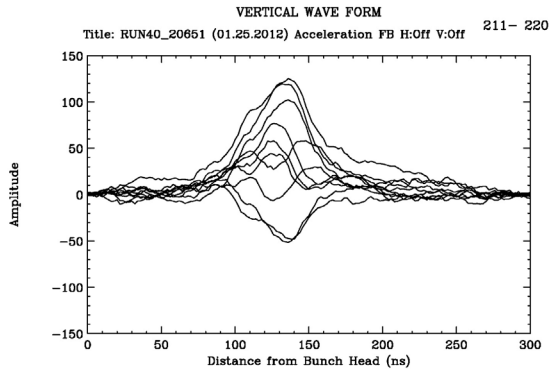

Figure 8: The vertical oscillation signals superimposed on 10 consecutive turns when FB is turned off.

Horizontal Instability at the Injection

The horizontal instabilities during the injection evolve from very different initial conditions compared to conventional head-tail instabilities. They start, not from noise, but from a large transverse displacement due to injection errors or ones by kicks by the mismatching field of the kicker magnets. There is no betatron phase difference along the bunch at the moment of the injection or the kicks by the mismatching field. Nevertheless, if we still apply the Sacherer's text book analysis to this case, the head count of head-tail modes that could be excited at 140kW is the m=3 mode by the low frequency resistive-wall impedance and the m=6 mode by the 10MHz kicker impedance. Figures 9 show the time evolution of the maximum amplitude of horizontal oscillation of the first bunch at the injection of the last batch when the FB is turned off (left) and on (right), respectively. Figures 10 show the measured horizontal oscillations of the same bunch for the FB on (left) and FB off (right) at the 1st (top), 250-th (middle) and 501-th (bottom) turns, respectively.

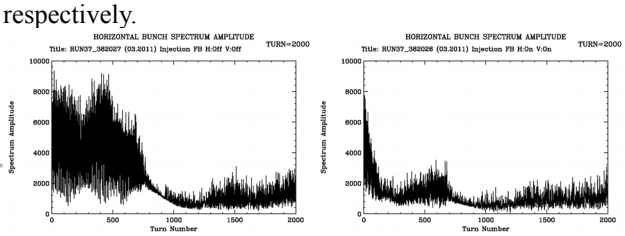

Figure 9: The time evolution of the maximum amplitude of horizontal oscillation of the first bunch at the injection of the last batch (K4) for the FB off (left) and on (right), respectively.

One can see that main growing mode with the FB off is the dipole mode and it is very quickly and effectively damped by the FB system. However, complex intra-bunch oscillations occasionally emerge and fade out. It looks like that a lower-order head-tail mode appears first and then it is transmuted into higher-order modes (m=6 or 7), and then transmuted back to the lower-order mode again after one full synchrotron oscillation period (~500 turns).

No large particle loss has been observed associated with these intra-bunch oscillations at present. However, if they are indeed head-tail modes excited by the 10MHz kicker impedance, it is likely that they will impose a significant limit on the beam power in future, since the present narrow-band FB system is ineffective to damp such intra-bunch oscillations. To defuse such possibility, first we started to develop a broadband intra-bunch feedback system based on the iGp12 module [5]. At the same time, we made more in-depth investigation of the measured intra-bunch oscillations to find their true identity.

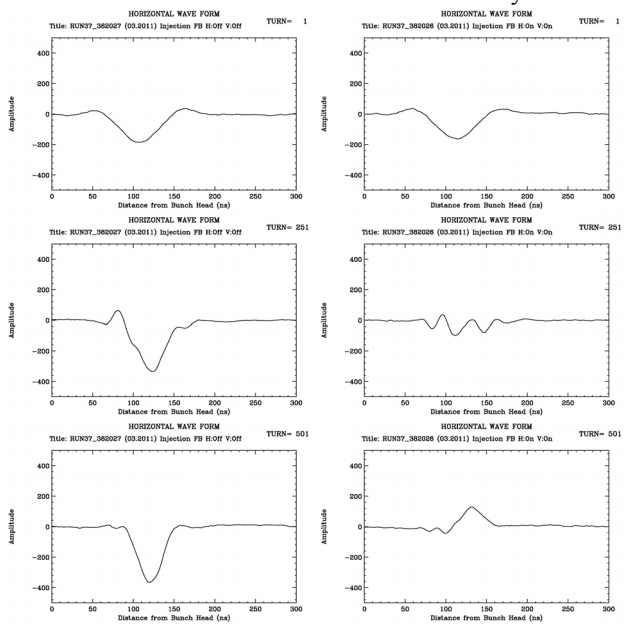

Figure 10: The measured horizontal oscillations of the first bunch at the injection of the last batch (K4) for the FB off (left) and FB on (right) at the 1st (top), 250-th (middle) and 501-th (bottom) turns, respectively.

The iGp12 digital signal processing module is widely used in electron rings. It is operated at the rate of RF frequency times 64 and replaces the present narrowband digital module shown in Fig. 1, which is operating at just the RF frequency. It divides each RF bucket into 64 segments (bins) and acts on each bin as if it is a small bunch (bunch-let) in a narrowband mode.

Let us take a closer look at the horizontal oscillations signals to see if they are forming envelops, one of signatures of head-tail modes. Figures 11 show the horizontal oscillation signals superimposed on 10 consecutive turns starting from 251-th turn. No clear node is visible in the both cases with and without active FB.

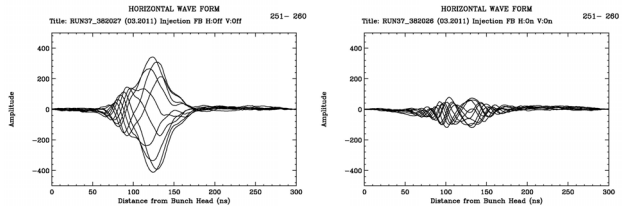

Figure 11: The horizontal oscillation signals superimposed on 10 consecutive turns starting 251-th turn for the FB off (left) and the FB on (right), respectively.

Copyright © 2013 CC-BY-3.0 and by the respective authors

One possible explanation is that the kicker 10MHz impedance is not strong enough to sustain higher-order head-tail modes alive for long period of time. Another possible explanation is that the simple application of Sacherer' text book analysis is inadequate in the present case.

Let us re-investigate how the betatron phase difference between the head and the tail of a bunch evolves over a full synchrotron oscillation period using the four particle model again (see Fig. 12). All the particles have the same betatron phase at the beginning. At every a quarter period of the full synchrotron oscillation, the phase difference between the head and the tail increases by $2\omega_\xi\hat{\tau}$ till the half of the synchrotron oscillation. Then, the phase difference starts to decrease and come back to zero at the full synchrotron oscillation (namely, the picture next to (d) comes back to (a)). More detailed analysis shows that the phase difference oscillates like

$$\chi = \phi_{\beta Tail} = \phi_{\beta Head} = \frac{\xi}{\eta}\omega_{\beta 0}\tau_L \cdot (1-\cos(2\pi\nu_s k)). \qquad (8)$$

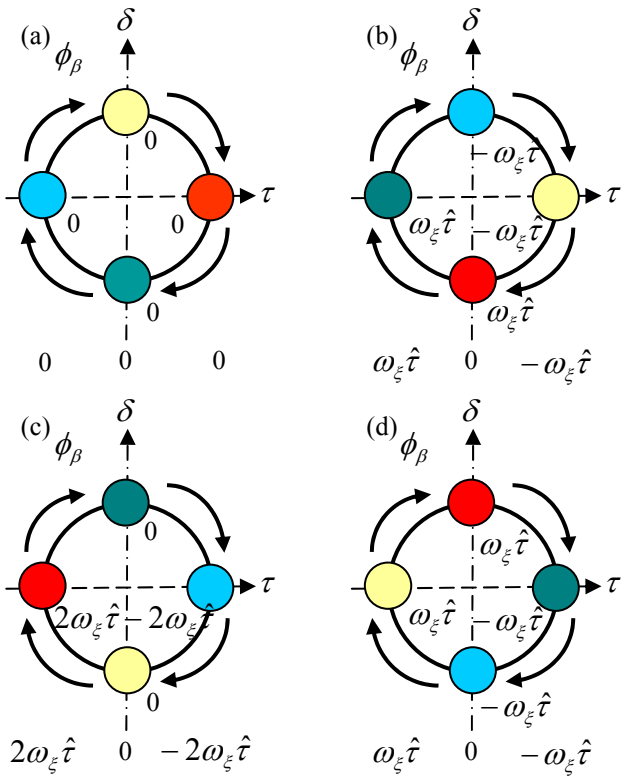

Figure 12: (a) The initial zero phase difference. (b-d) Change in phase advance after every quarter period of the full synchrotron oscillation. After (d), the phase difference comes back to (a).

Let us see how a simple dipole mode changes its oscillation appearance when the phase difference between the head and the tail oscillates as specified in Eq. (8). Figures 13 show the simulated horizontal oscillations and their superposition on 10 consecutive turns at the 1st (top), 251-th (middle) and 501-th (bottom) turns, respectively. They are strikingly similar to the right figures of Figs. 10 and Figs. 11. We also analysed the frequency spectra of the horizontal oscillation signals and found that the low frequency signal (lower than ~5MHz) is dominant and there is no clear peak at higher frequency. These results demonstrate that a simple dipole mode can create a temporal deceptive appearance of higher-order head-tail modes, when the betatron phase difference between the head and the tail of the bunch is oscillating as in Eq. (8).

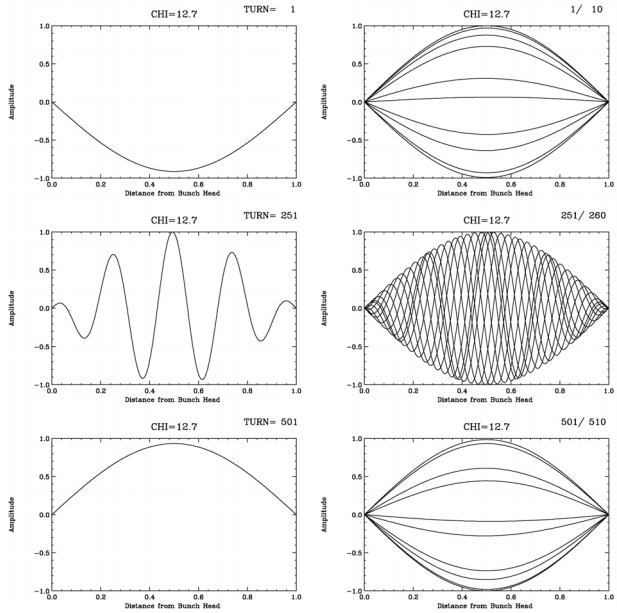

Figure 13: The simulated horizontal oscillations and their superposition on 10 consecutive turns at the 1st (top), 251-th (middle) and 501-th (bottom) turns, respectively.

SUMMARY

The present (narrowband) bunch-by-bunch feedback system is found to be quite effective to suppress transverse beam instabilities at MR, allowing the beam power to reach 230kW with only particle losses of 400W. The initial analysis of the horizontal instabilities during the injection raised concern over the excitation of higher-order head-tail modes. However, the detailed analysis revealed that a simple dipole oscillation can be deceived as higher-order head-tail modes, when a bunch starts to oscillate from a large transverse displacement. The new broadband intra-bunch feedback system is under testing.

TRANSVERSE IMPEDANCE AND TRANSVERSE INSTABILITIES IN THE FERMILAB BOOSTER*

A. Macridin, J. Amundson, P. Spentzouris, V. Lebedev, T. Zolkin Fermilab, Batavia, IL 60510, USA

Abstract

The Fermilab Booster is characterized by large space charge and large wake fields, leading to beam loss and instabilities at high intensity. Using the Synergia simulation package with a realistic lattice model and realistic wake functions we investigate the coherent tune shift and the instabilities at injection energy. We calculate the wake functions in the laminated magnets and find them to be four orders of magnitude larger than the wakes in the metallic straight sections. We find a large decrease of the vertical tune shift and a small increase of the horizontal tune shift with intensity, in good agreement with experiment. In agreement with measurements, we find that a large chromaticity is required to avoid a horizontal instability. The instability is caused by short-range bunch-bunch interaction and is due to the large coupling between the horizontal wake function and large lattice beta function at the locations of the focusing magnets.

INTRODUCTION

The Fermilab Booster [1] is a 40-year-old machine which provides protons for the Fermilab Main Injector. It runs at an intensity of 4.5×10^{12} protons per batch, which is about two times larger than the originally designed intensity. The machine shows beam loss and instabilities at high intensity. For machine improvements required by the demand of future Fermilab programs for high intensity beams, it is essential to have a good understanding of these instabilities.

The particular thing about the Booster is the presence of the dipole-quadrupole combined-function focusing (F) and defocusing (D) magnets, which cover about 60% of the machine length. The rest of the machine is made by straight metallic beam pipe sections. Since there is no beam pipe in the combined-functions magnets, the beam is exposed directly to the magnets' laminations. A consequence of the presence of bare laminations is the formation of very large wake fields. Since the machine runs at low energy (injection E/final $E = 0.4GeV/8GeV$), the space charge is also strong. The presence of both large wakes and space charge effects together with complex single-particle optics makes any attempt of analytical treatment very difficult.

*This work was performed at Fermilab, operated by Fermi Research Alliance, LLC under Contract No. De-AC02-07CH11359 with the United States Department of Energy. It was also supported by the ComPASS project, funded through the Scientific Discovery through Advanced Computing program in the DOE Office of High Energy Physics. We also used resources of the Argonne Leadership Computing Facility at Argonne National Laboratory, which is supported by the Office of Science of the U.S. Department of Energy under contract DE-AC02-06CH11357.

We address these effects by using Synergia [2], a state of the art simulation package developed at Fermilab. We perform single- and multibunch simulations at the injection energy. Since the RF sets the number of buckets in the Booster to 84, a full machine simulations requires simulations with 84 bunches.

In order to properly take into account the wake fields, we calculate the wake functions in the laminated magnets. We find that the wake functions in the laminated magnets have a non-metallic behavior and are four orders of magnitude larger than the wakes in the metallic pipe section.

The measurements of the coherent tune shift show a large negative shift for the vertical tune and a small positive shift for the horizontal tune [3, 4]. Close to injection, the beam is horizontally unstable unless the machine runs with a large horizontal chromaticity [5]. The result of our simulations are in good agreement with experiment. We find that the instability is due to short range bunch-bunch interactions. The instability is caused by the large value of the coupling between the lattice horizontal beta function and the horizontal wake at the location of the F magnets.

SYNERGIA CODE

Synergia [2] is a simulation package for beam dynamics in accelerators developed at Fermilab. It can address single-particle optics by using direct symplectic integration through the lattice elements or/and by using arbitrary-order polynomial maps. Collective effects are incorporated by employing the split-operator method [6]. A variety of space-charge solvers (such as 3D Poisson solvers with different boundary conditions, 2.5D solversand semi-analytical 2D solvers) can be used with Synergia. Synergia can accommodate arbitrary wake functions by reading them from external files.

In our Booster simulations, in order to account for the large nonlinear lattice effects, we used direct symplectic integration for particle propagation. Space charge was addressed by using three different 3D Poisson solvers with appropriate boundary conditions for the F magnets, D magnets and straight sections, respectively. We used different wake functions for the F and the D magnets. The wake functions for the laminated magnets were calculated separately, as is described in the next section.

WAKE AND IMPEDANCE

The electromagnetic field created by a particle moving through the accelerator induces currents in the vacuum chamber walls. The field created by these currents will affect a trailing particle. This effect can be addressed by a

Copyright © 2013 CC-BY-3.0 and by the respective authors

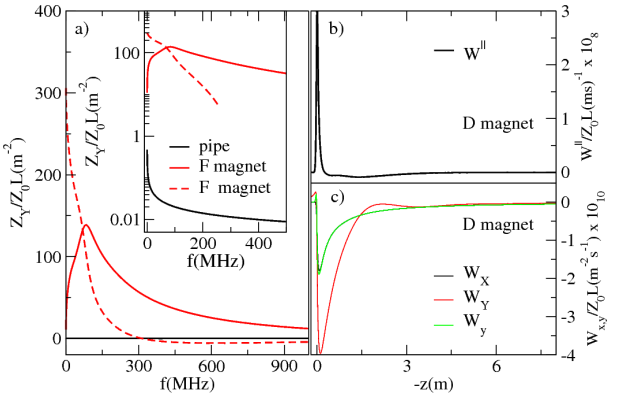

Figure 1: a) The vertical impedance caused by the source displacement in the F magnet ($ReZ_Y(\omega)$ -solid line, $Im(Z_Y(\omega)$ -dashed line) and in the pipe section. (See inset for the plot using a logarithmic scale). The impedance in the laminated magnets is four orders of magnitude larger than in the pipe. b) Longitudinal wake in the D magnet. c) Transverse horizontal and vertical wakes in the D magnet. The vertical wake caused by the source displacement (red) is about two times larger than the corresponding horizontal one (black). Due to nonultrarelativistic effects, the wakes are nonzero up to a small distance ($\approx 0.1m$) in front of the source particle.

simple formalism [7],

$$\beta c \Delta p_z = -qQW^{||}(z) \quad (1)$$

$$\beta c \Delta p_x = -qQ\left(W_X(z)X + W_x(z)x\right) \quad (2)$$

$$\beta c \Delta p_y = -qQ\left(W_Y(z)Y + W_y(z)y\right). \quad (3)$$

Here Q, X, Y (q, x, y) represent the charge and horizontal and vertical displacements of the source (witness) particle. The momentum of a witness particle going through a lattice element is kicked with a term proportional to a wake function which depends only on the distance, z, between the source and the witness particle. Only the terms up to the first order in the particles displacements are considered. Note that for highly symmetric chambers, such as circular or rectangular, and in the ultrarelativistic limit, the terms proportional to the witness particle displacement are zero. For a flat chamber like the one we use to model the Booster magnets, $W_X = -W_x$ due to the horizontal translational symmetry.

For a realistic simulation it is important to have an accurate estimate of the wake functions. Calculation of the wakes requires solving the electromagnetic problem for the vacuum chamber. This is usually done in the frequency domain. The impedance, which is related to the wake function via a Fourier transform is proportional to the force acting on the witness particle. The solution is dependent on the chamber geometry and on the boundary conditions for the electromagnetic field at the vacuum chamber walls.

Due to the exposure of the laminations, the impedance and wakes are orders of magnitude larger in the combined-function magnets than in the metallic pipes. The ultrarelativistic impedance calculation in the laminated structures is presented in [8], while the nonultrarelativistic effects for flat chambers are addressed in [9]. In Fig. 1 a) we show the vertical impedance Z_Y in the F magnet and compare it with the straight section vertical impedance. While the straight section impedance shows the conventional (i.e. metallic) $\omega^{-0.5}$ behavior in the frequency domain of interest, the real part of the F magnet impedance shows a broad peak around $80MHz$ and is four orders of magnitude larger. In Fig. 1 b) and c) we show the longitudinal and transverse wakes in the D magnet. The vertical wake W_Y is about two times larger the corresponding horizontal wake, W_X, while the vertical wake caused by the witness particle displacement W_y is close to the corresponding horizontal wake W_x. (They are equal in the ultrarelativistic limit). Note that due to the nonultrarelativistic effects, the wakes are nonzero up to a small distance ($\approx 0.1m$) in front of the source particle.

SIMULATION RESULTS

To ensure agreement between the lattice model and the real lattice the parameters of the dipole and quadrupole correctors were determined using Orbit Response Measurement fitting [10]. We performed single- and multi-bunch simulations up to 2000 turns at the injection energy $(0.4GeV)$.

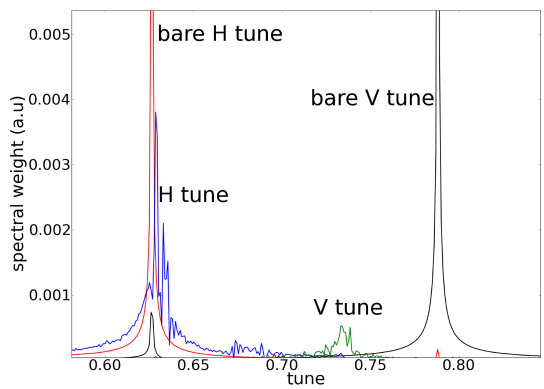

Figure 2: Fourier transform of the beam centroid horizontal and vertical displacements at intensity 4×10^{10} p per bunch for the full machine (84 bunches). When the collective effects are neglected (red and black), the spectral weight exhibits sharp peaks for frequencies corresponding to the bare tunes. The spectral weight shows small positive horizontal (blue) and large negative vertical (green) tune shifts when the collective effects are present. Note the wide spectral features when the collective effects are included.

The coherent tune was determined by Fourier transforming the beam centroid displacement as a function of the trajectory length. The spectral analysis is shown in Fig. 2. When no collective effects are included, the spectrum shows sharp peaks at frequencies corresponding to

Copyright © 2013 CC-BY-3.0 and by the respective authors

the bare tunes. With the collective effects taken into account, the spectral weight shows small positive horizontal and large negative vertical tune shifts. Aside from that, the spectral features are broad, indicating the evidence of an interaction between multiple modes.

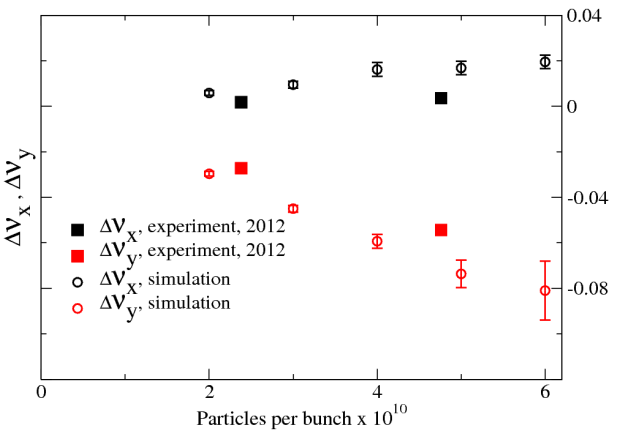

Figure 3: Comparison of the calculated coherent tune shifts for a full machine at injection with measurements. The simulation shows a slightly larger tune shift.

A comparison of the simulated coherent tune shift at injection with measurements [4] is shown in Fig. 3. As in the experiment, the simulations show a large decrease of the vertical tune and a small increase of the horizontal tune with increasing intensity. Our simulation shows a slightly larger tune shift ($\approx 10\%-15\%$) than the experiment. However, note the large error bar of the simulated tune shift which increases with increasing the intensity. The error bar is a consequence of the difficulty to uniquely determine the tune for a wide spectral feature.

Single-bunch simulations (not shown) suggest that, regarding beam loss, it is most favorable to have small values of chromaticity, $\frac{\omega_{\xi x}}{\beta c}, \frac{\omega_{\xi y}}{\beta c} \leq 2\pi \times 0.023 m^{-1}$. An increase of chromaticity results in an increase of the bunch transverse spatial dimensions. More particles hit the vacuum chamber walls and the beam loss is larger.

However, full machine (i.e. 84 bunch) simulations find that the beam is horizontally unstable for small horizontal chromaticity. The beam centroid horizontal displacement versus the turn number is shown in Fig.4 for different values of the horizontal chromaticity. This behavior is in very good agreement with the experiment [5]. In order to stabilize the beam, a large horizontal chromaticity, $\frac{\omega_{\xi x}}{\beta c} = 2\pi \times 0.091 m^{-1}$ [11] (which corresponds to $\xi_x = -19$ in Ref. [5]), should be chosen.

Simulations with a smaller number of bunches, occupying subsequent buckets also exhibit horizontal instability. In Fig. 5 the horizontal centroid displacement for different bunches in a 14-bunch train is shown. The instability is more pronounced for the bunches traveling at the end of the train. This result indicates that the instability is caused by short-range bunch-bunch interaction rather than by coupling to a resonant mode.

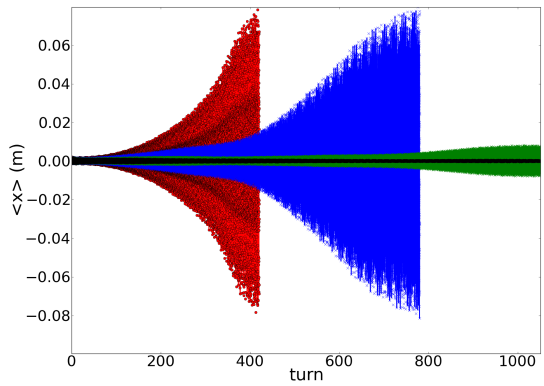

Figure 4: Full machine simulation. Beam centroid horizontal displacement at BPMs location versus turn number for different horizontal chromaticities, $\frac{\omega_{\xi x}}{\beta c} = 2\pi \times 0.023 m^{-1}$ (red), $\frac{\omega_{\xi x}}{\beta c} = 2\pi \times 0.046 m^{-1}$ (blue), $\frac{\omega_{\xi x}}{\beta c} = 2\pi \times 0.069 m^{-1}$ (green) and $\frac{\omega_{\xi x}}{\beta c} = 2\pi \times 0.091 m^{-1}$ (black). The vertical chromaticity is kept constant, $\frac{\omega_{\xi y}}{\beta c} = 2\pi \times 0.023 m^{-1}$. The intensity is 5×10^{10} p per bunch (i.e. 4.2×10^{12} p per batch). The beam shows horizontal instability unless a large horizontal chromaticity is considered, similar to the experiment [5]. In our units, the chromaticity is $\frac{\omega_{\xi x}}{\beta c} = 2\pi \times 0.091 m^{-1}$, which stabilizes the beam, corresponding to $\xi_x = -19$ in Ref. [5].

In order to understand the contribution of the different wake terms to the instability we performed simulations with modified wakes. First, we turned direct space charge [12] off in our simulations. The instability is still present, but the growth rate is smaller. Next, we ran simulations with the wake function terms (see Eqs. 1, 2, 3) modified. The instability growth rate is influenced very little by the multiplication of the longitudinal wake, $W^{||}$, or of the transverse wakes caused by the displacement of the witness particle, W_x and W_y, with a factor of two or by neglecting them (not shown). We also find that the vertical wake W_Y caused by the source displacement, has little contribution to the instability. This can be seen from Fig. 6, where the number of particles and centroid horizontal displacement are shown for both the original wakes and for enhanced W_Y. Nevertheless, we find that the instability is very sensitive to the horizontal wake W_X, as illustrated in Fig. 6. An increase of W_X by a factor of 1.5 strongly enhances the instability.

Considering that the vertical wake in the laminated magnets is about two times larger than the horizontal wake (remember Fig. 1 -c), it might seem counter intuitive that the system is prone to horizontal instability and not to vertical instability. However, note that the momentum kick is proportional to the wake coupled to the displacement. In a rough approximation, the instability growth rate should be proportional to the average over the machine length of the lattice beta function multiplied by the wake. Taking into

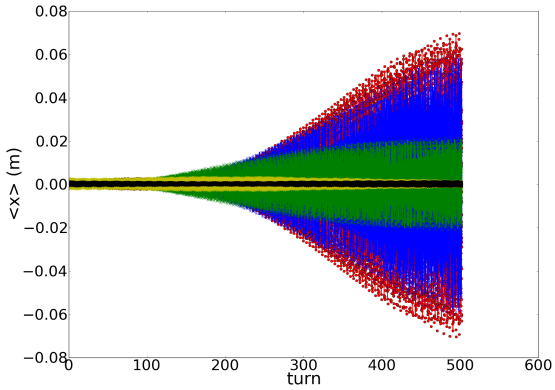

Figure 5: 14 bunch simulation with subsequent buckets occupied. $\frac{\omega_{\xi x}}{\beta c}, \frac{\omega_{\xi y}}{\beta c} = 2\pi \times 0.023 m^{-1}$. The intensity is 5×10^{10} p per bunch. The bunch centroid horizontal displacements versus turn number. $14^{\mathtt{th}}$ (red, the last bunch), $13^{\mathtt{th}}$ (blue), $9^{\mathtt{th}}$ (green), $4^{\mathtt{th}}$ (yellow), $1^{\mathtt{st}}$ (black, the leading bunch). The motion of the trailing bunches is unstable. The instability is caused by short-range bunch-bunch interaction rather than by a coupling to a resonant element.

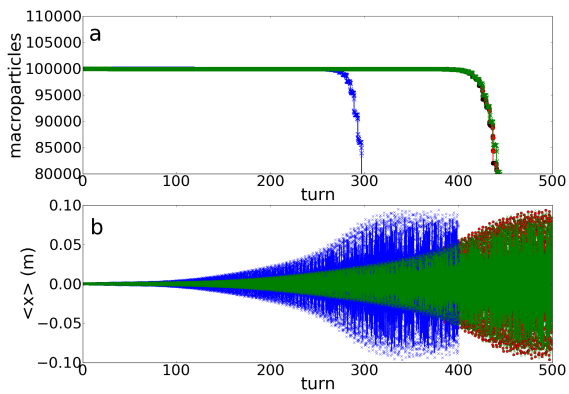

Figure 6: The number of macroparticles a) and beam centroid horizontal displacement b) versus turn number for different values of the wake functions. $\frac{\omega_{\xi x}}{\beta c}, \frac{\omega_{\xi y}}{\beta c} = 2\pi \times 0.023 m^{-1}$. The intensity is 5×10^{10} p per bunch. The direct space charge [12] is turned off. The instability is present for unmodified wakes (the ones corresponding to the real machine, red) and is very little affected by the increase of the vertical wake. (W_Y increased two times shown with green). However it is strongly enhanced by the increase of the horizontal wake caused by the source particle. (W_X increased 1.5 times shown with blue).

account that the average horizontal beta over the F magnets length is about 3.5 times larger than the corresponding average vertical beta ($< \beta_x >_F = 27.75$, $< \beta_y >_F = 8.15$), while the averages over the D magnets are of similar magnitude ($< \beta_x >_D = 12.78$, $< \beta_y >_D = 16.78$), one can conclude that the instability is caused by the large horizontal beta wake coupling at the location of the F magnets.

CONCLUSIONS

Experimental measurements show the presence of large wake fields and horizontal beam instability in the Fermilab Booster. We calculate the wakes in the laminated magnets and find them to be four order of magnitude larger than in the metallic straight section. Using Synergia we ran single- and multibunch simulations with a realistic lattice model, space charge and wake fields. The simulated coherent tune shift and the instability behavior are in good agreement with experiment. We find that the horizontal instability is caused by short-range bunch-bunch interaction rather than by a coupling to a resonant element. The instability is due to the large coupling between the horizontal wake and the horizontal lattice beta function at the location of the F magnets.

ACKNOWLEDGMENT

We want to thank M. McAteer, Y. Alexahin and W. Pellico for their contribution to this work.

THE JLAB 12 GEV ENERGY UPGRADE OF CEBAF *

Leigh Harwood (for the JLab 12 GeV project team)
Thomas Jefferson National Accelerator Facility, Newport News, VA 23606 USA

Abstract

CEBAF at Jefferson Lab was a 5-pass, recirculating cw electron linac operating at ~6 GeV and devoted to basic research in nuclear physics. The 12 GeV Upgrade is a major project, sponsored by the DOE Office of Nuclear Physics, that is expanding its research capabilities substantially by doubling the maximum energy and adding major new experimental apparatus. The Upgrade is illustrated in Figure 1 includes: doubling the accelerating voltages of the linacs by adding 10 new high-performance cryomodules; the requisite expansion of the 2K cryogenics plant and rf power systems to support these cryomodules; upgrading the beam transport system from 6 to 12 GeV through extensive re-use and/or modification of existing hardware; and the addition of one recirculation arc, a new experimental area, and the beamline to it; and the construction of major new experimental equipment for the GPD, high-xBjorken, and hybrid meson programs. The accelerator upgrade is essentially complete and the construction of the new experimental apparatus is well underway. This paper provides some details about the accelerator upgrade.

OVERVIEW

Scientific Motivation

In the 20+ years since the original design parameters of CEBAF were defined the understanding of the behavior of strongly interacting matter has evolved significantly, and important new classes of experimental questions have been identified that can be addressed optimally by a CEBAF-type accelerator at higher energy. The original design of the facility, coupled with developments in superconducting RF technology, makes it feasible to triple the initial design value of CEBAF's beam energy to 12 GeV in a cost-effective manner, providing a new research tool capable of addressing the science.

The science motivating the 12 GeV Upgrade includes breakthrough programs that will be launched in four main areas (they are described in detail in [1]):

- Discovering the quark structure of nuclei
- Probe potential new physics through high precision tests of the Standard Model using precision, parity-violating electron scattering experiments.

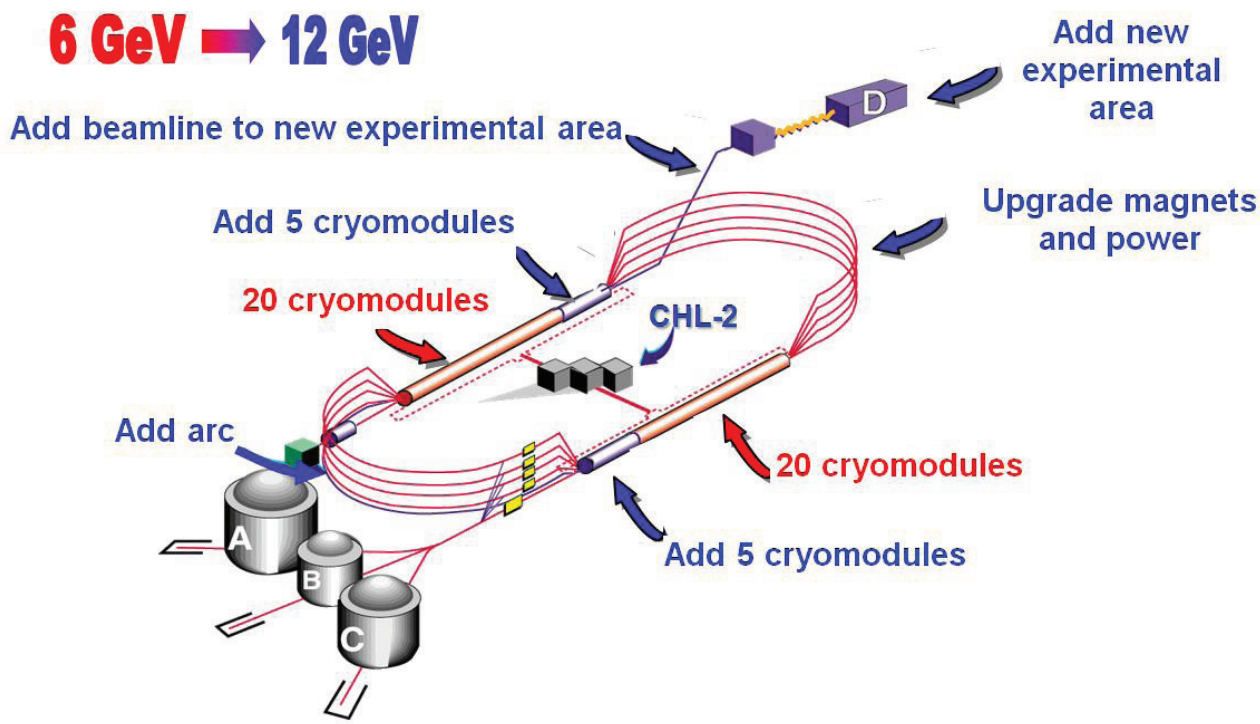

Figure 1: Changes to CEBAF.

* This work was supported by the U.S. Department of Energy Contract Number DE-AC05-06OR23177 under which Jefferson Science Associates, LLC operates Jefferson Lab

Copyright © 2013 CC-BY-3.0 and by the respective authors

- Explore the physical origins of quark confinement (GlueX experiment): A potential explanation, supported by lattice QCD calculations, is that quark confinement stems from the formation of a string-like "flux tube" between quarks. This conclusion (and proposed mechanisms of flux tube formation) can be tested by determining the spectrum of the gluonic excitations of mesons (referred to as "hybrid" mesons)

Base Requirements

The exotic meson spectroscopy program needs 9 GeV polarized photons for optimal production of the hybrid mesons and distinguishing them from the other meson excited states. Coherent bremsstrahlung, obtained by passing a high quality, cw beam of 12 GeV electrons through a crystal radiator, is the ideal source of these photons. Similar electron beam energies are nearly ideal for the other research programs outlined above.

CEBAF, which had originally been built to operate at 4 GeV, had been incrementally upgraded to 6GeV. Thus, to reach 12 GeV a net of 6 GV of acceleration had to be added. A new experimental area (for the hybrid meson program) has been added on the opposite end of the accelerator from three existing end stations, so the beam reaching it will transit one linac once more than beams for the existing end stations

12 GeV could have been achieved by increasing the linac capabilities or increasing the number of passes. An analysis determined that it would be more cost effective to increase the linac capabilities than to reconfigure (rebuild) the beam transport system for additional passes. Therefore, the 0.6 GV linacs have been upgraded to 1.1 GV. The hybrid meson studies need < 5 μA; the other programs need much larger beam currents. The original beam power limit of 1 MW has been retained.

The original beam transport system supported 5 pass beam at 6 GeV to the existing end stations. It has been modified to deliver 11 GeV beam to those halls and beam transport must be added to deliver the full 12 GeV beam to the photon radiator target for the new end station, including an additional recirculation arc.

BEAM PHYSICS

Beam Breakup

Beam breakup (BBU) driven by high-order modes (HOM) in the cavities must always be addressed when using srf cavities even if the beam current in the cavities, < 1 mA in this case, is not exceptional on the scale of storage rings. As was done for 4 GeV CEBAF, a BBU analysis was done [2] to set limits on the Q's of the HOM's. An impedance budget of $(R/Q)Qk < 2.4x10^{10}\ \Omega/m$ for transverse HOM's and $(R/Q)Q < 6.5x10^{11}$ for longitudinal modes came out of the study. The simulated cavities did not always meet those budgets when evaluated as single cavities because of longitudinal mode asymmetries and the presence of HOM dampers on only one end of the cavity. However, when evaluated as an assembled string, the fundamental power coupler on the adjacent cavity coupled out the asymmetric modes. The cavities on the ends of the cryomodule do not have that benefit so dampers were added in the waveguides for those cavities.

Emittance, Energy Spread, and Halo

Emittance growth from synchrotron radiation of the electrons in dispersive sections of the beam transport was not a limitation to meeting the 1 nm-rad specification for CEBAF at 4 GeV. For the Upgrade, cost containment drove a desire to forego extensive modifications to the existing optics. A so-called "double-bend achromat" lattice was adopted [3] for the higher-energy passes as it reduced the emittance growth relative to the original lattice without requiring reconfiguration of the beamline components. The resulting beam characteristics are summarized in Table 1. These values are consistent with the needs of the proposed research programs. Tracking calculations which included errors (misalignment, mispowering, field nonlinearities, etc) were carried out [4]. With all errors included in the model, the study found that the emittance and energy spread specifications will be met with some margin.

The hybrid meson experiment needs a very low beam halo to prevent unacceptable backgrounds. Particle-tracking calculations with multiple seeds for misalignment, mis-steering, field nonlinearities, and mispowering have shown [5] that the halo requirement for commissioning and early years of operation will be met.

Table 1: Beam Properties at 6 and 12 GeV

	6 GeV	12 GeV
Transverse emittance at Halls A, B, & C	$\varepsilon_x=\varepsilon_y=$ 1 nm-rad	ε_x=7 nm-rad ε_y=1 nm-rad
Transverse emittance at Hall D	NA	ε_x=10 nm-rad ε_y=2 nm-rad
δE/E at Halls A, B, & C	0.01%	0.02%

ACCELERATION

SRF

The additional 0.5 GV/linac is achieved by having added five new 100 MV cryomodules to each linac. Each cryomodule has eight 7-cell cavities. While only 17.5 MV/m is required for the cryomodule to reach 100 MV, the goal was set at 19.2 MV/m (on average for the ensemble in a linac) to deal with the likelihood (based on our operations experience with CEBAF) that some cavities might be off-line. The existing linacs could operate at the 5 pass equivalent of 5.6 GeV if none of the margin is needed for off-nominal conditions in the cryomodules.

Typically, the performance specification for cavities is stated as a Q0 at a particular gradient. We chose to keep with the parameters determined by the overall system. For 12 GeV we used a dynamic heat requirement rather

Copyright © 2013 CC-BY-3.0 and by the respective authors

than a Q0. After taking into account the load from the waveguides, the heat budget for dynamic load of each cavity was 29 W.

The cavity and cryomodule designs have undergone some evolution since the start of the design process. There had been a number of challenges that needed to be addressed during that evolution:

- RF windows: One of the developmental cryomodules used a single RF window on each cavity. It had some unexplained window failures. Those failures led to contamination of the cryomodule and seriously reduced performance. The incremental cost savings of using a single window did not offset the long term risk, so we returned to using both primary and secondary rf windows between the cavity and the external waveguide. All ten of the new cryomodules use the double-window configuration.
- Tuner: A new, less-expensive "rock crusher" tuner concept was developed for another of the developmental cryomodules. During testing some problems were experienced with the mechanical robustness of the tuner. Subsequent to that, SNS had some problems with their cryogenic motors. The original scissor-jack design was reworked for cost reduction. That design improved reliability with little cost impact, so it was used for all of the new cryomodules. It has the additional advantage that the motor and piezo-electric element are at room temperature, thus simplifying any required maintenance.
- Microphonics: During testing of the initial new cryomodules it was found that the cavity-tuner assembly was less stiff than those in previous JLab cryomodules with the result that their sensitivity to mechanical vibrations was much higher than had been seen in any of JLab's previous designs. It was determined that a number of factors (cell shape, lack of inter-cell stiffening rings, lack of bellows between the cavities, and a tuner-to-cavity interface that wasn't very stiff) were contributing factors. Finite element analysis indicated that a significant improvement in the overall stiffness could be achieved by a redesign of some of the tuner cavity interface components. That new design was implemented on the fourth cryomodule to be completed. The seven cryomodules with that change have ~2x lower microphonics than the three that were completed prior to the change.

All ten new cryomodules have been fabricated, tested, and installed. Nine have re-tested after installation. The performance goals have been met. The tenth cryomodule will be tested in October. A summary of the achieved voltages is given in Table 2.. Additional information can be found in the paper by John Hogan at this conference [6]

Table 2: Cryomodule Performance

Cryomodule	In-tunnel performance
#1	104 MV
#2	110 MV
#3	118 MV
#4	105 MV

#8	Testing in progress
#9	108 MV
#10	109 MV

RF

Each cavity is energized by its own klystron. In a 2001 overall system design initiative, the required saturated output power for the klystrons was based on the following criteria: 1) ≤450 μA of beam transiting the cavity (limited by 1 MW total beam power limit), 2) Qext is off-optimum by ≤30%, 3) maximum detuning ≤25 Hz of (4 Hz is 2x the tuner resolution and 21 Hz was 6σ of the measured microphonics spectrum on the original cavities), 4) some cavities would be able to operate at 21 MV/m (10% above the mean of the population but within the range that had been seen in early testing of prototype cavities) and stay within the cryogenic budget, 5) losses in the waveguides, and 6) add 10% so that the klystron would still have gain. The result of the calculation was 12.8 kW per cavity. In 2006 a study was performed to determine the cost-effectiveness of powering mutiple cavities with a single klystron. It was found that cost reduction was possible but only at the expense of failing to meet the phase and amplitude control goals. This option was not adopted and 12 GeV Upgrade uses one klystron per cavity. [7] Eighty 13 kW klystrons have been installed (one per cavity). Since the original klystron performance was established, cavity characteristics and waveguide losses have changed. The current de-tuning budget (static plus microphonics) with the 13kW klystrons is now 35Hz.

A new rf control module was developed using digital technology. Important control issues that were addressed were:

- Phase and amplitude control must meet the following specifications: 1) Amplitude noise <0.01% and 2) Phase noise < 0.2°
- The system has multi-valued resonance detuning curves resulting from the cavities' high fields and the accompanying high external Q (>2x107 for 12 GeV), as illustrated in Figure 2.

The new system has been completely installed and used to operate all of the installed new cryomodules including delivering beam at full system performance goals. [8]

Integrated RF-cryomodule Performance

Two of the new cryomodules were operating in the south linac during the 2011-2012 final nuclear physics run prior to shutting down to do the bulk of the upgrades. As

Copyright © 2013 CC-BY-3.0 and by the respective authors

the focus of that run was acquiring data for the nuclear physics experiments, the digital control algorithms could be optimized in only one of the two cryomodules. That one was able to deliver the targeted 108 MV with the full beam loading planned for the 12 GeV era. The nuclear physics experiment was a particularly precise measurement that required high quality beam. The users reported no change in beam quality.

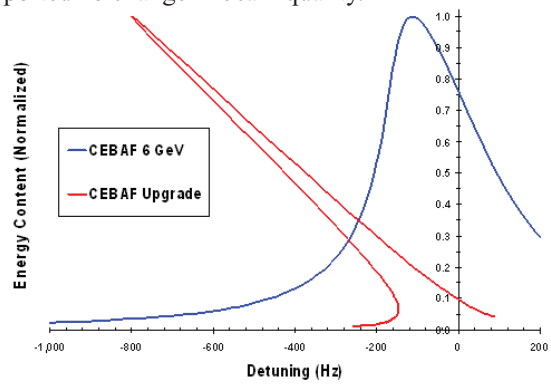

Figure 2: Detuning curves for 6 and 12 GeV.

As mentioned earlier, the cavities in the string were more mechanically coupled and "softer" than previous versions. As a result, if one cavity tripped off, then the others on that end of the cryomodule tripped as the field in the first one collapsed, thereby eliminating the Lorentz forces on that cavity which, in turn, pushed on the other cavities and took their resonant frequency outside the control band and they tripped also. Automated recovery of tripped cavities is still under development. For the 2012 run, a workaround was developed in which the cavities that don't trip are shifted to SEL mode and thus can stay energized; recovery is then simply turning on the resonance control then shifting back to phase and amplitude control once the cavity that tripped has been brought back up to full field.

Cryogenics

The original 2K helium plant was operating at its full capacity; any additional load, such as the new cryomodules, required an expansion. JLab had an unused 2K coldbox identical to the primary 2K coldbox. A plan was established to combine that 2K coldbox with a new 4.5K coldbox plus requisite new warm compressors to get a plant with maximum capacity of ~5kW at 2K. That new hardware has been fabricated, installed and successfully tested. [9] As the new 4.5K coldbox uses the JLab-patented "Ganni cycle", the power consumption of the new 4.5K plant is 30% less than that of the similarly sized original plant. Connections between the 4.5K and 2K systems have been completed. Commissioning of the integrated new plant is about to start.

BEAMLINES

Upgrading Existing Beamlines

The existing beam transport system consists of ~400 dipoles (BxL $\geq$ 0.2T-m) and ~700 quads. Simply replacing their power supplies was not viable because, at the approximately doubled fields, saturation in the return iron would require excessively large power supplies and installation of a large refrigerated cooling-water system. Replacing the magnets is also cost prohibitive. Happily, another alternative was identified.

For the majority of the dipoles, i.e. those in the nine 180° arcs and in the beamlines to the existing end stations, the present "C" shape was changed to "H" profiles by adding bolted on iron plates. The magnets will be operated at ~2x the original currents. The saturation would have exceeded 50% without that change. With the change the maximum is 1%. However, the roughly doubled currents result in much hotter magnets. The temperature rise (above the cooling water supply temperature) is now as much as 38C.

The dipoles in the spreaders and recombiners (S/R), i.e. the sections of the beam transport system which separate the co-linear beams after they exit the linacs or combine them before re-injection into the linacs, are so closely spaced that the bolt-on iron option is often not viable. A combination of three approaches was used: 1) reshape the poles to reduce the flux, and thus the saturation, 2) add coil packs and accept some saturation, and 3) add iron, but in lesser amounts than in the 180° arcs.

All the reused magnets were refurbished to extend their lives. The refurbishment included: replacing all the elastomers with material suited to the new operating temperatures, installing new coil constraints, re-silvering the contacts for the buss cables, and installing Belleville washers to insure that the bolts stay tight.

A small number of new magnets were for the spreaders and recombiners. They were procured with a build-to-print contract. Principal among the new magnets were seven 3m-long septa, which are critical for separating the beams in the higher passes. Six new curved dipoles were also bought. All of the magnets have been fabricated, received, inspected, field mapped, and installed.

The quadrupole fields required for the Upgrade exceeded the original design specifications of the original magnets for ~20% of the population. Testing found satisfactory field quality if the units were pushed to the required field levels, even though there was saturation. That ~20% of the quadrupoles are receiving new power supplies (20A vs the original 10A). The remainder were left as is. In some locations increasing the power supplies did not bring the quad to the required field. New magnets were bought for those locations; all of the new quads get the 20A supplies. Most of the 240 new 20A supplies have been received and installed.

The original dipole strings were energized by 32 power supplies varying in size from 35kW up to 260 kW. Half have been reused for the Upgrade. The rest are being replaced by larger units with output power ratings ranging up to 1.1MW. The new supplies are being fabricated by a commercial firm. The first three units have been received and onsite testing is underway.

Copyright © 2013 CC-BY-3.0 and by the respective authors

New Beamlines

A new recirculation arc was needed to return the beam to the north linac for its final acceleration before going to the new Hall D. Arc 10 uses the double-bend achromat mentioned above. Thirty six new 4m-long dipoles and forty five new quadrupoles were purchased for Arc 10 and the Hall D beamline. New units of existing diagnostics designs had been planned for Arc 10 and for the beamline to Hall D. However, it became impossible to find components for the beam position monitor electronics needed for the beamline to Hall D due to parts obsolescence, so a new system using stripline bpm's was designed and has been installed on the new beamlines. The other diagnostics used the original designs.

Extraction

A key to the effectiveness of CEBAF's research program has been the ability to deliver beam to multiple halls simultaneously. This feature has been retained in the Upgrade. One or two of the three interleaved but independent 499 MHz bunch streams can be extracted at any of the five passes. Extraction is done through the use of properly phased 499 MHz horizontally deflecting copper cavities; the horizontal split is amplified by the downstream lattice and a septum. A second, stronger septum completes the separation into two separate beamlines, one going to the beam switchyard and the other entering the recirculation arcs. This is done on all five passes.

The field integrals of the magnets and rf kickers was doubled for the Upgrade. The rf kick was increased by a combination of running some cavities at higher fields and increasing the number of cavities. The magnet integrals were increased by reuse of longer magnets from other locations. The optics for all five passes are identical.

CONTROL AND SAFETY SYSTEMS

The control network has been extended to cover the beamline to Hall D and Hall D itself. No new technology was required.

All of the safety systems have been expanded to incorporate Hall D and the beamline to the associated tagger dump. Specifically we upgraded the Personnel Safety System (PSS), the Beam Envelop Limit System (BELS), and Machine Protection System (MPS). The MPS and BELS modifications were simple extensions of the present systems. A new engineering approach was developed for the PSS in order to be in compliance with present regulations.

CHALLENGES ALONG THE WAY

Aside from the usual changes in funding profile, the 12 GeV Upgrade accelerator systems encountered some procurement challenges because of market conditions.

When contracting for the components of the new 4.5K coldbox we were in competition with major natural gas and oil companies. Those firms use similar equipment as some we needed and thus use the same vendors as we needed for those components. In addition, the price for the carbon steel was elevated due to international market conditions. As a result, the 4.5K coldbox was rather more expensive than had been anticipated and was delivered later than anticipated. Similarly, the srf cavities cost more than expected because of the market price for high RRR niobium.

A rather different problem occurred with the contract for the large magnet supplies. The original vendor had a large US manufacturing arm and a smaller offshore design arm. Well into the contract, the design arm went bankrupt and the manufacturing arm was unable to fulfill the contract. A new higher-priced contract was placed with a new vendor. Considerable schedule delay was incurred in the process, too.

STATUS

The upgrade of the accelerator is essentially complete. The beamlines to the end stations are still to be completed. Commissioning of the accelerator is scheduled to begin in Novermber of this year.

SUMMARY

An exciting new range of scientific inquiry into the quark nature of nuclear matter will soon be opened by the availability of a 12 GeV cw electron beam at JLab. The needed upgrade of the CEBAF accelerator is nearly complete and commissioning is about to begin. The new research program could begin as early as 2014.

FULL 3D STOCHASTIC COOLING AT RHIC*

K. Mernick#, M. Blaskiewicz, J.M. Brennan, BNL, Upton, NY 11973, USA

Abstract

Over the past several years, the installation of the full 3-dimensional stochastic cooling system in RHIC has been completed. The FY12 U-U and Cu-Au collider runs were the first to benefit from the full installation. In the U-U run, stochastic cooling improved the integrated luminosity by a factor of 5. This presentation provides an overview of the design of the stochastic cooling system and reviews the performance of the system during the FY12 heavy ion runs.

INTRODUCTION

Intra-beam scattering (IBS) is a primary cause of emittance growth of the heavy ion beams in the Relativistic Heavy Ion Collider (RHIC). A 3D bunched beam stochastic cooling system has been implemented to combat IBS and reduce the emittance of the beams. This system has been installed in stages over the past several years. The first operational use of stochastic cooling, in the longitudinal plane of the Yellow ring, began in 2007 [1,2]. The 2010 and 2011 collider runs had longitudinal and vertical cooling in both rings [3,4]. Commissioning of the horizontal cooling system in the 2012 run completed the full system.

SYSTEM DESIGN

The stochastic cooling system is essentially a wideband feedback damper. The momentum error of samples of particles within the bunch is measured and reduced via an applied kick. Longitudinal mixing randomizes the samples on subsequent turns and, over time, the emittance of the bunch is reduced. The time resolution of the samples and the resulting cooling rate are a function of the bandwidth of the system.

The layout of the fundamental components of the RHIC stochastic cooling systems is shown in Fig. 1. The longitudinal cooling pickups are located on either side of the 2 o'clock intersection region. The signals from these pickups are transmitted approximately 700m via microwave link to low-level electronics located near the kickers, which are in sector 4 for the Blue (clockwise) ring and sector 11 for the Yellow (counter-clockwise) ring. The longitudinal microwave links "cut the chord," transmitting the pickup signal across the center of the ring in the same direction the beam travels. This leaves only 200 ns for signal processing and cable delays. To minimize delay, the Blue ring electronics are located in the attic of the RF service building and cables are routed through a dedicated penetration to the tunnel. The Yellow ring electronics are located in a dedicated building on the berm above the tunnel.

#kmernick@bnl.gov

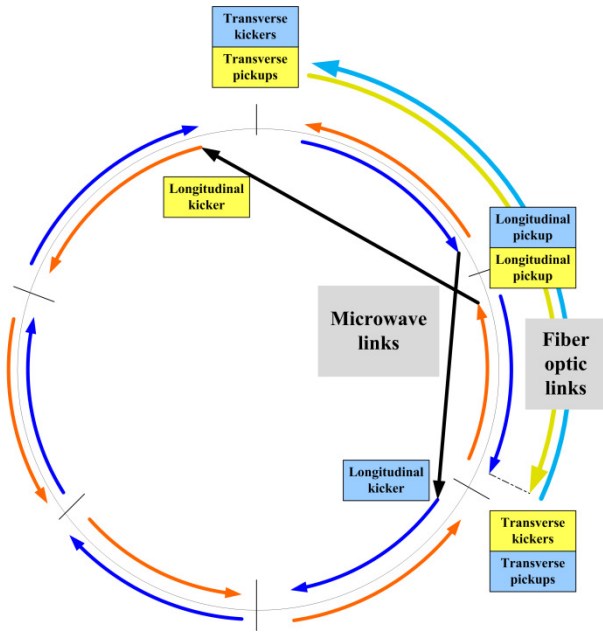

Figure 1: Locations of pickups and kickers (blue and yellow boxes), longitudinal system microwave links (black arrows), and transverse system fiber optic links (light blue and yellow arrows). The dark blue and orange arrows indicate the directions the beams travel.

In the Blue transverse system, signals from pickups in sector 3 are transmitted by fiber optic link to low-level electronics in the 12 o'clock service building, and from the electronics to the kickers in sector 12. The Yellow transverse system is the mirror-image of the Blue, with pickups in sector 12, electronics in a dedicated trailer outside the tunnel, and kickers in sector 3. The fiber optic link travels approximately 1/3 of the ring, while the beam travels 2/3 of the ring in the opposite direction.

Longitudinal Pickups

The longitudinal pickups measure fluctuations in the beam current as a function of the longitudinal position in the bunch. New longitudinal pickups have been designed and installed since the end of the 2012 run. These pickups consist of a keyhole-shaped vacuum chamber, shown in Fig. 2, with a 7 cm aperture round section and a 2 cm high rectangular section. During injection and ramping, the beam circulates in the large round section of the chamber. At top energy, the pickup chamber is moved, with pivoting double bellows on either side, to center the beam in the rectangular section. The small aperture cuts off the propagation of waveguide modes up to 9 GHz. The beam couples to top and bottom WRD-475 double-ridge waveguides parallel to the rectangular section through 8 mm by 6 mm slots. The top and bottom slots are offset in the beam direction, which improves the flatness of the pickup gain across the 6 to 9 GHz operating range.

Copyright © 2013 CC-BY-3.0 and by the respective authors

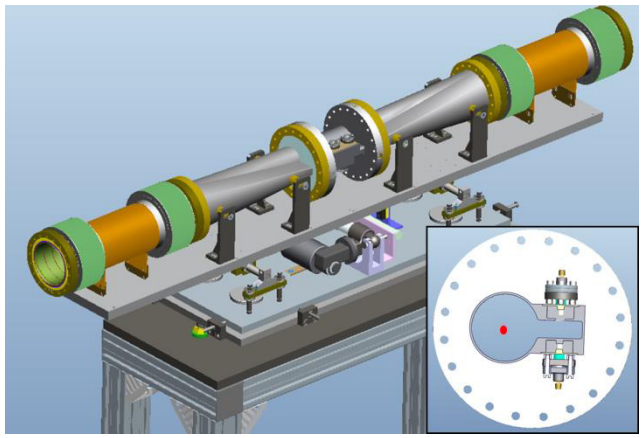

Figure 2: The longitudinal pickup vacuum chamber, drive assembly and stand (main figure) with a cross-sectional view of the active area of the pickup (inset). The red dot in the inset indicates the beam trajectory at injection and while ramping.

The pickup is driven by a DC motor coupled to the vacuum chamber through a gearbox that disengages when it reaches its maximum travel. This determines the in and out positions of the pickup without relying on precise control of the motors. Shape transition pieces provide a smooth transition from the 13 cm RHIC warm bore pipe to the keyhole cross-section. Along with custom RF shields for the welded bellows, these shape transitions minimize the impedance seen by the beam.

The new longitudinal pickup design was tested during the RHIC polarized proton run in 2013. The observed beam spectra are shown in Fig. 3. The response of the pickup across the 6 – 9 GHz band is much flatter than the previous version of the longitudinal pickups, which consisted of waveguides coupled to ceramic windows in a 7 cm round chamber.

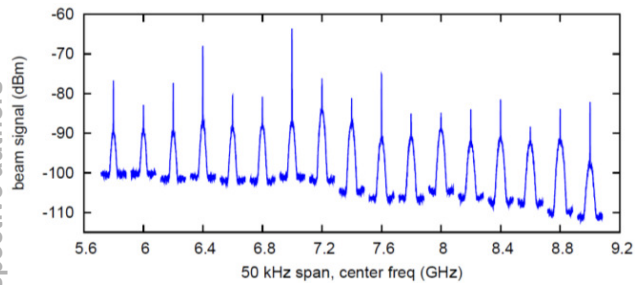

Figure 3: Beam spectra for polarized protons using the keyhole longitudinal pickup. The traces are centered at 5.8, 6.0, …, 9.0 GHz and each have a 50 kHz span.

Transverse Pickups

The transverse pickups measure the fluctuations in transverse position as a function of longitudinal position in the bunch. Each pickup contains two planar loop arrays, originally designed and built at Fermilab for stochastic cooling studies in the Tevatron [5], located above and below (for vertical) or inside and outside (for horizontal) the beam trajectory. The signals from the two pickup arrays must be subtracted with good common-mode rejection. Precision alignment and control of the positions of the two array plates are provided using linear

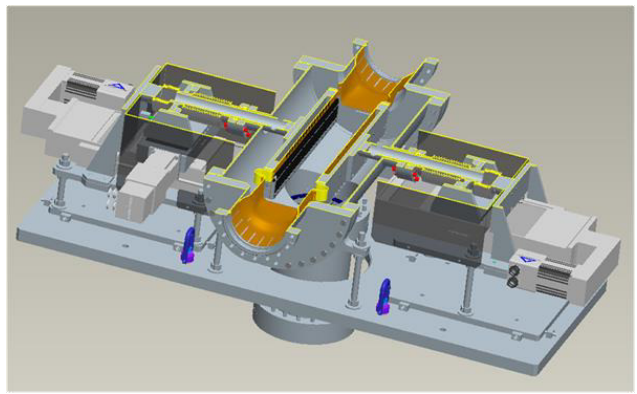

Figure 4: A cross-sectional view of the horizontal pickup vacuum chamber and assembly.

stages from Aerotech. The RF signals from the two plates are routed through matched coaxial cables and vacuum feedthroughs to an external hybrid. For additional fine-tuning of the common-mode rejection, one side has an additional linear stage to adjust the z-axis (beam direction) position of the pickup plate, and remotely adjustable trombones provide adjustable delay matching for the signals before the hybrid.

The design of the pickups, which is described in greater detail elsewhere in these proceedings [6], is nearly identical for the horizontal and vertical planes. The support plates and stands are modified to orient the pickup in the required plane. A cross-sectional view of the horizontally-mounted pickup is shown in Fig. 4.

Kickers

A novel feature of the RHIC stochastic cooling system is that the kickers are composed of an array of high Q resonant cavities. The RHIC beam is bunched with a bunching frequency of approximately 10 MHz and a bunch length of approximately 5 ns. Each kicker consists of 16 cavities, with resonant frequencies spaced by 200 MHz, the reciprocal of the bunch length, and bandwidths of 10 MHz. This allows a Fourier synthesis of the kick waveform to match the broadband signal for the 5 ns length of the bunch, and for the amplitude and phase of the signal to change bunch-by-bunch. This is illustrated schematically in Fig. 5.

In order to match the filling time of the cavities, the bunch signal at the pickup is periodically extended with a traversal filter, whose output is given by

$$y(t) = \sum_{k=0}^{15} u(t - k\tau)$$

with $\tau = 5.0$ ns. This filter is implemented with a series of coaxial cable delay lines, tuned with a resolution of 1 ps. There are no active components in these filters that could saturate and cause distortion. The traversal filter also serves to reduce the dynamic range of the signal before it is sent over either the fiber optic or microwave link.

The Fourier synthesis approach to creating the kick greatly reduces the required drive power. Each cavity is driven with a 40 W solid-state amplifier, and the kicker

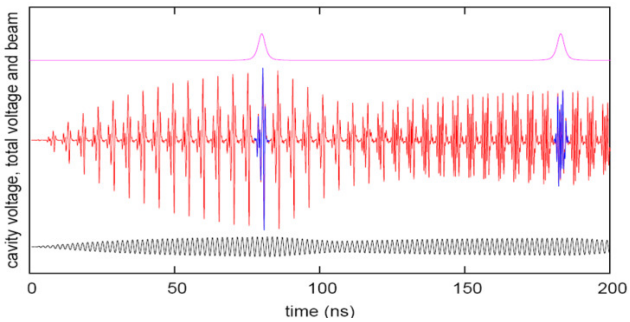

Figure 5: Schematic representation of the synthesis of the kicker waveform. The top trace indicates the time of arrival of two bunches at the kicker. The bottom trace indicates the voltage present on a single kicker cavity, and the middle trace indicates the sum of the voltage on the 16 cavities (red). The blue sections of the middle trace indicate the desired broadband kicker waveform.

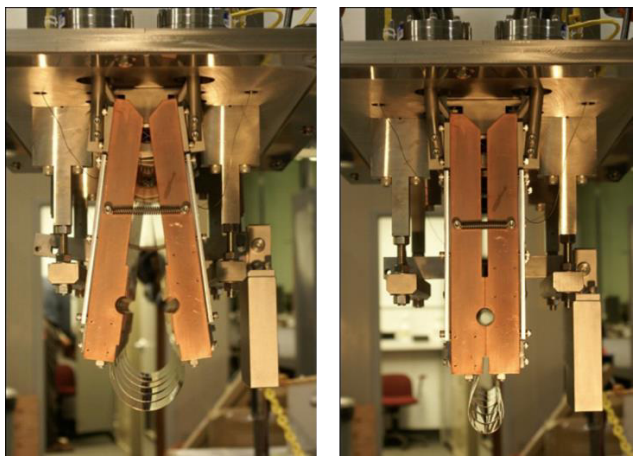

Figure 6: Photographs of the first Blue vertical kicker cavity assembly that used the scissor design, in the open position (left) and the closed position (right). The aperture in the closed position is 2 cm.

generates a kick of several kilovolts. The cost savings due to this method made the RHIC stochastic cooling system possible.

The RHIC stochastic cooling system presently uses three different mechanical designs for the kicker vacuum tanks. The longitudinal kickers are made from retrofitted vacuum tanks originally designed for the Tevatron [7]. Each kicker consists of three vacuum tanks, with either 5 or 6 cavities in each tank. The cavities in this design are split down the middle, allowing them to open to increase the available aperture during injection and acceleration. The cavity bodies are supported on a stainless steel strongback, which is rigidly attached to the drive mechanism. The linear bearings in these tanks have galled and seized on several occasions. Modifications made while refurbishing the kickers prior to the 2011 and 2012 runs have reduced the likelihood of these problems, but it is still a potential failure risk.

The vertical kicker in the Yellow ring was the first to be built in a vacuum vessel designed at BNL. This version of the kicker houses all 16 cavities in a single vacuum tank. This design required very delicate and time-consuming alignment adjustments during assembly, which made it impractical for production. The lessons learned working with this kicker and the Fermilab tanks led to a new design which has been used for all the subsequent kickers.

The vertical kicker in the Blue ring and the horizontal kickers in both rings use a scissor-like pivoting motion on a "flexi-hinge" to allow the cavities to open and close (see Fig. 6). This design has no sliding joints in vacuum. In the closed position, one cavity plate assembly rests against a hard stop and the linkage to the motor goes slack. The other half of the cavity assembly closes against the side supported by the hard stop and its motor linkage goes slack as well. This provides a repeatable closed position, while relaxing the requirements for precise motion control. Further detail on the mechanical design of these kickers is provided elsewhere in these proceedings [8].

During the present shutdown period, new longitudinal kickers are being fabricated using the scissor design. In addition to addressing the reliability concerns mentioned previously, the new longitudinal kickers have several enhancements. The 4-cell cavities in the existing kickers are being replaced by 6-cell cavities in the new kickers. With a higher R/Q, these cavities will provide a larger kick for the same input power. Power is now fed to the cavities through waveguides, rather than coaxial cable, and new coax-to-waveguide transition feedthroughs are used. These changes eliminate the Teflon dielectric in the vacuum chamber, allowing an increased bakeout temperature. The previous kickers all were designed with water cooling of the cavity bodies. The new longitudinal kickers will use radiant heaters to transfer heat to the cavities through glass vacuum windows. A control loop will monitor the cavity temperature and balance the radiant heat input with the RF losses in the cavities and conduction losses to the outside of the vacuum vessel to maintain a constant temperature. These kickers are expected to be completed and installed before the beginning of the 2014 heavy ion run.

Electronics

There are minimal RF electronics located in the RHIC tunnel at the pickups and kickers, but the majority of the electronics are housed outside the tunnel in service buildings. The electronics at the each pickup consist of a digitally-controlled step attenuator, several gain stages, the traversal filter, and low- and high-pass filters to match the system bandwidth and minimize the dynamic range of the signal. At each kicker, there are the 16 power amplifiers that drive the cavities, along with their DC power supplies and monitoring electronics. In addition, some motion control electronics – such as motors, linear potentiometers, limit switches, and resolvers – and PIN diode based beam loss monitors are also located at the pickups and kickers.

The transverse systems use the Photonics Systems PSI-1600 series fiber optic links to transmit the filtered pickup signal to the service buildings. In the longitudinal systems, the filtered pickup signal is used to amplitude

Figure 7: The microwave link transmitter for the Yellow ring, above the pickup in sector 2, is shown in the foreground. The receiver and dedicated electronics trailer, above the kicker in sector 11, are shown in the distance and the inset.

modulate the carrier of a 70 GHz E-Band microwave link, built by HXI Millimeter Wave Products. The microwave link installation is shown in Fig. 7. A pilot tone is added to the pickup signal, transmitted over the link, and used to correct phase modulation introduced by the link [9].

A block diagram of the electronics for one of the transverse systems is shown in Fig. 8. The optical signal from the pickup is amplified using an Erbium-doped Fiber Amplifier (EDFA), and routed through a delay line to the fiber optic receiver. The length of the delay line is determined to make the signal propagation time from the pickup to kicker match the beam's travel time. The output from the fiber optic receiver is routed through a series of splitters, amplifiers, and band-pass filters with 100 MHz bandwidth to generate the 16 input signals that are sent to the kicker cavities. Each of these 16 signals is connected through an independent I/Q modulator, which is used to optimize the amplitude and phase of the open-loop response. In this way, each cooling system can be tuned as 16 independent feedback systems, and the required precision for matching the pickup to kicker delay is only on the order of a few nanoseconds.

In the longitudinal systems, the microwave link replaces the fiber optic link, and the received signal is filtered with a one-turn delay notch filter prior to the 16-way fanout. The notch filter differentiates the pickup signal, giving an output proportional to the momentum error. A block diagram of the notch filter is shown in Fig. 9. The response of the notch filter is measured by a network analyzer, and the delay is calculated with 0.1 ps resolution. A feedback system regulates the length of the 12.8 μs fiber optic delay line with a piezoelectric line stretcher that provides ±40 ps of adjustment. The entire fiber optic assembly is mounted in a digitally controlled thermal chamber, and a second feedback loop regulates the temperature to keep the delay correction within the range of the line stretcher.

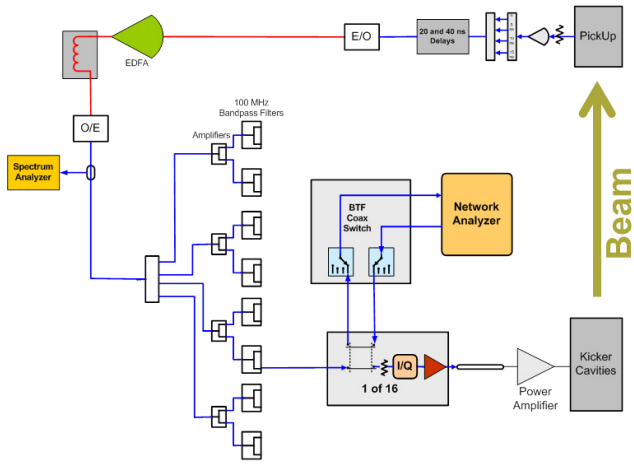

Figure 8: Electronics block diagram for one of the transverse systems. Red lines indicate fiber optic signal paths; blue lines indicate electrical signal paths.

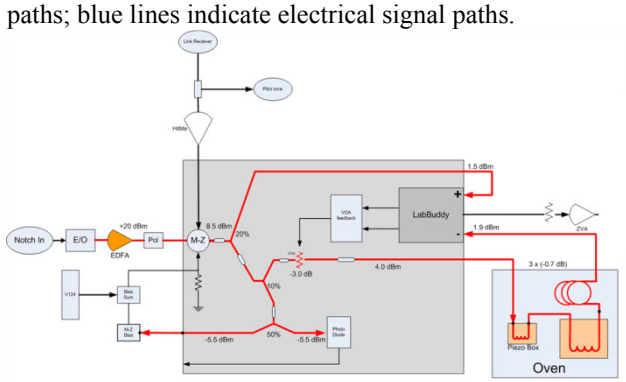

Figure 9: One-turn delay notch filter block diagram. The input from the microwave link is at the top. The block on the left labelled "Notch In" is for the network analyzer measurements. The output at the right of this diagram is connected to the input of the signal fanout.

Control and Operation

Transfer switches in the I/Q modulators and coax relay-based multiplexers allow measurement of the system transfer functions and real-time monitoring of signals while the system is operating. The gain and phase settings of the I/Q modules and the switch settings are sent on a locally broadcast serial "NIM link." This 10 Mbps, bi-phase mark encoded link is electrically identical, and functionally similar, to the RHIC Real Time Data Link [10], allowing common support hardware to be used.

Routine operation of the stochastic cooling systems is fully automated with the "tape" sequencer program. When beam has reached top energy, the sequencer sends commands to control system managers and accelerator device objects (ADOs) to start the cooling system. Several control system managers handle closing and opening of the pickups and kickers, and provide interlocks and alarms if beam loss monitor readings exceed a threshold. Once the pickups and kickers are in the operating positions, the sequencer enables the ADOs that control the low-level electronics.

The low-level software enables the electronics for one cavity at a time and measures the system open-loop

transfer function. The I/Q modulator gain and phase are modified to minimize the error between the measured and reference transfer functions. The reference transfer function is stored during setup at the beginning of the run after manually optimizing the gain and phase while observing the amount and symmetry of signal suppression [11] in the Schottky spectrum. Once the system is running, the control software continues to automatically measure and correct the transfer functions approximately every 15 minutes. These periodic corrections compensate slow drifts of system delays and changes in the beam conditions.

FY12 RESULTS

In the 2012 heavy ion run, RHIC provided Uranium-Uranium collisions at 96.4 GeV/nucleon and Copper-Gold collisions at 100 GeV/nucleon [12].

Uranium-Uranium

The 2012 Uranium run was the first RHIC run with Uranium, as well as the first to use the EBIS source. The number of ions per bunch was approximately 3 x 10^8, significantly fewer than the 1 – 1.5 x 10^9 Gold ions per bunch in previous runs. This, along with the addition of horizontal cooling, was expected to increase the benefit provided by stochastic cooling.

In the 2011 Gold run, longitudinal and vertical stochastic cooling doubled integrated luminosity. For the 2012 Uranium run, stores with only longitudinal and vertical cooling yielded an improvement by a factor of 3.75. After the horizontal cooling was commissioned, stores with full 3D cooling showed a factor of 5 improvement in integrated luminosity [13]. Peak luminosity was tripled with 3D cooling, the first time in RHIC that the initial luminosity was not also the peak.

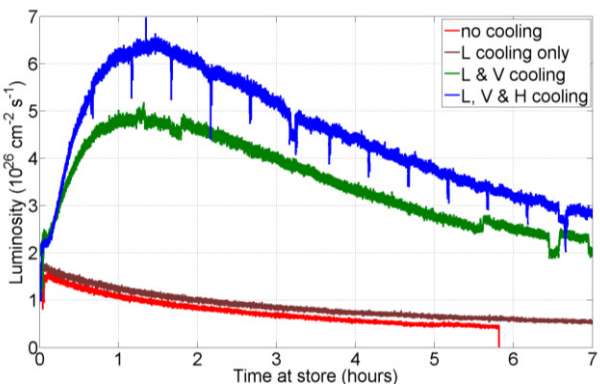

Figure 10: Effect of stochastic cooling on Uranium-Uranium luminosity.

Copper-Gold

The 2012 Copper-Gold run was the first in RHIC with this combination of ions. In addition, it was the first run with different ion species in the two rings with the transverse cooling systems available. Significant improvements in beam intensity were made throughout the run, mostly as a result of improvements at the EBIS source and tuning and introduction of additional bunch merges in the injectors. Ultimately, intensities of 4.0 x 10^9 Copper and 1.3 x 10^9 Gold ions per bunch were reached. Due to changing beam conditions, exact store-to-store comparisons are not possible. However, qualitatively, the benefit from stochastic cooling was clear.

The major operational challenge of the Copper-Gold run was managing the transverse emittance of the Gold beam. Due to the smaller number of ions per bunch, the cooling time for Gold was approximately 1/3 that for Copper. If both beams were cooled with the systems operating at peak performance, the Gold beam emittance was reduced to a much smaller value than the Copper beam. In this circumstance, the beam-beam interaction caused poor lifetime of the Copper beam [14]. To preserve the Copper beam, and maximize integrated luminosity, the transverse cooling for the Gold beam was slowed by turning off the horizontal cooling system and reducing the gain of the vertical system. More detail is available elsewhere in these proceedings [14].

ACKNOWLEDGMENT

We thank the members of the C-AD Accelerator Components & Instrumentation, Controls, Mechanical Systems, Operations, and RF groups for their work implementing these designs.

Abstract

The TRIUMF Advanced Rare Isotope Laboratory (ARIEL) phase I is funded since 2010 June by federal and BC provincial governments. ARIEL I comprises buildings and electron linac; the future phase II includes hot cells, target stations, mass separators and beam transport to ISAC experimental areas. The linac vault and He compressor building were completed 2012. The ARIEL targets building completion is 2013 August. With the exception of the 30 MeV accelerator cryomodule and second klystron and HV power supply, the linac major procurements are complete. This paper reports progress for the following systems: locally manufactured niobium 9-cell cavity, 300 keV electron gun, 4 K cryogenic plant and sub-atmospheric pumps, 290 kW cw klystron and 65 kV DC power supply. Status of the 10 MeV injector cryomodule assembly and beamlines construction will also be addressed.

CONVENTIONAL INFRASTRUCTURE

The ARIEL project, described in Refs. [1,2], is essentially a new front end for the existing ISAC I & II experimental complex. The project contains two new "drive beams" and two target stations to supplement those at ISAC. The conventional infrastructure consists of four main contracts: the ARIEL construction, demolition and excavation, the Stores building, and Badge building. The new Compressor Building forms part of the ARIEL package as does major renovation of the former Proton Hall that has segregated the Electron Hall (e-hall) area from the future BL4N protons vault.

The Stores and Badge building construction was completed in 2011. The e-hall and Compressor building occupancy were taken 2012 November 1st and December 1st respectively. The ARIEL building occupancy was taken 2013 September 1st; and the connecting tunnel was completed one month prior.

The ARIEL cooling water system which provides capacities of 3 MW each to the ARIEL building and e-linac, and 0.3 MW to the compressor building, was completed 2013 June 1st. The site electrical connections to the 5 MW utility feed are made through a 12.5 kV switchgear supplied by Siemens. This connection supplies up to 1.5 MW to klystrons, 0.5 MW emergency power, 1 MW to compressor building, and 2 MW to the ARIEL building. Switchgear was energized 2012 December. A rack farm for magnet power supplies, beam diagnostic and LLRF controls is now complete on the e-hall roof.

*TRIUMF is funded under a contribution agreement with the National Research Council of Canada.

Figure 1: ARIEL building, view south.

ELECTRON GUN

The thermionic gun provides 300 keV kinetic energy electron bunches with charge up to 16 pC at a repetition frequency of 650 MHz. Unique features of the gun are its inverted cathode/anode geometry to reduce dark current, and transmission of rf modulation via a ceramic waveguide through SF6 dielectric. An impedance network inside an HV shroud matches the waveguide to the gridded cathode. The waveguide was received 2012 September from Kyocera. The HV cage containing the Glassman 300 kV supply, isolation transformer and bias and heater supplies was completed 2013 March. The gun electrodes polishing and assembly to the ceramic was completed 2013 May. The SF6 vessel also was received and installed in May. The vessel internal corona domes and shroud were fabricated and installed in the SF6 vessel 2013 September. 200 kV High voltage was first applied in October and a breakdown encountered with the receptacle connecting to the conditioning resistor.

INJECTOR TEST FACILITY

The Injector test facility, under collaboration between TRIUMF and VECC of Kolkata, India, provides an ideal proving ground for e-linac design and operation strategies. It duplicates the e-linac up to the exit of the injector cryo-module with enhanced diagnostic capability. Commissioning this facility began Nov 2011 with a 100kV gun and low energy solenoid beam transport and continued to 2013 Feb. The primary objective is a complete 6D phase space characterisation of the 100 kV beam. The 99% longitudinal phase is ±18.8 deg at 650 MHz and $\Delta p/p \pm 3.7\times10^{-4}$. The measured transverse r.m.s. normalized emittance is 9.3 µm horizontal and

Copyright © 2013 CC-BY-3.0 and by the respective authors

9.5 µm vertical. Further, a transverse deflecting cavity and scintillator view screen in the momentum analysis stub was used to visualize longitudinal phase space rotation effected by the buncher cavity, and to calibrate and adjust the settings to those believed to be needed to match the beam to that of the injector cryomodule acceptance.

BEAM LINES

The beam transport sections after the Injector are: the EMBT "Merger" section; the EABT and EHAT before and after the accelerator cryomodule; the EHDT to a 100 kW beam dump; and the EHBT, which transports to the photo-fission targets, consists mainly of a periodic section consisting of six 90° FODO cells, each 4 m in length. The EMBT contains a 36° bend section, the EHDT, a 90-degree section, and the EHBT two doglegs and a bend section to target. All insertions are achromatic. After the Injector, the focusing is performed by magnetic quadrupoles. These are grouped in three classes: (i) weak, < 0.2 T; (ii) medium, < 0.5 T; (iii) strong, < 1.3 T. The weak and medium designs retain the same spherical [4] poles and yolks, but differ in their coils and cooling: air-cooled or chill-plates, respectively. The strong quads follow a conventional water-cooled design, and have cylindrical poles. Prototypes were received 2013 February from *Buckley Systems*, leading to shipments completed in August totaling 80 magnets.

Dipole procurements have followed a separate path using a variety of vendors and custom designs. The three EMBT dipoles were received 2013 July. The eight S34 bends used in EABD and final EHBT bends before the east and west target stations are in shipment from *Everson-Tesla*. The contract for three Y30 bends used in EHDT and the EHBT dogleg was awarded 2013 September. The final tender, for two vertical dipoles for the dogleg, will be let in November.

Beam Diagnostics

Initial beam threading will be facilitated by profile monitors equipped with scintillators and OTR screens. 17 camera boxes and actuator assemblies are now complete. Orbit correction will be performed with the backbone system of 56 four-button type position monitors. All parts are acquired, and assembly in progress. The BPM electronics, which operates in pulse and cw. modes, comprises three blocks: a commercial front-end to down convert the input 650 MHz signals to the IF frequency, a 14-bit ADC and a Spartan-6 FPGA for the digital signal demodulation and filtering. The electronics is currently in production phase. 26 units are needed for the e-hall by 2014 May; 3 are complete, 7 in assembly, and remainder on track.

CRYOMODULES AND CAVITIES

Due to heavy beam loading, five 9-cell cavities at 100 kW/cavity are required to reach the 0.5 MW beam power. The injector cryomodule (EINJ) contains a single 9-cell cavity, and is designed and constructed in collaboration with VECC. The accelerator cryomodules (EACA,B) each house two 9-cell cavities.

The cryomodule design [2] utilizes a box vessel with a top-loading cold mass. A 4 K phase separator, 4 K/2 K heat exchanger and Joule-Thomson expansion valve are installed within each module to produce 2 K liquid. The cold mass is suspended from the lid with mounting posts, struts and strong back; and is surrounded by a LN2-cooled copper box for thermal isolation. A 1 mm warm mu-metal shield is fastened to the inside of the vacuum vessel. The cold mass consists of the cavity hermetic unit, a cold mu metal layer and the tuner. The tuner cold part is the Jefferson lab style scissor type; and is actuated by warm rotary servo motor mounted on the lid. The hermetic unit includes the cavity(s), power couplers, rf pick-up(s), the warm-cold transitions with HOM damping material and warm isolation valves.

The 4 K/2 K cryo-insert has undergone cold testing since 2013 January. Measured: static load of 4 K (2 W) and 2 K (0.5 W) reservoirs. Measured: efficiency of 2 K conversion is 66% at 0.5 g/s mass flow. Measured: 4 K siphon circuit efficiency – extra heat load caused by convection in 4 K reservoir ~15-20 W. After modification, the siphon loop is well behaved with a static load of 1.6 W.

All sub-assemblies of the EINJ are fabricated, and many are assembled. The tank is complete, and the entire assembly that is suspended from the lid is the subject of a mock up to verify that there are no conflicts or interferences. During the final assembly, 2013 Nov., the Nb cavity will substitute a dummy used in the mock up.

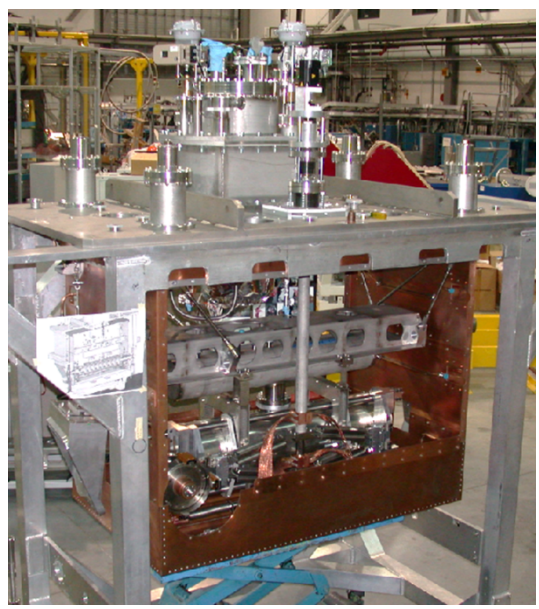

Figure 2: Injector cryomodule internal assembly.

Concerning the accelerator cryomodule, EACA, 95% of the design and detailing tasks are performed and fabrication is imminent. The lid is already received and the tank ordered.

The nine-cell 1.3 GHz elliptical cavity borrows the TESLA/ILC type inner cell geometry but uses modified

Copyright © 2013 CC-BY-3.0 and by the respective authors

end groups to accommodate the large power couplers and to mitigate HOMs. The HOM spectrum of the copper prototype has been measured [5] up to 4 GHz.

The first ARIEL cavity was received from *PAVAC Industries* of Richmond 2013 May 28. Subsequently, the cells were tuned to achieve field flatness, the cavity BCP etched, and cavity tested. No quenching or field emission was detected up to a field of 10 MV/m. The measured quality factor ($Q = 3\times10^9$) is not adequate, and the cavity has been sent for furnace degassing at FNAL. The second cavity is fabricated, tuned and etched, and ready for testing. The third cavity is in fabrication.

CRYOGENIC EQUIPMENT

In essence the cryogenics contains two components: a system responsible to deliver 4 K liquid He to a dewar; and a system to produce 2 K sub-atmospheric He inside the cryomodules. The first comprises a helium refrigerator-liquefier (HELIAL 2000 cold-box), and oil removal and gas management systems (OR/GMS), both delivered by *Air Liquide Advanced Technologies* (France) in 2013 March; and main and recovery compressors delivered by *Kaeser* in 2013 January; and 1000 litre dewar. Further, this system contains a helium gas storage tank fabricated locally, and variety of warm He piping completed 2013 September. All connections and services for this equipment are now complete. Presently, preparations are underway for the 4 K acceptance test in November.

Figure 3: Helium dewar (left) and 4 K coldbox (right).

Concerning the 2 K sub-atmospheric system, four pumps were delivered by *Busch* 2013 March and one successfully tested; the forward 4 K line to cryomodules is anticipated delivered October, the return line is recently tendered, the return heat exchanger is expected delivered in October; and the 4 K/2 K (in-cryomodule) insert is prototyped and installed in the Injector.

RADIO-FREQUENCY EQUIPMENT

The ARIEL project has procured two 290 kW klystrons from CPI, and two 600 kW HV supplies from *Ampegon/ Comark* (formerly *Thomson*). The first klystron was factory tested to 300 kW in 2013 January, and installed at TRIUMF [3] in June; and the 300 kW circulator and water-cooled loads added in September. The 65 kV power supply was factory tested in May and installed at TRIUMF 2013 August. All connections and services for this equipment are now complete. Presently, preparations are underway for the acceptance test in October. The second klystron and HV power supply will be delivered 2014 March.

Figure 4: klystron, circulator and loads.

The first klystron will initially be deployed to drive the injector cryomodule (EINJ) for a beam test starting 2014 May. After the second klystron is installed, the first will be switched to drive the accelerator cryomodule (EACA). In the ARIEL II phase of the project, the second klystron will drive the second cryomodule EACB, and a dedicated 150 kW RF source will be found for EINJ.

Power Coupler Conditioning Station

A routine procedure is now established: one week bakeout of warm window under N2 flow at 100 C. Four couplers have been conditioned at room temperature. 12.5 kW cw in traveling wave (TW) and 10 kW pulsed in standing wave (equivalent to 40 kW in TW) are achieved.

CONCLUSION

We are justified to report excellent progress across all areas: delivery and test of 1st ARIEL cavity; ARIEL building occupancy; imminent acceptance tests of Klystron & HVPS and 4 K Cryogenic Plant. The following milestones are anticipated: e-gun complete 2013 Nov; Injector Cryomodule complete 2013 Dec; beam test start at ISAC/VECC 2014 January; and Accelerator Cryomodule beam test 2014 Sept.

Abstract

A novel polarization technique has been successfully implemented for the upgrade of the RHIC polarized H^- ion source to higher intensity and polarization. In this technique, a proton beam inside the high magnetic field solenoid is produced by ionization of the atomic hydrogen beam (from an external source) in the He-gas ionizer cell. Proton polarization is produced by the process of polarized electron capture from the optically-pumped Rb vapor. Polarized beam intensity produced in the source exceeds 4.0 mA. Strong space-charge effects cause significant beam losses in the LEBT (Low Energy Beam Transport, 35.0 keV beam energy) line. The LEBT was modified to reduce losses. As a result, 1.4 mA of polarized beam was transported to the RFQ and 0.7 mA was accelerated in linac to 200 MeV. A maximum polarization of 84% (in the 200 MeV polarimeter) was measured at 0.3 mA beam intensity and 80% polarization was measured at 0.5 mA. The upgraded source reliably delivered beam for the 2013 polarized run in RHIC at √S=510 GeV. This was a major factor contributing to the increase in RHIC polarization to over 60 % for colliding beams.

OPPIS UPGRADE WITH THE ATOMIC HYDROGEN BEAM INJECTOR

The polarized beam for the RHIC spin physics experimental program is produced in the Optically-Pumped Polarized H^- Ion Source (OPPIS) [1].

An Electron Cyclotron Resonance (ECR) ion source was used as the primary proton source in the old operational polarized source. The ECR source was operated in a high magnetic field. The proton beam produced in the ECR source had a comparatively low emission current density and high beam divergence.

In pulsed operation, suitable for application at high-energy accelerators and colliders, the ECR source limitations can be overcome by using a high brightness proton source outside the magnetic field instead of the ECR source. In this technique (which was implemented for the first time at INR, Moscow [2]), the proton beam is focussed and neutralized in a hydrogen cell producing the high brightness 6.0-8.0 keV atomic H° beam. The atomic H^0 beam is injected into the superconducting solenoid, where both the He ionizer cell and the optically-pumped Rb cell are situated in the 25-30 kG solenoid field. The solenoid field is produced by a new superconducting solenoid with a re-condensing cooling system. The injected H atoms are ionized in the He cell with 60-80% efficiency to form a low emittance intense proton beam and then enter the polarized Rb vapour cell (see Figure 1). The protons pick up polarized electrons from the Rb atoms to become a beam of electron-spin polarized H atoms (similar to the ECR based OPPIS). A negative bias of about 3.0-5.0 kV applied to the He cell decelerate the proton beam produced in the cell to the 3.0 keV beam energy, optimal for the charge– exchange collisions in the rubidium and sodium cells. This allows energy separation of the polarized hydrogen atoms produced after lower energy proton neutralization in Rb-vapour and residual hydrogen atoms of the primary beam.

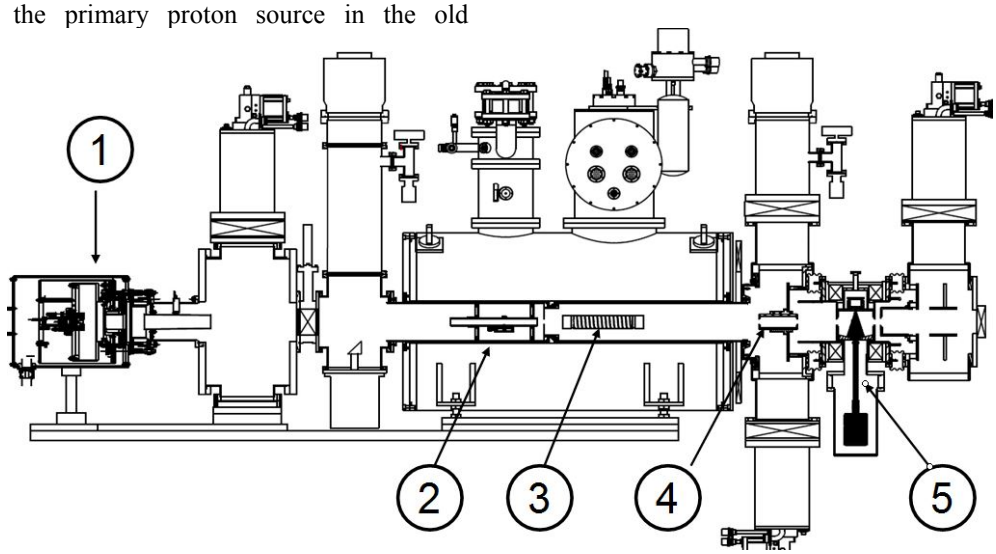

Figure 1: A new polarized source layout: 1–atomic hydrogen injector; 2–pulsed He –gaseous ionizer cell; 3–optically-pumped Rb-vapour cell; 4–Sona-transition; 5–Na-jet ionizer cell.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Residual atomic H beam is converted to un-polarized H^- ion beam with lower yield (3-4% at 6.0-8.0 keV atomic beam energy). The H^- ion beam acceleration (by applying a pulsed -32 kV voltage to the ionizer cell) produces polarized H^- ions with beam energy of 35 keV and un-polarized beam with energy of 38-40 keV. Further suppression of un-polarized higher energy ion beam is produced by magnetic separation in the LEBT.

Atomic hydrogen beam currents of equivalent densities in excess of a 100 mA/cm^2 were obtained at the Na jet ionizer location (about 240 cm from the source) by using a high brightness fast atomic beam source which was developed in collaboration with BINP, Novosibirsk. Estimated polarized H^- ion beam current of about 5-10 mA is expected in this source after upgrade completion (assuming 50% ionization efficiency in He-cell and 50 % neutralization efficiency in the optically-pumped Rb-vapour cell). In feasibility studies of this technique (performed at TRIUMF) in excess of 10 mA polarized H^- and 50 mA proton beam intensities were demonstrated [3]. The beam losses during proton beam deceleration introduced additional losses. Higher polarization is also expected with the fast atomic beam source due to: a) elimination of neutralization in residual hydrogen; b) better Sona-transition efficiency for the smaller ~ 1.5 cm diameter beam; c) use of higher ionizer field (up to 3.0 kG). All these factors combined should increase polarization in the pulsed OPPIS to over 85%.

ATOMIC BEAM SOURCE DEVELOPMENT

In the atomic hydrogen beam source the primary proton beam is produced by a four-grid multi-aperture ion extraction optical system and neutralized in the H_2 gas cell downstream from the grids. A high-brightness atomic hydrogen beam was obtained in this injector by using a plasma emitter with a low transverse ion temperature (of about 0.2 eV), which is formed by plasma jet expansion from the arc plasma generator [4]. The multi-hole grids are spherically shaped to produce "geometrical" beam focusing. The grids are made of 0.4 mm thick molybdenum plates. Holes (0.8 mm diameter) in the plates were produced by photo-etching techniques. The hole array form a hexagonal structure with a step of 1.1 mm and outer diameter of 5.0 cm. The grids were shaped by re-crystallization under pressure at high temperature and were welded to stainless steel holders by a pulsed CO_2 laser. At an emission current density of 470 mA/cm^2, the angular divergence of the produced beam was measured to be ~ 10-12 mrad.

The focal length of the spherical ion extraction system was optimized for the OPPIS application, which is characterized by a long polarizing structure of the charge-exchange cells and small (2.0 cm diameter) Na-jet ionizer cell, which is located 240 cm from the source (see Figure 1). An optimal drift-space length of about 140 cm is required for convergence of the 5 cm (initial diameter) beam to 2.5 cm diameter He-ionizer cell. About 20% of the total beam intensity (~3.5 A) can be transported through the Na-jet cell acceptance by using the optimal extraction grid system with a focal length: $F \sim 200$ cm. Three spherical IOS were tested on the test-bench at BNL. The focusing lengths of IOS #1 and #3 were ~150 cm and for IOS#3 F~250 cm, which allowed study of optimal beam formation. IOS#2 produced about 500 mA equivalent atomic H beam within the 2.0 cm diameter Na-jet ionizer acceptance (at the distance 240 cm from the source) and 16 mA H^- ion beam current.

HELIUM IONIZER CELL. BEAM ENERGY SEPARATION

The He-ionizer cell is a 40 cm long stainless steel tube with an inside diameter 25.4 mm. A new fast "electro-dynamic" valve for He-gas injection to the cell was developed for operation in the 30 kG solenoid field. In this valve, a pulsed current of about 100 A is passed through the flexible springing plate (made of beryllium bronze foil with a thickness of 0.5 mm). The Lorentz force: $\mathbf{F} = eL\,[\,\mathbf{I}\times\mathbf{B}] = 15$ N for a L=5 cm long plate. The plate is fixed at one end and this force bends the plate and opens the small (0.5 mm diameter) hole which is sealed with a Viton O-ring. The pulsed current rise-time is ~ 50 μs and gas pressure rise time is about 100 μs

The proton beam produced in the He cell is decelerated from 6.0 keV to 2.5 keV by a negative potential of 3.5 keV applied to the cell. At the 2.5 keV beam energy, the H^- ion yield in the sodium ionizer cell is near maximum (~ 8.4%) and the polarized electron capture cross-section from Rb atoms is also near the maximum of ~ $0.8\cdot10^{-14}$ cm^2. The deceleration was produced by a precisely aligned (to reduce beam losses) three wire-grid system. A small negative bias was applied to the first grid at the cell entrance and second grid at the cell exit to trap electrons in the cell for space-charge compensation. Fine tuning of the grids voltages is required for the polarized beam current optimization and total current reduction of the He-cell pulsed power supply.

About 40% residual (which passed the He-cell without ionization) atomic beam component at 6.0 keV energy will pass through the deceleration system and Rb cell and be ionized in Na-cell producing H^- ion beam. The H^- ion yield at 6 keV is about 4%. This is a significant suppression in comparison with the main 2.5 keV beam, but it would be a strong polarization dilution unless further suppression is applied. The H^- ion beam acceleration produce polarized H^- ion beam with 35 keV beam energy and un-polarized beam with 38.5 keV energy. The un-polarized 38.5 keV beam component is well separated after the 24 degree bending magnet in the LEBT. In measurements of beam separation, the beam energy was varied by the accelerating voltage applied to the Na-jet ionizer cell. At 32.5 keV accelerating voltage (where the polarized beam component of 2.5 keV beam energy accelerated to 35.0 keV, optimal for injection into the RFQ) the transmission of residual 6.0 keV un-polarized beam component is strongly suppressed (to less than 2 % of polarized beam component).

EXPERIMENTAL RESULTS

The beam polarization was measured in the precision absolute polarimeter at 200 MeV beam energy after the Linac [5]. The polarization and H^- beam current measurements (after acceleration to 200 MeV in the Linac) vs. Rb-vapor thickness is presented in Figure 2.

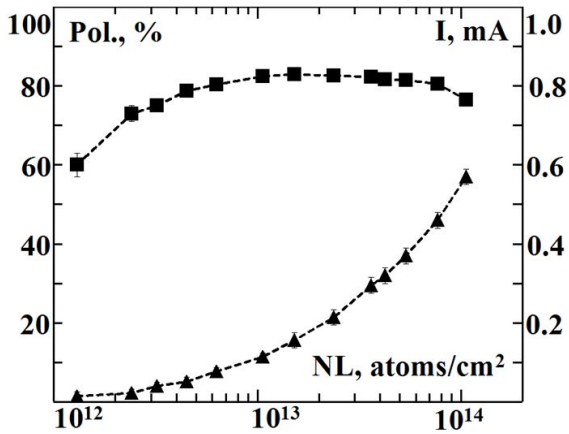

Figure 2: Polarization (squares at the left axis) and beam intensity (triangles- in mA at the right axis) vs. Rb-vapour thickness.

At low Rb-vapor densities, the residual (un-polarized) H^- ion beam current produced by neutralization in residual gas and incomplete energy separation is less than 0.01 mA. Therefore, the polarization dilution due to these factors does not exceed ~ 2%. There was observed some polarization drop at **NL** $\geq 10^{14}$ atoms/cm^2 (**N** ~ $3 \cdot 10^{13}$ atoms/ cm^3, Rb-cell length - **L**=30 cm). Depolarization due to "radiation trapping" is small (at this density Rb-vapor), but some polarization losses may occur due to reduced polarization near the cell walls. This limits the proton beam size and requires good matching between the beam and the Rb-cell diameter. These losses depend on atomic beam intensity and were reduced by laser tuning and atomic beam parameters optimization.

Polarized beam intensity produced in the source exceeds 4.0 mA. The H^- ion beam produced in the sodium-jet ionizer cell is accelerated to 35 keV. This energy increase is essential for the high intensity beam transport. Strong space-charge effects cause significant beam losses in the LEBT line. Basic limitations on the high-intensity polarized H^- ion beam production and transport were experimentally studied in charge-exchange collisions of the neutral atomic hydrogen beam in the Na-vapor-jet ionizer cell. The LEBT was modified to reduce losses and 1.4 mA of polarized beam (after energy separation in the bending magnet and after 6 m in LEBT) was transported to the RFQ and ~ 0.7 mA of beam was accelerated in the Linac to 200 MeV. This current can be further increased by increases in the atomic beam intensity and reduction of the beam losses in LEBT.

Electron depolarization due to spin-orbital interaction in exited (2S, 2P) states of hydrogen atoms should be suppressed by high magnetic field in the Rb-cell [6]. Polarization dependence on magnetic field in the Rb-cell is presented in Figure 3. At every field set-point, the Sona-transition field distribution was optimized by correction – coil tuning. The polarization saturation was observed at super-conducting solenoid fields ≥ 25 kG.

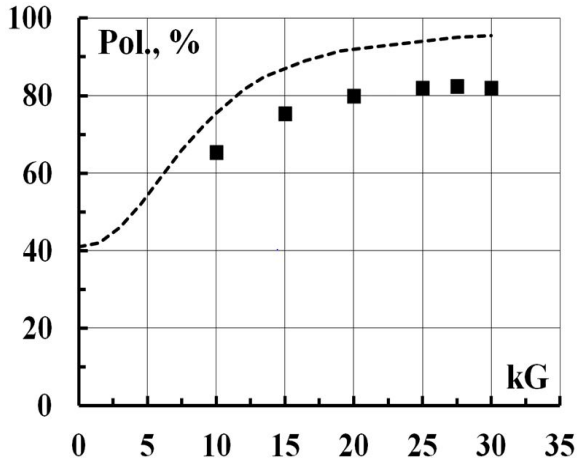

Figure 3: Squares-polarization vs. magnetic field in the Rb-cell. Dashed line–calculations [6].

SUMMARY

The performance of the new source in Run 13 is presented in Table 1 (Rb-cell thickness **NL**$\times 10^{13}$ atoms/cm^2. Linac pulse duration-300 μs. Booster input $\times 10^{11}$ ions/pulse):

Table 1: New Source Performance in Run 13

Rb-cell thickness, **NL**	3.6	5.3	7.6	10.6
Linac Current, μA	295	370	430	570
Booster Input $\times 10^{11}$	4.9	6.2	7.3	9.0
Pol. %, at 200 MeV	84	83	80.5	78

Very reliable operation and reduced maintenance time was demonstrated. In the first year of operation, the new source performance exceeded the old ECR-based source parameters. This was a major factor contributing to the polarization increase to about 60 % for the RHIC colliding beams.

CERN, Geneva, Switzerland

Abstract

Linac4 is a normal-conducting 160 MeV H^- linear accelerator presently under construction at CERN. It will replace the present 50 MeV Linac2 as injector of the proton accelerator complex as part of a project to increase the LHC luminosity. The Linac front-end, composed of a 45 keV ion source, a Low Energy Beam Transport (LEBT), a 352.2 MHz Radio Frequency Quadrupole (RFQ) and a Medium Energy Beam Transport (MEBT) housing a beam chopper, have been commissioned at the 3 MeV test stand during the first half of 2013. The status of the installation and the results of the first commissioning stage are presented in this paper.

THE LINAC4 PROJECT

Linac4 is a new accelerator, first part of a project to improve the CERN proton accelerator chain [1]. The higher injection energy (160 MeV vs 50 MeV for Linac2) and the H^- charge exchange injection will make it possible to inject more intensity into the PS Booster. The 80 m long accelerator will be housed in a 101 m tunnel, 12 m underground. A view of the Linac in its tunnel is shown in Figure 1. It consists in a 45 keV RF ion source, a 2 magnetic solenoid LEBT; a 352.2 MHz RFQ accelerating the beam to 3 MeV; a MEBT housing a fast beam chopper; a 50 MeV Drift Tube Linac (DTL) composed of 3 tanks; a 100 MeV Coupled Cell Drift Tube Linac made of 7 modules of 3 coupled tanks and a Pi Mode Structure (PIMS) up to 160 MeV. The schematic layout is shown in Figure 2. The Linac will be connected by a 60 m transfer line to the present Linac2-PSB line. Figure 3 represents the integration of Linac4 in the PS complex. The linac positioning was also designed to be compatible with an extension to 5 GeV as part of the Superconducting Proton Linac (SPL) [2].

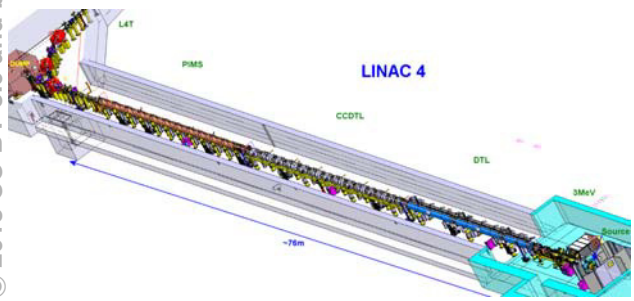

Figure 1: Linac4 in its tunnel.

Figure 2: Linac4 layout.

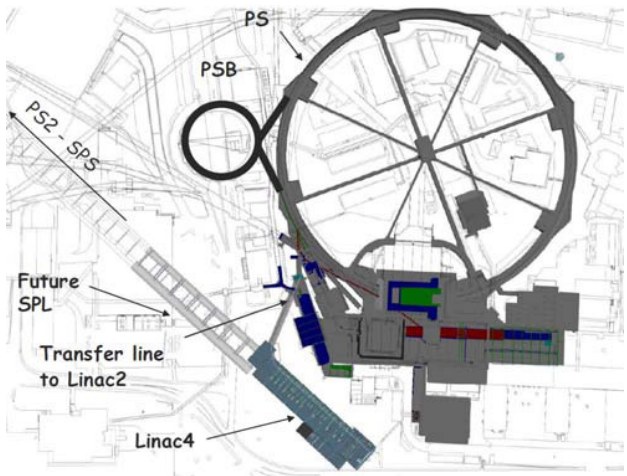

Figure 3: Linac4 integration in the CERN PS complex.

The Linac4 energy and repetition rate (160 MeV, 1.1 Hz) are defined by the PSB while the 352.2 MHz operation frequency is that of the LEP accelerator, from which a large inventory of RF equipment is recuperated. The design parameters are given in Table 1.

Table 1: Linac4 Design Parameters

Ion Species	H^-	
Length	77	m
Output Energy	160	MeV
Frequency	352.2	MHz
Repetition rate	1.1 (max. 2)	Hz
Pulse length	400 (max. 1200)	μs
Chopping factor	62	%
Source current	80	mA
Linac pulse current	40	mA

5 COMMISSIONING STAGES

The commissioning of Linac4 is foreseen in 5 stages at the energies of 3, 12, 50, 105 and 160 MeV, corresponding to the commissioning of the different accelerating structures composing the accelerator [3]. At each stage a dedicated beam diagnostic bench will be temporarily installed.

A first pre-commissioning at 3 MeV was completed in June 2013 in a dedicated test stand before removal and installation of the RFQ and chopper line to the final location in the tunnel. From October 2013, beam commissioning in the tunnel will start with the aim of finishing the commissioning of the 3 MeV part. Once completed, the first tank of the DTL will be installed and the beam should reach an energy of 12 MeV in the first half of 2014. Beam commissioning and machine installation periods will then be interlaced until 2015: Tank 2 and 3 of the DTL to 50 MeV, the 7 CCDTL modules and the first PIMS cavity to 105 MeV and all the PIMS section up to 160 MeV. In order to set the transverse and longitudinal beam parameters, 2 movable diagnostic benches will be used in addition to the diagnostics permanently installed in the Linac. The first bench with an emittance meter and a spectrometer line will be used up to 12 MeV. The second one, with quadrupoles and transverse profile diagnostics (SEM-Grids) for emittance reconstruction with the forward method and with phase pick-ups (BPMs) for Time Of Flight (TOF), will be used at 50 and 105 MeV. This second diagnostic line can be seen in Figure 4. For the last stage, beam commissioning at 160 MeV, the diagnostics permanently installed in the straight line going to the main beam dump will be used.

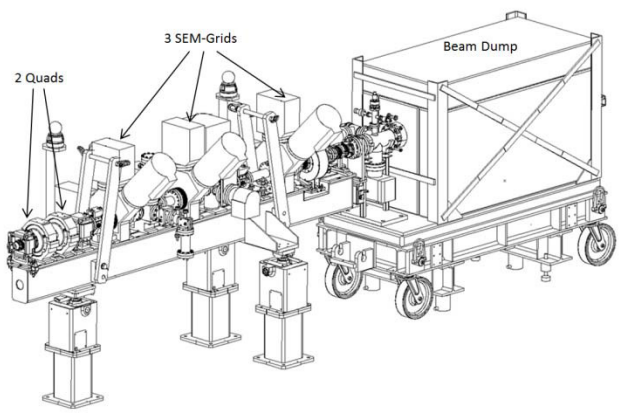

Figure 4: Technical drawing of the 50-105 MeV diagnostic bench attached to the commissioning beam dump.

THE 3 MEV TEST STAND

Experience with other linacs and dedicated beam dynamics studies show that the most difficult part to master is the low energy part, where the beam is strongly influenced by the space charge. This is also the part where there are 2 very critical devices defining the transverse and longitudinal beam characteristics, the ion source and the RFQ. Beam current, distribution and emittance from the source, space charge neutralization in the LEBT, capture and longitudinal emittance in the RFQ, matching and chopping efficiency in the MEBT are all parameters that define the quality of the beam delivered to the PSB. In order to have enough time to study and characterize the low energy beam, it was decided to have a dedicated test stand comprising the ion source, the LEBT, the RFQ, the chopper-line and a temporary diagnostic bench. The test stand was operational in the first half of 2013. Detailed results of the measurement campaign are given in the following paragraphs. A view of the 3 MeV test stand is shown in Figure 5.

Figure 5: View of the test stand.

In the top-left corner, the 45 keV ion source inside the high voltage cage and the RFQ, followed by the MEBT and the diagnostic bench. On the right, the RFQ klystron and wave guides.

Diagnostic Bench

In addition to the diagnostics permanently installed in the line, a temporary diagnostic bench was designed in order to fully characterize the beam at 3 MeV including:

- Beam Current Transformers (BCTs), for intensity measurements.
- Beam Position Monitors (BPMs) which determine the position of beam as well as its intensity.
- An emittance meter, consisting of a 200 µm slit producing a beamlet whose angular distribution is measured with a wire grid 3 m downstream.
- A spectrometer line to measure the beam energy spread.
- A Bunch Shape Monitor (BSM) [4], which provides a measurement of the longitudinal distribution in a micro bunch.
- A halo monitor [5] used to measure not only the transverse beam halo but also the remaining part of the incompletely chopped bunches (time resolved chopping efficiency).

Copyright © 2013 CC-BY-3.0 and by the respective authors

A detailed drawing of the 3 MeV diagnostic bench, straight line and spectrometer line, is shown in Figure 6.

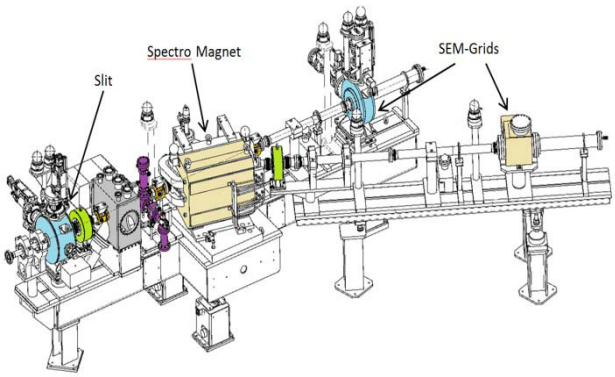

Figure 6: The 3 MeV diagnostic bench.

COMMISSIONING RESULTS

Source and LEBT

The Linac4 ion source consists of a plasma generator and a multi-electrode extraction system (Figure 7). During the commissioning, it was operated in a pulsed mode at 1.2 s interval, keeping the beam output as stable and reliable as possible. During 4 months it was running without any major problems. After typically 2 hours of warming up (stabilization time) it provided stable energy and H- beam current of 16 mA. The source used at the 3 MeV test stand is not the final source of Linac4; the new Cesiated source is presently under construction and test. An operating source with increased performances is due in June 2014.

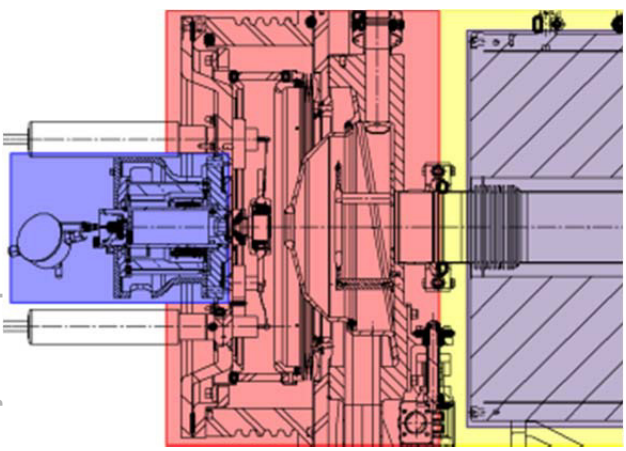

Figure 7: The ion source used at the test stand. Plasma generator (blue), front-end (red) and first part of the LEBT (yellow) including the first solenoid (purple).

The beam transverse emittance was measured with the LEBT emittance meter positioned after the first solenoid for different solenoid settings. These measurements were back-traced with the code Travel [6] to the output of the source, giving a realistic beam distribution further used for simulating the matching to the RFQ. We can see on Figure 8 five different measurements corresponding to different solenoid settings and the respective "back traced" source beam outputs which are all very similar. For the preparation of the RFQ commissioning (matching, transmission studies etc…), the superimposition of these 5 beams was taken as the source beam output distribution for the multiparticle tracking code. The measured RMS normalized transverse emittance out of the source is equal to 0.8 mm.mrad.

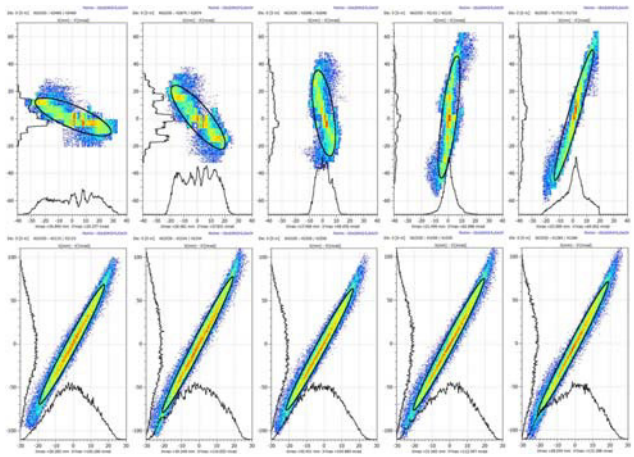

Figure 8: On the top, horizontal emittance measurement for 5 different solenoid settings; on the bottom, the 5 corresponding back-traced source output beam.

In the LEBT, the space charge compensation caused by the secondary particles created by ionization of the residual gas plays an important role in the beam dynamics. The evolution of the transverse emittance ellipse along the beam pulse has been measured for different residual pressures [7]. Figures 9a and 9b show the evolution of the transverse emittance and the Twiss parameter β along the pulse. The stabilization time of the space charge compensation is shorter for high residual gas pressure but the resulting emittance is then larger.

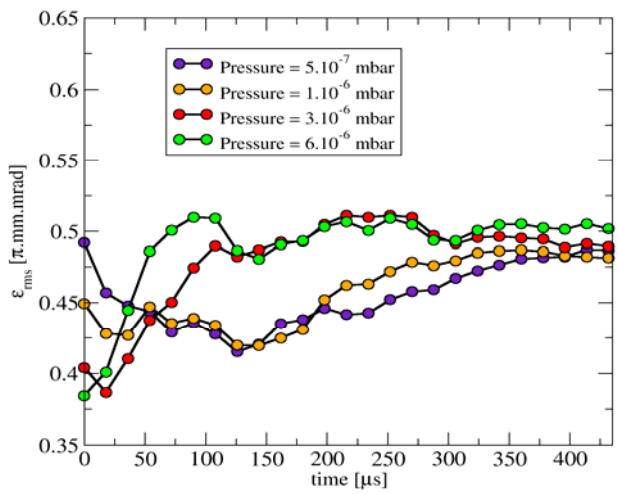

Figure 9a: Transverse emittance evolution along the beam pulse for different residual gas pressure.

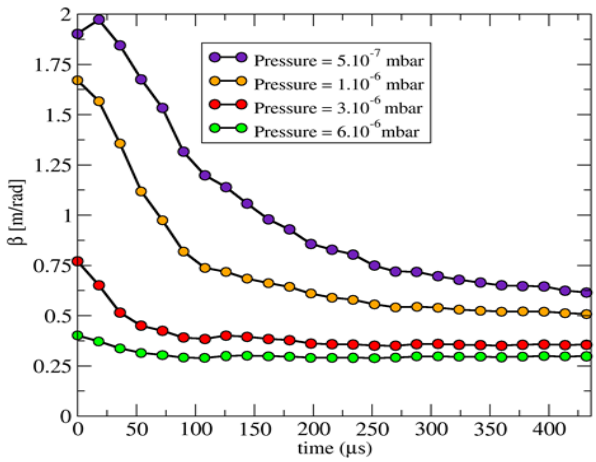

Figure 9b: Beta parameter evolution along the beam pulse for different residual gas pressure.

RFQ

The Linac4 RFQ was designed and manufactured at CERN [8]. The first H- ion beam was injected on March 13th 2013 and the first accelerated beam was observed at the RFQ output after 10 minutes of LEBT solenoids and steerer magnets fine tuning. The empirically optimised solenoid settings were within 3% of the one expected from simulations with Travel code, demonstrating the quality of the RFQ machining and of the LEBT modelling. The first 3 MeV BCT signal observed on that day is shown in Figure 10 (10 mA steady state H- beam current).

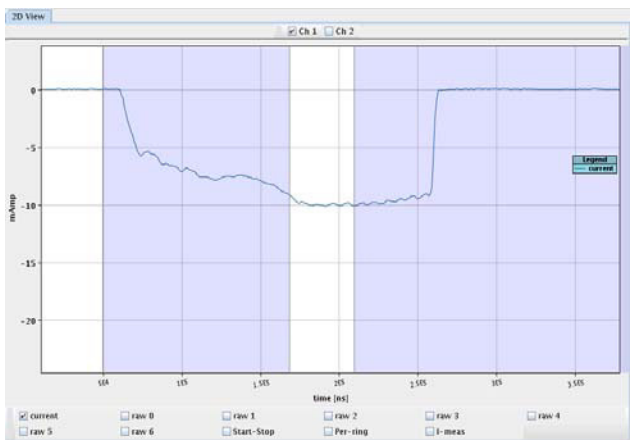

Figure 10: RFQ output beam current – 2013/03/13.

After retuning beam focusing and steering in the LEBT, the RFQ maximum transmission was reached, giving a 12 mA peak current at 3 MeV (75% transmission). The RFQ transmission was studied with Parmteq [9] and Toutatis [10] codes, taking into account the beam parameters measured in the LEBT. Given that the emittance from the source is larger than expected, 25% of the beam from the source is bound to be lost in the first centimetres of the RFQ. Figure 11 shows the comparison of the emittance measured in the LEBT and the RFQ acceptance.

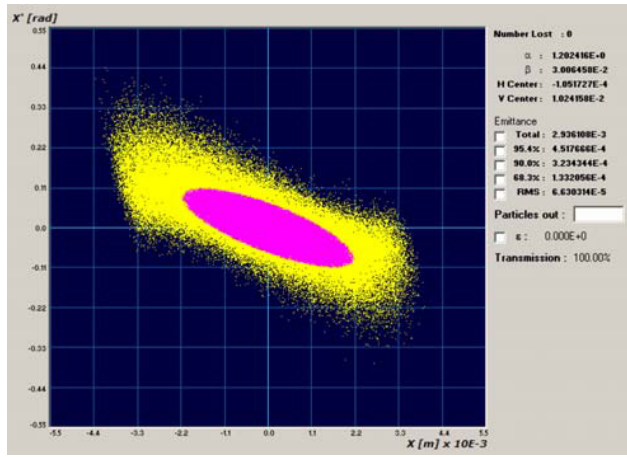

Figure 11: Comparison of measured emittance (yellow) and RFQ acceptance (pink).

Figure 12 shows a comparison of the simulated RFQ transmission (purple dots) and measured transmission for different gas pressure in the LEBT and RF power. It should be noted that the solenoids and steering magnets were optimized, for the case corresponding to 1.e-6 mbar pressure in the LEBT.

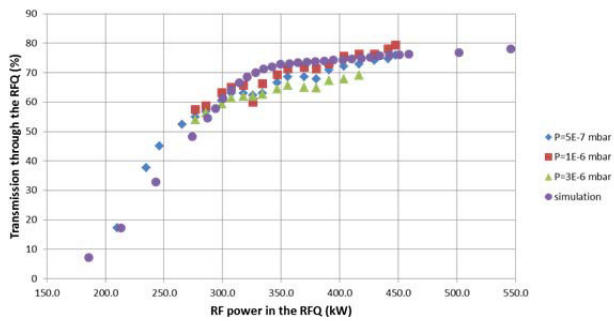

Figure 12: RFQ transmission vs power for different gas pressure in the LEBT.

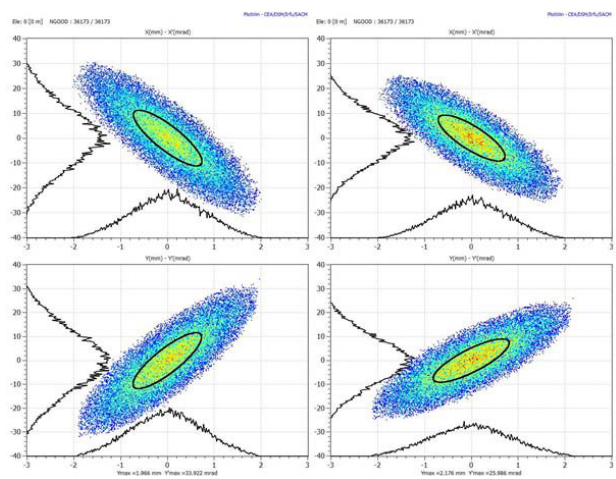

Figure 13: Beam distribution in the Horizontal (top) and vertical (bottom) phase planes at RFQ output; Left: expected from simulation, Right: reconstructed with the forward method.

Copyright © 2013 CC-BY-3.0 and by the respective authors

The transverse emittance was reconstructed after the RFQ with the so-called forward method [3]. The beam profile was measured for different test bench quadrupole settings and the corresponding emittance at the RFQ output computed with the Travel code taking the space charge effects into account. The reconstructed normalized emittance is equal to 0.32 and 0.34 mm.mrad in horizontal and vertical plane respectively compared to 0.36 and 0.37 mm.mrad expected from the simulations. The comparison of the reconstructed and expected phase space distribution is given in Figure 13.

Chopper-Line

The MEBT was installed after the RFQ commissioning was completed. It aims to match the beam to the DTL and modify the time structure of the pulse in order to reduce losses at the PSB injection. The fast chopper is based on an original "low-voltage" concept: the micro bunches that should not be injected in the PSB see a relatively low electric field, generated by two chopper plates. The resulting kick in the phase space is further transferred in the real space by a defocusing quadrupole located at 90° phase advance. The chopped bunches are then collected in a conical aperture beam dump. Figure 14 shows the comparison of the simulated and measured transmission of the chopper-line for chopper ON and OFF varying a MEBT quadrupole gradient. We can see a very good correspondence between simulation and measurements for chopper OFF. For the chopper ON, it turned out that the experimental results are better than simulations, indicating a chopper efficiency better than expected. This could be explained by a coverage factor of the field generated by the chopper higher than expected or by a transverse distribution more Gaussian than assumed in the simulations. The rise and fall time of the chopper is expected to be a few ns; a preliminary measurement with a fast BCT indicates that it is below 10 ns.

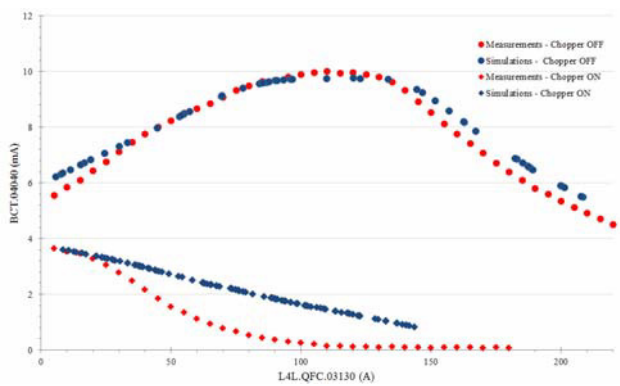

Figure 14: Measured and simulated transmission in the MEBT for chopper ON and OFF.

The longitudinal distribution of the beam was also reconstructed using a method equivalent to the 3 gradients method in the longitudinal plane. The beam phase spread was measured with a BSM for different settings of the second MEBT buncher cavity. As for the transverse plane, we applied the forward method to reconstruct the emittance ellipse in the Phi/E phase space at the output of the RFQ. The measured energy spread is equal to 22 keV RMS compared to the 21 keV expected from simulation.

The matching to the DTL, time resolved measurement with the halo monitor and comparison between TOF and spectrometer measurement will be studied once the line moved in the tunnel.

PROJECT STATUS AND SCHEDULE

The installation of general infrastructure and services is now completed in the Linac4 tunnel. After the successful measurement at the test stand, the 3 MeV line was installed and will be re-commissioned from October 2013. The DTL and CCDTL will be installed and commissioned in 2014, and the PIMS in 2015. A one year reliability run is foreseen in 2016 before the connection of the Linac to the PS Booster foreseen in 2017-18, during an extended stop of the LHC injector chain. Figure 15 shows a view of the Linac4 tunnel in September 2013.

PROTON ACCELERATOR DEVELOPMENT IN CHINA

S.N. Fu, IHEP, Beijing 100049, China

Abstract

The China Spallation Neutron Source (CSNS) and the Chinese Accelerator Driven Systems (C-ADS) projects are both underway in China. The CSNS includes a 100 kW RCS accelerator and first beam on target is planned for 2017. The C-ADS project includes a high power superconducting linac with a low energy (25-50 MeV) initial stage by 2015 and higher power deployment later. In addition to these intense-beam proton accelerators, some other proton accelerators for various applications are also under construction or planned. In this paper, the plans, R&D and construction activities of these projects will be discussed.

INTRODUCTION

Proton accelerator becomes a new direction in Chinese accelerator community for its many important applications. It will be used for neutron source for neutron scattering applications, Accelerator Driven Subcritical system (ADS) for nuclear waste transmutation, proton therapy for cancer treatment, as well as the space radiation effects research. China Spallation Neutron Source started construction in 2011[1]. Its accelerator provides a proton beam of 100 kW power onto the target in the first phase, and then will be upgraded to 500 kW beam power in the second phase. And meanwhile, a small neutron source is under construction in Tsinghua University[2]. In 2010 a Chinese roadmap for long-term development of ADS was proposed by Chinese Academy of Sciences[3] and the first budget of about $260M has be allocated for an ADS test setup construction. This year, Chinese central government has approved two proton accelerator-based big-science projects in its five-year plan: ADS program and space radiation effect research program. These proton accelerator-related projects, no matter big or small, give a great chance to Chinese accelerator community to develop the cutting-edge high-technology of proton accelerator in China. This paper will present an overview of these projects at different stage, including their design, key technology R&D, construction and future plan.

CHINA SPALLATION NEUTRON SOURCE

The CSNS is designed to accelerate proton beam pulses to 1.6 GeV kinetic energy at 25 Hz repetition rate, striking a solid metal target to produce spallation neutrons. The accelerator provides a beam power of 100 kW on the target in the first phase. It will be upgraded to 500kW beam power at the same repetition rate and same output energy in the second phase. For this reason, the present design has reserved a long beam line in LRBT for superconducting spoke cavity installation for the linac energy upgrade in order to compensate for space-charge effect in the RCS when the beam current becomes 5-times higher. Table 1 lists the major parameters of the accelerator in the two phases.

Table1: CSNS Design Parameters

Project Phase	I	II
Beam Power on target [kW]	100	500
Proton energy [GeV]	1.6	1.6
Average beam current [μ A]	62.5	312.5
Pulse repetition rate [Hz]	25	25
Linac energy [MeV]	80	250
Linac type	DTL	+Spoke
Linac RF frequency [MHz]	324	324
Macropulse. ave current [mA]	15	40
Macropulse duty factor	1.0	1.7
RCS circumference [m]	228	228
RCS harmonic number	2	2
RCS Acceptance [πmm-mrad]	540	540
Target Material	Tungsten	Tungsten

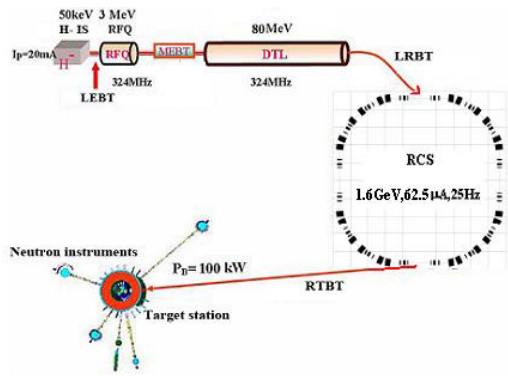

Figure 1: Schematics of the CSNS complex.

A schematic layout of CSNS phase-1 complex is shown in Figure 1. In the phase-1, an ion source produces a peak current of 25mA H^- beam. RFQ linac bunches and accelerates it to 3MeV. DTL linac raises the beam energy to 80MeV. After H^- beam is converted to proton beam via a stripping foil, RCS accumulates and accelerates the proton beam to 1.6GeV before extracting it to the target. 20 neutron channels are designed surrounding the target, but only 3 spectrometers will be built in the first phase due to limited budget.

The CSNS project started construction in September 2011 after the site land and the access road had been

Copyright © 2013 CC-BY-3.0 and by the respective authors

prepared by the local government. The architectures for the linac tunnel has been completed and klystron gallery are under construction. We plan to start installation of the front end of linac in November, 2013. The civil construction status is shown in Figure 2.

Figure 2: Civil construction status of CSNS project.

Front-end

Penning H^- surface source is chosen for CSNS. Based on prototype experience and some optimization in design, a new source for the project has been fabricated and set up at the laboratory of the Dongguan University of Technology for beam extraction test before the test hall is available, as shown in Figure 3.

Figure 3: CSNS H^- ion source in beam extraction test.

RFQ accelerates H^- beam from 50keV to 3MeV, with duty factor of 1.05%. A four-vane type RFQ at 324 MHz has total length of 3.62 m, composed of four technical modules. Two section cavities are resonantly coupled together with a coupling plate in between, as shown in Figure 4. The four module cavities are ready for assembly to form a whole cavity for field tuning. Two sets of 1000 *l*/s ion pumps and 500 *l*/s turbo-molecular pumps are designed for an order of 10^{-7} Torr dynamic vacuum pressure. Another set of backup pumps can be easily added. The RFQ cavity has been fabricated and is ready for assembly for field tuning measurement. Two sets of Burle 4616 Tetrode feed 530 kW total RF power to the RFQ through two coaxial power couplers. In the power test, each source reached 400 kW pulse power with pulse length of 700 μ s at 25 Hz, as shown in Figure 5.

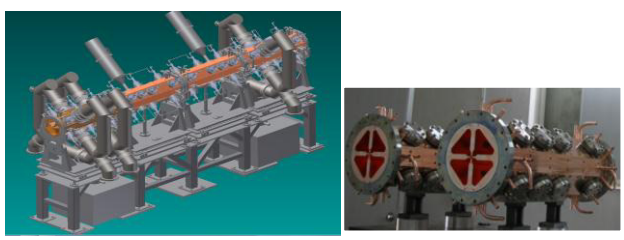

Figure 4: RFQ design and assembled cavity for field tuning.

Figure 5: RFQ power source and its output power in test.

The total length of MEBT is about 3 m, including 10 qaudrupole magnets, 2 bunchers, 12 steering magnets, as well as some beam diagnostics, including 8 BPM, 5 FCT, 4 BPrM, 3 BLM, 2 CT and EM. As the LEBT chopper has already reach a rise/fall time less than 17ns, we will not install the RF choppers in the MEBT in Phase-I, but leaves space for them for upgrade.

DTL Linac

The 324 MHz DTL accelerates the 3 MeV beam from the RFQ to 80 MeV. The DTL linac is composed of 4 tanks with a total length of 35 m. Each tank is about 9m long and assembled with three technical modules. Mass production of the tank and tube started in early 2012 and the first DTL tank has been fabricated. Figure 6 shows the fabricated tubes and tank. They will soon be assembled for field measurement and field tuning with slug tuners and coupling stems.

Figure 6: The fabricated drift tubes and tank.

The RF power source for DTL is 324 MHz klystron from CPI, with maximum output power of 3 MW. The adopted HVPS scheme is 400 Hz AC series resonance high voltage power supply. One power supply feeds the same voltage of 120 kV to two klystron cathodes through their m-anode modulators. We proposed such a new type of HVPS for klystron and demonstrated its feasibility with a 100 Hz prototype. Two sets of the power supply are under manufacture for CSNS DTL. Figure 7 shows the klystron and its HVPS under assembly.

Figure 7: 3MW klystron and its 120 kV HVPS under manufacture.

RCS

The RCS lattice consists of 48 quadrupoles and 24 dipole magnets, forming a four-fold ring with

Copyright © 2013 CC-BY-3.0 and by the respective authors

circumference of 227.92m. In the each super period, an 11m long drift space is left in a triplet cell. These four uninterrupted long straight sections are arranged with injection, extraction, RF acceleration and transverse collimation respectively. To reduce space charge effect, H^- beam from linac is stripped by a carbon foil and painted into a large phase space about 240 π mm-mrad in two transversal directions with 8 pulsed bump magnets. The maximum space charge tune shift is -0.28 in bunching stage. A two-stage collimator system with an acceptance of 350 π mm-mrad is utilized for removing halo particles.

The RCS AC dipole and quadrupole magnets is in mass production. The first dipole and quadrupole magnets in mass production have been produced(Figure 8). They have been continuously operated with full AC current of 877 A for 72 hours. The coils and cores of the magnets are robust enough, and no crack was found on their surfaces. The field of these two types of magnets has also been measured, and the results meet the specification. The magnet installation in the ring tunnel is foreseen in the middle of 2015 when the tunnel is available.

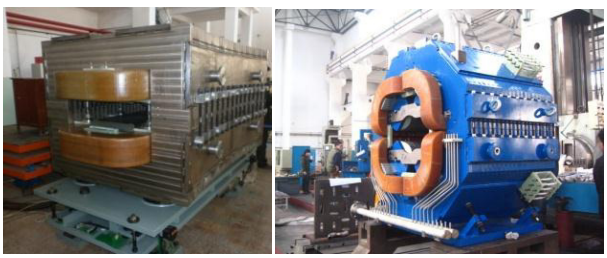

Figure 8: RCS dipole and quadrupole magnets in mass production.

The power supply for the magnets uses White resonant circuits to avoid the impact to the grid. Due to nonlinear feature of the magnet core, a pure sinusoid AC current from the power supply will result in a deformed sinusoid magnetic field with an unacceptable tracking error. To deal with this issue, high order harmonic current is injected into the power supply for compensating for the nonlinearity. The 24 dipole magnets are powered with one set of current supply and the 48 quadrupole magnets are powered with 5 sets of current supplies. All of these power supplies are under mass production.

The RCS has eight ferrite-loaded cavities for proton acceleration, of which seven cavities provide total 165 kV RF voltage with additional one as backup. The cavity resonant frequency shifts from 1.02 MHz to 2.44 MHz in 20 ms by a bias current supply. In the prototype RF system, the response bandwidth of the bias current supply has been improved up to 10 kHz by adding a small linear shunt modulator to the existing switching power supply. The resulted tracking error apparently reduced within the specification of ±0.2%. Based on the experience of high power operation of the RF system prototype, the design of the RF cavity structure has been optimized to ameliorate the cavity and RF transmitter performance. Manufacture of 8 sets of RF cavities and 500 kW transmitters has been in good progress. Figure 9 shows the fabricated cavity and its RF power source.

Figure 9: Ferrite-loaded RCS cavity and its RF power source in mass production.

Ceramic vacuum chambers are used in the RCS dipole and quadrupole magnets, injection bumps and extraction kickers to avoid the eddy current. The chamber size for dipole magnet is rather large with a length of 2.8 m and a cross-section of 135(V)×218(H) mm in inner diameter. All of these chambers have started mass production by a Germany vendor FRIATECH and domestic vendors. The inner surface of the chamber will be coated with TiN for low SEE. Figure 10 is the ceramic chamber for dipole magnet.

Figure 10: Ceramic chamber for dipole magnet.

The Beam Lines and Interface

The LRBT transports the H^- beam to the ring and it 47quadrupoles and 4 bending magnets. Some of the quadrupoles have been produced. A rebuncher is installed for reduction of the beam momentum spread. The injection stripping foil facility has been manufactured with 20 carbon foils on a rotating frame, as shown in Figure 11.

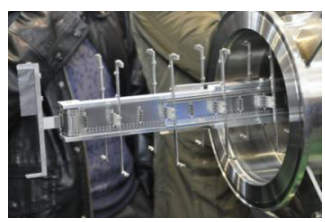

Figure 11: Stripping foil for H^- injection.

C-ADS CW PROTON LINAC

ADS in China is applied for nuclear waste transmutation, as a backup to the rapid nuclear power development. The accumulated waste is estimated to be more than 10k tons in 2020, and it will be doubled in 2030. ADS has been recognized as the best option for the nuclear waste final disposal. Roadmap of ADS development has been scheduled in four phases in China, as shown in Figure 12. In phase-I from 2011 to 2015, as R&D period, A 25-50 MeV linac will output a beam

Copyright © 2013 CC-BY-3.0 and by the respective authors

current of 10 mA in CW; phase-II will take a few years to increase the beam energy up to 250 MeV with superconducting spoke cavities and the accelerator will be coupled with a subcritical reactor to form an ADS research system. In Phase-III, until 2022, the beam energy will further rise to 0.6-1 GeV to drive a subcritical system of 100 MW thermal power. In phase-IV, more superconducting elliptical cavities will be added to the linac to raise beam energy up to 1.2-1.5 GeV until 2032, serving for a full-scale ADS demonstration facility.

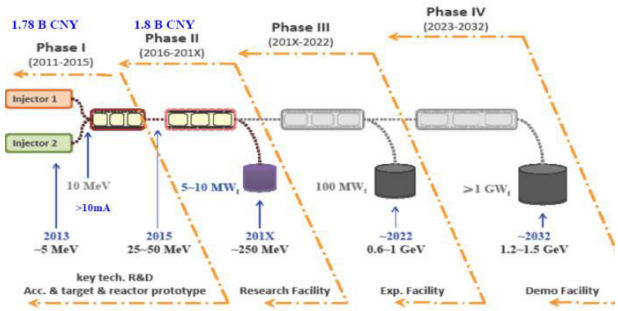

Figure 12: Roadmap for ADS development in China.

Linac Design

In the preliminary design a 1.5 GeV linac consists of two injectors, two spoke cavity sections and two elliptical cavity sections, as shown in Figure 13. In operation, only one injector runs and another is hot standby for a high reliability which is a key requirement for the target and reactor. To explore different technology at present, the two injectors have different design: the Injector-I is mainly composed with an ECR ion source, a 3.2 MeV room temperature RFQ at 325 MHz and superconducting spoke cavities at 325 MHz; while the Injector-II mainly consists of an ECR ion source, a 2.1 MeV room-temperature RFQ at 162.5 MHz and superconducting HWR cavities at 162.5 MHz. IHEP is in charge of the Injector-I, and IMP in charge of Injector-II.

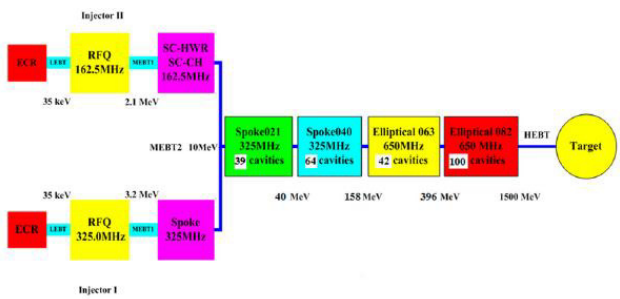

Figure 13: Layout of the C-ADS linac.

Key Technology R&D

Ion source An ECR ion source has been set up for beam extraction test at IMP, as shown in Figure 14(left). It can provide the RFQ with a CW proton beam of 25 mA at 35 KeV. This ion source together with LEBT will recently be installed in the tunnel at IHEP. At present the major work focus on the long-term operation stability of the ion source.

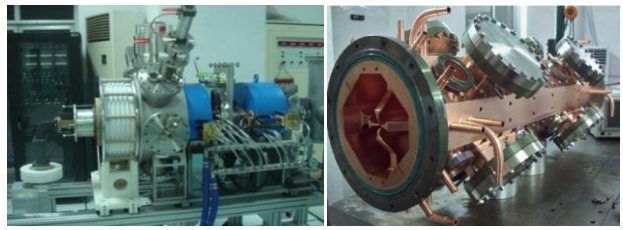

Figure 14: ECR ion source together with LEBT(left), and RFQ cavity(right) for Injector-I.

RFQ-I This four-vane type 325MHz RFQ will operate in CW mode at room temperature with RF power consumption about 273 kW. The full length of the vane is about 4.7m and maximum power density on the surface is 3.77 W/cm^2. Fabrication of the RFQ cavity is finished (Figure14) and RF measurement result shows that the design values have been achieved. Toshiba 600kW 325MHz CW klystron and 80 kV PSM power supply are adopted as the RF power source for the RFQ.

RFQ-II This four-vane type 162.5 MHz RFQ uses the PI-mode stabilizer for a wide mode separation between working quadrupole mode and the nearby modes. Fabrication of such a large cavity is not easy, and thus a short model cavity has been made for manufacture technology development, as shown in Figure 15.

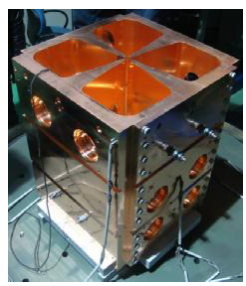

Figure 15：Short model cavity of 162.5 MHz RFQ for Injector-II.

Spoke012 This 325 MHz superconducting spoke cavity follows the 3.2 MeV RFQ-I. Two such low-β of 0.12 cavities has been fabricated. The horizontal test has been completed at 4K and Q_0 value reaches 2.2x10^8 at E=6.5 MV/m, as shown in Figure 16.

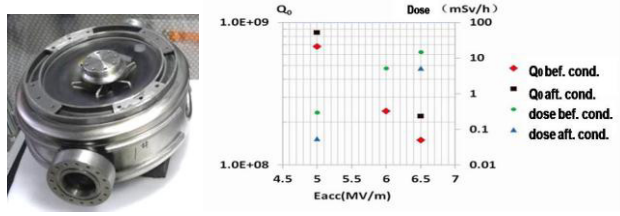

Figure 16: Spoke012 cavity and its horizontal test result for Injector-I.

HWR This 162.5 MHz superconducting cavity of β =0.1 follows 2.1 MeV RFQ-II. Two prototype cavities have been made (Figure 17) with measured Q_0=4.1x10^8 at 8.3 MV/m.

Figure 17: Prototype QWR cavity with β =0.1 for Injector-II.

Spoke021 and elliptic cavity In addition to the low energy section, superconducting cavities for medium and high energy sections are also under development. At present, two 325 MHz spoke cavities of β = 0.21 and some 650 MHz elliptical cavities of β =0.82 are under development, as shown in Figure 18.

Figure 18: Prototype development of 325 MHz spoke cavities with β = 0.21 and some 650 MHz elliptical cavities with β =0.82, for main linc.

OTHER PROTON ACCELERATORS

Except for the two high intensity proton accelerators for CSNS and C-ADS, some other proton accelerators are also under construction or in planning.

CPHS Accelerator

The Compact Pulsed Hadron Source (CPHS) in Tsinghua University, is driven by a pulsed high-current proton linac with a beam duty factor of 3%. The accelerator consists of an ECR ion source, a LEBT, an RFQ, a DTL and a HEBT beam line. The linac accelerates the proton beam to 13MeV, and delivers it to a Beryllium target. Four neutron beam lines are planned in the CPHS project, among which two lines are being constructed for the SANS and Neutron Imaging.

The 325 MHz RFQ has a four-vane structure and accelerates protons from 50keV to 3MeV. The inter-vane voltage increases with the beam energy. The total length of the RFQ is greatly shortened with a high transmission rate. The coupling plates become unnecessary for the 3m-long RFQ. The RFQ are designed to be matched to the DTL directly without MEBT. The 13MeV DTL adopts Samarium-cobalt permanent magnets with a field gradient almost constant (84.6T/m) in lattice structure of FDFD, which ensures small envelop of the beam.

At present, the 3MeV RFQ has been installed for beam tuning (Figure 18). In March 2013, its output peak current of 44 mA was achieved and the transmission efficiency was 88% while the input peak current was 50 mA with 50 μs pulse length at 50 Hz. The following DTL is under fabrication.

Figure 19: CPHS linac under beam tuning.

First neutron beam was obtained in July, 2013 by 22 mA proton beam with pulse length of 80 μs at 50 Hz. The total estimated neutron flux is about 2.8×10^{10} n/s.

APTron Accelerator

The Advanced Proton Therapy Facility (APTron) is proton therapy machine serving as a hospital-based facility [4]. It will be built at Jiading district of Shanghai with the technical support from Shanghai Institute of Applied Physics, CAS. The accelerator consists of a 7 MeV linac injector, a 24.6m circumference synchrotron capable of accelerating protons up to 250MeV, two horizontal fixed beam line and an isocentric gantry beam line in phase I, and can be upgraded to 3 gantry beam lines in total in phase II. The 7-MeV injector is composed of a RFQ and a short DTL tank. A proton beam is extracted from the synchrotron in an energy range of 70~250MeV with proton particles of 8×10^{10}p/spill at a repetition frequency of 0.1~0.67 Hz. This project has been funded by the local government.

Proton Accelerator for Space Radiation Test

Space radiation effect study calls for a proton accelerator with a weak beam current and micro-size beam spot on sample. This accelerator consists of a tandem with terminal voltage of 6 MV and a synchrotron with output energy range from 10-300 MeV. Beam from the tandem and the synchrotron will be sent to several test stands. A preliminary design of the accelerator has been proposed by IHEP. And this project has been approved in principle by the central government and it is foreseen the project will start construction in a couple of years.

ACKNOWLEDGEMENTS

ACCELERATOR-DRIVEN SUBCRITICAL FISSION TO DESTROY TRANSURANICS AND CLOSE THE NUCLEAR FUEL CYCLE*

S. Assadi, C. Collins, J. Comeaux, K. Damborsky, J. Kellams, F. Lu, P. McIntyre#, K. Melconian, N. Pogue, M. Salanne, A. Sattarov, E. Sooby, and P. Tsvetkov, Texas A&M University, College Station, TX 77845 USA

Abstract

A design for accelerator-driven subcritical fission in a molten salt core (ADAM) has been made for the purpose of destroying the transuranic elements in used nuclear fuel as fast as they are made in a conventional nuclear power plant. The oxide fuel is extracted from the used fuel assemblies into molten chloride salt using pyroprocessing, and the transuranic, uranium, and fission product salts are separated into three batches using electroseparation. The transuranic salt is then transferred to a subcritical core, with neutron gain 0.97. The core is driven by 800 MeV proton beams from a 12 mA CW strong-focusing cyclotron. The transuranics are destroyed and the fission heat is used to produce electric power. Simulations of many potential failure modes have been performed; the core cannot reach criticality in any failure-mode scenario considered. It operates as an energy amplifier with an energy gain ~5.5.

INTRODUCTION

Today nuclear power plants generate 20% of the electric power in the United States [1]. Until recently nuclear power comprised 20% of the grid in Germany and 30% in Japan, but Germany has moved to end their nuclear power production and Japan has idled their reactor fleet. Those decisions reflect a growing public concern about the safety of nuclear power. The meltdowns at Three Mile Island [2], Chernobyl [3], and Fukushima [4] underscore that this abundant source of energy can also produce extreme hazards.

The most enduring hazard of nuclear power is the large quantity of hazardous radioisotopes in used nuclear fuel (UNF). The most dangerous among those are transuranics (TRU, elements beyond uranium in the periodic table). The transuranics contained in the ~70,000 tons of UNF in the US have a radiotoxicity $>10^{13}$ Sv and half-lives of 10^5-10^6 years. The present accumulation of UNF also still contains about 1/3 of the entire US reserves of uranium. Long-term storage would pose the risk unto the generations of future release of immense radiotoxicity, and would sequester a major portion of available uranium resources. ADAM has been designed to offer an alternative: to destroy the transuranics, to recover the uranium for future use, and to produce 10x more energy than was produced in the first use of the fuel.

ADAM OVERVIEW

ADS Core Neutronics

The individual ADS core must be sized to optimize the normalized burn rate $\dot{T}/T$; i.e. to minimize the TRU inventory required to sustain core operation. Figure 3 shows the energy dependence for neutron capture on ^{238}Uwhich breeds TRU) and for n-induced fission of the dominant TRU isotopes. The fission cross sections for most TRU isotopes are significant only for ultra-fast neutrons (>1 MeV). Optimization of fast spectrum for the ADAM core places strong constraints upon the core size and geometry and upon the fuel salt composition. The optimized core is shown in Figure 1, and its neutronics properties are summarized in Table 1. In its spectrum 20% of the neutrons have >1 MeV energy. It operates with a neutron gain k_{eff} = 0.97, produces 280 MW_{th}, and requires a 10 MW proton driver. The optimized burn rate is $\dot{T}/T = 5.6\%/year$, corresponding to a destruction time of 18 years.

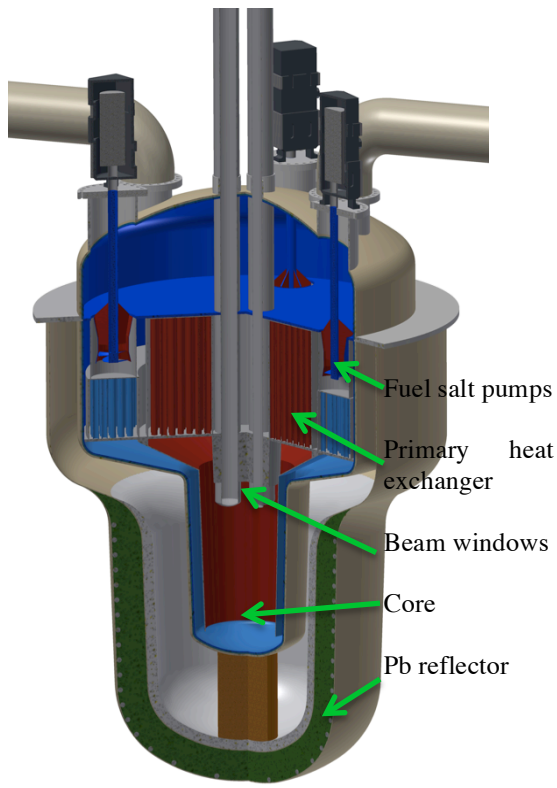

Figure 1: ADS molten salt core assembly.

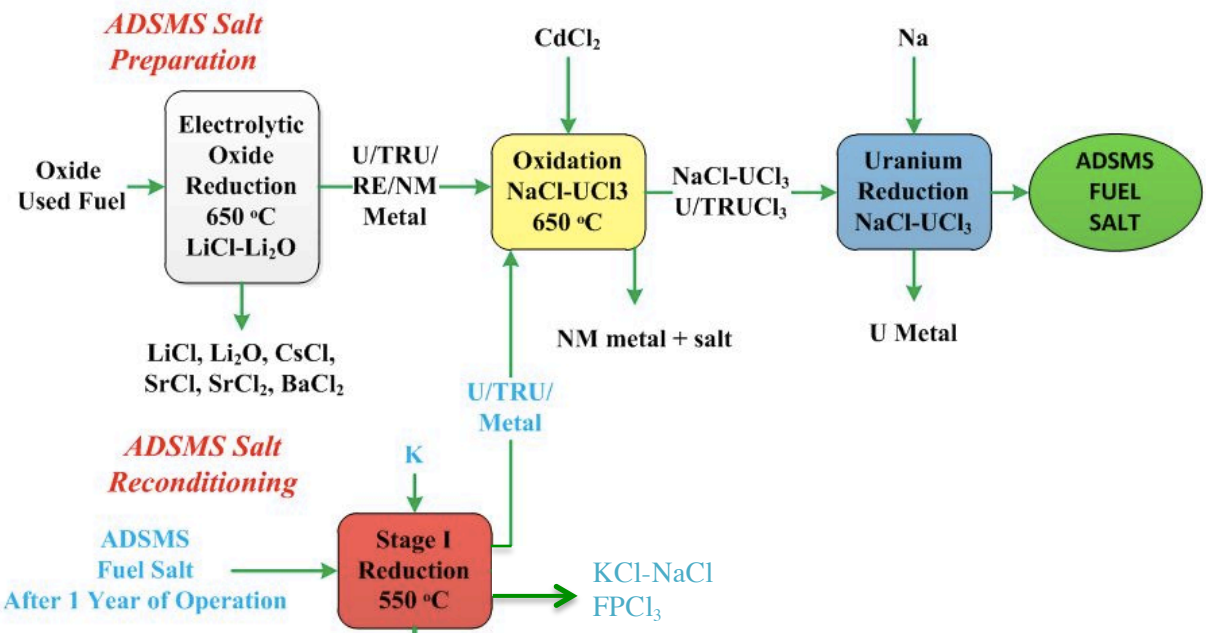

Figure 2: Pyroprocessing and electro-separation to prepare the fuel salt.

Fuel Salt Preparation and Reconditioning

The fuel salt for the ADAM core is a eutectic of $TRUCl_3$, UCl_3, and NaCl. It is prepared by a sequence of reduction and oxidation steps, shown in Figure 2. Fuel assemblies are chopped and crushed, and the oxide fuel is extracted from its Zircalloy cladding into molten salt (pyroprocessing [5]). Successive oxidation and reduction steps are used to plate out the uranium and to separate the remnant into separate batches of $TRUCl_3$ and $FPCl_3$ (FP = fission products). All of the steps of this electroprocessing have been developed into small-scale practice at ANL, INL, and KAERI [6].

The ADAM fuel salt contains as molar constituents $TRUCl_3$ (15.2%), UCl_3 (13.6%), NaCl (70%), and $FPCl_3$ (1.2%) [7]. The fuel salt has a melt temperature of 525 C and a boiling point of ~1500 C. The primary heat exchanger is integrated directly into the Ni vessel, and operates with an inlet temperature of 675 C and outlet temperature of 575 C.

As the ADAM core burns TRU its k_{eff} decreases. We modulate the proton beam power to maintain constant thermal power in the cores (increase the drive beam power from 8 MW to 10 MW) for a period of 3 months. At the end of 3 months we restore k_{eff} to its starting value by adding 90 kg of $TRUCl_3$. We can continue doing this for 5 years (20 cycles), at which time the fuel salt is transferred back to the electro-processing system, the accumulated $FPCl_3$ is removed, and the fuel salt is returned to the core vessel to begin another 5-year operating period.

Proton Driver

Each ADAM core requires a total of 12 mA of 800 MeV continuous proton drive beam. We have developed a design for a two-stage strong-focusing cyclotron (SFC) that can provide that performance [8]. The acceleration sequence is shown in Figure 5. It begins with acceleration of 100 mA CW to 6.5 MeV in the 350 MHz LEDA rf

Table 1: Main Parameters and TRU-burning Performance of ADAM Core compared to Fast Critical Reactor Designs

System	ADAM	SFR	GFR	LFR	
Net TRU Destruction	0.84	0.74	0.76	0.75	g/MW_t-day
System Power	**290**	**840**	**600**	**840**	**MW_t**
Outlet Temperature	665	510	850	560	C
Thermal Efficiency	44	38	45	43	%
Power Density	200	300	103	77	W/cc

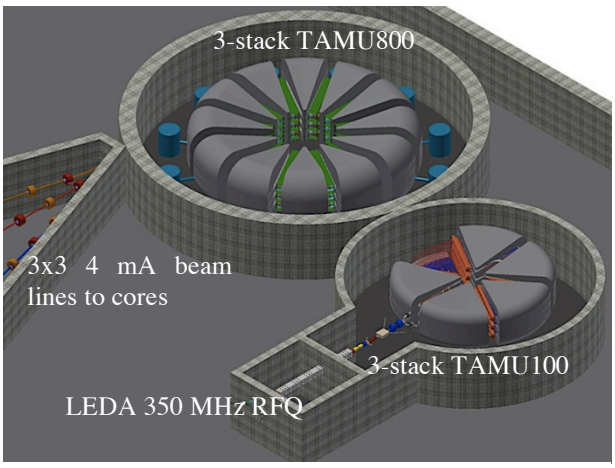

Figure 5: Acceleration chain for an ADAM site.

quadrupole (RFQ) [9]. The beam is then subharmonic-modulated, split into three 117 MHz beams, and passed through a sequence of 6-D collimators to yield three beams each with a normalized emittance < $1\pi10^{-6}$m and a phase width ±5°. The beams are then injected into a 3-stack of 100 MeV strong-focusing cyclotrons.

The world-record CW beam power for a proton accelerator is the PSI isochronous cyclotron [10]. It produces 2.2 mA CW at 590 MeV. Two issues pose the main limits to beam current in a cyclotron: the succeeding orbits overlap strongly so the defocusing action of space charge is exacerbated; and it has only weak focusing so that the betatron tunes migrate throughout acceleration and cross multiple resonances. We solved both of these problems in the SFC by incorporating two new elements: superconducting ¼-wave slot-geometry cavities that provide sufficient energy gain per turn to fully separate the orbits; and beam transport channels that provide alternating-gradient strong focusing to maintain constant betatron tunes throughout acceleration.

The details of the SFC design have been presented previously [8]. Three SFCs are configured as a flux-coupled stack, in which the dipole field for each SFC is created by

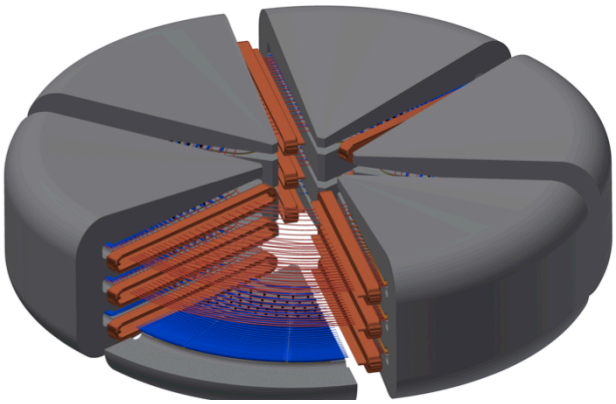

Figure 6: 3-stack of 100 MeV strong-focusing cyclotrons, with cutaway to show cavities, BTCs, and orbits.

a pair of cold-iron flux plates (Figure 4b) that are supported within a warm-iron flux return so that Lorentz forces on each flux plate cancel [11].

The superconducting cavity and beam transport channels are shown in Figure 6. The Nb superconducting cavity operates at 4.2 K and produces a ~2 MV acceleration. It is designed with fairly conservative surface field limits – 21 MV/m, 54 mT, and has provisions to suppress multipacting [12]. The rf power for each cavity is delivered to a linear array of input couplers, distributed along the upper and lower lobes of the cavity as shown in Figure 4a. Each coupler is driven by a solid-stage power source, and the linear array makes it possible to deliver input power in the same spatial distribution that is delivered to the circulating orbits of beam, so that beam loading does not drive transverse modes.

The beam transport channel (BTC) contains a single layer wire-wound Panofsky quadrupole winding and a window-frame dipole winding, both utilizing the superconductor MgB_2 which operates in the 15-20 K temperature range. An arc-shaped BTC is aligned along each equilibrium orbit in each sector as shown in Figure 4b, and is configured as an F-D doublet. The dipole winding is used to maintain precise isochronicity on all turns.

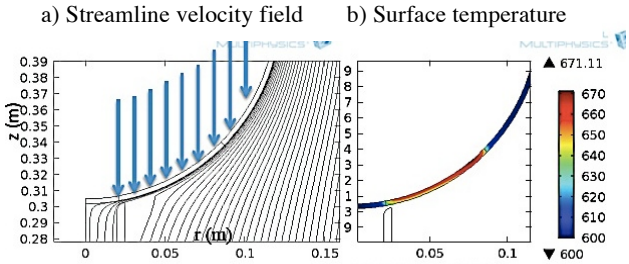

Figure 7: a) Molten salt flow on a proton beam window; b) Temperature profile on the window with 4 mA beam.

A companion paper [13] presents studies of the beam dynamics of the SFC for low-loss acceleration of high-current proton beam. We find that the elimination of overlapping orbits, the control of betatron tunes, and the suppression of transverse mode excitation by wake fields enables us to maintain stable acceleration of 12 mA CW through both SFCs to 800 MeV energy without beam breakup and with low loss for injection and extraction.

Delivery of 4 mA Proton Beam into Molten Salt

Each core requires a total of 12 mA drive beam. In order to operate within presently achieved beam window limits, we chop the proton beam after the RFQ to deliver ~10 μs bunch trains for acceleration, we split the 800 MeV bunch trains from each SFC to feed 3 transport lines, and we deliver the 3 bunch trains to 3 hemispherical Nb windows (Figure 1). The closed-circuit flow of molten salt in the core is channelled to deliver a chimney flow to cool each beam window, as simulated in **Error! Reference source not found.**.

Safety Considerations

The molten salt provides the spallation target and heat transfer medium for the beam windows, and it cannot be shocked by interruption of drive beam. All ADS designs that utilize a core based upon solid fuel pins have the problem that interruptions of drive beam (which happen every day at any extant accelerator) would thermally shock the fuel cladding which can lead to cracking.

All of the fuel salt is completely contained within the Ni core vessel and 5 shells of outer structure throughout a 5-year operating period. By contrast all previous core designs using molten salt pass the molten salt frequently through external circuits for reprocessing and re-conditioning, opening the risk of leaks.

The core vessel contains a removable inner vessel (in contact with the fuel salt) made from a single-piece of CVD Ni with no weld seam, which is resistant against molten salt corrosion. The Ni is much more robust against embrittlement from neutron damage in the ultra-fast spectrum of the ADAM core than it would be for a thermal spectrum. The CVD Ni vessel is encased in a spiral-wrap Hastelloy-N structure that provides mechanical support for the Ni can. An array of K vapor heat pipes is bonded to the outer surface of the Hastelloy shell and passively heat-sinks its surface to ~400 C during normal operation (consuming ~2 MW of heat) and during power and cooling failure modes. Maintaining the temperature of the Hastelloy at 400 C preserves its high tensile strength and toughness, which would be compromised if the Hastelloy operated at core temperature.

Many failure modes have been modeled, including loss of primary and/or secondary heat exchanger, loss of drive beam, loss of controls, and cracking of the core vessel. No failure mode studied can lead to leaking fuel salt beyond the multi-layer vessel, and no failure mode can produce criticality.

IMPLEMENTATION TO DESTROY TRANSURANICS

The ADAM core is sized to optimize the destruction of transuranics $\dot{T}/T$. Three ADAM cores are required to destroy TRU at the same rate that it is produced in a typical GW_e nuclear power plant. Figure 8 shows the site plan for an ADAM facility containing three cores and a 3-

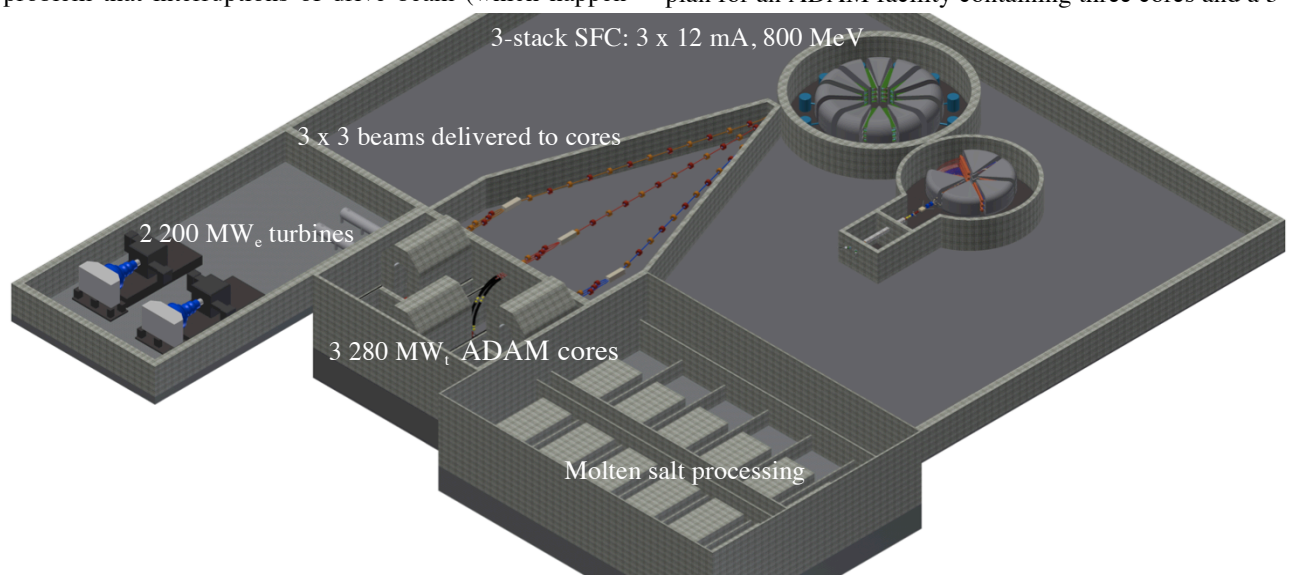

Figure 8: ADAM facility that destroys transuranics at the same rate they are produced by a GW_e nuclear power plant.

Copyright © 2013 CC-BY-3.0 and by the respective authors

stack SFC proton driver. It is appropriate in capacity to co-locate with an existing power plant, process its spent nuclear fuel, destroy the transuranics, recover the uranium, and generate uranium. The three ADAM units produce 3x290 MW_t of heat, which generates ~44%x870 = 380 MW_e. The SFC systems operate with ~50% efficiency, so it requires ~3x10MW/50% = 60 MW_e to operate the ADAM installation. The ADAM installation therefore is essentially an energy amplifier with a gain ~5.5. For as long as the adjoining GW_e power plant operates, its ADAM companion will generate ~320 MW_e of co-generated power to augment the plant's output while it destroys its hazardous waste.

Table 1 summarizes the performance parameters of the ADAM core, and compares them with the performance of several fast critical reactors that have been designed to destroy transuranics [14]: SFR is a sodium-cooled fast reactor; GFR is a high-temperature He gas-cooled fast reactor; and LFR is a molten lead-cooled fast reactor. Notably the ADAM core performs as well or better than any critical core design, and conveys the benefits for safe subcritical operation discussed above. ADAM provides a feasible candidate method to destroy the transuranics in used nuclear fuel and close the nuclear fuel cycle.

ACKNOWLEDGMENTS

We wish to thank Dan Barth (Friatech NA) for his help in designing molten salt pumps for the heat exchanger, and Jesse Johns (Texas A&M) for simulations of transient dynamics of the ADAM core. Michael Simpson (University of Utah) and Suprathorn Phongikaroon (Old Dominion University) are collaborating with us in developing the molten salt processing technology. Paul Madden (Oxford) and Matthieu Salanne (Université Pierre et Marie Curie) have collaborated with us in developing molecular dynamics models for the fuel salt. We wish to thank all members of the External Review of the ADAM project who conducted an in-depth review in January 2013: Ed Temple, Rick Baartman, Robert Hamm, Edward Hoffman, Pete Miller, Steve Myers, Bojan Petrovic, Gary Rochau, and Mark Williamson. It is a pleasure to acknowledge helpful discussions with Marvin Adams, Abe Clearfield, Richard Garwin, and Burton Richter.

Abstract

The Advanced Superconducting Test Accelerator (ASTA) currently in construction at Fermilab will enable a broad range of beam-based experiments to study fundamental limitations to beam intensity and to develop transformative approaches to particle-beam generation, acceleration and manipulation. ASTA incorporates a superconducting radiofrequency (SRF) linac coupled to a photoinjector and small-circumference storage ring capable of storing electrons or protons.This report describes the facility, its capabilities, and provide an overview of enabled research thrusts.

INTRODUCTION

The Advanced Superconducting Test Accelerator (ASTA) currently in construction at Fermilab will establish a unique resource for R&D towards Energy Frontier facilities and a test-bed for superconducting radiofrequency (SRF) accelerators and high-brightness beam applications. The unique features of ASTA include: (1) a high repetition-rate, (2) one of the highest peak and average brightness within the U.S., (3) a GeV-scale beam energy, (4) an extremely stable beam, (5) the availability of SRF and high-quality beams together, and (6) a storage ring capable of supporting a broad range of ring-based advanced beam dynamics experiments. These unique features will foster a broad program in advanced accelerator R&D which cannot be carried out elsewhere.

ACCELERATOR OVERVIEW

The backbone of the ASTA facility is a radio-frequency (RF) photoinjector coupled with 1.3-GHz superconducting accelerating cryomodules (CMs); see Fig. 1 [1]. The electron source consists of a 1-1/2 cell 1.3-GHz cylindrical-symmetric RF gun comprising a Cs_2Te photocathode illuminated by an ultraviolet (UV, $\lambda = 263$ nm) laser pulse obtained from frequency quadrupling of an amplified infrared IR pulse The photocathode drive laser produces a train of bunches repeated at 3 MHz within a 1-ms-duration macropulse.

The $\sim$ 5-MeV electron bunches exiting the RF gun are then accelerated with two SRF TESLA-type cavities (CAV1 and CAV2) to approximately 50 MeV. Downstream of this accelerating section the beamline includes quadrupole and steering dipole magnets, along with a four-bend magnetic compression chicane (BC1) [2]. The beamline also incorporates a round-to-flat-beam transformer (RTFB) capable of manipulating the beam to generate a high transverse-emittance ratio. In the early stages of operation, the bunches will be compressed in BC1. In this scenario the longitudinal phase space is strongly distorted and the achievable peak current limited to less than 3 kA. Eventually, a third-harmonic cavity (CAV39) operating at 3.9 GHz will be added enabling the generation of bunches with $\sim$ 10 kA peak currents by linearizing the longitudinal phase space. In addition CAV39 could also be used

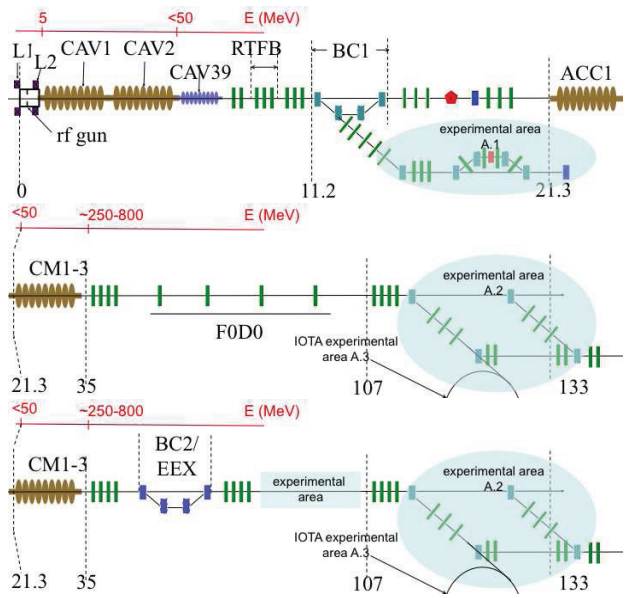

Figure 1: Overview of ASTA photoinjector (top); ASTA nominal high-energy transport beamline (middle) and modified high-energy transport beamline to accomodate a second-stage bunch compressor (bottom); "L1" "L2" stand for solenoids, "CAV1", "CAV2", and "CAV39" correspond to accelerating cavities, "CM1-3" to an ILC cryomodule string, "BC1" and "BC2/EEX" to bunch compressors, and "DL" to a dogleg beamline. "PEX" represents a possible reconfiguration of "BC2" to act as a transverse-to-longitudinal phase space exchanger.

to shape the current profile of the electron bunch [4]. The photoinjector was extensively simulated and optimized [3]. The photoinjector also includes an off-axis experimental beamline branching off at the second dipole of BC1 that will support beam physics experiments and diagnostics R&D.

The 50-MeV beam is injected into the SRF linac, which will eventually consist of three, 12-m long, TESLA/ILC-type CMs. Each CM includes eight 1.3-GHz nine-cell cavities. The first two cryomodules (CM1 and CM2) are a TESLA Type-III+ design, whereas the third (CM3), will be an ILC-Type IV design [5]. Together, these three CM constitute a complete ILC RF Unit. The SRF linac will be capable of generating a beam energy gain of $\sim$ 750 MeV. The installation of the cryomodules will be staged pending the completion of their construction. The first CM has already been installed in the ASTA Facility [6].

Downstream of the linac is the test beam line section, which consists of an array of multiple high-energy beam lines that transport the electron beam from the accelerating cryomodules to one of two beam dumps. In addition to testing the accelerator components, the intent of this facility is to also test the support systems required for a future SRF linac. The facility anticipated beam parameters appear in Table 1.

Table 1: Beam Parameters Expected at the ASTA Facility

parameter	nominal value	range
wnergy (A1) [MeV]	50	[5,50]
energy (A2) [MeV]	[250-800]	[50,820]
bunch charge Q [nC]	3.2	[0.02,20]
bunch freq. f_b [MHz]	3	see $^{(a)}$
macr. duration [ms] τ	1	≤ 1
macr. freq. f_{mac} [Hz]	5	[0.5, 1, 5]
num. bunch/macro. N_b	3000	[1,3000]$^{(b)}$
trans. emit$^{(b)}$ [μm]	$2.11Q^{0.69}$	[0.1, 100]
long. emit$^{(b)}$ [μm]	$30.05Q^{0.84}$	[5, 500]
peak current $\hat{I}$ $^{(c)}$	~ 3	≤ 10

$^{(a)}$ f_b and N_b are quoted for the nominal photocathode laser. Optical pulse stacking methods or field-emission sources could lead to smaller bunch separation within the rf macropulse.

$^{(b)}$ normalized rms values for an uncompressed beam. The scaling laws are obtained from Ref. [3] and correspond to an uncompressed case. Bunch compression results in larger horizontal emittances; see Ref. [2].

$^{(c)}$ the nominal value corresponds to a 3.2-nC compressed bunch without operation of CAV39. Higher values of $\hat{I}$ are possible with CAV39. For the uncompressed case, we have $I[\text{A}] \simeq 54.95Q[\text{nC}]^{-0.87}$.

During the first high energy beam operation and commissioning, only one CM will be installed allowing for the production of bunches with energies up to $\sim$ 300 MeV. Eventually, the second and third cryomodules will be installed in Stage II. Together, the three cryomodules plus the RF power systems will make up one complete ILC RF unit. During Stage II operation the beam energy will reach approximately 800 MeV. Beyond that stage several options are under consideration, including the installation of a 4th cryomodule downstream of a phase-space-manipulation beamline (either a simple magnetic bunch compressor or a phase space exchanger) [7, 8].

ASTA was designed with the provision for incorporating a small storage ring to enable a ring-based AARD program in advanced beam dynamics of relevance to both Intensity and Energy Frontier accelerators. The Integrable Optics Test Accelerator (IOTA) ring is 39 meters in circumference capable of storing 50 to 100-MeV electrons to explore, e.g, optical stochastic cooling methods [10] and integrable optics [11].

It is planned to expand capabilities for AARD in ASTA by the installation of the 2.5-MeV proton/H- RFQ accelerator which was previously used for High Intensity Neutrino Source (HINS) research at Fermilab [12]. That accelerator starts with a 50-keV, 40-mA proton (or H- ion) source followed by a 2-solenoid low-energy beam-transport line. The protons/ions are then accelerated by the pulsed 325-MHz RFQ to 2.5 MeV (with 1 ms pulse duration) prior to injection into IOTA.

USER OPPORTUNITIES

ASTA is intended to be operated as a scientific user facility for advanced accelerator research and development [13]. All the characteristics of a national user facility will be in evidence in the operation of ASTA and its user program. The facility is open to all interested potential users and the facility resources will be determined by merit review of the proposed work. The user program will be proposal-driven and peer-reviewed in order to ensure that the facility focuses on the highest quality research. Proposals will be evaluated by an external Program Committee (the ASTA Program Advisory Committee), consisting of internationally recognized scientists. Proposal evaluation will be carried out according to established merit review guidelines. We expect the first batch of proposal submitted as part of our proposal to DOE [14] will be reviewed during the fiscal year (FY) 2014.

Three experimental areas [A1, A2, and A3 (IOTA) in Fig. 1] will be available to users for installation of experiments. Area A1, situated in an off-axis beamline within the photoinjector, will provide electron bunches, possibly compressed, with energies up to 50 MeV. The current layout of the off-axis beamline includes a chicane-like transverse-to-longitudinal phase space exchanger, and provision for the installation of a short undulator for beam-laser interaction (e.g., to enable microbunching studies). The high-energy experimental area A2 consists of three parallel beamlines. Two of the beamlines are downstream of doglegs while one is inline with the ASTA linac. Experiments in the three user beamlines and IOTA could be ran simultaneously (switching the beam from one beamline to the other would only require minor optical-lattice adjustment). Fi-

Copyright © 2013 CC-BY-3.0 and by the respective authors

nally, the eventual availability of a H- source would allow IOTA to be operated independently of the ASTA electron-beam users. In addition, in order to accomodate additional experiments during the stage I, we are considering the installation of a chicane that could operate as a second-stage bunch compressor or transverse-to-longitudinal phase space exchanger (BC2/EEX in Fig. 1).

ANTICIPATED RESEARCH THRUSTS

In this Section we highlight expression of interests to perform experiments along the five main research thrusts enabled at ASTA.

Accelerator R&D for Particle Physics at the Intensity and Energy Frontiers

The combination of a state-of-the-art superconducting linear accelerator and a flexible storage ring enables a broad research program directed at the particle physics accelerators of the future.

The proposed research program includes at IOTA has expanded well beyond its initial goal to test non-linear, integrable, accelerator lattices, which have the potential to shift the paradigm of future circular accelerator design [15, 16, 17]. IOTA will also be used to explore optical-stochastic cooling [10]. The addition of an H^- source will also enable the investigation of integrable optics in presence of significant space charge effects. The H^- beam will also open the path to the study of space-charge compensation schemes in high-intensity circular accelerators [18]. IOTA will also support some fundamental Physics studies such as the measurement of the wave-function associated to a single electron using a method similar to an experiment previously attempted [19].

The availability of advanced phase space manipulations will also support the development and test of beam-driven acceleration methods, which would greatly benefit from shaped current profiles [21, 22, 23] to significantly increase the transformer ratio – the energy gain of the accelerated bunch over the energy loss of the driving bunch. When combined with the aforementioned round-to-flat beam transformation, this shaping technique could produce flat beams with tailored current profiles suitable for test of beam-driven acceleration methods based on, e g., slab dielectric-loaded waveguide (DLW) [24, 23], Other advanced acceleration techniques to be explored at ASTA include the acceleration and cooling of muon beams based on carbon-based crystal structures [25],

Finally, the high-power beam produced by the SRF linac will provide opportunities for high-energy Physics detector R&D. These include the high-power tests of target required for the Long-Baseline Neutrino Experiment (LBNE) and the generation of tagged-photon beams necessary to test components associated to the Project-X detectors.

Accelerator R&D for Future SRF Accelerators

High gradient, high-power SRF systems are critical for many accelerator facilities under planning for the needs of high-energy physics, basic energy sciences and other applications. ASTA offers a unique opportunity to explore most critical issues related to the SRF technology and beam dynamics in SRF cryomodules. The low injection energy ~ 50 MeV combined with achievable low emittance beams is well suited to explore beam dynamics effects and especially beam degradation due to the time-dependent field asymmetries introduced by the input and higher-order mode (HOM) couplers. The pulsed operation of SRF cavities at high-gradient while accelerating mA beam currents over long period of time has also relevance to the International Linear Collider program. Furthermore, the SRF linac will provide an experimental platform necessary to develop the required low-level RF controls for the Project-X pulsed linac [26]. Additionally, comprehensive beam-based measurements of long-range wakefield in SRF CMs are being planned using an upgraded version of the photocathode laser that would enable the production of charge-modulated bunch trains. Scanning the charge-modulation frequency and recording the HOM-induced beam displacements downstream of the cryomodule(s) under test would enable the characterization of HOMs over a continuous range of frequencies [27]. Finally, a precise characterization of the jitter and beam-based stabilization of the SRF module has been proposed. It relies on the measurement of the bunch relative time of flight downstream of a bunch compressor, bunch energy and on the detection of coherent synchrotron radiation. These measurements are fed to an algorithm and used to control the phase and amplitude of the SRF cryomodule(s) [28].

It was also pointed out that with adequate changes in the RF system, the ILC-type cryomodule installed at ASTA could in principle be operated in CW mode to perform tests relevant to the proposed next-generation CW light sources [30]. The maximum gradient attainable by the cavities is limited by the cryogenic system and HOM coupler. Cryogenic considerations indicate that the maximum gradient would be limited to $\sim 5-7$ MV/m. Likewise, the ILC-type input coupler design nominally used at ASTA would limit the average beam current to ≤ 1 mA [29].

Accelerator R&D for Novel Radiation Sources

High energy, high-peak and high-average brightness electron beams are crucial to the generation of high-brillance high-flux light sources with photo energies ranging from keVs to MeVs. The high average power and brightness of the ASTA electron beam has unmatched potential for development of several novel radiation-source concepts. Head-on collision of the electron bunch with an intense laser produces radiation with maximum up-shifted frequency $\omega \simeq 4\gamma_l^2\omega_L$ where γ_l is the bunch's Lorentz factor and ω_L the laser frequency. At ASTA, colliding the bunch with a 800-nm laser would provide γ rays with energies ranging from 1 to 20 MeV; see typical spectrum in Fig. 2 (left). If the laser repetition frequency matches the electron bunch frequency, an unprecedented γ-ray brilliance in excess of 10^{24}

Copyright © 2013 CC-BY-3.0 and by the respective authors

phot.mm^{-2}.mrad^{-2}.s^{-1}/(0.1%BW) could be attained [31]. The main technical challenge will be to develop a laser capable of producing Joule-level pulse energy with MHz repetition rate and will rely on a recirculating optical cavity [32, 33]. Such high-flux γ-ray source is foreseen to be extremely beneficial to the measurement of the cross section associated to the $^{12}C(\alpha,\gamma)^{16}O$ reaction which is crucial in nuclear astrophysics as it enters in the synthesis of many elements. Due to its low cross section, a precise measurement of this reaction using a nucleation process in a bubble chamber remains elusive with presently available γ-ray sources (as only a handful of events per year are expected). The potential availability of a high-flux γ-ray source at ASTA could result in significantly higher statistics (up to 200,000 events per year).

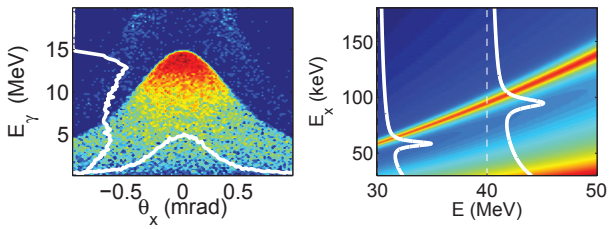

Figure 2: left: Spectral-angular distribution of γ rays produced by a 800-nm laser pulse backscattered on the ASTA 800-MeV beam (the density is plotted using a logarithmic color scale). right: X rays spectral yield as function of electron beam energy and photon energy for the $1 \rightarrow 0$ transition in (110) plane of diamond. Both CR and bremsstrahlung are considered in these calculations. The white traces are expected photon-energy spectrum for 30 and 40-MeV electrons

In the photoinjector area, it is foreseen to test a concept enabling the production of high-brilliance x rays by combining the low-emittance beam produced out of the photoinjector with channeling radiation (CR) [34]. The production of CR will occur downstream of the bunch compressor (BC1). Several crystal materials will be tested. Simulations using a $\sim$ 40 μm-thick diamond crystal indicate the production of x rays energy in the [10-150] keV range for the electron-beam energies available in the ASTA phtoinjector (15 to 50 MeV); see Fig. 2 (right).

Additionally, it was suggested that the available long stable bunch train could serve for a proof-of-principle experiment of an extreme-ultraviolet (EUV) FEL oscillator at 13.4 nm wavelength. Preliminary simulations indicate that saturation of the FEL process occurs after 300-350 passes [35]. Initial experiments could be conducted at low energy (250-300 MeV) and provide 120-nm FEL radiation.

Finally, the combination flat beams with long bunch train could support the test of micro-undulators [36]. These micro-undulators, made of laser-micromachined bulk rare-earth magnetic materials (SmCo and NdFeB), have magnetic fields with spatial period on the order of a few 100 μm. The associated undulator parameter is on the order of $K \sim 10^{-2}$ which results in a low photon yield $\sim \alpha K^2$ (where α is the fine-structure constant). Therefore the test and characterization of the associated undulator radiation would greatly benefit from the long bunch train available at ASTA.

Accelerator R&D for Stewardship and Applications

With its high energy, high brightness, high repetition rate, and the capability of emittance manipulations built-in to the facility design, ASTA is an ideal platform for exploring novel accelerator techniques of interest for very broad scientific community beyond high energy physics.

Some of the experiments include the development and test of subsystem and beam-manipulation scheme to improve the performance and decrease the cost of next-generation accelerator-based light sources. An example include the combination of the aforementioned phase-space manipulations to taylor the emittance partition within the three degrees of freedom to produce ultra-low emittance beams for future hard X-ray free-electron lasers [37].

Several proposals aim at developing techniques to "dechirp" the beam, i.e. to remove the residual correlated energy spread that generally subsists downstream of the final bunch compression stage in FEL drivers. The proposed dechirping methods include (i) the use of short-range wakefields impressed on the bunch as it passes in a dielectric [38, 39] or corrugated [40] passive structure, or (ii) the judicious arrangement of three transverse-deflecting cavities to produce a transfer matrix with a non-vanishing R_{56}. In addition using these passive structures to further control the longitudinal-phase-space nonlinearities could also be test at ASTA [41]. Demonstrating the compatibility of these techniques with high-repetition rate beam available at ASTA could lead to their inclusions in proposed CW FEL projects.

The flat-beam transformation available at ASTA could also support tests relevant to nuclear-physics accelerator R&D, e.g., to validate the concept of a fast beam-beam kicker [42] for the Medium-energy Electron-Ion Collider (MEIC) [43] being under design at Jefferson Laboratory.

Finally, the beam available at ASTA will foster the development and tests of advanced beam diagnostics relevant to, e.g., CW FELs or energy-recovery linacs. Some of these diagnostics especially those capable of measuring single-bunch parameters within the RF macropulse, will be crucial for optimizing the feedback system needed to stably operate the ASTA SRF cryomodule(s).

STATUS

The ASTA accelerator is currently under construction [44]: the electron source and associated subsystems were installed and are being commissioned; see Fig. 3. First electrons were produce in June 2013 from a temporary molybdenum cathode resulting in a 8-pC electron bunch. Typical operating parameters during the commis-

Figure 3: Photographs of the RF gun assembly used to produce first electrons (left) and of the cryomodule CM1 installation (right).

sioning phase are 80 μs-long RF macropulse, 31.5 MV/m peak electric field on the cathode surface and $f_b = 1$ Hz repetition frequency. The measured beam's kinetic energy at the gun exit is $E_k = 3.24 \pm 0.1$ MeV.

In parallel the 50-MeV injector line is being assembled and we anticipate that 50-MeV electron bunches will be produced early in CY2014. Further acceleration in one CM is foreseen late in FY14, once the high-energy beamline assembly is completed.

A program advisory committee (PAC) was formed and the first ASTA users' and PAC meeting was held at Fermilab on July 23-24, 2013. The meeting had $\sim$ 80 attendees (about 2/3 were external to Fermilab) and led to 24 expressions of interest. Further details on this users' meeting can be found in Ref. [45].

THE AWAKE PROTON-DRIVEN PLASMA WAKEFIELD ACCELERATION EXPERIMENT AT CERN

P. Muggli*, Max Planck Institute for Physics, Munich, Germany
for the AWAKE Collaboration

Abstract

We briefly outline the proposed AWAKE plasma wakefield accelerator (PWFA) experiment to be performed with the CERN SPS proton bunches. We focus on the experimental setup, allude to some of the physics involved and describe some of the measurements that are planned.

INTRODUCTION

A new high-gradient acceleration technique for electrons (e^-) and positrons (e^+) is required. Among those currently proposed and explored, plasma-based acceleration has led to the largest energy gain (>40 GeV) over a meter-scale distance [1]. However, producing with plasmas beams with parameters equal to or better than those produced by conventional, RF-based accelerators remains challenging. One of the challenges arises from the energy of the drive bunch that limits the energy gain of the witness bunch. Current short laser pulses or e^- bunches carry less than ∼100 J. Therefore, staging of a large number of plasma accelerator sections, with all the ensuing issues (alignment, timing, gradient dilution, etc.), is required to reach the desired energy (TeV range).

Proton (p^+) bunches available today, e.g. at CERN, carry much more energy than that carried by a future e^-/e^+ collider bunches: ∼1.6 kJ for 2×10^{10} particles at 500 GeV. With 10^{11} p^+, CERN SPS (400 GeV) and LHC (7 TeV) bunches carry 6.4 and 112 kJ, respectively. However, these bunches are long (σ_z ∼10 cm). For single-bunch operation at a plasma e^- density n_{e0} such that the electron plasma wave period $\lambda_{pe} = 2\pi c\left(\epsilon_0 m_e/n_{e0}e^2\right)^{1/2}$ matches the bunch length ($\lambda_{pe}\sim\sigma_z$, as in [1]) would result in a very low maximum accelerating field: $\leq E_{WB} = \left(2\pi m_e c^2/e\right)/\lambda_{pe} \cong 3.2\times10^9/\sigma_z(mm) \cong$32 MV/m in a plasma with $n_{e0}\sim10^{11}$ cm^{-3}. Short p^+ bunches (σ_z ∼0.1-1 mm) are thus necessary to reach fields higher than in RF cavities (>200 MeV/m).

P^+-DRIVEN PWFA

The potential for a p^+-bunch driven, plasma-based accelerator to produce a high energy e^- bunch was demonstrated in proof-of-principle simulations [2, 3]. An energy gain of ∼500 GeV in a plasma ∼500 m-long with a density of 6×10^{14} cm^{-3} with a σ_z ∼100 μm-long drive bunch was achieved. A train of short bunches can be produced out of a long bunch ($\sigma_z \gg \lambda_{pe}$) by the plasma itself through a transverse self-modulation instability (SMI) [4]. Thanks to the periodic focusing/defocusing fields of the initial wakefields, the SMI produces a train of $\sim\lambda_{pe}/2$-long bunches separated by $\sim\lambda_{pe}$ that can then resonantly drive the wakefields to large amplitudes. Interestingly, the amplitude of the wakefields is comparable the one that would be driven if all the charge were in a single short bunch. However, using the long bunch and the SMI to drive wakefields brings new challenges.

When the SMI grows from noise it needs a long plasma length to saturate. Also, the final relative phase of the wakefields is unknown and varies from event to event, which prevents the deterministic injection of the witness bunch into the accelerating and focusing phase of the wakefields. Over this long propagation distance the long bunch is subject to a competing, but asymmetric transverse instability, the hose instability (HI) [5]. The HI can break-up the bunch before the SMI can grow or before the witness bunch can gain large amounts of energy. Calculations and simulations indicate that the growth length of the SMI can be shortened, the phase of the wakefields determined and the occurrence of the HI mitigated by seeding the SMI with a signal of large amplitude [6] and known phase. They also indicate that in certain regimes the full bunch self modulation can effectively prevent the HI from developing over the acceleration region [7].

Even when seeded, the phase velocity of the SMI is slower than that of the drive and witness bunch during the growth phase of the SMI [8]. This leads to dephasing of the witness bunch with respect to the wakefields and to its loss through strong defocusing. The witness bunch must therefore be injected after the SMI has saturated and the bunch is fully self-modulated.

The SMI also grows along the bunch (convective instability) and the witness bunch must be injected many plasma periods behind the start of the wakefields ($\sim1\sigma_z \gg \lambda_{pe}$). Therefore the proper position within the drive bunch for the witness bunch to be focused and accelerated ($\sim\lambda_{pe}/4$) over a long distance is rather sensitive to plasma density variations since $\delta\lambda_{pe}/\lambda_{pe} = -\frac{1}{2}(\delta n_{e0}/n_{e0})$. When injecting the witness bunch $N\sim\sigma_z/\lambda_{pe}$ periods after the start of the wakefields the density uniformity requirements becomes $|\delta n_{e0}/n_{e0}| \leq (1/2N)$ (for a $\leq\lambda_{pe}/4$ phase shift). This requirement must be met over the plasma length, but only over the time scale of the interaction ($\sim\sigma_z/c$).

THE AWAKE EXPERIMENT

The AWAKE collaboration proposed an experiment to be performed at CERN to study the physics of self-modulation of long p^+ bunches in plasmas, to determine the potential of plasma-based accelerators driven by self-

modulated p^+ bunches and to explore the possibility of using short p^+ bunches to accelerate e^- to very high energies.

The baseline parameters for the AWAKE experiment using the p^+ bunches from the CERN SPS-CNGS beam line [9] are given in Table 1. A schematic of the experiment is shown in Fig. 1. Note that many standard beam line diagnostics are not shown (alignment screen, beam position monitors, toroids, etc.) [9]. The bunch is extracted from the SPS and transported to the CNGS beam line with an energy of 400 and up to 3×10^{11} p^+. It is focused to a rms radius σ_r^*=200 μm ($\beta^* \cong 5\ m$ $\beta^* \cong$5 m) near the entrance of a 10 m-long ($\sim 2\beta^*$) plasma. After the plasma the p^+ bunch free streams to the beam dump. The plasma density can be varied in the $10^{14} - 10^{15}$ cm^{-3} range to keep $k_{pe}\sigma_r^* \leq 1$ ($k_{pe} = 2\pi/\lambda_{pe}$) in order to avoid beam transverse filamentation [10]. The plasma is created by laser field-ionization of a rubidium (Rb) vapor. The vapor with a very uniform density is created in a Rb vapor source with a very uniform temperature [11]. The seeding of the SMI is insured by propagating the short ($\ll \lambda_{pe}$) laser pulse within the p^+ bunch itself [12] (see (2) on Fig. 1). Note that the interaction between the three beams (p^+, e^- and laser) is locally over after approximately one p^+ bunch length ($\sim$12 cm or $\sim$400 ps). Therefore the plasma once locally created by the laser pulse within the p^+ bunch needs to remain uniform only over that time scale. Long-term plasma evolution through diffusion, recombination, etc. common to most other sources is therefore avoided. Over the first few meters of plasma (typically $\sim$4) the SMI develops, saturates and the bunch becomes self-modulated (see (4') on Fig. 1).

The focus of the first experiments will be the study of the SMI. Simulations indicate that with the parameters of Table 1 the SMI does not develop unless seeded. The radial modulation of the p^+ bunch will be measured using various diagnostics. The p^+ bunch will emit incoherent optical transition radiation (OTR) when traversing a thin metal foil placed downstream from the plasma. The OTR light can be time resolved, for example with a streak camera, to directly measure the period of modulation through its intensity variations and perhaps to obtain information about the bunch transverse size. The modulation period and the depth of modulation can also be inferred from electro-optic (EO) measurements. Since there is a large number of modulation periods within the bunch ($\sim 100/\sigma_z$) EO measurements can be made in the frequency rather than in the time domain. EO measurement can either sample the coherent

transition radiation (CTR) emitted by the p^+ bunch or the transverse CTR recently proposed [13]. Measurements of the CTR frequency using cut-off waveguides or heterodyne microwave systems (f_{pe}=239 GHz with n_{e0}) will be used to detect the occurrence of SMI and measure the frequency of the bunch self-modulation as a function of n_{e0}.

The wakefields themselves will be sampled by externally injecting e^-. These e^- will be produced by an RF photo-injector gun driven by a laser pulse derived from the ionization laser system [9]. This is necessary to be able to chose the injection position of the e^- bunch with respect to the p^+ bunch and to the wakefields (see (2) on Fig. 1), i.e., at their peak and in the accelerating and focusing phase. First injection experiments will use side-injection [14]. This method avoids splitting the plasma source in two, as necessary for on-axis injection thereby avoiding issues related to local plasma density non-uniformities and precise density adjustment between sources. Also, it can be realized with a long e^- bunch ($> \lambda_{pe}$) letting the wakefields trap a fraction of the incoming e^-. Simulations show that e^- with an energy of ∼15 MeV crossing the p^+ bunch path at an angle of a few mrad can be trapped when injected along the plasma after SMI saturation (>4 m). Bunches with energies larger than 2 GeV and an energy spread of a few % have been observed after the plasma in simulations with the parameters of Table 1. Note that inherently short (a few fs), high-current (kA) e^- bunches routinely produced by laser-driven plasma-based accelerators (LWFAs) could also be considered for injection.

Later experiments will use two plasmas for on-axis injection of the e^- bunch and accelerator physics experiments. The first source will be a laser-ionized alkali metal vapor source to preserve the SMI seeding ability. However, the second source, used exclusively for e^- acceleration in the wakefields resonantly driven by the modulated p^+ bunch can be of a different, simpler type. Discharge and helicon sources are possible candidates. These sources can be scaled to very long lengths, while the length of the laser-ionized source does not scale well. An interesting option afforded by the two-source scheme (but also with single vapor sources with two heating systems [11]) is the possibility of introducing a step in the plasma density. Simulations suggest that a step up of a few percent during the growth of the SMI can help mitigating the decrease in wake amplitude generally observed after SMI saturation [3]. This decrease is due to the continued evolution of the bunch train and wakefields structure and is most pronounced with positively charged bunches.

OUTLOOK

Using the SMI to produce a train of short bunches and resonantly drive wakefields to large amplitudes is an attractive method when single bunches with suitable properties are not available. However, with the SMI a large fraction of the long initial bunch (at least half) is defocused and does not contribute to the wakefields generation. Another fraction is excluded by the seeding mechanism chosen here. The long distance along the bunch it takes for the SMI to saturate forces the injection of the e^- many plasma periods into the wakefields. This in turn leads to a very tight requirement on the plasma density uniformity. Some of these issues can me mitigated, for example by compressing the bunch and thereby reducing its relative length ($k_{pe}\sigma_z$). Compressions by a factor of a few is possible in the SPS ring and will be explored [9] as a means of increasing wakefields and better understanding SMI physics. However, methods to produce short p^+ bunches (∼100 μm) will also be explored to reach the single-bunch non-resonant regime of PWFA excitation and circumvent the issues related to the use of SMI.

SUMMARY

The AWAKE plasma wakefield accelerator experiment is in its preparation phase. We described the high-level experimental set-up, some of the physics involved as well as planned and possible measurements that will be used to test the physics of the SMI and of the acceleration of externally injected e^- in the wakefields driven by the long p^+ bunch. These experiments are tentatively scheduled to start at the end of 2016. These will be the first p^+-driven PWFA experiments and will explore PWFA in a low density range with $\sim GV/m$ accelerating fields that can be sustained over many meters of plasma and potentially accelerate e^- to very large energies in a single (or a few) plasma section [2]. Operation at lower density decreases the accelerating gradient (∼1 vs. 100's GeV/m) and increases the plasma length for reaching a fixed final energy. However, operating with a larger accelerating structure ($\sim \lambda_{pe}^3 \propto n_e^{-3/2}$) simplifies the drive and witness bunch production as well as the spatial and temporal alignment of the two bunches. It also increases the beam beta function matched to the plasma focusing force ($\beta_{matched} \propto n_e^{-1/2}$ in the blow out regime) and makes it easier to capture the bunch exiting the plasma.

BEAM-BEAM LIMIT IN AN INTEGRABLE SYSTEM*

A. Valishev#, S. Nagaitsev, FNAL, Batavia, IL 60510, USA

Abstract

Round colliding beams have been proposed as a way to push the attainable beam-beam tune shift limit, and recent successful experiments at the VEPP-2000 collider at BINP demonstrated the viability of the concept. In a round-beam system the dynamical stability is improved by introducing an additional integral of motion, which effectively reduces the system from a two and a half dimensional to one and a half dimensional. In this report we discuss the possible further improvement through adding the second integral of motion and thus making the system fully integrable. We explore the ultimate beam-beam limit in such a system using numerical simulations taking into account various imperfections.

INTRODUCTION

The strong nonlinearity of transverse focusing force is inherent to beam-beam interaction and affects the stability of particle motion in the present circular colliders. The beam-beam kick localized in a short interaction length along the accelerator circumference represents a nonlinear and time-dependent excitation of the otherwise linear betatron motion in the rest of the machine. In such systems, a multitude of resonances lead to particle diffusion and to chaotic-bounded motion, which limits the attainable beam brightness and collider performance. The typical maximum value of beam-beam parameter ξ in such 'conventional' machines is about 0.05÷0.06 for electron colliders, and up to 0.03 for hadron colliders due to the absence of synchrotron radiation damping.

In an attempt to mitigate the beam-beam effect, Krishnagopal and Siemann [1] analyzed the effect of the strong bunch length σ_z on the magnitude of resonances with the use of canonical perturbation theory. They concluded that '…the finite longitudinal extent of the beam-beam interaction results in averaging of the betatron phase over the collision, which mitigates the destructive effects of resonances'. Conversely, the synchrotron oscillations of the test particle lead to a greater depth of modulation and enhance the effect of resonances. Since the lengths of the two colliding bunches are usually equal, an optimal length should exist at which the two effects are compensating one another. The ratio of the bunch length to the beta-function of the order of one was determined as viable.

In further work along this direction Y. Alexahin [2] and T.Sen [3] studied the effect of phase averaging on the Tevatron performance, and also predicted the optimal $\sigma_z/b^* \approx 1$.

The growing interest to integrable systems in mathematical physics motivated Danilov and Perevedentsev to investigate the application of these systems to accelerators and colliding beams in particular [4, 5]. In a round colliding beams system, the beam-beam interactions as well as the transport through accelerator lattice possess axial symmetry. This results in the existence of an additional integral of motion, the longitudinal component of the angular momentum. An important consequence of the additional integral of motion is the elimination of transverse coupling resonances.

In Ref. [5], a round colliding beam system is proposed, which has two integrals of motion. The full integrability is achieved through proper shaping of the longitudinal bunch density, which makes the system Hamiltonian time-independent. The line charge density λ in this case must be inversely proportional to the beta-function β: $\lambda(2s)=C/\beta(s)$. In the case of no external focusing in the interaction region, the beta-function is a quadratic function of the azimuth s, $\beta(s)= \beta^*+s^2/\beta^*$, and the proper 'ideal' longitudinal distribution is

$$\lambda(s) = \frac{C}{1+(s/2\beta^*)^2}.$$

An important property of the fully integrable system is that the exact shape of transverse density distribution is irrelevant and does not affect the stability. However, the complete integrability is valid only for the center particles in the weak bunch, and synchrotron oscillations introduce modulation that disturbs the system. Also, the longitudinal distribution in a typical collider is Gaussian. Numerous numerical simulations have been performed to explore the stability of the round colliding beam systems to these imperfections (see e.g. [6, 7]). More importantly, the experimental implementation of the concept at the VEPP-2000 collider (BINP, Novosibirsk), where the record-high value of ξ=0.25 was achieved (at $\sigma_z/\beta^*\approx1$), demonstrated its viability [8, 9].

This, and the recent progress in the development of nonlinear integrable systems [10] motivated us to re-visit the question of optimization of a round colliding beam system with the goal to achieve even higher beam-beam parameters. We use the Lifetrac weak-strong particle tracking code [11] to perform numerical simulations, and characterize the tracking data with the Frequency Map Analysis [12, 13].

SIMULATION MODEL

The layout of the test lattice used in simulations is presented in Fig. 1. The machine consists of two main elements: a) a linear arc cell with axially symmetric focusing and phase advance of $\pi \times n$ (n is integer) in both planes; b) interaction region (IR), which is a drift space with length L and phase advance $2\pi Q_0$. The horizontal and vertical beta-functions in the IR are equal, with the minimum at the center of the drift. The well known relation between the phase advance and beta-function in a drift determines the value of the beta-function minimum β^*: $\pi Q_0 = \text{atan}(L/2\beta^*)$. The purpose of the arc cell is to match the beginning and the end of the IR lattice functions, otherwise being transparent – we consider dispersion and focusing chromaticity to be zero everywhere.

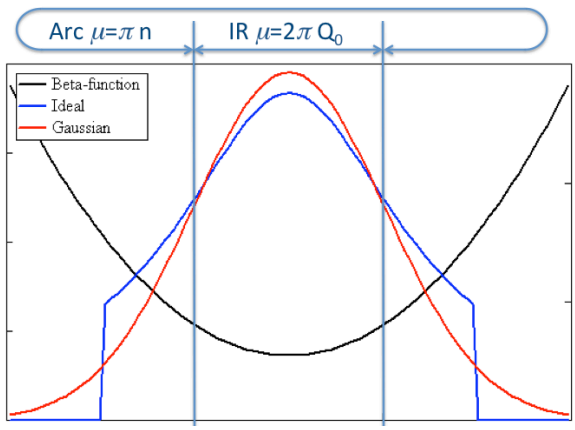

Figure 1: Schematic of the model lattice. Beta-function (black trace), ideal bunch density $\lambda=1/\beta$ (blue) and Gaussian density with $\sigma_z=\sqrt{2}\ \beta^*$ (red) as a function of azimuth. $Q_0=0.3$. Bunch length for the ideal case is $2\times L$ due to the counter-propagation of two beams.

Note that a significant difference between this model and the system proposed in [5] is that the betatron tune working point does not need to be close to integer or half-integer. Indeed, the betatron tune is $n/2+Q_0$, and Q_0 is determined by the ratio of β^* and L.

Next, we track a number of test particles with different initial conditions through the lattice with beam-beam interaction, and plot the tune variation along the trajectory as a color chart either in tune space (footprint) or in betatron amplitude space. The regions with significant tune variation represent either resonances or the chaotic motion.

RESULTS

For the synchronous particle in a weak bunch, in the case of ideal bunch density the system has two integrals of motion and the motion is infinitely stable for any value of beam-beam parameter. Figure 2 shows the tune footprint for $\xi=1$ (throughout this report the focusing beam-beam interaction with Gaussian transverse profile is used). The limited number of longitudinal slices of beam-beam interaction explains the existence of resonance lines. The motion also remains stable for $\xi=5$, 10.

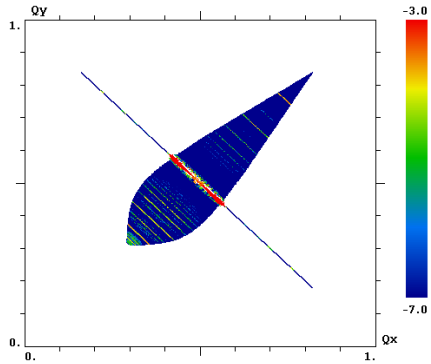

Figure 2: Tune footprint for the case of ideal bunch density $\lambda=1/\beta$, $Q_0=0.3$, and zero synchrotron amplitude. Beam-beam parameter $\xi=1$. Particles with betatron amplitudes up to 20 σ. The color represents tune jitter according to the scale on the right (log scale).

For the case of Gaussian longitudinal density, the integrability is lost and one can see the strong overlapping of resonances at $\xi=1$ (Fig. 3) but still no significant resonances at $\xi=0.5$ (Fig. 4). Note that in either case the large amplitude motion is stable, which could allow using such systems for purposes other than colliders, for example to create large betatron tune spread.

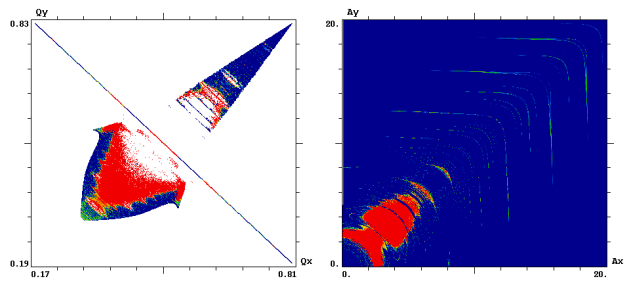

Figure 3: FMA plots for the case of Gaussian bunch density $\sigma_z=\sqrt{2}\ \beta^*$, $Q_0=0.3$, $\xi=1$, and zero synchrotron amplitude. Particles with betatron amplitudes up to 20 σ. Tune footprint (left), FMA in amplitude space (right).

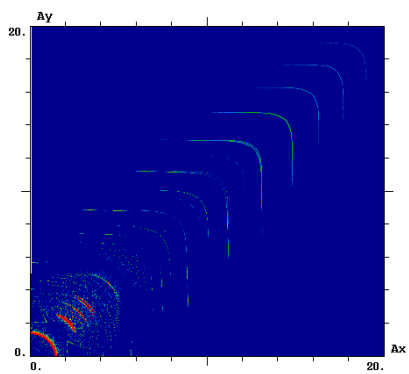

Figure 4: FMA for Gaussian bunch density $\sigma_z=\sqrt{2}\ \beta^*$, $Q_0=0.3$, and zero synchrotron amplitude. $\xi=0.5$.

Copyright © 2013 CC-BY-3.0 and by the respective authors

In the simulations for particles with non-zero synchrotron amplitude, we investigated the effect of the bunch length ratio for weak and strong bunch, and of the synchrotron tune. The variation of synchrotron tune does change the resonance configuration, emphasizing some betatron amplitudes more than the others, but does not reduce resonances in a large enough area. As one could expect, the shortening of weak bunch length has a profound effect on the system stability. Simulations suggest that beam-beam parameter of 0.5 could be sustained for the bunch length ratio of about 1/10 (Fig. 5).

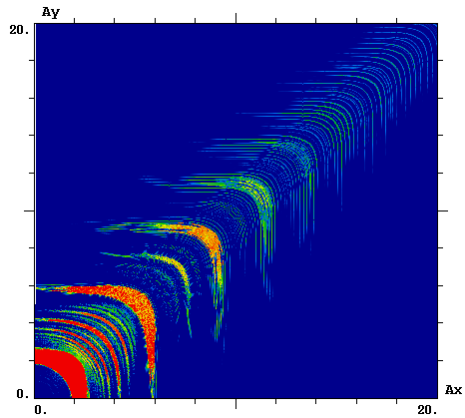

Figure 5: FMA for Gaussian bunch density $\sigma_z=\sqrt{2}\ \beta^*$, Q_0=0.3, ξ=0.5. Synchrotron amplitude 0.1 σ_z.

The results of multi-particle simulations for the VEPP-2000 lattice, taking into account the dynamic beta-function and emittance, synchrotron radiation damping and quantum excitation, are not very encouraging. We observe a reduction of the luminosity with the increase of σ_z/β^* ratio exceeding that expected from the hour-glass effect.

CONCLUSION

We confirmed that in a specially designed accelerator lattice, and by a careful shaping of the longitudinal profile of strong bunch, the value of beam-beam parameter exceeding one could be achieved for particles with zero synchrotron amplitude. The approach described in this report is advantageous with respect to the previously considered schemes because the machine betatron tune does not need to be close to integer or half-integer. This makes the scheme less sensitive to imperfections of the accelerator lattice.

For particles with non-zero synchrotron amplitude, the integrability is lost but their motion remains stable even at large amplitudes, although a significant emittance growth is induced by the overlapping resonances. Simulations predict that a scheme with the bunch length ratio between the weak and the strong bunch of about 1/10 may be feasible, which could be useful for asymmetric machines such as the electron-ion colliders.

A more rigorous study of the feasibility of the scheme in a real accelerator is in progress.

A MODEL RING WITH EXACTLY SOLVABLE NONLINEAR MOTION

T. Zolkin*, The University of Chicago, Department of Physics, Chicago, IL 60637–1434, USA

S. Nagaitsev‡, FNAL, Batavia, IL 60510–5011, USA

Abstract

Recently, a concept of nonlinear accelerator lattices with two analytic invariants has been proposed [1]. Based on further studies [2], the Integrable Optics Test Accelerator (IOTA) was designed and is being constructed at FNAL. Despite the clarity and transparency of the proposed idea, the detailed analysis of the beam motion remains quite complicated and should be understood better even for the case when no perturbations are taken into account. In this paper we will review one of the three proposed realizations of integrable optics, where the variables separation is possible in polar coordinates. This system allows for an exact analytical solution expressed in terms of elliptic integrals and Jacobi elliptic functions [3]. It gives the possibility to check numerical algorithms used for tracking and to perform more rigorous analysis of the motion in comparison with the "crude" analysis of the topology of the phase space. In addition we will discuss some difficulties associated with numerical simulations of such a comparatively complex dynamical system and will take a look at the possible perturbations for a model machine.

INTRODUCTION

Below we will consider the design of the accelerator lattice which includes nonlinear lens, while the transverse motion remains integrable. Several such systems possessing a second invariant of motion, which is quadratic in momentum, have been proposed in [1]. One of the possible realization is based on the application of a point-like magnetic quadrupole inserted into the center of a vacuum pipe. In this case, the motion allows the variables separation in polar coordinates and its analytical solution was described in [3]. Here, we will focus on the implementation of this idea and will design a model accelerator ring. For more details on dynamics in such a magnetic field one should consult the list of references.

ACCELERATOR LATTICE DESIGN

The particle dynamics in the magnetic field of point-like magnetic quadrupole is unusual in that there is no equilibrium orbit of motion; trapped particles are only in dynamical equilibrium, i.e. in constant motion in at least one degree of freedom. This feature is related to the presence of singularity at the origin. On the other hand, it means that under the action of friction force, let say caused by the synchrotron radiation, particles will fall towards the singularity and eventually will be lost on the inner aperture of the vacuum pipe, ρ_{in}. Thus, below we will consider the design of an accelerator ring for protons, so far as the damping of oscillations due to radiation effects is negligible for them.

Axially Symmetric Focusing

As it was described in [1], the concept of nonlinear integrable optics under consideration requires an axially symmetric focusing in the accelerator ring. A super-period of such a lattice can be realized as $\frac{F}{2}O\frac{F}{2}$ lattice, with a drift space of length L, where the nonlinear lens is located, and an optics insert (also so-called T-insert), which is equivalent to a thin axially symmetric lens with the focal length equal to $1/k$ (see Fig. 1).

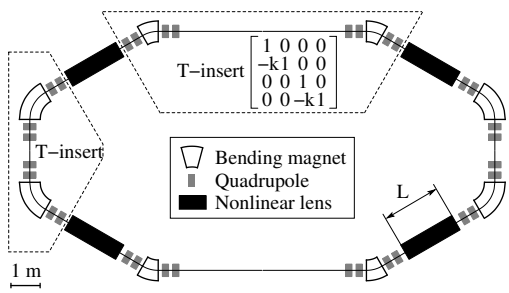

Figure 1: Schematic layout of the IOTA ring.

To study the transverse motion of the monochromatic beam the principal realization of the optics insert is not essential, and for all further simulations we will use a parameters designed for IOTA ring [2]. The dependence of the minimum and maximum of beta function in the drift space as well as betatron frequency as a function of the T-insert strength are show in Fig. 2. Main parameters of the ring are listed in Table 1.

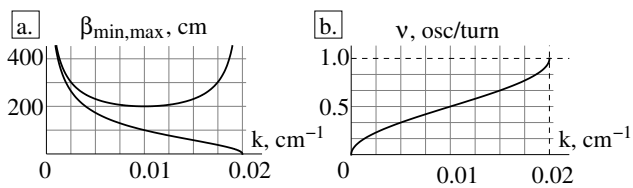

Figure 2: Minimum and maximum of beta-function (a.) and betatron frequency (b.) as a function of axially symmetric lens strength parameter, k.

Nonlinear Lens

The design of nonlinear lenses, corresponding to integrable potentials proposed at [1], brings in two major inevitable perturbations. They are associated with the special longitudinal dependence of the field, and, the physical realization of poles of the lens. The first condition is automatically satisfied due to invariance of the potential under the transformation to normalized coordinates and time, except the effect from the fringe fields. While the second one can not be realized without introducing the perturbation, since poles can not be placed at the same point in the space.

Point-like magnetic quadrupole can be approximated with four wires of diameter D, which are spaced very closely to each other at the vertices of a square, $\vec{R}_\alpha$, and numbered counter-clockwise from the corner located at $\vec{R}_1 = (b, 0)$ (see Fig. 3). "Dot" and "cross" symbols in the figure show the current direction: coming out and into the page (along the beam direction) respectively. In order to keep particles which are performing the libration ($0 < W < \mathsf{A}$), the vacuum chamber can be made of two nested half-cylinders of radii $\rho_{\rm in,out}$, forming a c-shape.

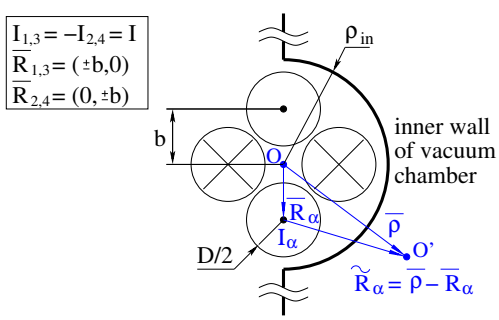

Figure 3: Schematic plot of the nonlinear lens geometry along with inner part of vacuum pipe. Points O and O' represents the origin of coordinates and the point inside the vacuum chamber where the field induced by the lens should be considered, $\vec{\rho} = \overline{OO'}$.

Indeed, in ordinary polar coordinates

$$\rho = \sqrt{x^2 + z^2}, \qquad \theta = \arctan(z/x),$$

the longitudinal component of the magnetic vector potential $\mathbf{A} = (0, A_s, 0)$ created by such a quadrupole structure can be easily calculated and expressed as a multipole series

$$\begin{aligned} A_s &= -\frac{\mu_0}{2\pi} \sum_{\alpha=1,2,3,4} I_\alpha \ln|\widetilde{R}_\alpha| \\ &= \frac{\mu_0 I}{\pi} \sum_{n=0}^{\infty} \left(\frac{b}{\rho}\right)^{2+4n} \frac{\cos[(2+4n)\theta]}{1+2n} \\ &= \frac{\mu_0 I}{\pi} \left(b^2 \frac{\cos 2\theta}{\rho^2} + \frac{b^6}{3} \frac{\cos 6\theta}{\rho^6} + O\left[\left(\frac{b}{\rho}\right)^{10}\right] \right), \end{aligned}$$

where μ_0 is a vacuum permeability. As one can see that first perturbing term corresponds to the dodecapole field which is significantly suppressed by 4 orders of magnitude in a smallness parameter (b/ρ). It shows that the drawing apart of wires does not create a strong perturbation since all additional terms are rapidly decay with the growth of ρ. The nonlinear potential in the Hamiltonian is related to A_s as

$$V(\rho, \theta) = \frac{U(r, \theta)}{\beta(s)} = \frac{\mathsf{A} \sin(2\theta + \varphi)}{\rho^2} = -\frac{eA_s}{P_{\rm eq}},$$

which gives the expression for the field amplitude:

$$\mathsf{A} = \frac{\mu_0 e I b^2}{\pi P_{\rm eq}}.$$

Due to a presence of the physical aperture, the following inequality should be satisfied

$$\frac{\rho^4_{\rm in}}{\beta^2(L/2)} < \mathsf{A} < \frac{\rho^4_{\rm out}}{\beta^2(L)}, \qquad (1)$$

in order to have a suitable admittance. Among the transverse geometrical parameters of the lens there is only one independent since we want to pack all wires as tightly as we can. Thus for a given current density in a wire, $\rho_I = 4I/\pi D^2$, the optimization of A becomes a problem of a single parameter variation. For example, the value of the diameter of a wire allows to approximate the wire displacement and the inner radius of vacuum pipe as

$$b \approx D/\sqrt{2}, \qquad \rho_{\rm in} \approx (1 + \sqrt{2})D/2.$$

Possible choice of A is presented in Fig. 4.

For simulations we considered 2 possible scenarios: lens with water cooling and the superconducting one. Parameters for both cases are listed in a Table 2. It is worth noting that the use of high current is limited from technical limitations, while the use of low current lens leads to the shrink of admittance, which can be compensated by decreasing the energy of a beam.

In order to study the monochromatic beam motion in a lattice with perturbations, we decided to use the Poincaré

Abstract

In the present analysis we study the weakly nonlinear interaction between trains of electromagnetic pulses and space-charge fields in laser-plasma systems. We direct the analysis to regimes evolving with the co-moving coordinate of the beam frame, but do not make any assumptions on paraxial or underdense approximate conditions. The model thus constructed allows us to investigate regimes where transverse and longitudinal length scales of the pulses are comparable. Resonant and nonresonant regimes of space-charge wave excitation are analyzed. In both cases, with aid of analytical estimates and numerical simulations, we examine how far trains of electromagnetic pulses can travel before being affected by the destructive transverse effects.

INTRODUCTION

The propagation of localized radiation pulses in plasmas has been the subject of continuous interest in a variety of areas, including nonlinear wave excitation [1, 2] and particle acceleration [3, 4, 5]. Pulses are formed as large amplitude electromagnetic waves undergo the process of modulational instability in the plasma, breaking up into a series of narrow quasi-isolated structures. This is a typical behavior in soliton turbulence [6] and in self modulated laser accelerators, once an option in laser acceleration, whose interest has been reignited recently [7].

Pioneering works [8, 9] have studied the self-consistent problem of electromagnetic pulses propagating in plasmas and the space-charge waves generated by this propagation in one dimensional models. These models, however, usually refers to nonparaxial solutions (where dependence of the field on transverse coordinates is completely neglected) or the opposite, the paraxial limit (where transverse effects dominate the dynamics). In several occasions, a laser beam reaches operational conditions where longitudinal and transverse sizes become similar in magnitude [10, 11]. Under these conditions, an accurate account of the dynamics should treat transverse and longitudinal effects on the same footing.

The objective of the present work is to perform an analysis of the nonlinear interaction of electromagnetic and space-charge without invoking 1D, paraxial, or approximate nonparaxial approaches [12, 13]. Our main interest will be to determine how the the transverse structure affects a train of solitons, typically formed after an initially injected pulse breaks up through self-modulation [14].

THE MODEL

We can model this system with the following coupled equations for the laser field a and for the space-charge potential $\varphi \equiv v_g^2 n - a^2/2$,

$$\kappa \frac{\partial^2 a}{\partial \xi^2} = \delta a + \frac{1}{v_g^2}\varphi\, a + \frac{\kappa}{2v_g^2} a^3 - \nabla_\perp^2 a, \qquad (1)$$

$$\frac{\partial^2 \varphi}{\partial \xi^2} + \frac{1}{v_g^2}\varphi = -\frac{1}{2v_g^2} a^2 + \frac{1}{2}\nabla_\perp^2 a^2, \qquad (2)$$

derived in details in our previous work [15]. If the transverse structure is neglected, this set becomes similar to models analyzed in the past [9] and one can think of it as describing the coupled nonlinear dynamics of fields a and φ as a function of the co-moving coordinate ξ, which plays the role of time. With the transverse structure included, it describes the weakly nonlinear, spatio-temporal interaction of laser and space-charge field. Coordinate ξ can still be seen as time, and space is associated with the transverse structure itself. These Eqs. are solved numerically with the following initial conditions

$$a(0, x_\perp) = a_0\, e^{-\lambda x_\perp^2} \;\;,\;\; \partial a/\partial\xi|_{\xi=0} = 0 \qquad (3)$$

$$\varphi(0, x_\perp) = -a(0, x_\perp)^2/2 \;\;,\;\; \partial\varphi/\partial\xi|_{\xi=0} = 0 \qquad (4)$$

EVOLUTION OF THE TRAIN OF PULSES.

Examining Eqs. (1) and (2) together with the initial conditions we find that $(\delta/\kappa)^{-1/2}$ is the time scale for pulse formation along the propagation axis, $(\lambda/\kappa)^{-1/2}$ is the time scale for transverse effects. When $\lambda \ll \delta$, pulses are formed before being affected by transversal effects, and when the inequality reverses, one recognizes the typical instability associated with the transverse term, shown in a recent work to be of the form $a \sim e^{\lambda\xi^2/\kappa}$ [15]. Depending on the relative magnitude of the parameters δ and λ one thus may or may not observe pulses in the system.

In order to see how the electromagnetic pulses evolve as they move into the plasma, we will split the analysis into nonresonant and resonant regimes. Nonresonant regimes are the ones where the adiabatic approximation would remain valid throughout the entire dynamics, if the transverse derivatives were turned off. Resonant regimes, on the other hand, are the ones where adiabaticity is broken and proper plasma waves are excited, even in the absence of the transverse structure.

Nonresonant Regimes

Nonresonant cases are those where the time scale for the dynamics is much longer than the plasma time scale scale. In our dimensionless system, this means that $1/v_g^2$ is sufficiently large that the the corresponding terms in Eq. (2) are much larger than the term with the ξ-derivative. In this case $\varphi = -a^2/2$ and one says that the φ field becomes enslaved to the field a, which allows to use Eq. (1) as a closed, governing equation (with transverse derivatives turned off) for field a in the adiabatic regime:

$$\kappa \frac{\partial^2 a}{\partial \xi^2} = \delta a - \frac{a^3}{2}. \qquad (5)$$

As Eq. (5) describes a nonlinear oscillator with stable equilibria at $a = \pm\sqrt{2\,\delta}$, each transverse coordinate $x_\perp$ the laser oscillates with a different, local nonlinear frequency $\Omega = \Omega(x_\perp)$. When the transverse derivatives are turned on, it is only a matter of the time ξ until the gradient of the phase $\Omega(x_\perp)\,\xi$ along $x_\perp$ monotonically grows to any desired value. As one turns the transverse term on, even if initially small, the associated transverse derivatives will eventually grow and affect the dynamics. In the nonresonant case we are investigating, a quick estimate can be made on the value of ξ where the transverse term is expected to become comparable with the terms already present in Eq. (5). We first observe that for noise-like initial conditions, the right-hand-side of the energy conserving Eq. (5) keeps oscillating within the region $\mathcal{R}$ bounded by the limits $-2\delta^{3/2} \le \mathcal{R} \le 2\delta^{3/2}(2/27)^{1/2}$. To obtain the estimate, we simply integrate Eq. (5) for all $x_\perp$'s using the initial profile provided by Eq. (3), calculate $\nabla_\perp^2 a$ with basis on the solution for a yielded by the very same Eq. (5), and take note of the earliest time where $\nabla_\perp^2 a$ cross the boundaries of $\mathcal{R}$.

Figure 1 displays the corresponding behavior. Once again we choose $\delta = 10^{-2}$, along with $v_g^2 = 0.2$ and $\lambda = 10^{-3}$. The upper and lower straight lines represent the boundaries of $\mathcal{R}$ and we can see how the magnitude of $\nabla_\perp^2 a$ grows in time. At $\xi \sim 35$ the transverse Laplacian reaches the boundaries of $\mathcal{R}$ at $\lambda^{1/2}x_\perp \sim 1$, and at this time one can expect to see the effects of the transverse derivatives on the pulse dynamics.

Let us then integrate the full space-time system formed by Eqs. (1) and (2) to make comparisons with the estimates in some instances. Results are displayed in Fig. 2.

Panel (a) of Fig. 2 represents the case with the transverse term turned off. We repeat the parameters used in Fig. 1: $\delta = 10^{-2}$, $v_g^2 = 0.2$ and $\lambda = 10^{-3}$. For the given initial conditions (3) and (4), the tridimensional plot displays the regular behavior of the corresponding nonlinear pulses. At each $x_\perp$ the laser oscillates, but with a steady phase slippage rate existing along this transverse axis. This is why one observes curved wave fronts as ξ grows.

Keeping the parameters of panel (a), in panel (b) of the same Fig. 2 the transverse term is turned on. We see that the train of pulses starts to develop sharp spikes before

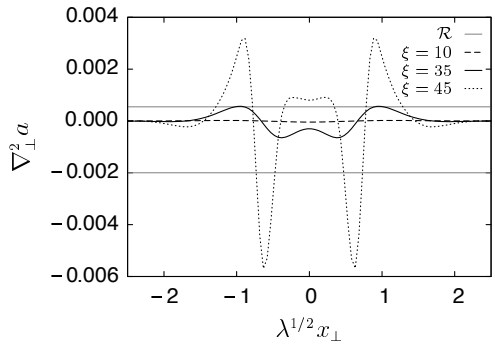

Figure 1: Magnitude of the transverse Laplacian as a function of $x_\perp$ and ξ. At $\xi = 35$ the Laplacian touches the boundary of region $\mathcal{R}$, which signals the instant where its corresponding effects become noticeable.

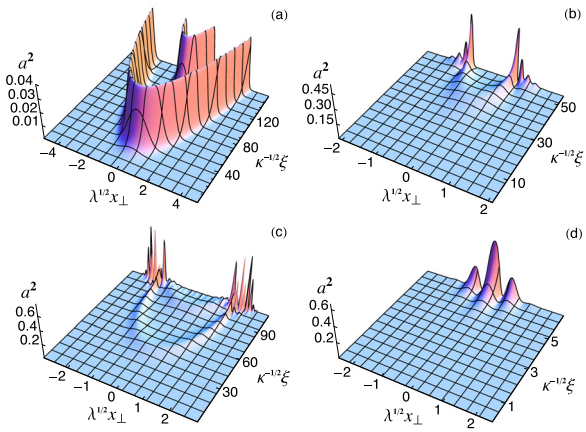

Figure 2: Space-time dynamics of the laser field in the nonresonant regime. In all cases we take $\delta = 10^{-2}$ and $v_g^2 = 0.2$. In panel (a) we consider $\lambda = 10^{-3}$ but keep the transverse Laplacian switched off. In the remaining panels the Laplacian is turned on with $\lambda = 10^{-3}$ in (b), $\lambda = 2.5 \times 10^{-4}$ in (c), and $\lambda = 10^{-1}$ in (d).

$\xi = 50$, which agrees with the previous estimates. The spikes arise from the action of the second derivatives along $x_\perp$, as can be seen again from Fig. 1, and shortly afterwards the space-time dynamics merges into a chaotic pattern. The chaotic pattern cannot be followed for long due to the fact that, in that stage, the fields grow to values beyond our weakly nonlinear approximation. However, the important information to be gathered here is on how far solitary pulses behave as such, before being affected by the transversal effects.

For sake of comparison, in panel (c) we also examine what happens when the initial beam width is extended, with a smaller λ given by $\lambda = 2.5\times10^{-4}$ (remaining parameters are kept with the same previous values). In that case our estimate indicates that, as expected, the transverse term takes longer to affect the pulse dynamics. The critical time ξ, once again obtained as the one where $\nabla_\perp^2 a$ escapes region

Copyright © 2013 CC-BY-3.0 and by the respective authors

$\mathcal{R}$, reads $\xi \sim 70$, which agrees with the curves displayed in the present Fig. 2 (c). The case with large values of λ, say $\lambda = 10^{-1}$ ($\gg \delta$), is also worthy of inspection, as done in Fig. 2(d). In this case the transverse term dominates the dynamics, generating the exponential growth commented earlier [15]. As a matter of fact, in this latter case of large λ, the maximum of $\nabla_\perp^2 a$, here located at $x_\perp = 0$, already starts off from a value beyond the boundaries of $\mathcal{R}$.

Resonant Regimes

Since with transverse derivatives neglected the system already displays a nonintegrable behavior in the resonant regime, the quasi-integrable estimates based on the reduced - and integrable - equation (5) becomes inaccurate. However, one can still be tempted to associate the time scale $(\delta/\kappa)^{-1/2}$ with the longitudinal dynamics, and the time scale $(\lambda/\kappa)^{-1/2}$ with the transverse term, as discussed previously. In panel (a) of Fig. 3 we take $v_g^2 = 0.9$ and $\delta = 10^{-2}$, along with $\lambda = 10^{-4}$. Here λ is much smaller than the mismatch δ and we are therefore under circumstances where pulses have time enough to be formed, even if in an irregular fashion. This is essentially what happens, as can be appreciated from the figure. In panel (b) we analyze the dynamics with the same set of control parameters, but with the transverse term switched off. A comparison between both panels allows us to realize that the presence of the transverse structure, even for λ as small as $\lambda = 10^{-4}$, already has a relatively noticeable effect on the dynamics of the laser amplitude a. In fact, the transverse term shortens somewhat the characteristic oscillatory time scale, what is expected from the larger transverse gradients associated with a chaotic case. The shortening of the time scales becomes gradually more pronounced as λ grows.

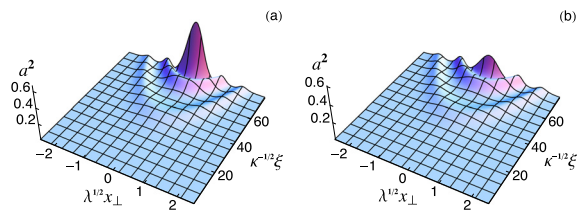

Figure 3: Space-time dynamics of the laser field in the resonant regime. In panel (a) we take $\delta = 10^{-2}$ and $v_g^2 = 0.9$, along with $\lambda = 10^{-4}$. Panel (b) is plotted for the same parameters, but with the transverse term switched off.

CONCLUSIONS

Space-charge waves are excited as the pulses travels into the plasma. Both resonant and nonresonant cases of space-charge plasma wave excitation were examined. In the nonresonant regime, accurate estimate of the transverse effects is possible. One can, for instance, predict, with relatively narrow margins of error, how far does a soliton train move into a plasma before being distorted.

In resonant cases estimates become less accurate due to the nonintegrability of the overall dynamics, but one can still produce reliable predictions on the wave pattern. In the case specifically studied here, the transverse scale $(\lambda/\kappa)^{-1/2}$ is sufficiently larger than the pulse length $(\delta/\kappa)^{-1/2}$ and localized structures can be observed before being affected by the transversal effects.

In general, the number of unperturbed pulses in a train can be roughly estimated as $(\delta/\lambda)^{1/2}$. Since the amplitude a_p of the pulses is proportional to $\delta^{1/2}$, one sees that the number of pulses in a train can be rewritten as $a_p\,\lambda^{-1/2}$. The factor $\lambda^{-1/2}$ itself is the transverse length measured in units of the plasma wavelength. If the laser beam is wide with $\lambda^{-1/2} \gg 1$ the number of pulses can still be appreciable even with a_p small. This is the case of a beam width $50\mu m$ and plasma wavelength $0.5\mu m$, which matches one of the cases studied in the text, where $\lambda = 10^{-4}$. In extreme cases where $\lambda^{-1/2} \sim 1$, only strong lasers can form pulses; otherwise, no pulses are formed as in the cases with $\lambda \sim 10^{-1}$ also investigated in the work.

The present analysis essentially adds transverse effects to the known one-dimensional behavior of train of planar pulses. As an overall conclusion, we see that transversal effects become already important even when the cross section of the radiation beam is relatively larger than the longitudinal pulse size.

Abstract

We describe some of the measurements that will be performed to study the physics of the self-modulation instability of electron and positron bunches. These measurements will be performed at SLAC-FACET in the E209 experiment. The effect of the SMI on the drive bunch itself (electron or positron) will be studied. Differences between electron and positron bunches are expected since the wakefields are driven into the nonlinear regime.

INTRODUCTION

It was recently proposed to use the self-modulation instability (SMI) of long charged particle bunches in dense plasmas to drive large amplitude (∼1 GV/m) accelerating wakefields [1]. Using the SMI is a method to produce a train of short bunches out of long bunches available today. Long bunches are interesting for driving wakefields and possibly accelerating particles because they can cary large amounts of energy, between 6 and 110 kJ for the p^+ bunches produced by the CERN SPS or LHC with σ_z ≅10-12 cm. Short bunches are desirable because the maximum amplitude of the accelerating field scales as $E_{WB} = \left(2\pi m_e c^2/e\right)/\lambda_{pe}$ and wakefields are most efficiently driven by bunches with $\sigma_z \cong \lambda_{pe}$, therefore $E_{max} \propto 1/\sigma_z$. Since $\lambda_{pe} = 2\pi c/\omega_{pe} = 2\pi c/\left(n_{e0}e^2/\epsilon_0 m_e\right)^{1/2}$, shorter bunches also require larger plasma densities n_{e0}.

We proposed to use the long e^- and e^+ bunches the SLAC linac produced for early plasma wakefield accelerator (PWFA) experiments (σ_z ≅500-700 μm) [2, 3, 4] and the high density plasma available for current experiments n_{e0} ≅10^{16}-10^{17} cm^{-3} [5] to test some of the SMI physics [6].

Theory and simulations predict that as long as the wakefields are in the linear regime, the SMI of positively and negatively charged particle bunches are identical (all other parameters being the same). The wakefields are in the linear regime as long as $E_z \approx (\delta n_e/n_{e0})\, E_{WB} \ll E_{WB}$, i.e., the electron density perturbation δn_e that sustains the wakefields satisfies $\delta n_e \ll n_{e0}$. But the nonlinear wakefield regime with $\delta n_e \sim n_{e0}$ is interesting because the accelerating field can reach the wave breaking field amplitude. In this regime the wakefields become anharmonic and in general more favorable for propagation and acceleration of negatively charged bunches. This is due to the pure ion column (focusing for electrons, defocusing for positrons, for example) occupying most of the phase of the wakefields. This regime is often referred to as the blowout or bubble regime. While the wakefields driven by the (long) unmodulated bunch are in the linear regime ($\delta n_{e0} \cong n_{b0} \ll n_{e0}$, see Table 1), the self-modulation and the ensuing resonant wakefield excitation drives the wakefields into the nonlinear regime. As a result, different quantitative outcomes are expected when changing only the sign of the drive bunch charge.

With the beam and plasma parameters available at SLAC-FACET many of the physics aspects of the SMI, including the asymmetry between negatively and positively charged drive bunches can be studied [6]. We outline here some of the measurements currently planned in experiment tentatively scheduled for this Fall and beyond.

PLANNED MEASUREMENTS

The experiment aims at observing as many of the characteristics of the SMI as possible with the FACET infrastructure. The nominal parameters for the beam and plasma are given in Table 1. However, these parameters will be varied over as large a range as possible depending on the setup that will be available at the time of the experiments.

Table 1: E209 Experiment Parameters

Parameter & Symbol	Value
Bunch population, N_b	<2× 10^{10}
Length, σ_z	500 μm
Radius, σ_r	>30 μm
Density, n_{b0}	<2.8 × 10^{15} cm^{-3}
Energy, W_b	20 GeV
Plasma density, n_{e0}	1-30 × 10^{16} cm^{-3}
Wavelength, λ_{pe}	334-61 μm
Frequency, f_{pe}	0.9-5 THz
Length, L_{plasma}	1 m
Relative bunch density, n_b/n_{e0}	0.1-0.003
Bunch length, $k_{pe}\sigma_z$	3.5-51
Bunch radius, $k_{pe}\sigma_r$	0.6-3
Plasma length, $k_{pe}L_{plasma}$	19,000-103,000

Energy Gain/Loss

The first evidence that SMI has occurred can be obtained by comparing the energy spectrum of the bunch downstream from the plasma location with and without plasma. Without plasma the energy spectrum is that of the incoming bunch, i.e., around 20 GeV and with a correlated energy spread on the order of 1%. The imaging magnetic spectrometer has an energy range from ~11 GeV to >60 GeV with sub-GeV resolution, reaching ~100 MeV for the nominal energy [7]. With the plasma, but without occurrence of SMI, the maximum energy gain and loss would be given by the longitudinal wakefields amplitude driven the long bunch multiplied by the plasma length. This amplitude can be calculated from 2D linear theory [8]. The longitudinal field amplitude far behind a symmetric Gaussian current profile distribution bunch with N particles is: $E_{\pm} \cong \frac{e}{4\pi\epsilon_0} N_b k_{pe}^2 e^{\frac{-k_{pe}^2\sigma_z^2}{2}}$, where $k_{pe} = 2\pi/\lambda_{pe}$. Note that this expression is valid for narrow bunches ($k_{pe}\sigma_r \ll 1$, σ_r the rms Gaussian bunch radius), and it overestimates the fields driven in the $k_{pe}\sigma_r \sim 1$ bunches of these experiments. With the parameters of Table 1 (n_{e0}=10^{16} cm^{-3}), this amplitude is ≅630 MV/m. Therefore, for the case of a 1 m-long plasma, the energy gain/loss would be less than 0.63 GeV, much lower than the one predicted by simulations when SMI occurs (>5 GeV both for electrons and positrons, see Fig. 5 in [6]). The wakefield amplitude and thus the energy gain are even smaller at larger plasma density (larger $k_{pe}\sigma_r$). Even the product of the post-saturation amplitude (>7 GV/m, see Fig. 3 in [6]) with a 1 m plasma length leads to multi-GeV gain and loss.

For these experiments the plasma will be created by laser-ionization of an alkaline metal vapor [9]. The laser pulse is focused to a line along the beam propagation axis by an axicon lens. The axicon maps the radial intensity of the laser pulse onto position along the line focus. Therefore, the plasma length can in principle be varied by changing the transverse size of the laser pulse on the axicon, for example by an iris. Variation of the plasma length could provide information about variations of the longitudinal wakefields along the plasma, or even, with short enough plasma length, about the growth of the SMI itself.

Note that since the energy gain and loss are much larger than the incoming energy content of the bunch, no evidence of the periodic structure of the wakefields is expected in the energy spectra. This is unlike what was observed in experiments at BNL-ATF with a 50 pC, 60 MeV electron bunch and a 2 cm-long plasma [10]. Note also that unlike in experiments planed for example at CERN, in these experiments the plasma length (~1 m) is much larger than the saturation length of the SMI (~5-10 cm). Also, the expected energy gain and loss can be comparable to the bunch incoming energy. Therefore, energy change by drive bunch particles is a suitable diagnostic for SMI occurrence.

Transverse Modulation

Of course, the SMI occurs because of the transverse wakefields. The observation of the effect of the longitudinal wakefields, although the goal of particle acceleration experiments, is only indirect evidence of SMI development. The longitudinally periodic modulation of the bunch density is the result of local focusing and defocusing. Transition radiation [11] is often used to characterize the time structure of charged particle bunches. While incoherent optical transition radiation (OTR) carries direct information about the bunch time structure it is difficult to measure in the plasma frequency range of these experiments (~1-5 THz). The information contained in the long wavelength, coherent range of transition radiation (or CTR) can be measured using interferometry. In this case the information is contained in the transverse, bunch radius dependent form factor. The effect of this bunch factor has been observed at lower energy at the FLASH facility [12]. While the effect of radial modulation tends to be suppressed for high-energy bunches that emit CTR essentially in the forward direction (peak angle at $\sim 1/\gamma$, γ the particles' relativistic factor), this effect has previously been observed at FACET [13].

Therefore, CTR interferometry should reveal the time structure of the bunch when SMI occurs. With a typical Mach-Zender interferometer arrangement, the periodicity is expected with a path length difference $\Delta z \cong \lambda_{pe}/2$. Note that the interferometer trace will be obtained from multiple SMI events with parameters as similar as possible. Although the amplitude of the modulation and its phase along the bunch may vary, its periodicity should remain essentially constant, as long as the plasma density is reproducible. The metal vapor is produced in a system with a long thermal time constant (minutes) [14]. The laser ionization is a threshold process rather insensitive to the small shot-to-shot laser intensity variations expected. These variations should therefore not impede the SMI period determination.

Seeding and Hose Instability

An important topic is that of the seeding of the SMI. The SMI can be seeded to reduce the plasma length for it to reach saturation at the same maximizing the length available for acceleration with a fixed plasma length. In addition, the seeding should allow for the fixing of the phase of the wakefields along the drive bunch. Without seeding, the SMI grows from noise and the phase of the SMI wakefield is random with respect to position along the bunch. The position of the seed (short laser pulse or particle bunch, ionizing laser pulse, sharp bunch leading edge) determines the wakefields starting point. A witness bunch to be accelerated can then be injected into the optimum accelerating and focusing phase of the wakefields once their zero is fixed.

Another important issue is the mitigation of the competing transverse hose instability (HI) [15]. This instability competes with SMI and could destroy the drive bunch before SMI or acceleration can occur. This effect has been

Copyright © 2013 CC-BY-3.0 and by the respective authors

illustrated for the case of a proton bunch in Ref. [16]. Calculations and simulations indicate that seeding the SMI allows it to win over the HI, at least under some circumstances and plasma length [6, 17].

A notch collimator method is available at FACET to produce a drive/witness bunch train for PWFA experiments [5, 18]. This method will be used to create a sharp (when compared to λ_{pe}) leading edge at various positions along the bunch. The effect of seeding on energy gain and hosing will be studied.

Varying Parameters

The development of the SMI and of the HI depend on the initial beam and plasma parameters. The effect of the bunch charge species, population, radius, as well as of the plasma density and length on all the above measurements will be studied in details.

SUMMARY

The E209 experiment was proposed to SLAC FACET to study the physics of SMI thanks to the available long ($\sim$500 μm) particle bunches (electron/positron), source of dense plasma (n_{e0}=10^{16}-10^{17} cm^{-3}), seeding mechanism (notch collimator) and diagnostics: large range, good resolution energy spectrometer, OTR, CTR, etc. The effects of SMI onto the drive bunch only will be measured, no particles will be injected in the wakefields to be accelerated. These experiments are scheduled for the Fall 2013 and beyond.

PHOTONIC CRYSTAL AS A PASSIVELY DRIVEN STRUCTURE TO BOOST BEAM ENERGY*

B.R. Poole#, LLNL, Livermore, CA 94550, USA
J.R. Harris, S.V. Milton, Colorado State University, Fort Collins, CO 80523, USA

Abstract

The use of electromagnetic structures to couple energy to a charged particle beam is well known. These structures are usually driven by an external source of electromagnetic energy and the structure distributes that energy in such a way as being favorable to accelerate charged particles. Photonic crystals which typically consist of periodic arrays of metal and/or dielectric structures spaced on a scale comparable to the wavelength of interest, have been investigated for use both as sources of microwave radiation and as particle accelerators. In this case we consider driving a photonic crystal structure using a repetitive sequence of charge bunches driven from a photo-injector to resonantly excite the structure to produce an acceleration field to accelerate a suitably-delayed witness bunch to high energy. We examine the generation of the acceleration field as well as spurious modes. The characteristics of the witness bunch are examined to determine the longitudinal dynamics of the bunch and the energy spectra.

INTRODUCTION

Periodic structures are commonly used in the accelerator community for particle accelerators and as slow wave structures for microwave sources. The use of an L-band RF source to drive an X-band linac structure consisting of a disk loaded waveguide to accelerate properly phased electron bunches has been described [1]. Periodic structures with alternative geometries may be considered for the same task. For example, a structure consisting of a waveguide with a periodic array of metal rings at two radii was demonstrated as a microwave source operating as a backward wave oscillator [2] and such configurations in principle could be used to add energy to the beam rather than extracting energy from it In this paper we consider several structures for use with an L-band source for passive acceleration including the disk loaded waveguide and two ring array geometries The dispersion properties of various structures are determined using the COMSOL MultiPhysics RF package eigenmode solver [3]. The 2-D PIC code OOPIC [4] is then used to examine the excitation of the X-band structure at the 9th harmonic of the 1.3 GHz L-band source. The effect of higher order modes (HOMs) are investigated as well as the dynamics of a witness bunch.

MODELING AND SIMULATIONS

Three X-band structures were considered in this paper. All the structures have the same π-mode resonance at 11.7 GHz, the 9th harmonic of the 1.3 GHz electron source by adjusting various geometric structure parameters. The only fixed parameter was the spatial periodicity d, to maintain the π-mode axial wavenumber $k_z = \pi/d$. The drive beam consisted of 6 MeV, 1.3 GHz Gaussian-like bunches with 100 A peak current, 10 ps FWHM, and 1.23 nC of charge per bunch with a bunch radius of 2 mm. The Fourier spectrum of the drive beam current is a comb of frequencies with 1.3 GHz spacing as shown in Fig. 1. The witness bunch is injected into the structure typically after 50-100 ns (65-130 drive pulses) during the accelerating phase of the fields established by the drive bunch.

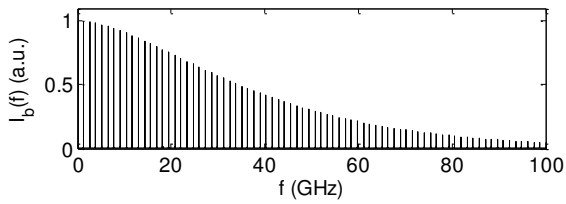

Figure 1: Beam current 1.3 GHz frequency comb.

Disk Loaded Waveguide

The first structure considered is the disk loaded waveguide shown in Fig. 2 with $R_0 = 1$ cm, $a = 0.3$ cm, $w = 0.2$ cm, and $d = 1.2$ cm.

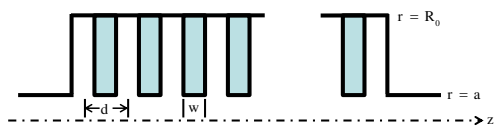

Figure 2: Disk loaded waveguide.

The TM_{0n} dispersion properties are shown in Fig. 3 and Fig.4 shows the axial electric field distribution for the 11.7 GHz π-mode.

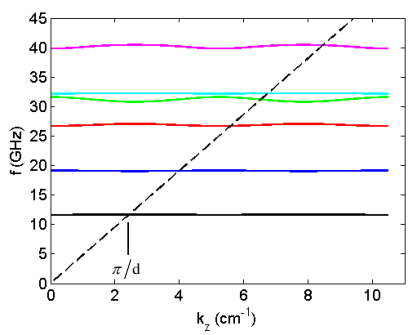

Figure 3: TM_{0n} modes of disk loaded waveguide.

The response of the structure to a single bunch was found using OOPIC to verify the various structure resonances. Figure 5 shows this response with resonances located at

the intersection of the structure modes with the beam mode, $\omega = k_z \beta c$.

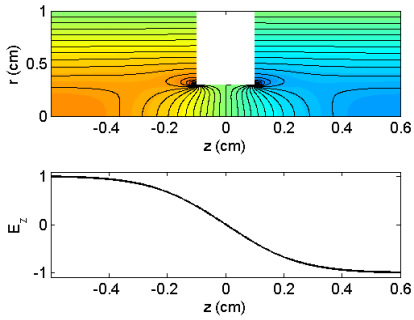

Figure 4: Axial electric field distribution at 11.7 GHz.

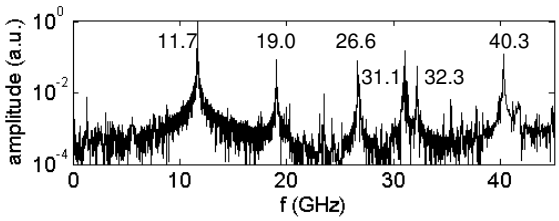

Figure 5: Single bunch response of disk loaded waveguide showing mode resonances.

A 1.3 GHz bunch sequence with the frequency comb spectra shown in Fig. 1 will resonantly excite the 9th harmonic 11.7 GHz π-mode in the linac structure. This field may then be used to accelerate a witness bunch to higher energy. Figure 6 shows a typical accelerating field greater than 1 MV/cm in the linac at 74.49 ns. The drive bunch has lost nearly 5 MeV of energy at this time.

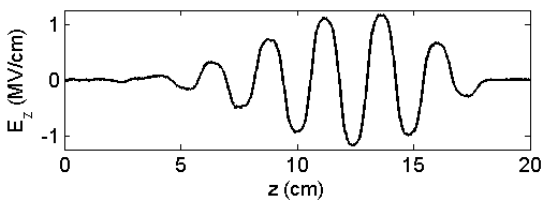

Figure 6: Acceleration field at 74.49 ns.

The evolution of the witness bunch energy distribution is shown in Fig. 7 and the evolution of the mean energy of both the drive and witness bunches shown in Fig.8. The maximum acceleration gradient is 1.2 MV/cm producing an energy boost of nearly 7 MeV for the witness bunch.

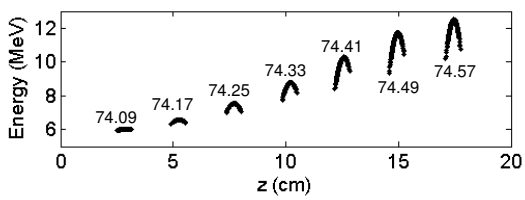

Figure 7: Snapshots of witness bunch energy distributions. The times indicated in the plot are in ns.

Note that the energy gain of the witness bunch benefits from the integrated energy stored in the linac structure accumulated from the previous drive bunches.

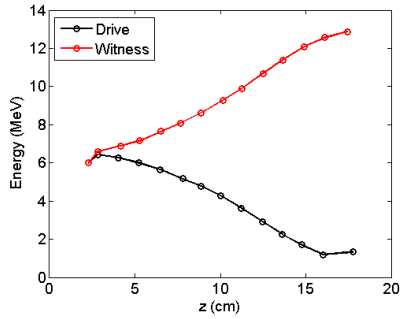

Figure 8: Mean energy of drive and witness bunches near the time of maximum acceleration gradient.

Single Ring Array

The single ring array consists of an axial array of circular rings, in this case with rectangular cross-section as shown in Fig. 9.

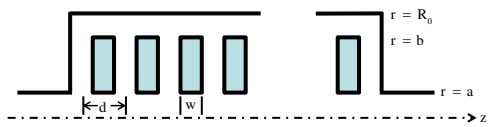

Figure 9: Single axial ring array loaded waveguide.

The structure dimensions are $R_0 = 1.475$ cm, $a = 0.3$ cm, $b = 1.1$ cm, $w = 0.2$ cm, and $d = 1.2$ cm. Figure 10 shows the TM_{0n} dispersion properties.

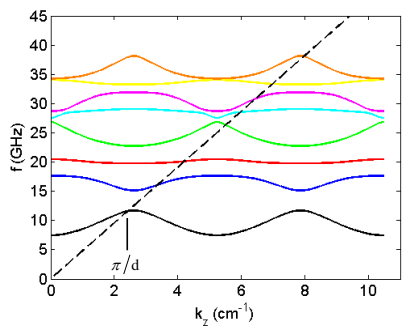

Figure 10: TM_{0n} modes of single ring array structure.

The dispersion curves in this structure exhibit much larger passbands compared to the disk loaded waveguide. There are also two additional modes for frequencies less than 40 GHz. This is due to increased coupling between the periodic cells and additional capacitance elements between the rings and the waveguide wall. Figure 11 shows the single bunch response for this structure which allows many additional discrete resonances in each of the modal passbands. It is easily seen in Fig. 11 that modes with larger passbands have more discrete resonances. The strength of these discrete resonances depends on the interaction with the bunch, the field distribution, as well as axial boundary conditions associated with the finite length periodic structure. Based on this spectral response, HOM's are expected to be more severe and tuning of the structure more difficult. Figure 12 shows the evolution of the drive and witness bunch mean energies showing an energy boost of only 4 MeV.

Copyright © 2013 CC-BY-3.0 and by the respective authors

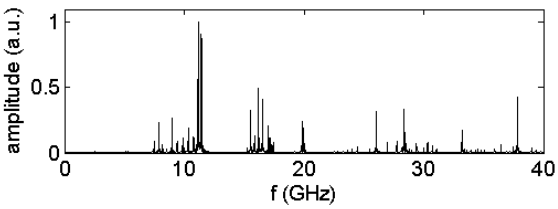

Figure 11: Single ring array single bunch response showing discrete resonances within each passband.

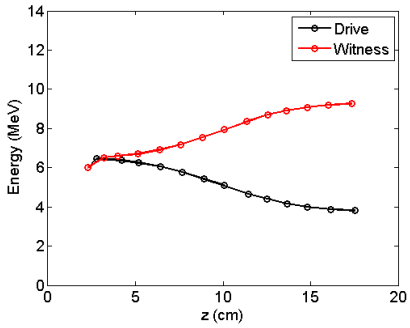

Figure 12: Mean energy of drive and witness bunches for single ring array structure.

Double Ring Array

The double ring array consists of two radial layers of an axial array of circular rings as shown in Fig. 13 with $R_0 = 1.73$ cm, $a_1 = 0.3$ cm, $b_1 = 0.7$ cm, $a_2 = 1$ cm, $b_2 = 1.4$ cm, $w = 0.3$ cm, and $d = 1.2$ cm.

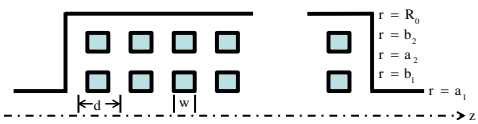

Figure 13: Double axial ring array loaded waveguide.

Figure 14 shows the TM_{0n} dispersion properties showing an additional mode for frequencies less than 30 GHz, and significantly wider passbands compared to the single array structure allowing for a significant number of discrete modes within each passband.

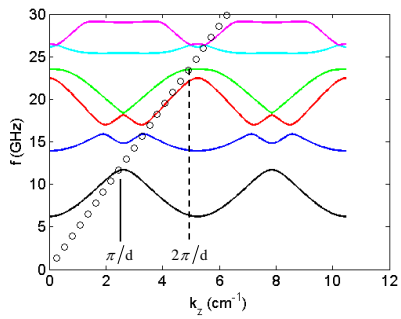

Figure 14: TM_{0n} modes of double ring array structure.

Also evident in Fig. 14 is the presence of a driven 2π-mode resonance for the 4th mode near 23.4 GHz at the 18th harmonic of the L-band source. This HOM competes with the 11.7 GHz π-mode and makes energy transfer to the witness bunch more difficult. To detune the 23.4 GHz resonance, the outer ring layer was moved radially inward by 1 mm moving the resonance upward by about 400 MHz. Simulations with the 1.3 GHz bunch sequence were run for both cases. Figure 15 shows typical spectra for both cases. It is easily seen, that both resonances appear in the original structure (Case A) with the 23.4 GHz resonance dominating and after shifting the outer rings the 23.4 GHz resonance is eliminated and the 11.7 GHz resonance become prominent (Case B). Figure 16 shows the energy evolution for both cases showing an energy boost of 1 MeV for Case A and 1.8 MeV for Case B.

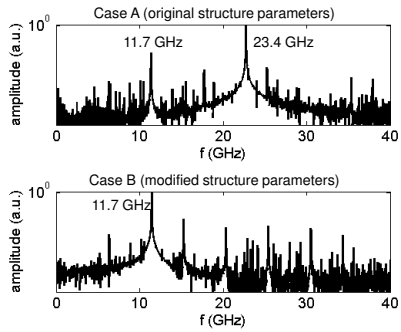

Figure 15: Double ring array response to 1.3 GHz bunch sequence showing effect of detuning 23.4 GHz mode.

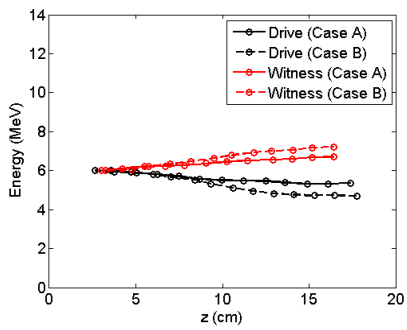

Figure 16: Mean energy of drive and witness bunches for double ring array structure.

CONCLUSION

X-band structures for passive acceleration were studied for their effectiveness in providing an energy boost to a 6 MeV witness bunch when driven with a 1.3 GHz 6 MeV bunch sequence. It was found that the disk loaded waveguide was able to boost the energy by 7 MeV while the open ring array structures provided more modest energy boosts. This is due to the open nature of the ring structures which reduce the electric field near the axis due to higher capacitance and the presence of HOM's.

LONG TERM EVOLUTION OF PLASMA WAKEFIELDS*

A.A. Sahai†, T.C. Katsouleas,

Abstract

We study the long-term evolution (LTE) of plasma wakefields over multiple plasma-electron periods and few plasma-ion periods, much less than a recombination time. The evolution and relaxation of such a wakefield-perturbed plasma over these timescales has important implications for the upper limits of repetition-rates in plasma colliders. Intense fields in relativistic lasers (or intense beams) create plasma wakefields (modes around ω_{pe}) by transferring energy to the plasma electrons. Charged-particle beams in the right phase may be accelerated with acceleration/focusing gradients of tens of GeV/m. However, wakefields leave behind a plasma not in equilibrium, with a relaxation time of multiple plasma-electron periods. Ion motion over ion timescales, caused by energy transfer from the driven plasma-electrons to the plasma-ions can create interesting plasma states. Eventually during LTE, the dynamics of plasma de-coheres (multiple modes through instability driven mixing), thermalizing into random motion (second law of thermodynamics), dissipating energy away from the wakefields. Wakefield-drivers interacting with such a relativistically hot-plasma lead to plasma wakefields that differ from the wakefields in a cold-plasma.

INTRODUCTION

Intense laser and particle beams interacting with plasma can force plasma electrons to relativistic energies. Under the appropriate plasma conditions, energy gained by the plasma electrons can be used to create short-lived coherent structures in the plasma. These structures (such as linear electron waves and bubble) have been extensively studied and employed as accelerating and focussing systems for charged-particle beams. The structures created in the plasma have spatio-temporal scales that are defined by the characteristic of the plasma. The spatial scales by the plasma skin-depth, $\frac{c}{\omega_{pe}}$ ($\omega_{pe} = \sqrt{4\pi e^2/m_e}\sqrt{n_e/\gamma_e}$). And the temporal scales by the plasma frequency, $\frac{1}{\omega_{pe}}$. It should be noted that the wakefield theory assumes fixed background ions. In addition to this, the plasma structures are used only over a few plasma electron periods. However, when these plasma structures evolve over time, ion-dynamics which occurs over ion-acoustic wave times $\frac{1}{\omega_{ia}}$ ($\omega_{ia} = \omega_{pe}\sqrt{m_e/M_i}$) becomes significant. For instance, in electron-proton plasma, $\omega_{pe} = 43\ \omega_{ia}$. If plasma density, $n_e = 10^{18}$, $\frac{1}{\omega_{pe}} \simeq 20fs$ and $\frac{1}{\omega_{ia}} \simeq 1ps$. These timescales are important to understand the upper limits of the repetition-rate (and hence luminosity) in a future plasma collider [1]. Also, highly relativistic plasmas are created in astrophysical entities such as Active Galactic Nuclei (AGN such as Centaurus-A (NGC-5128), M-87) and lab-based hot plasmas can better explain phenomenon such as the relativistic jets emanating from AGNs. These particle jets interact with surrounding gravitationally heated hot plasma and can exhibit phenomenon such as self-focussing, hosing and radiation generation.

The plasma wave is *coherent* under the cold-plasma approximation as seen from its dispersion characteristic, $\omega^2 = \omega_{pe}^2 + 3k^2v_{th}^2$ which under, $v_{phase} \gg v_{th}$ is excited over a narrow-band mode centered around ω_{pe}. However, if the plasma is thermally inhomogeneous or the electrons have a large thermal spread the plasma wave mode begins to lose its narrowband characteristic. When a plasma wave evolves in time, plasma spatial inhomogeneities, driver spatial non-uniformity and ion motion introduce a new set of frequencies into the plasma. With non-linearity and instability driven phase mixing between these modes, the plasma wave further de-coheres and equilibriates into random thermal motion. This increase in the entropy of the system follows from the second law of thermodynamics which makes the energy distribution equipartitioned between all possible modes of a system, driving it towards equilibrium.

In a future plasma collider, the need for high luminosity would require each plasma stage to be re-used within a finite interval (depending upon the drive bunch-train design). The fraction of drive-bunch energy coupled into the plasma that is absorbed by the accelerated-bunch has been shown to be $\simeq 50\%$ under optimal non-linear beam-loading which implies significant energy leftover in the accelerating plasma structure. Hence the next drive bunch would be affected by the thermalization of the wake from the previous pulses. In this paper we discuss the long-term evolution of a wake-perturbed plasma in terms of its temperature and density profile. We look at the electron momenta to determine if unabsorbed energy from a previous drive-bunch could heat the plasma to relativistic temperatures ($k_BT_e \simeq 0.5MeV$). We use simulations to estimate the plasma diffusion timescales. Past experimental work have imaged about 10 plasma periods behind the driver [2].

ENERGY IN A PLASMA WAVE

The planar electron plasma wave in 1-D can be denoted as $\vec{E}_{pw}(x) = \hat{x}\ E^0_{pw}\ e^{\mathbf{i}(\omega_{pe}t - k_{pe}x)}$. The force equation of the plasma wave acting on a single plasma electron is $m_e\frac{d\vec{v_e}}{dt} =$

$-e\vec{E}_{pw}$. Therefore, $\vec{v_e} = \frac{-eE^0_{pw}}{m_e}\int e^{\mathbf{i}(\omega_{pe}t-k_{pe}x)}\hat{x} = \frac{e\vec{E}_{pw}}{m_e\omega_{pe}}e^{\mathbf{i}\pi/2}$ and $|\vec{v_e}|/c = \frac{e|\vec{E}_{pw}|}{m_e c\omega_{pe}}$. From the electron velocity we can estimate the kinetic energy of the single electron in the plasma wave, $\mathcal{E}_k = \frac{1}{2}\left(\frac{e|\vec{E}_{pw}|}{m_e c\omega_{pe}}\right)^2 m_e c^2$. If all the plasma electrons are picked up by the plasma wave, we can estimate the kinetic energy density of the electrons in the plasma wave as $\mathcal{E}_k/unit\ volume = \frac{1}{2}\left(\frac{e|\vec{E}_{pw}|}{m_e c\omega_{pe}}\right)^2 m_e c^2\ n_e$. The field energy density in the plasma wave fields is $\mathcal{W}_f = \frac{|\vec{E}_{pw}|^2}{8\pi} = \left(\frac{e|\vec{E}_{pw}|}{m_e c\omega_{pe}}\right)^2 \frac{m_e^2c^2\omega_{pe}^2}{8\pi e^2}$. Using $\omega_{pe}^2 = \frac{4\pi n_e e^2}{m_e}$, we have $\mathcal{W}_f = \frac{1}{2}\frac{m_e\omega_{pe}^2}{4\pi n_e e^2}\left(\frac{e|\vec{E}_{pw}|}{m_e c\omega_{pe}}\right)^2 m_e c^2 n_e = \frac{1}{2}\left(\frac{e|\vec{E}_{pw}|}{m_e c\omega_{pe}}\right)^2 m_e c^2 n_e$. As $\mathcal{E}_k = \mathcal{W}_f$, there is an energy exchange between the kinetic energy of the oscillating electrons and the electric field of the wave.

If the beam-loading of the plasma wave by an accelerated beam is 50%, the energy leftover in the plasma can be estimated as $\mathcal{E}_{plasma}/unit\ volume = \frac{1}{2}\left(\frac{e|\vec{E}_{pw}|}{m_e c\omega_{pe}}\right)^2 m_e c^2\ n_e$. We study the density and temperature distribution of the plasma (electrons and ions) over $\simeq$ 10000 cycle of $\frac{1}{\omega_{pe}}$ and $\simeq$ 1000 cycle of $\frac{1}{\omega_{ia}}$.

SIMULATIONS OF LONG TERM EVOLUTION OF LASER DRIVEN WAKEFIELD

To study the LTE of a laser wakefield in the plasma, we use $2\frac{1}{2}D$ OSIRIS[3] PIC code with Eulerian specification of the plasma dynamics. We initialize the plasma density to $0.01n_c$ with background ions of $10m_p$ and pre-ionized singly-charged state. We have intentionally chosen a relatively high density plasma because $\omega_{pe} = \omega_0 \times \sqrt{n_e/n_c}$. We resolve and reference the real time in simulation to the laser period $2\pi/\omega_0$ thereby the dynamics within a single plasma cycle is simulated in just $\sqrt{n_c/n_e} = 10$ laser cycles. We discretize the space with 20 cells per skin-depth (c/ω_{pe}) in the longitudinal and 10 cells per c/ω_{pe} in the transverse direction. The simulation space size is chosen as 300 c/ω_{pe} x 600 c/ω_{pe}. We use absorbing boundary conditions for fields and particles of all species. The laser pulse is chosen to be a circularly polarized Gaussian pulse with normalized vector potential $a_0 = 4.0$ with pulse width of $10fs$.

From the simulations we observe that a plasma bubble is excited by the laser pulse, as seen in Fig. 1[a] at $264\frac{1}{\omega_{pe}}$. The ions are stationary as seen from the ion density in Fig. 2[a]. We observe that the bubble oscillates for about 20 plasma periods. The more the oscillations are delayed in time, the more the bubble's transverse size decreases and the electron sheath around the bubble curves with smaller radii towards the back of the bubble. We also observe at the end of the bubble oscillations that the density of electrons in the sheath around the bubble reduces and the electron density is modulated further away from the axis of the bubble in the transverse direction. Such a weak bubble with

curved electron sheath may be observed around $200\frac{c}{\omega_{pe}}$ in Fig. 1[b].

At later times we also observe that neighboring plasma bubbles merge into each other and the electrons in the sheath execute motion around the merged ion cavity. The merged bubbles can be seen around $100\frac{c}{\omega_{pe}}$. The ion density at the same time as Fig. 1[b] is shown in Fig. 2[b]. From the ion density snapshot in Fig. 2[b] a feature can be observed in the background ions around $100\frac{c}{\omega_{pe}}$ which has shape similar to the merged bubble in electron density. The

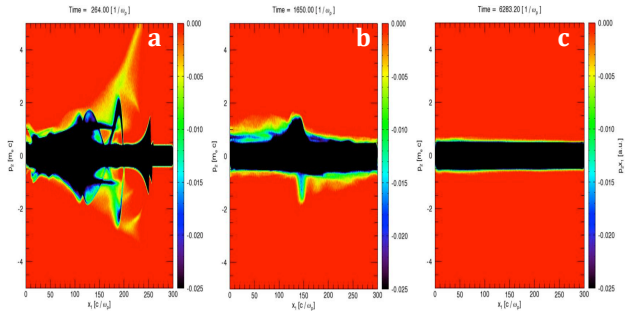

Figure 4: LTE snapshots of **electron transverse momentum phase space** along the longitudinal direction at times, t= **(a)** $264\frac{1}{\omega_{pe}}$ **(b)** $1650\frac{1}{\omega_{pe}}$ **(c)** $6283.20\frac{1}{\omega_{pe}}$.

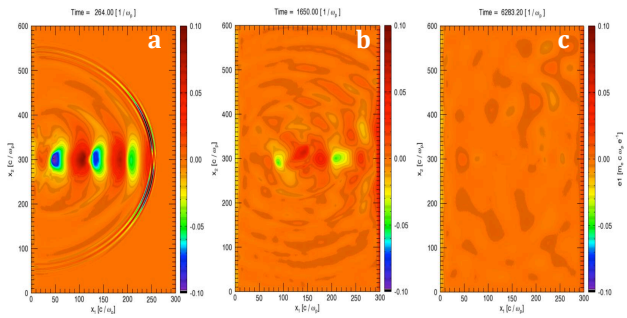

Figure 5: LTE snapshots of **longitudinal electric field in real space** along the longitudinal direction at times, t= **(a)** $264\frac{1}{\omega_{pe}}$ **(b)** $1650\frac{1}{\omega_{pe}}$ **(c)** $6283.20\frac{1}{\omega_{pe}}$.

ion motion occurs as expected at the ion acoustic timescales as the Fig. 2[b] is shown is around $10\frac{1}{\omega_{ia}}$. After the onset of ion motion we observe structures with very low phase velocities in comparison to the plasma wave, as seen in Fig. 1[c] and Fig. 2[c]. In Fig. 2[c] we see ion expansion away from the axis and an ion channel is seen.

In Fig. 3 and Fig. 4, we show the momentum phase spaces corresponding to the density snapshots. In Fig. 5 and Fig. 6, we show the fields in the real space corresponding to the density snapshots. It can be seen from the fields much after the short laser pulse ($10fs$ long) has passed by and the plasma wave has evolved and decayed there is still significant trapped electric field (Fig. 6[b] and Fig. 5[b]) in the merged bubble seen in the Fig.1[b]. This is the characteristic of a *caviton*. In the laser driven wake we can observe trapped laser radiation, however in beam driven case there is no driving radiation and hence the characteristic of beam-driven wake LTE differ from the laser-driven wake LTE.

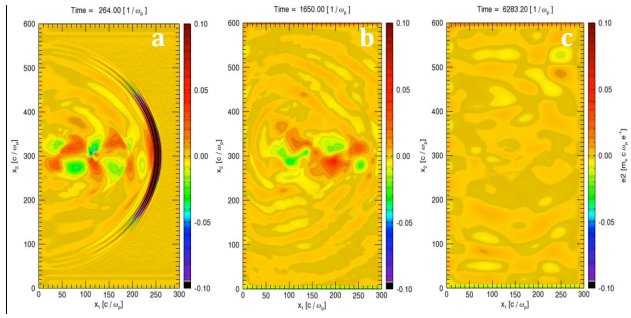

Figure 6: LTE snapshots of **transverse electric field in real space** along the longitudinal direction at times, t = **(a)** $264\frac{1}{\omega_{pe}}$ **(b)** $1650\frac{1}{\omega_{pe}}$ **(c)** $6283.20\frac{1}{\omega_{pe}}$.

ANALYSIS OF HIGH REPETITION RATE EFFECTS IN DIELECTRIC WAKEFIELD ACCELERATORS*

Paul Schoessow#, Sergey P. Antipov, Chunguang Jing, Alexei Kanareykin, Stanley Zuo

Abstract

Recently the question has arisen of whether dielectric charging might become a significant limiting effect on the performance of the DLAs (dielectric loaded accelerators), leading either to deflection of the beam by the static electric field generated, or to breakdown of the structure. In experiments to date this has not been problematic with appropriate choice of dielectric material. However, given the high repetition rate that would be required, the device would be subjected to essentially a dc bombardment from the beam halo and thus be vulnerable to these effects because there is no time between machine pulses for discharge of the dielectric. We have begun re-examining this problem, emphasizing the expected charging rate and charge distribution in a thin walled dielectric device and the physics of conductivity and discharge phenomena in a dielectric medium. Simulations of the charging process will be presented. We will review early work on beam-induced charging of dielectric structures and also results from deep charging of satellite components by cosmic rays. Ageing and induced conductivity under large radiation doses are also to be investigated.

IRRADIATION EFFECTS ON DLAS

The physical processes involved with the unwanted interception of beam electrons by a dielectric accelerating structure are complex and interacting:

- Asymmetric charging of the dielectric, leading to beam deflection;
- Breakdown (with structure damage). Although breakdown thresholds ~14 GV/m have been demonstrated for very short (<330 fs) pulses [1], maximum DC fields that can be supported are considerably lower;
- Changes in material properties with absorbed dose and repeated DC breakdowns;
- Dynamics of the charging/discharge process in the presence of high dose rates. Table 1 lists the characteristic discharge times for a number of dielectric materials used in DLAs, nearly all of which do not reflect the observed resistance to charging. This seems to suggest that other effects are compensating, for example ionization induced conductivity.

Charging effects were studied by the Argonne group as an incidental part of the first dielectric wakefield acceleration tests in 1988 [2]. In these experiments the charging originated from missteering of the drive beam through the dielectric structure. Transverse deflection of the beam through large angles by the induced DC field was sufficiently large as to deflect the beam outside the acceptance of the spectrometer focal plane detector. The initial tests used dielectric tubes made from plastics. Rexolite and Nylon dielectrics showed rather different behaviors under charging.

Table 1: Characteristic discharge times $\tau_c=\varepsilon/\sigma$ for commonly used dielectrics [6]. Here σ is the dc conductivity and ε is the (SI) permittivity.

Material	τ_c
Alumina	>0.78 s
Delrin ®	310 s
Kapton ®	3.5 d
Mylar ®	3.1 d
Polystyrene	37 min
Fused Quartz	>38 d
Borosilicate glass	0.41 s (variable) [7]
Teflon ®	2.1 d

Rexolite was found to charge until the beam was deflected and to hold its charge (and maintain the dc electrostatic field) for an extended time (~ 1 hr). No breakdowns were seen under the test conditions. Nylon would charge up and deflect the beam until breakdown occurred, snapping the beam back to its nominal undeflected position. The charge-discharge period was found to be ~ 30 s. It is worth noting that no permanent damage to the nylon structure was observed (based on repeated longitudinal wakefield measurements) despite being subjected to many charge-discharge cycles.

The rexolite structure was field-modified by depositing a thin layer of graphite powder on the interior surface of the tube. A thin conducting layer can short out the static field but be thin enough (<< 1 skin depth) to allow the rf fields of the structure to penetrate into the vacuum channel as before. It was determined that the graphite layer did in fact have the desired effect, although some trial and error was necessary to obtain a sufficiently thin layer. While use of graphite in this fashion is impractical for high energy acceleration, the principle of using an interior conductive coating was demonstrated. Ultimately the best approach was found to be tuning the beam through an electrically isolated aluminum tube in place of the dielectric, minimizing the intercepted beam current, and then swapping in the dielectric under test for the aluminum tube.

Later AATF and AWA experiments used borosilicate glass as the dielectric [3]. This material exhibits a large temperature dependent electrical conductivity. Measurements on wakefield structures made of this material showed no detectable charging and no apparent degradation in the magnitude of the wakefield excitation. While borosilicate glass does indeed possess a short discharge time, fused quartz has a discharge time longer than 30 days, while repeated experiments at the AWA and elsewhere have not observed DC charging effects with this material.

Euclid and ANL have begun a systematic study of radiation effects in dielectric wakefield accelerators, with the goal of understanding both acute (charging, dose rate, electric field) and long term (material damage) effects. This project involves both experimental and computational aspects; here we focus on the status of the simulation effort.

COMPUTATIONAL APPROACH

A complete model of DLA irradiation effects needs to include

- characteristics of the halo (energy spectrum, angular distribution) either determined experimentally or from a simulation of the accelerator;
- interaction of the halo particles with the dielectric structure (spatial distribution of stopped charges and energy deposited in the dielectric);
- computation of the electric field in the dielectric from the trapped charge distribution using a self-consistent determination of the conductivity. This will give the dependence of the equilibrium electric field on the halo current.

Dielectric Irradiation by Halo Electrons

The Geant4 Monte-Carlo code [4] will be used to transport the halo electrons through the dielectric structure, simulating their electromagnetic interactions with the material and scoring the distribution of charges injected into the material. User-written C++ routines are used to code the geometry and material of the target structure, and a Tcl/Tk interface is used to input parameters to control the execution of the program. While originally designed for high energy physics applications, a number of authors ([5], e.g.) have used Geant4 for the study of dielectric charging in spacecraft.

We have begun looking at some test problems to study charging in dielectric structures. Fig. 1 shows a Geant4 simulation of 100 MeV electrons striking the interior of a quartz wakefield structure at glancing incidence to simulate beam halo. The user code we developed flags the location of each stopping electron and also the location where an effective positive charge is created (for example where an electron is removed by a Compton scattering event). In this way the distribution of charge internal to the dielectric induced by the halo is computed (Fig. 2-3). At the same time, the energy deposited in the dielectric and any induced temperature rise is also calculated. The charge and energy deposition results are then input to a field calculator.

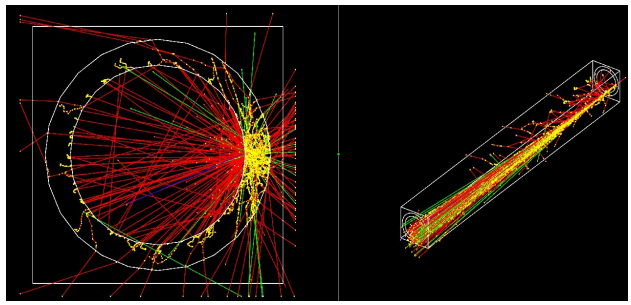

Figure 1: Geant4 simulation of 100 MeV electrons striking a quartz tube (0.35 mm inner radius, 0.45 mm outer radius, 10 mm long, 336 GHz fundamental TM_{01} mode) at glancing incidence to a point on the inner surface. The plots are a sum of 100 events. Red tracks: photons; green: e^+ and e^-. The yellow rectangles indicate the segmentation of the tracks.

This part of the simulation code will use the spatial dependence of the stopped charges from Geant4 and a Poisson solver to compute the dc field inside the dielectric. Using the electric field and the energy deposited in the dielectric, the conductivity can be determined as a function of position. Finally, the trapped charges can be updated using Ohm's law. The procedure is iterated to obtain the time dependence of the field and charges in the dielectric.

An assumption is made here that the quasistatic electric field and its effect on the conductivity are independent of the rf fields induced by the beam. If needed, rf effects could be incorporated through the use of a FDTD EM solver.

Dielectric Conductivity

There are a number of empirical relations used in the literature to parameterize the time, temperature and electric field and dose rate dependence [8-11] of the dielectric conductivity σ.

$$\sigma(t)= \frac{\sigma_1}{F(1+bt)} \qquad \text{(time)} \qquad (1)$$

$$\sigma(T)= \sigma_\infty \exp(-\frac{E_A}{kT}) \qquad \text{(temperature)} \qquad (2)$$

$$\sigma(E,T) = \frac{1}{3}\sigma(T)\times [2+\cosh(\frac{\beta_F E^{1/2}}{2kT})][\frac{2kT}{eE\delta}\sinh(\frac{eE\delta}{2kT})] \qquad \text{(electric field)} \qquad (3)$$

$$\sigma(\frac{dD}{dt})= \sigma_0 + k_p(\frac{dD}{dt})^\Delta \qquad \text{(Dose rate)} \qquad (4)$$

here $\beta_F = \sqrt{e^3/\pi\varepsilon}$, E is the electric field strength, and D is the absorbed radiation dose (rads). k_p and Δ are positive constants, with Δ in the range 0.6-1.0; these and the other free parameters in eq. (1)-(4) need to be determined

experimentally. We note that the conductivity increases with increasing dose rate and electric field, leading to

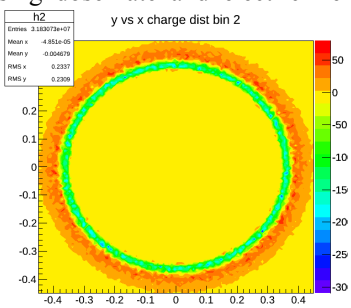

Figure 2: Trapped charge distribution in a 1 mm axial segment for 100 MeV electrons incident symmetrically around the circumference of the tube in Fig. 1. Note that regions with excess electrons and depleted in electrons both occur.

reduced discharge times of accumulated charge in an accelerator environment.

Modeling of Beam Halos

Machine parameters (rf, optics, vacuum) are input to a halo simulation code. (Alternatively, if sufficient data from the accelerator exists, they could be parameterized and input directly to the particle transport code.) The tracking code Placet [12] incorporating the halo simulator htgen [13] has been chosen as a reference to perform the machine simulation. The accelerator lattice and other parameters are input via Tcl/Tk scripts.

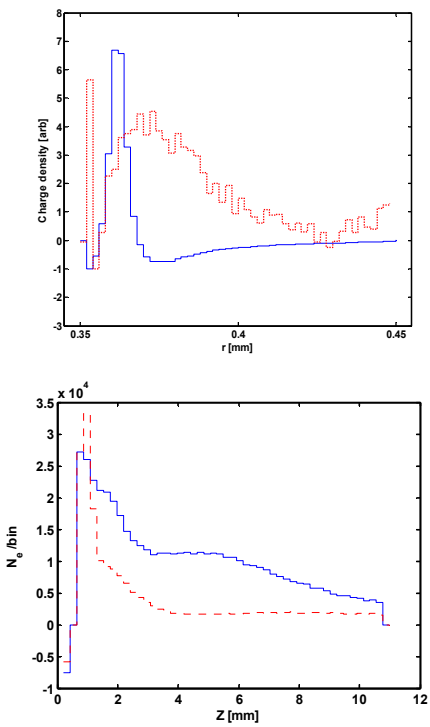

Figure 3: Trapped charge distribution as a function of (a) radial (b) axial position. in the geometry shown in Fig. 2. (Solid: 100 MeV e^-; dotted: 10 MeV e^-.)

Htgen models the effects of beam-gas scattering and bremsstrahlung from scraping on collimators and other beamline components, using the Placet components to model the beam and also transport the halo particles produced to the dielectric structure.

SUMMARY

We have begun investigating the effects of irradiation on dielectric wakefield structures. We consider developing a simulation code to calculate the interaction of halo electrons with DLA structures. Because of the more complex geometry the problem presents challenges not treated in previous analyses.

ASTA AT FERMILAB: ACCELERATOR PHYSICS AND ACCELERATOR EDUCATION PROGRAMS AT THE MODERN ACCELERATOR R&D USERS FACILITY FOR HEP AND ACCELERATOR APPLICATIONS*

V. Shiltsev#, P. Piot, Fermilab, Batavia, IL 60510, USA

Abstract

We present the current and planned beam physics research program and accelerator education program at Advanced Superconducting Test Accelerator (ASTA) at Fermilab.

ASTA FACILITY

The Advanced Superconducting Test Accelerator (ASTA) at Fermilab will enable a broad range of beam-based experiments to study fundamental limitations to beam intensity and to develop transformative approaches to particle-beam generation, acceleration and manipulation. ASTA incorporates a superconducting radiofrequency (SRF) linac coupled to a photoinjector and small-circumference storage ring capable of storing electrons or protons. ASTA will establish a unique resource for R&D towards Energy Frontier facilities and a test-bed for SRF accelerators and high-brightness beam applications. The unique features of ASTA include: (1) a high repetition-rate, (2) one of the highest peak and average brightness within the U.S., (3) a GeV-scale beam energy, (4) an extremely stable beam, (5) the availability of SRF and high-quality beams together, and (6) a storage ring capable of supporting a broad range of ring-based advanced beam dynamics experiments. These unique features will foster a broad program in advanced accelerator R&D and accelerator education which cannot be carried out elsewhere. Several experiments and test can be carried out at ASTA simultaneously at three experimental areas – see Fig.1. Detail description of ASTA can be found elsewhere [1,2]

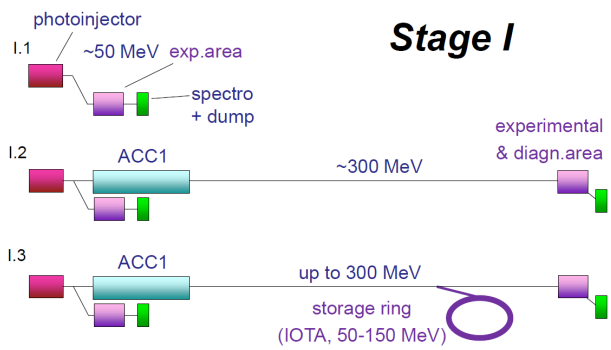

Figure 1: Schematics of ASTA (Stage I configuration).

ASTA ACCELERATOR R&D THRUSTS

Accelerator R&D for Particle Physics at the Intensity and Energy Frontiers

The combination of a state-of-the-art superconducting linear accelerator and a flexible storage ring enables a broad research program directed at the particle physics accelerators of the future. The corresponding research program includes a number of proposals:

i) Test of non-linear, integrable, accelerator lattices (the Integrable Optics Test Accelerator) which have the potential to shift the paradigm of future circular accelerator design
ii) Test of space charge compensation in high intensity circular accelerators
iii) Advanced phase space manipulations
iv) Test of optical stochastic cooling
v) Flat-beam-driven dielectric-wakefield acceleration in slab structures
vi) Investigation of acceleration and cooling of carbon-based crystal structures for muon accelerators
vii) Measurement of the electron wave function size in a storage ring
viii) Studies of beam echo phenomena in a storage ring
ix) Development of a quadrupole pickup and study of the quadrupole mode dynamics in space-charge dominated beams
x) High power targetry studies for LBNE
xi) A tagged photon beam at ASTA for Detector R&D
xii) HEP applications of inverse Compton scattered photons.

It was specifically noted at the 2013 Community Summer Study ("Snowmass-2013" [2]) that there is obvious lack of accelerator test facilities where many burning accelerator science and technology issues of the Intensity Frontier (IF) accelerators [4] can be addressed. ASTA will provide this so-much needed platform for the IF accelerator R&D.

Accelerator R&D for Future SC RF Accelerators

High gradient, high power SC RF systems are critical for many accelerator facilities under planning for the needs of high-energy physics, basic energy sciences and other applications. ASTA offers a unique opportunity to explore the most critical issues related to SC RF technology and beam dynamics in SC RF cryomodules, such as:

Copyright © 2013 CC-BY-3.0 and by the respective authors

i) Demonstration of High Power High Gradient SRF Cryomodules with Intense Beams
ii) Demonstration of technology and beam parameters for the Project X pulsed linac
iii) Wakefield measurements in the SC RF cryomodules
iv) Demonstration of ultra-stable operation of SC RF cryomoduyles with beam-based feedback
v) Development and experimental test of neural network based control systems and optimization tools for SRF accelerators
vi) Exploration of CW mode of operation of the ILC-type SRF cryomodule

Accelerator R&D for Novel Radiation Sources

High energy (up to 1 GeV), high peak and average power and high brightness electron beams have tremendous potential for generation of high-brightness high energy photon beams spanning the range from keVs to dozens of MeV. The high average power and brightness of the ASTA electron beam has unmatched potential for development of several novel radiation source ideas, such as:

i) High brightness X-ray channeling as a compact x-ray radiation source
ii) Inverse Compton scattering gamma-ray source and its applications
iii) Demonstration of feasibility of an XUV FEL oscillator
iv) Production of narrow-band gamma-rays
v) Laser-induced microbunching studies with high micropulse-repetition rate electron beams

Accelerator R&D for Stewardship and Applications

With its high energy, high brightness, high repetition rate, and the capability of emittance manipulations built-in to the facility design, ASTA is an ideal platform for exploring novel accelerator techniques of interest for very broad scientific community beyond high energy physics. The proposed research program includes several proposals and expressions of interest for such explorations:

i) Demonstration of techniques to generate and manipulate ultra-low emittance beams for future hard X-ray free-electron lasers
ii) Beam energy dechirper using corrugated pipes
iii) Development and test of a beam-beam kicker
iv) Coherent diffraction radiation measurements of bunch length

All the proposals can be found in [1] and have been discussed by the Fermilab's Accelerator Advisory Committee (February 6-8, 2013). Later, all of them have been presented at the 1st ASTA User's Meeting and reviewed by the ASTA Program Advisory Committee (July 23-24, 2013).

ACCELERATOR EDUCATION OPPORTUNITIES AT ASTA, ASTA AND IARC

Accelerators have taken an increasingly important role in our Society and improving their performances, downsizing their footprints, or reducing their cost will be a long and challenging endeavour that will strongly rely on future generation of accelerator scientists. In addition, the multidisciplinary nature of Accelerator Science makes accelerators ideal platforms for student education over a vast range of topics.

New beam physics issues associated with future accelerators have emerged (single-bunch and multi-bunch collective effects in high brightness electron accelerators, simulations of large emittance beams in heavy ions and/or multi state charge accelerators) and more intricate accelerator physics tools capable of accounting for all these effects are being developed and need to be carefully validated at available facilities. Such models are mandatory to efficiently design and test the performance of these accelerators prior to their construction. Similarly, future accelerators will require the development of precise diagnostics and controls capable of measuring and/or correcting unprecedented beam parameters (sub-micrometer size, femtosecond duration, with high average current). Most of these topics will be explored to some extent at ASTA and could form the basis of research projects for PhD, Masters, or internships.

Interdisciplinary research projects involving the engineering discipline will also be possible at ASTA. Examples that come to mind are fabrication of state-of-the-art accelerator components requiring precision modeling, drafting and manufacturing. RF engineering R&D examples are ubiquitous in accelerator physics. Likewise, novel synchronization techniques and feedback systems will be needed, e.g. to insure that the accelerating fields in the superconducting linear accelerators are very stable.

Over the last decade the number of Educational Institutions that have taken on developing a curriculum in Accelerator Science has increased from a couple to about 10 [5]. None of these Universities currently operates a full-fledged accelerator complex and generally rely on facilities available at National Laboratories to carry most of their experiments. National laboratories have developed programs to foster partnership with Universities. Fermilab was actually the first laboratory to initiate such a selective program, which offers to financially support students to carry-out Accelerator-Science research at Fermilab's facilities [6]. This program – the Joint University - Fermilab Doctoral Program in Accelerator Physics and Technology – has graduated close to 40 students since its initiation in 1987. More than half of the program's graduates have remained in the field of Accelerator Science, and approximately one quarter of them are prominent scientists with leadership positions in national laboratories or universities.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Fermilab also created prestigious fellowships to attract promising scientists to carry-out research in Accelerator Science: the Peoples fellowshipwas created in 2001 and the Bardeen-Engineering Leadership fellowship [7] was created in 2005. The John Bardeen Engineering Leadership Program is designed to provide entry-level opportunities for outstanding engineering graduates who are interested in working in a cutting edge research environment. Fermilab provides opportunities in the fields of electrical, electronics, radio frequency systems, power distribution, magnets, RF cavities, mechanical, materials science and cryogenic engineering. The Peoples Fellowship was created at Fermilab with the goal of attracting outstanding accelerator scientists early in their careers, both to enhance Fermilab's capabilities in accelerator science and related technologies, and to train and develop the accelerator scientists and technologists who will carry our field forward in the future. Together these fellowship programs have attracted and trained approximately 20 people within the last decade. Most of these fellows still carry-out research in Accelerator Science.

Finally, Fermilab has also been active in involving younger scientists (undergraduate students) through various summer programs. One of these programs, the Lee Teng Undergraduate Internship in Accelerator Science and Engineering established by Fermilab and Argonne, aims at attracting undergraduate students into the world of particle accelerator physics and technology. The selected students first attend a two-week general accelerator physics class at the summer US particle accelerator school thereby gaining a broad overview of Accelerator Science. They then work on a research project for the following weeks under the supervision of Fermilab and Argonne staff members. ASTA offers the possibility of significantly enhancing the Lee Teng program by incorporating a "hands-on" component to the students' summer research experience, making it a truly unique internship with the potential to attract future accelerator scientists at the critical undergraduate stage.

In addition to these laboratory-driven programs, Fermilab has also welcomed students from University groups carrying out research at Fermilab funded by grants to universities. Examples includes the development of photo-emission laser with University of Rochester, research on flat-beam generation with University of Chicago, or the investigation of beam-driven plasma wakefield acceleration with University of California, Los Angeles.

ASTA will be an excellent platform that could support and enhance the aforementioned education programs and support extramural research engaging students from Universities. Given the breath of the scientific program described in this proposal, we expect ASTA to provide support for topics of research in Advanced Accelerator R&D, laser science, beam diagnostics and synchronization, accelerator-based light source, superconducting RF system, and Beam Physics. Finally, some of the proposed topics could also foster research beyond Accelerator Science such as the utilization of single-cycle Terahertz pulses for solid-state Physics research or the use of X-rays for developing phase-contrast imaging (with possible spin-off to medical imaging).

ASTA will also offer a unique opportunities for the US Particle Accelerator School [8] sessions and classes. A number of hand-on, practical training laboratory sessions can use the ASTA accelerators – the photoinjector, the SRF cryomodule and the IOTA ring. Among them, those which were very popular in the past US PAS sessions:

a. Modern RF systems class
b. Beam Instrumentation Lab
c. Fundamentals of Accelerator Instrumentation
d. Beam Measurements and Diagnostics in Linacs and Rings
e. Beam Dynamics Experiments at the IOTA ring
f. Beam Measurements, Manipulation and Instrumentation in SRF Linac

Proximity of the Illinois Accelerator Research Center (IARC) at Fermilab [9] will make these classes attractive for the industrialists and technologists. At the IARC, scientists and engineers from Fermilab, Argonne and Illinois universities will work side by side with industrial partners to research and develop breakthroughs in accelerator science and translate them into applications for the nation's health, wealth and security. Besides a dedicated state-of-the-art facility that will house offices, technical and educational space to study cutting-edge accelerator technologies, it is anticipated that IARC's private industry partners will have access to the nearby ASTA facility to perform high power beam tests and collaborate with ASTA users from the US universities in training a new generation of scientists, engineers and technical staff in accelerator technology. These partnerships will make critical contributions to the technological and economic health of Illinois and the nation in general.

ISSUES AND R&D REQUIRED FOR THE INTENSITY FRONTIER ACCELERATORS*

V.Shiltsev#, S.Henderson, P.Hurh, I.Kourbanis, V.Lebedev, Fermilab, Batavia, IL 60510, USA

Abstract

Operation, upgrade and development of accelerators for Intensity Frontier face formidable challenges in order to satisfy both the near-term and long-term Particle Physics program. Here we discuss key issues and R&D required for the Intensity Frontier accelerators.

INTENSITY FRONTIER ACCELERATORS

The near-term program of HEP research at the Intensity Frontier continuing throughout this decade includes the long-baseline neutrino experiments and a muon program focused on precision/rare processes. It requires: a) double the beam power capability of the Booster; b) double the beam power capability of the Main Injector; and c) build-out the muon campus infrastructure and capability based on the 8 GeV proton source. The long-term needs of the Intensity Frontier community are expected to be based on the following experiments: a) long-baseline neutrino experiments to unravel neutrino sector, CP-violation, etc.; and b) rare and precision measurements of muons, kaons, neutrons to probe mass-scales beyond LHC.

Both types of experiments will require MW-class beams. The Project-X construction is expected to address these challenges [1]. The Project X represents a modern, flexible, Multi-MW proton accelerator (see Fig.1).

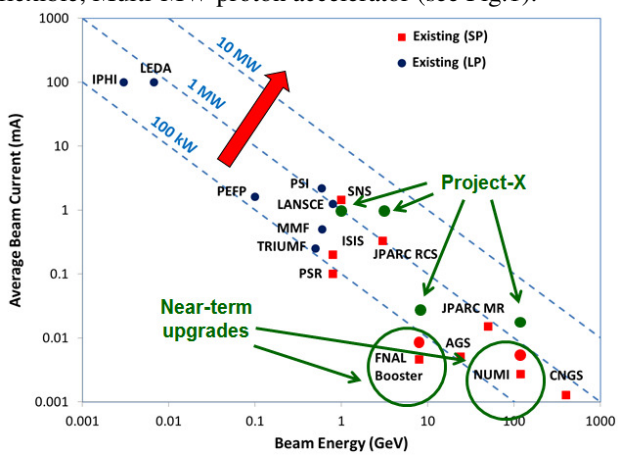

Figure 1: Accelerator beam power landscape.

High power hadron accelerators for the Intensity Frontier have two over-riding design constraints [2]:
Minimizing beam loss (typical beam loss requirements for a MW proton beam: < 1 Watt/m, or/and < 1×10^{-4} total beam loss), and
Proper beam structure (the required formats significantly vary from experiment to experiment – from a quasi-CW for rare particle decays to a single ~2-ns long bunch for MC/NF). The key challenges to satisfy these constrains include:

- Producing high current, high-quality and high brightness beams with required bunch structure;
- Accelerating high beam currents to high energy with (1) high-duty factors required for high resolution experiments and (2) very low duty factors for neutrino experiments;
- Running multiple experiments in parallel (quasi-simultaneously) required means for beam manipulations on the bunch-by-bunch base – see Fig.2;
- Transporting high power beams while maintaining beam loss at a level where routine maintenance is possible – see Fig.3;
- Acceleration of beams from keVs to GeVs preserving emittance and minimizing amplitude growth for large-amplitude particles ("beam halo");
- Low-loss extraction of the beams;
- Target systems capable of handling extreme power densities and extreme radiation environments – see Fig.4;
- A related challenge is producing intense, high-quality beams of secondary particles (muons, kaons, …).

ACCELERATOR R&D NEEDED

Below we outline the directions of the accelerator R&D needed to address the above challenges (we omit specific Project X R&D needs which are addressed elsewhere [3], and focus mostly on other important needs, especially, for the Fermilab's future intensity frontier program, which have not been articulated yet):

High Intensity beam sources: Radio-frequency quadrupoles (RFQs) are the injector technology of choice at present; the state of the art performance of 100 mA CW demonstrated at LANL/LEDA with 6.7 MeV output energy; is there an alternative technology which could compete with conventional technology?);

Beam dynamics issues with high intensity beams in existing accelerators (e-cloud, impedances/instabilities): RF systems (how to provide RF power for beam acceleration with many-fold higher beam current when the beam induced voltage greatly exceeds RF voltage?);

Space Charge issues (need to understand the Space Charge losses with the higher intensity slipped stacked bunches in MI and Recycler; the need collimators in

*Fermi Research Alliance, LLC operates Fermilab under contract No. DE-AC02-07CH11359 with the U.S. Department of Energy
#shiltsev@fnal.gov

Copyright © 2013 CC-BY-3.0 and by the respective authors

Recycler (?); realistic Space Charge MI simulations with predictive power that we can compare with data);

SYNERGIA simulations (to include all apertures and magnetic multipoles; compare with beam data);

Electron-Cloud (most effective coating and scrubbing; *in situ* SEY measurements, micro-wave measurements in the Main Injector);

Transition Crossing (evaluation need of a gamma-t jump in MI, transition crossing in Booster);

Injection issues (investigation of painting scenarios and other potential mitigation schemes - such as use of laser assisted stripping and R&D on rotating injection foil technology - Ultra Nano Crystalline Diamond (UNCD) technology, rotating graphene foil technology);

Loss Control (the need and design of the most efficient collimation schemes)

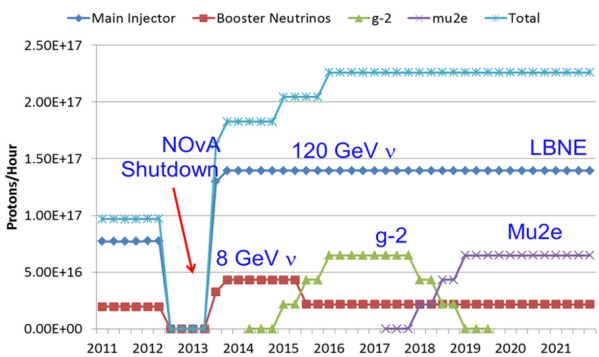

Figure 2: Fermilab's Proton Source proton flux ramp up expectations for the Intensity Frontier experiments.

Advanced simulation/modeling capabilities for high-intensity beams : We definitely will need to capitalize on the theoretical developments in beam physics theory and further develop the theory itself. Understanding the coherent instabilities is the corner-stone of the Intensity Frontier developments. Theory of coherent motion of coasting and bunched beams needs to be further studied in various approximations with several complimentary approaches.

Characterization of the loss mechanisms will have significant impact on the entire field of high-intensity accelerators – it is fundamental to loss minimization and control.

Development of a (flexible) beam dynamics framework with fully 3D PIC capabilities (eg on base of SYNERGIA) which will include space-charge & impedance capabilities, both single and multi-bunch effects, single-particle physics with full dynamics and which could run on on desktops, clusters and supercomputers.

Further development of Energy Deposition modeling tools (eg MARS) including: (1) updates related to recent developments in nuclear interaction model; (2) implementation of polarized particle transport and interaction, (3) recent developments of radiation damage models and transfer matrix algorithms in accelerator material-free regions; and (4) further enhancement of the geometry modules.

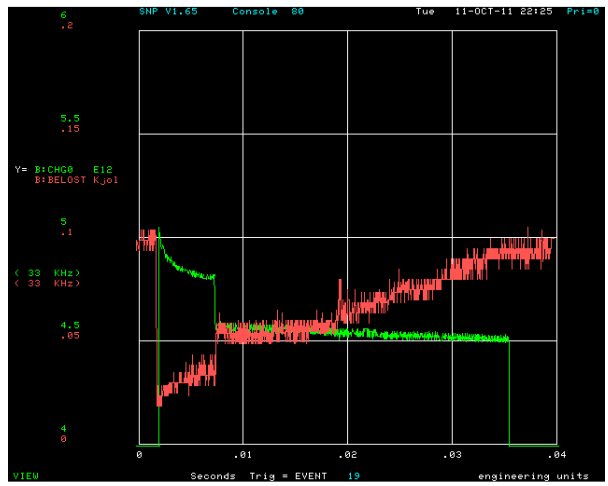

Figure 3: Losses in 8 GeV Fermilab Booster during its 15 Hz cycle occure at injection due to poorly captured beam, at the moment of notch creation (gap for extraction created with a kicker, particles lost in a gradient magnet). slow losses at high-energy (due to optics issues, RF variation), and losses at the transition energy (courtesy of Fermilab's Proton Improvement Plan team).

There is a need in a trustable weak-strong fully symplectic particle tracking codes with a comprehensive set of features for simulation of beam dynamics effects in electron and hadron storage rings, such as dynamics in integrable optics, in presence of space-charge forces and electron compensators, which could also do element-by-element tracking through machine lattice, incorporate FMA methods to assess particle diffusion, etc.

Transfer knowledge from theory and modeling to general R&D (support of the Intensity Frontier-related experiments in existing accelerators and beam test facilities, e.g., ASTA [4]) further into the projects.

Beam-stripping and beam-chopping with laser-based methods: The conventional approach to accumulating high proton intensities in a ring is to use multi-turn charge-exchange injection of H- beams, but it is very challenging to apply to >MW class beams, esp. CW beams. Novel laser stripping idea from *Danilov, et. al.* [5] has been demonstrated, but scaling to realistic accelerator parameters is needed. Laser chopping offers very attractive way to form the required beam current structures, and needs to be explored in realistic beam environment.

Targetry and collimation for Fermilab's future plans, delivery of 2MW beam power on the Long-Baseline Neutrino Experiment (LBNE) target, etc. [6, 7]:

Copyright © 2013 CC-BY-3.0 and by the respective authors

There is a need in enhanced modeling of beam energy deposition, secondary particle production and collection, radiation damage (DPA), transmutation products (gas production), and residual dose. Also required are advanced simulations of target material (non-linear) response using FEA codes including fracture and/or phase change; exploration/determination radiation damage effects in candidate target and collimator materials at accelerator target facility operating parameters (e.g., via the RaDIATE Collaboration: Radiation Damage In Accelerator Target Environments).Verification and benchmarking of the above mentioned simulation tools and material properties is needed through dedicated testing at beam facilities and autopsy of existing materials.

Figure 4: A downstream cooling water turn-around end of NuMI target NT-06 that failed after 4 month of operation at peak beam power of 340kW (toatl of 1.3e20 protons on target, 2011, courtesy J.Hylen, Fermilab)

One also needs to explore and compare high heat flux cooling methods through analysis and testing; to develop novel target and beam window concepts for use in proposed facilities; to develop target facility conceptual designs taking into account full life-cycle and radiation protection issues (remote handling, radioactive component disposal, tritium mitigation, etc.) and diagnostics for use in high radiation environments. We need to continue to engage in the high power targetry community to leverage the collaborative expertise and knowledge base to address the challenges of the High Intensity Frontier.

New ideas for clean slow extraction: Slow spills of high intensity beams are needed in particle physics, but beam loss limits intensity. Are there novel ways to cleanly achieve slow spills of high intensity beams? E.g., the resonant extraction - can it be extended to higher orders? Can crystals be used for high-power proton extraction or can electron beams be used to extract protons [8]? Are there other absolutely novel ideas which can employ lasers or high brightness electron beams?

Revolutionary ideas for Intensity Frontier accelerators: Integrable Optics [9] promises significant advance for low-loss operation of the IF facilities and must be tested at the IOTA ring at Fermilab's ASTA facility.

Space-charge compensation with either electron columns or electron lenses [10, 11] also has a promise of significant benefit for high intensity beams (due to improved emittance and loss control in high intensity beams) and also needs to be tested at the IOTA in ASTA [12].

Experimental Characterization and Understanding of High Intensity Beams and Underlying Dynamics (Advanced Instrumentation): reliable beam instrumentation is needed for precise halo (and emittance) measurements and connection to simulation in a reliable way. Novel diagnostics is required for in-depth understanding of intra-bunch and multi-bunch dynamics (position, modes, tunes, chromaticities, etc.).

One has to note that many of the above listed R&D thrusts are synergetic with the needs of the Accelerator Driven Systems (ADS) [13].

The facilities where the above listed R&D can/will be carried out include existing accelerators (Fermilab's Booster, Recycler and Main Injector) and the ASTA facility. Radiation damage studies for high power targetry may need dedicated facilities for required irradiations and examinations, such as BLIP at BNL for high energy proton irradiations or the proposed UK triple-beam facility, TRITON, for low energy ion irradiations. Verification studies for high power targetry will need dedicated areas at beam facilities capable of delivering intense beam pulses on heavily instrumented test samples, such as HiRadMat at CERN [14-16].

RF-COMPONENTS EMBEDDED WITH PHOTONIC-BAND-GAP (PBG) AND FISHNET-METAMATERIAL STRUCTURES FOR HIGH FREQUENCY ACCELERATOR APPLICATION

[1]Sara Robak, [1]Daniel Boyden, and [1, 2]Young-Min Shin
[1]Department of Physics, Northern Illinois University, Dekalb, IL, 60115, USA
[2]Fermi National Accelerator Laboratory (FNAL), Batavia, IL 60510, USA

Abstract

In the development of high efficiency and high gradient RF-accelerators, RF waveguides and cavities have been designed with Photonic Band Gap (PBG) and fishnet-metamaterial structures. The designed structures are comprised of a periodically corrugated channel sandwiched between two photonic crystal slabs with alternating high to low dielectric constants and a multi-cell cavity-resonator designed with fishnet-metamaterial apertures. The structural designs of our interest are intended to only allow an operating-mode or -band within a narrow frequency range to propagate. The simulation analysis shows that trapped non-PBG modes are effectively suppressed down to ~ -14.3 dB/cm, while PBG modes propagated with ~2 dB of insertion loss, corresponding to ~1.14 dB/cm attenuation. The preliminary modeling analysis on the fishnet-embedded cavity shows noticeable improvement of Q-factor and field gradient of the operating mode (TM_{010}) compared to those of typical pillbox- or PBG-cavities. Fabrication of the Ka-band PBG-waveguide and S-band fishnet cavity structures is currently underway and they will be tested with a microwave test bench/8510C Network Analyzer and 5.5 MW S-band klystron. These structures can be applied to stable short-bunch formation and mono chromatic radiation in high frequency accelerators.

INTRODUCTION

Periodic conducting structures have been utilized as active slow wave media interacting with high energy electron beams in a wide range of applications from high gradient linear accelerators to coherent power radiation sources. The distorted dispersion relation of metallic lattices constitutes effective plasmonic modes with negative permittivity (epsilon-negative materials, $\varepsilon < 0$) [1 – 4]. The non-radiative waves have been widely used in microwave regimes as they can be readily guided in passive components or strongly excited by energy-momentum-coupling with kinetic electrons as an active medium [5]. The confined evanescent waves induce electron bunches when the current density exceeds thermo-dynamic divergence ($\propto f^{-2}$) [6]. This gives rise to a strong coherent electron-photon interaction that is commonly used for high intensity photon generation or high gradient RF acceleration. The spectral regime of the electronic RF devices has rapidly increased from microwave to near terahertz (near-THz) wave regime (0.1–1 THz) as device size can be significantly reduced proportional to the wavelength.

Energy conversion efficiency on the photon- emission or -absorption process is thus noticeably reduced as the optical cycle is decreased [7, 8] Recent trends in the development of THz electron beam devices have gradually transitioned to elliptical sheet beams from round ones as enlarging the beam width either increases radiation intensity or reduces beam current loading. Among various planar slow wave structures (SWSs) recently micro-channels with an asymmetrically aligned double grating array [9] were intensively studied for frequency-tunable coherent radiation source application as they have large instantaneous bandwidth of plasmonic modes that are strongly confined in the beam channel with small ohmic losses. However, this broad band characteristic can lead to unstable oscillation of abnormal modes, which possibly destabilize beam-wave interactions, and perturb normal electronic energy conversion. In particular, the structure becomes heavily overmoded (TE → TEM) as its aspect ratio between x-y transverse dimensions is increased to expand the beam-wave interactive area. It is thus certain that there is a limitation in increasing the aspect ratio of the sheet beam structure due to low-energy mode excitation. A substantial solution to the issue could be obtained from bandgap structures. This paper will present the band-selective planar waveguide combined with the photonic crystal slabs and fishnet-type metamaterial slab. The composite structure permits only non-radiative photonic-band-gap (PBG) modes [2–4] to propagate through the sub-wavelength micro-channel. Comparative numerical analysis and test results on the spectral response and field distribution will be discussed in detail.

PHOTONIC BAND GAP WAVEGUIDE

In principle, the lowest frequency (cutoff) of a rectangular TE-mode waveguide is determined by waveguide width, so TE modes become closer to TEM modes as the cutoff decreases. Figure 1 shows the 0^{th} order dispersion curves (m = 0) of TE- and TEM-waveguides. Normalized structural dimensions of the designed models are specified with $a_0/d_0 = 0.75$, $L_0/d_0 = 0.6$, $b_0/d_0 = 0.33$, and $h_0/d_0 = 1.674$, where d_0 is the grating period of a unit cell. The surface wall conductivity is defined with oxygen-free high-conductivity (OFHC) copper ($\sigma = 5.8 \times 10^8$ [$\Omega^{-1}m^{-1}$]). With an increase in the guide width, the entire eigenfrequencies of the fundamental band (grey solid → grey dashed) are lowered as the other dimensions remain consistent with the ones of the TE mode waveguide. In the 2^{nd} TEM waveguide (grey

Copyright © 2013 CC-BY-3.0 and by the respective authors

dashed line), the grating height (L_0) is shortened to keep the upper cutoff (stop-band) at the same frequency as the TM mode dispersion curve, which further extends the x-y dimensional aspect ratio. The passband of the 2nd TEM SWS (higher aspect ratio: black solid) thus tends to become even more heavily overmoded with larger phase and group velocities. As aforementioned, spatial harmonic components of lower frequency modes are readily coupled with low energy electrons, so that while haunting around in the structure, once excited, they are often self-amplified by phase-mismatching condition, which can cause strong perturbation to electron-photon coupling.

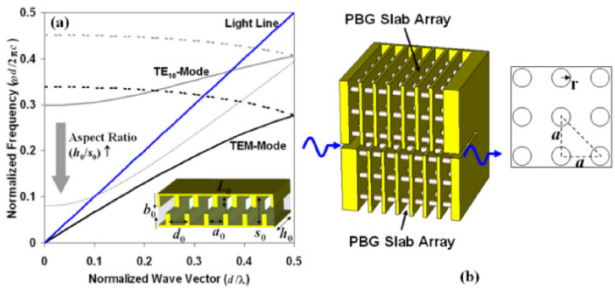

Figure 1: (a) Dispersion graph of the overmoded planar SWS. Inset is the schematic drawing of the staggered double grating arrayed waveguide with the dimensional parameters (TEM-mode) (b) 3D drawing of the PBG-slab-arrayed waveguide and unit cell of the designed PBG slab.

Embodiment of PBG elements in guided wave structures significantly reduces background noise level, including non-PBG modes, in the dynamic spectral range. In Fig. 1(b), the top and bottom gratings are replaced with the arrayed PBG slabs, which consist of alumina (Al_2O_3: ε_r = 9.4, tanδ = 0.0004) rods. In the crystal designed with the lattice constant of a/λ = 0.3 and filling ratio of r/a = 0.25, normalized global band-gap emerges at f (= $\omega d_0 /2\pi c$) = 0.25 –0.3. As depicted in Fig. 1(b), like an ordinary confined slow wave structure, electromagnetic (EM) waves bouncing back from the crystal lattices in the band-gap spectra that satisfy the Bragg condition propagate through the channel between the two PBG slab-arrays with strong field confinement. On the other hand, non-resonant eigenmodes outside the band gaps are freely radiated through the lattices, which are thereby strongly suppressed in the channel. Figure 2 shows dispersion curves, (a), of the TEM waveguide with the staggered vane arrays and transmission spectra of the photonic crystal slab, (b), and the PBG-slab embedded TEM waveguide, (c), with respect to two filing ratios, r/a = 0.2 and 0.3. In Fig. 3(b), the crystal slab arrays with r/a = 0.2 and 0.3 have three band gaps below the coalesced mode (upper cutoff) of the fundamental passband (a). Therefore, only the eigenmodes in the band gaps are allowed to propagate through the beam channel. Figure 3(c) shows an apparent emergence of three spectral bands with zero insertion loss which are exactly matched with the band gaps in Fig. 3(b). The background loss level of radiative non-PBG modes is about _45 dB that is low so as not to cause an abnormal beam-wave interaction. In Figs. 2(b) and 2(c), it is readily noticeable that the band-gap widths of r/a = 0.3 is only about half of widths of r/a = 0.2, which implies that increase of the rod size relative to the lattice constant leads to raising population density of guided photonic eigenstates with narrowing their intrinsic bandwidths. This indicates that the active spectral range and dispersion characteristics of confined waves are primarily determined by a lattice constant and a filling ratio of the photonic crystal filter rather than by the grating dimensions.

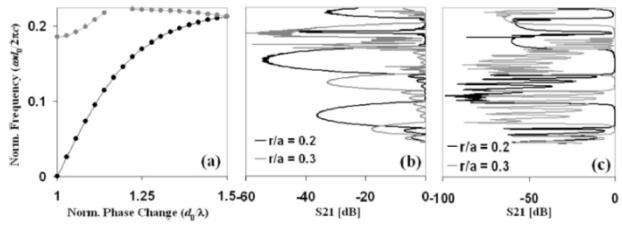

Figure 2: (a) 0_{th} order dispersion graph of TEM-mode SWS and transmission spectra of the PBG-slabs (b), and the PBG slab-arrayed SWS (c), of r/a = 0.2 (black) and 0.3 (grey).

The simulation models in Figures 2 and 3 are designed to be the ideal TEM-mode waveguide with the magnetic boundaries in the major transverse axis that appear impractical in actual application. The actual device model is thus designed with the oversized TE-mode waveguide that has an electric boundary. Figure 3(a) is the dispersion curves of the two slow waveguide structures embedded with the grating arrays (grey) and the photonic crystal slab arrays (red) that are procured by the finite-integral-technique (FIT) eigenmode solver.

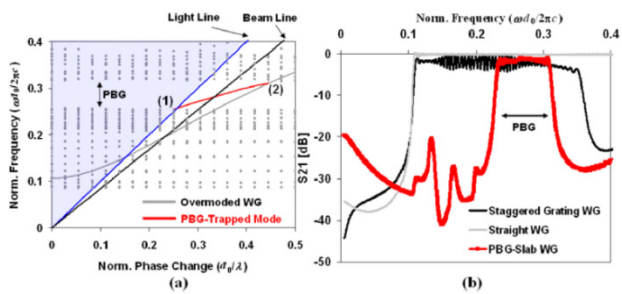

Figure 3: (a) 0_{th} order dispersion graphs (band-diagram) of the PBG-slab-arrayed SWS and TEM-mode SWS. (b) Transmission spectra (S21) of staggered grating waveguide, straight waveguide, and PBG-slab-arrayed waveguide.

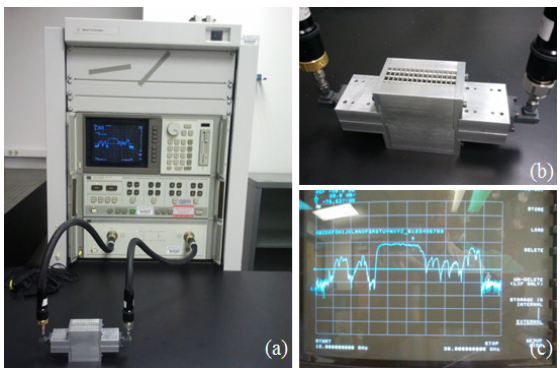
The blue-shaded and white colored areas represent the photonic zone (far-field, $k < 2\pi/\lambda$) and plasmonic one (near-field, $k > 2\pi/\lambda$), respectively. The plotted points indicate all scattering modes corresponding to a phase change per period of the staggered corrugation. These unguided waves travel around and radiate in free space, and therefore have no interaction with the electron beam. In Fig. 3(b), the global band-gap noticeably emerges from f = 0.265 to f = 0.31 at either the photonic or plasmonic

Copyright © 2013 CC-BY-3.0 and by the respective authors

wave area. There is no other photon mode than interactive plasmon modes in the first forbidden band. The channel confined interaction modes disappear beyond the stop-band as they radiate to annihilate owing to the non-resonant matching condition with the crystal lattices. Note that the PBG-modes are considerably more dispersive than fundamental eigenmodes of the oversized waveguide (grey line). Figure 4 (a) shows a K-band test device machined and assembled with two PBG slabs. The reflection and transmission coefficients (S_{11} and S_{21}) are measured by a vector network analyzer (HP8510C), as shown in Fig. 4(b). The experimental data, well agreeing with simulation result, clearly show the PBG band in the transmission spectrum. The transmission spectrum of the PBG band is ~ 25 dB higher than that of the non-resonant band.



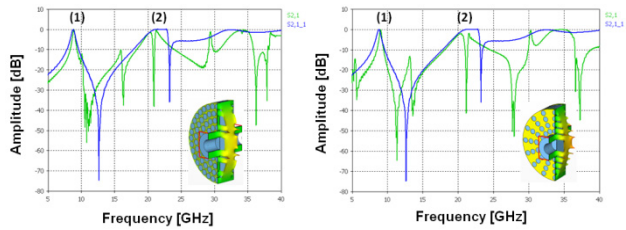


Figure 4: (a) Experiment setup with HP8510C vector network analyzer (b) K-band test device (c) transmission spectrum (S_{21}) of 12 – 38 GHz.

FISHNET-METAMATERIAL RF CAVITY

A higher frequency SRF cryomodule will make a great benefit that can save construction and operation costs, in addition to reduce a physical size of facility and to increase accelerating gradients. Also, operating at high frequency and low bunch charge reduces the risks of brightness degradation during beam transport. However, presence of higher-order-mode (HOMs) wakefields in the high-Q cavities possibly decreases RF energy conversion efficiency, plus inducing thermal heating. Especially, for high-duty-factor machines the heat is not easily extracted, which possible causes deformation or even quenching. The wakefields, normally proportional to a cube of the frequency, can significantly reduce luminosity and cause a beam breakup (BBU), which can severely destabilize acceleration and collision of beams in the long-pulse or CW mode operation. A fishnet structure [ref], consisting of the sandwiched metal-dielectric-metal layer [2 – 4], is one of the simplest double negative meta-materials with negative refractive indexes at resonances. The negative field response can efficiently remove HOMs from a beam interaction area over the broad spectral range. We designed two types of pillbox cavities with fishnet absorbers. Figure 5 shows the cavities strongly suppress a level of HOM wakefields down to - 30 ~ 40 dB in the transmission spectrum. Note that the accelerating mode becomes much narrower with the fishnet-embedded cavities. It is found that a small size cavity with the same physical dimensions with an accelerating mode (TM_{010}) cavity can be used to suppress or filter HOMs with the structure (over-sizing cavity volume is unnecessary). We also observed that implementing the structure in the cavity doubles Q-values (loaded Q, Q_L). It is expected that negative dispersion response of the novel RF component have potential to advance SRF technology and we will look into its field characteristics and thermal properties of HOMs by simulation and experimentation.

(a) (b)

Figure 5: Transmission spectrums of fishnet metamaterial RF cavities (a) type-1 and (b) type-2 ((1) TM010 and (2) HOM)

CONCLUSION

The staggered double PBG-slab arrays enable over-moded planar slow waveguides to induce monochromatic wave propagation of a single plasmonic mode within a narrow band-gap. This highly selective band filtering noticeably improves spectral purity of plasma-interactive evanescent waves in the over-moded slow waveguides, free from the instability problems. A fishnet meta-material absorber strongly suppresses HOM wakefields down to – 30 ~ 40 dB range in a high-Q RF cavity. The quasi-optical mode-filtering/damping/absorbing devices support efficient energy conversion, which can be utilized as a passive or active component for various optoelectronic and electron beam devices.

Abstract

Crystal channeling technology has offered various opportunities in accelerator community with a viability of ultrahigh gradient (TV/m) acceleration for future HEP collider in Energy Frontier. The major challenge of the channeling acceleration is that ultimate acceleration gradients might require high power driver at hard x-ray regime (~ 40 keV), exceeding those conceivable for x-rays as of today, though x-ray lasers can efficiently excite solid plasma and accelerate particles inside a crystal channel. Moreover, only disposable crystal accelerators are possible at such high externally excited fields which would exceed the ionization thresholds destroying the atomic structure, so acceleration will take place only in a short time before full dissociation of the lattice. Carbon-based nanostructures have great potential with a wide range of flexibility and superior physical strength, which can be applied to channeling acceleration. This paper present beam-driven channeling acceleration concept with CNTs and discuss feasible experiments with the Advanced Superconducting Test Area (ASTA) in Fermilab and beyond.

INTRODUCTION

The cost models of the modern colliders are quite complicated, but one may safely assume that a future facility should not exceed a few tens of km in length and simultaneously require less than 10 to a few tens of MW of beam. To get to the energies of interest within the given footprint, fast particle acceleration is inevitable. Plasma-wakefield acceleration (PWA) has become of great interest because of the promise to offer extremely large acceleration gradients, on the order of E0 ≈ n01/2 [GeV/m], where n0 is the ambient electron number density (n0 [1018cm-3]), on the order of 30-100 GV/m at plasma densities of n0 = 1017 – 1018 cm-3.[1] The density of charge carriers (conduction electrons) in solids n0 = ~ 1020 – 1023 cm-3 is significantly higher than what was considered above in plasma, and correspondingly, wakefields of up to 100 GeV/cm or 10 TV/m are possible. In the solid plasma, as escaping from a driving field due to fast pitch-angle diffusion resulting from increased scattering rates, particles must be accelerated along major crystallographic directions. This is called "channeling acceleration". Normally, crystal channeling has been applied to high energy beam control such as collimation, bending, and refraction [2]. For high energy beam optics, carbon nanotubes (CNTs) have been considered for bending and collimation [3, 4] on account of the much wider range of flexibility, including superior physical strength, which also ideally fits with channeling acceleration. CNTs, composed of graphene sheets rolled into seamless hollow cylinders with diameters ranging from 1nm to about sub-micron, exhibit unique physical and chemical properties as a quasi-one dimensional material [5]. In principle, both straight and bent CNTs can effectively be used for high-energy particle channeling [6], provided the technological challenge of achieving an almost perfect alignment of CNTs with respect to the beam direction could be tackled effectively in the synthesis of samples.

Recently, Fermilab built the Advanced Superconducting Test Accelerator (ASTA) facility (50 MeV and several hundreds of MeV energy beams) that will enable a broad range of electron beam-based experiments to study fundamental limitations to beam intensity and to developing transformative approaches to particle-beam generation, acceleration and manipulation, which is ideally suited for the channeling acceleration experiment. We plan to detect a measurable energy gain from the electron bunches passing through CNTs. Successful demonstration of the experiment with this beam driven method will verify the viability of CNT channeling interaction for ultra-high gradient acceleration, which will also prove the feasibility of the laser-driven channeling acceleration. The experimental setup will be accommodated to a 50 MeV main stream beamline and high energy (50 – 300 MeV) beamline in our plan. In the research, beam energies and radiation spectra of CNT samples will be mainly characterized by beam tests at relativistic regimes.

CHANNELING ACCELERATION

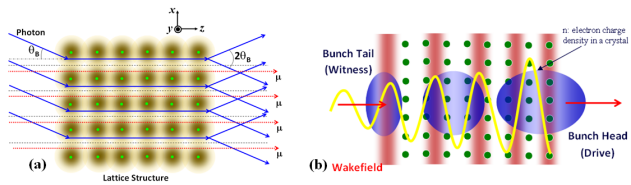

Figure 1: (a) Laser (x-ray) driven acceleration (muon, proton) (b) beam-driven acceleration (electron).

Wakefields in crystals can be excited by two sorts of driving sources: x-ray laser (Fig. 1(a)) or short electron bunch (Fig. 1(b)). With the x-ray pumping method [7], a crystal channel can hold > 1013 V/cm transverse and 109 V/cm longitudinal fields of diffracted traveling EM-waves at the Bragg diffraction condition ($\lambda/2b = \sin\theta B$), where b is the lattice constant and θB is the diffraction angle) However, to hold the ultimate gradients, the acceleration requires coherent hard x-rays ($\hbar\omega \approx 40$ keV) of ≥ 3 GW to compensate for radiation losses, which

Copyright © 2013 CC-BY-3.0 and by the respective authors

exceed those conceivable today. The x-ray driving method thus fits for heavy particles, e.g. muons and protons, which have relatively smaller radiation losses. For electrons, the beam-driven acceleration is more favorably applicable to channeling acceleration as the energy losses of a drive beam can be transformed into acceleration energy of a witness beam [8]. The highly intensive plasma interaction in a crystal channel induces thermal radiations and collisional impacts accompanied by a large amount of heat energy, which would exceed the ionization thresholds and may even destroy the atomic structure. Only disposable forms of crystals such as fibers or films can be used for channeling acceleration. Also, lattice structures of crystals have fixed atomic dimensions, which thereby have some limits in designing acceleration parameters to mitigate physical constraints in solid plasma channels. Carbon nanostructures have potential advantages over crystals for channeling acceleration such as wider channels (weaker de-channeling), broader beams (using nanotube ropes), wider acceptance angles (< 0.1 rad), 3D beam control over greater lengths, and in particular excellent thermal and mechanical strength, which are ideally fit to channeling acceleration and cooling applications, plus beam extraction, steering, and collimation. CNTs are comprised entirely of *sp*2 bonds, which are extremely stable and thermally and mechanically stronger than crystals, steels, and even diamonds (*sp*3 bond). Nanotubes thus have a higher probability of surviving in an extremely intense channeling, radiation, and acceleration environment.

Plasma frequencies of CNTs are normally in the THz range, which need a beam bunch duration within an order of microns for wakefield generation in the linear regime, an electron bunch in the pico-second range, which is readily obtained from conventional RF photoemission technique, would need to be either compressed down to an order of a femto-second or split into microbunches. It is well known that injecting a driver beam with multiple microbunches in a plasma channel improves field gradient, transformer ratio, and energy efficiency of plasma wakefield acceleration. With the multiple microbunches, phase matching conditions between a plasma wave and a modulated beam can be selectively tuned in order to maximize wakefield, transformer ratio, or energy efficiency.

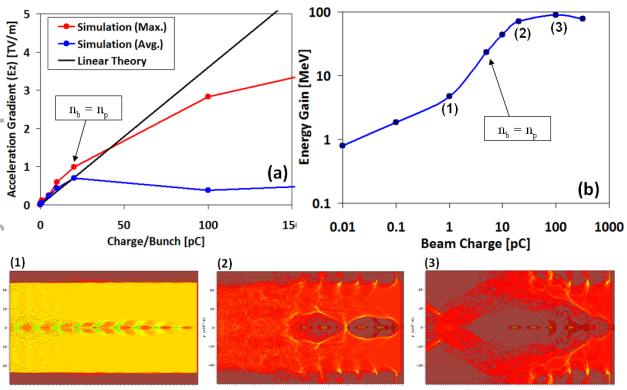

Figure 2: Channeling acceleration analysis, obtained from the linear wakefield theory and computer simulations: top - (a) acceleration gradients and (b) energy gain versus beam charge and bottom - spatial charge distributions of plasma and beam (1) 10 pC (2) 200 pC (3) 1 nC.

SIMULATION ANALYSIS

The basic pattern of channeling acceleration has been analyzed by theoretical model and computer simulation with the nominal ASTA beam parameters: bunch-to-bunch space = 10 μm, beam energy = 50 MeV, charge density of plasma channel = 10^{25} m^{-1}, bunch length = 2 ~ 3μm. Figure 2 shows summarized acceleration gradient and energy gain graphs with respect to beam charges, obtained from the 1D linear wakefield theory and plasma accelerating simulator (VORPAL). The simulation data agree well with the theoretical graph in the linear regime. This result clearly verifies that micro-spaced electron bunches gain energy up to ~ 70 MeV (~ 200 pC) along a 100 μm long channel, corresponding to a ~ 0.7 TeV/m acceleration gradient. The analysis indicates that further increase of the beam charge excessively blows out the ambient plasma charges in the channel ((3) of Fig. 3: bottom). It strongly pushes plasma waves out of phase-synchronization with the beam wave, which rather decreases the energy gain. The analyzed parameters will be implemented into the design process of the experimental setup. This kind of simulation method will be continuously used to analyze/design the beam-driven accelerator with various channeling conditions.

EXPERIEMNTAL LAYOUT

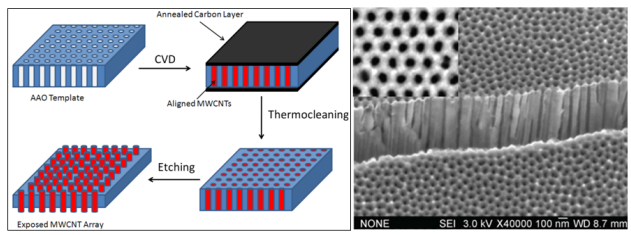

Figure 3: (a) Schematic diagram of an AAO template process (b) SEM image of an AAO film, inset is the enlarged SEM image.

Two kinds of channeling accelerator structures, crystals (silicon or diamond) and arrayed CNT bundles, will be manufactured and tested and compared in the first experiment. Crystal samples will be obtained by a similar fabrication technique used for silicon samples in channeling experiments in Tevatron of Fermilab: cleaved and cut silicon wafers [9]. The sample holder, used for the experiment, will also be re-used for crystal acceleration tests, but only with the straight section (no bending). A test device with a straight multi-wall CNT bundle will be prepared using an anodic aluminum oxide (AAO) template (Fig. 3(a)) [10]. We plan to test a 100 μm long, 200 nm wide CNT structure first, which may possibly be manufactured within 2 ~ 3 months. It is expected that these types of crystal channels induce plasmonic waves of $\lambda_p \leq \sim 10$ μm.

Copyright © 2013 CC-BY-3.0 and by the respective authors

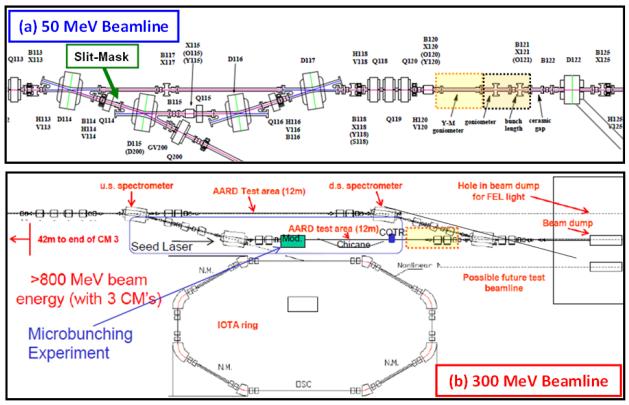

Figure 4: Prospective locations of experiment setup: 50 MeV beam line (top) and 300 MeV (bottom).

As we plan to conduct the 1st experiment at 50 MeV beamline of the Fermilab-ASTA, test equipment will be installed downstream of the capture cavity-2 (CC-2) and bunch compressor before the 1st cryomodule. Figure 4 shows the beam line drawing, describing the currently planned location of the proposed experiment. The boxed areas indicate prospective locations of the vacuum-compatible goniometer to be loaded with a test sample. While passing through the BC, the slit-mask placed in the BC will produce microbunch trains by imprinting the shadow of a periodic mask onto a bunch with a correlated energy spread. Once passing through a test device in the goniometer, beam energies will be measured by a spectrometer with a dipole magnet and yttrium aluminum garnet (YAG) screen positioned in the beamline toward a beam dump. A test with higher energy beams is also planned, so the experiment will be accommodated to the Development of a Compact Photo-injector with RF-Focusing Lens for Short Pulse Electron Source Application mainly consider the slit-mask technique, which is the simplest way to create multiple sub-ps micro-bunches [11], and an inverse free electron lasing technique. Currently, a laser-induced microbunching (LIM) scheme with the FEL undulator is proposed in the ASTA stewardship program, which is potentially employed to generate microbunches to the channeling acceleration test.

The proposed experimental scheme will need several positions to monitor bunch profiles and measure their spatiotemporal radiation patterns and energy spectra of accelerated beams. We measure the time pattern of a masked beam entering the dispersion-free region of the beam line using coherent transmission radiation (CTR) interferometry. The broadband transition radiation emitted by the electrons when entering a copper mirror placed after the dogleg, near the experimental region, is sent to a Martin-Puplett interferometer. After the energy-analyzed and collimated beam of electrons is transported through the bunch compressor into the experimental area, it is defocused by an asymmetrically split quadrupole triplet to give a low-divergence (nearly parallel) beam incident upon the crystal in its goniometer. A critical factor in performing channeling acceleration experiments is the divergence of the incident beam. Since the characteristic angle for the process is $1/\gamma$, an angular resolution at least an order of magnitude smaller is required in order to obtain data of sufficient precision to compare with the results of theoretical calculations; for $\gamma \sim 100$, a beam divergence larger than 1 mrad is inadequate. Moreover, the critical angle for channeling is a few mrad for electrons of a few tens of MeV, and varies as $\gamma^{-1/2}$; therefore, in order that a large fraction of the beam be channeled, a beam divergence ≤ 1 mrad is required. The experimental arrangement is used for obtaining a very-low-divergence beam, which is used as well for measurements of the transmission of electrons through crystals.

CONCLUSION

Despite the great potential of HEP colliders, excessively high driving energy and power requirements accompanied by the insufficient durability of crystal structures has removed channeling acceleration from primary consideration for high gradient (HG) accelerators. However, replacing crystals with nano-structures makes this possible by mitigating the power and energy requirements, with the advantage of improved physical strength. The fundamental mechanisms of plasmon excitation and photon-particle coupling of the nanotube can thus be studied at Fermilab-ASTA. Successful demonstration of all the simulations and experimental tests will open new opportunities for HG accelerator research efforts by merging nanotechnology and high energy physics. All of the new techniques and methods developed from heuristics will indeed be incorporated into existing technologies for current HEP collider R&D programs.

ACKNOWLEDGEMENT

We thank Alex Lumpkin for his suggestion on micro-bunching technique. We thank Philippe R. G. Piot for helpful discussion and support for the proposal and Chris Prokop for sharing his ASTA simulation design parameters.

Abstract

The Neutralized Drift Compression Experiment (NDCX-II) is a new induction accelerator facility designed to facilitate user experiments in high energy density laboratory physics, intense beam physics, and materials processing and testing with intense, pulsed ion beams. The facility has completed the initial commissioning phase of its injector, 27-cell solenoid transport lattice, induction accelerator modules and non-neutral pulse compression section. Space-charge-dominated Li^+ beams carrying 20-50 nC have been generated from the 133 kV pulsed, ~1.0 microsecond (FWHM), 65-mA injector, and compressed to 20-30 ns with 0.75-1.3 A peak currents and amplification factors of 10-20. We report results of non-neutral beam compression and transport studies to generate variable ion beam fluences on to solid targets. We also report on studies of dose rate effects in pulsed ion implantation and on the recombination dynamics of radiation-induced defects in semiconductors using the NDCX-II Li^+ beam.

INTRODUCTION

The NDCX-II facility [1, 2] was constructed between July 2009 and December 2012. Commissioning results of the source and injector systems has already been reported [3]. The induction accelerator modules with pulsed, 2-3 T solenoid magnet transport were added in several stages (5-cell, 11-cell, 27-cell) to facilitate the integration of diagnostic and controls systems [4].The 27-cell beamline configuration is shown in Fig. 1, with schematic representation indicating the position of the active induction cell modules, diagnostic cells, injector and end station. Each cell is instrumented with a pulse solenoid for transport.

The original complement of beam diagnostics for commissioning included a movable end station complemented with a Faraday cup, slit and slit-cup pairs, and scintillator viewable through downstream flange window. A pepper-pot mask and dedicated scintillator were added later, with the removal of the slit/slit-cup pairs. Other non-interceptive beam diagnostics included 6 capacitive plate beam position monitors at the diagnostic cell locations, solenoid current transformers, and accelerator cell voltage resistive monitors. This level of beam instrumentation was sufficient for initial beam transmission studies and beam quality measurements.

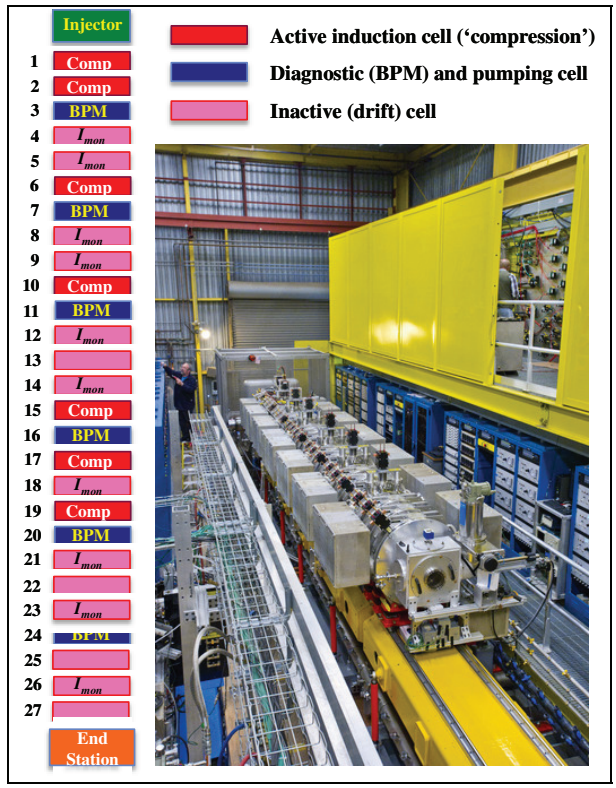

Figure 1: NDCX-II beamline and schematic.

ENHANCED DIAGNOSTICS AND COMMISSIONING STRATEGY

The modular beamline is built up from 21 identical induction cells and 6 diagnostic cells. For these commissioning exercises, only 7 of the induction cells are active, with the remaining inactive cells providing drift length for longitudinal compression. We utilized an additional 10 inactive cells as reciprocal inductive current monitors. The drive matching circuits for these cells were modified to provide a ~5Ω termination, and measured *L/R* response times were in the range of 1.6 – 2.2 µs.

These additional current diagnostics increased the spatial resolution of time-of-flight measurements along the beamline, and permitted determination of velocity and beam energy to within accepted error margins. Furthermore, interpolation of the beam arrival time and beam pulse duration to the active induction cell positions permits fine tuning of the accelerating voltage waveform amplitude and delay, enabling optimization of the bunch compression process and tailoring of the magnetic solenoid lattice.

LONGITUDINAL COMPRESSION AND ACCELERATION

The 7 active induction cells function to impress a time-varying energy (or velocity) ramp on the beam and, with the additional drift lengths between them, to allow the beam to compress longitudinally with concurrent increase in the peak current. The injector and induction cell voltage waveforms are shown in Fig. 2 for a particular tune of delays and amplitudes.

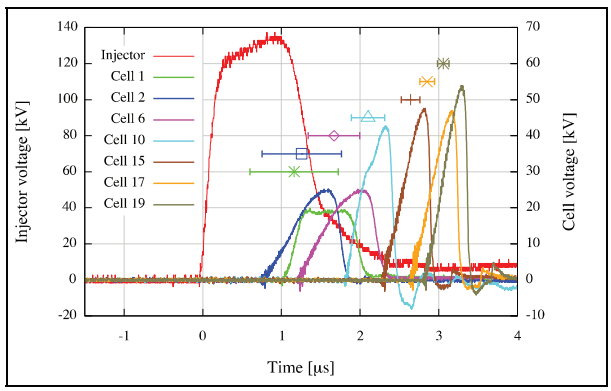

Figure 2: Injector and induction cell voltages. Interpolated beam arrival times and pulse durations are indicated.

Beam line charge density profiles and beam current profiles are measured with the BPMs and inductive current monitors, respectively. The current waveforms are shown in Fig. 3.

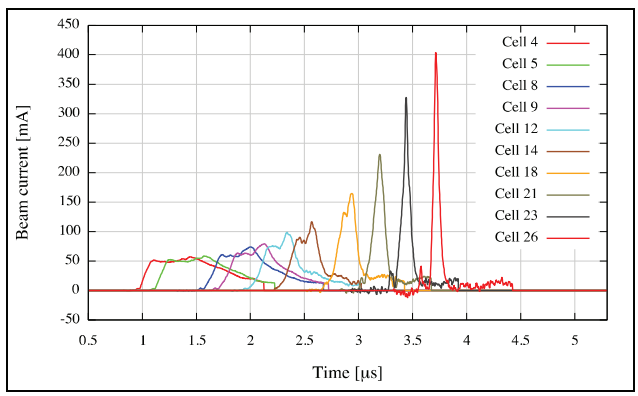

Figure 3: Evolution of beam current profile.

Time-of-flight calculations based on the arrival times of the pulse leading edge at the monitoring stations is used to generate a profile of the beam velocity and energy evolution through the machine. The peak current, average beam energy, and pulse duration (FWHM) are shown in Fig. 4.

BEAM TRANSPORT

Several classes of solenoid focusing lattice tunes were examined for beam matching and transmission in the drifting (i.e. not accelerator or compressed) case. Simple space-charge dominated envelope simulations were performed and are shown in Fig. 5.

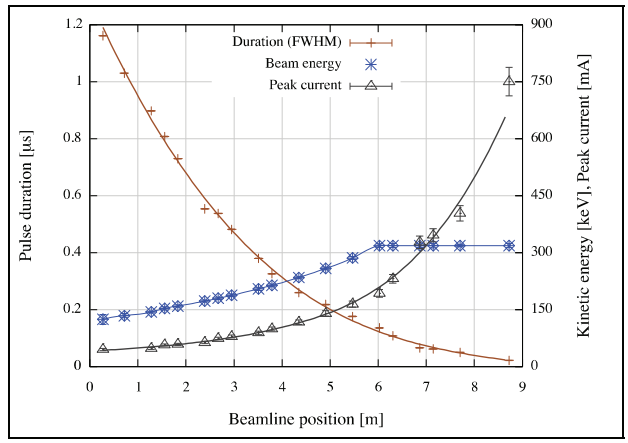

Figure 4: Evolution of longitudinal beam parameters.

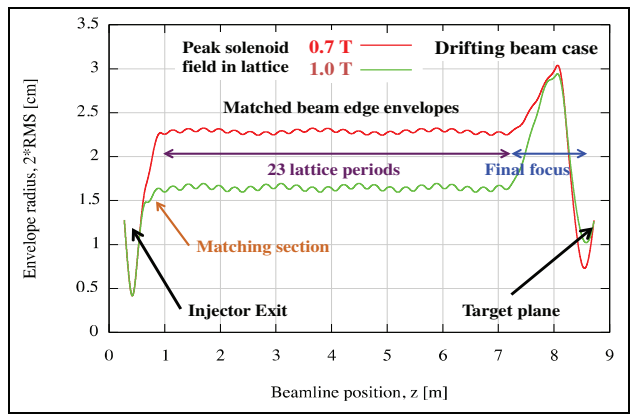

Figure 5: Solenoid transport tune classes for 135 keV, 65 mA drifting beam.

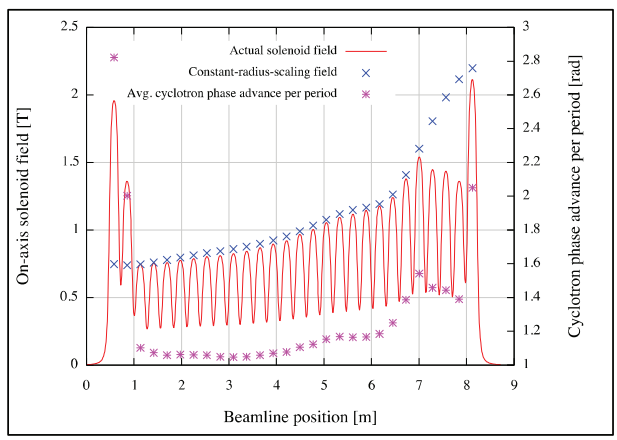

Figure 6: Solenoid field profile match to evolving beam current and energy.

These tune classes provide a basis for tuning the compressed pulse case. Using the field scaling $B^2 \sim I_{pk}/v_{avg}$, where I_{pk} and v_{avg} are the peak currents and average bunch velocity, respectively, we retune the solenoid field (Fig. 6) to maintain constant beam radius along the accelerator.

BEAM EMITTANCE AND FLUENCE

At the target plane, a scintillator captures the beam transverse profile, while a pepper-pot is used to measure the 4D phase space distribution. The last solenoid is scanned to vary the beam envelope and convergence angle. The resultant variation in the radius, peak fluence, and emittances is shown in Fig. 7 for the compressed beam case (Table 1).

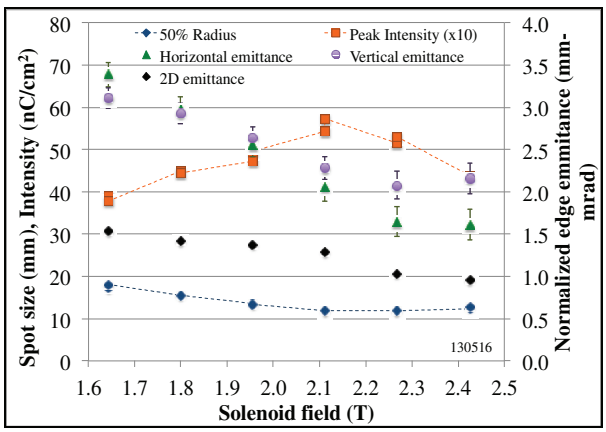

Figure 7: Peak intensity and emittances at target plane.

Table 1: Target Plane Beam Parameters

	Drifting	Compressed
Final energy (keV)	135	315
Peak current (mA)	65	760
Pulse length, FWHM (ns)	450	20
50% beam radius (mm)	5.1	11.8
Average fluence (mJ/cm^2)	3	0.84
Peak intensity (kW/cm^2)	8.8	88

INITIAL TARGET EXPERIMENTS

Intense, short ion beam pulses enable pump-probe type experiments to access the multi-scale (ps to many seconds) dynamics of radiation induced defects in materials [5, 6]. Using NDCX-II, we are conducting studies to examine the pulse length and peak fluence dependence on lattice defect generation and recovery in single crystal silicon and metals. First, we irradiated single crystal silicon (100) samples and performed *ex situ* SIMS (Secondary Ion Mass Spectrometry) analysis of Li ion depth profiles [5]. Here, damage built-up during ion implantation shots reduces the probability for ions to channel along high index crystal directions. When varying dose rates (~0.1 - 50 mA/cm^2) and pulse lengths (~20 - 500 ns), we saw evidence for defect recombination on a 100 ns time scale.

In the next series of experiments we utilize a thin (1-µm) single crystal silicon (100) membrane to intercept the beam. The membrane thickness is chosen to block the randomly scattered ions while allowing the channeled ion flux to pass. A fast Faraday cup (FFC) on the downstream side of the membrane is used to collect the transmitted ions with a time resolution of a few ns. The effect of pulse duration and peak fluence on transmitted beam is shown in Fig. 8. In the long pulse/lower fluence (137 keV, 640 ns, 6 nC) case, the transmitted flux profile reproduces the control case without the Si membrane, indicating low effective angles for the uncompressed beam. In the short pulse case (261 keV, 40 ns, 2.2 nC), the transmitted ion current profile deviates significantly from the control case. For the tuning conditions of this 40 ns shot, ions in the pulse peak are mostly absorbed in the membrane, indicating effective beam angles of a few degrees, while trailing ions later in the pulse transmit the membrane, indicating beam angles <1°. The critical angle for channeling of ~300 keV Li^+ ions in Si (100) is about 1°. Ion transmission tracking provides *in situ* feedback for tuning of effective beam angles. For the short pulse tune in Fig. 8, ions in the peak generate defects (vacancies and interstitials) and the disordered lattice is probed by ions that arrive later on channeling trajectories. For the relatively low dose rates present in the shots shown in Figure 8, we see no evidence for damage built-up. Dose rates will be increased 10 to 50 fold in experiments with shorter (~15 ns), more intense (~40 nC) pulses. Tuning of pump-probe type ion beam pulses shapes [6] and implementation of auxiliary diagnostics will enable unprecedented access to multi-scale defect dynamics in materials.

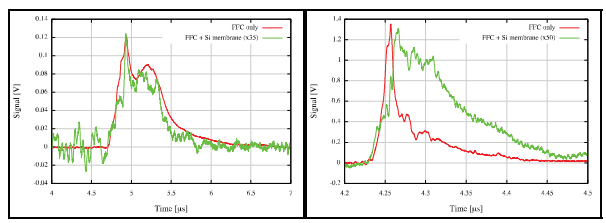

Figure 8: Current traces for a single 640 ns long (left) and 40 ns short pulse, (right), with (green) and without (red) Silicon membrane target in front of the FFC.

SUMMARY

We have implemented diagnostics and tuning techniques to produce a variety of target plane conditions on NDCX-II, with unneutralized pulse compression ratios of 10-20 for high perveance (~10^{-2}) beams. The measured beam quality matches numerical predictions. We present results from experiments that utilize the unique short pulse capabilities of NDCX-II.

Abstract

Betatron x-rays with multi-keV photon energies have been observed from a GeV-class laser-plasma accelerator. The experiment was performed using the 200 TW Callisto laser system at LLNL to produce and simultaneously observe GeV-class electron beams and keV Betatron x-rays. The laser was focused into various gas cells with sizes ranging from 3 to 10 mm, and containing mixed gases (He, N, CO2, Ar, Ne) to accelerate large amounts of charge in the ionization induced trapping regime. KeV betatron x-rays were observed for various concentrations of gases. Electron spectra were measured on large image plates with the two-screen method after being deflected by a large 0.42 Tesla magnet spectrometer.

INTRODUCTION

Laser Wakefield Acceleration (LWFA)[1] is one of the most notable applications of petawatt-class laser systems. Since the discovery that this mechanism can accelerate monoenergetic electron beams up to energies comparable to those obtained with conventional rf accelerators[2, 3, 4] but in a table-top setup, novel applications of these electron beams have been constantly increasing. Concurrently, x-ray sources such as synchrotrons, or more recently free-electrons lasers such as the Linac Coherent Light Source (LCLS)[5] continue to explore new properties of atoms, molecules, condensed matter, warm dense matter or plasmas. In this context, LWFA beams are very attractive to seed the next generation of light sources. Such beams can either be wiggled by an external periodic magnetic structure[6] or directly by the plasma in the wake of the laser pulse[7, 8] to produce keV x-rays. The latter example, the betatron x-ray source, first observed in a beam-driven plasma channel[9] is the subject of this work, and its mechanism can be described as follows: an ultrashort (femtosecond), ultraintense ($I > 10^{18}$ W/cm^2) laser pulse is focused under vacuum on the edge of a gas target. The gas is fully ionized to form a plasma. The laser ponderomotive force (proportional to the gradient of light intensity) plows the electrons of the plasma away from the strong light intensity regions. Because of the very short duration of the laser pulse, the heavier ions stay immobile and a bubble free of electrons is formed in the wake of the pulse. At the back of this bubble, some electrons are trapped, accelerated and wiggled by the electrical fields present in the plasma: these electrons emit the betatron x-rays. This source produces broadband, synchrotron-like radiation in the keV energy range[10, 11], within a source size of a few microns[12, 13], a divergence of less than 100 mrad[14], and a pulse duration of less than 100 fs[15]. Since betatron x-rays are directly related to the electrons emitting them, the source is also widely used as an electron beam diagnostic. The electron beam emittance and size can be deduced from the x-ray beam profile[14], spectrum[16] or source size[17], using various x-ray spectroscopy and imaging techniques. Traditionally, betatron x-rays are produced in the blowout regime of laser wakefield acceleration[18] using pure helium gas, where electrons are self-injected into the wake. This paper investigates the properties of betatron x-ray radiation produced in mixed gases.

BETATRON RADIATION MODELING

The motion of an electron accelerated along $\vec{u_z}$ with momentum $\vec{p}$ and position $\vec{r}$ in the wake of a laser pulse can be described by the Lorentz equation of motion:

$$\frac{d\vec{p}}{dt} = -m\omega_p^2 \frac{\vec{r}}{2} + \alpha \frac{mc\omega_p}{e}\vec{u_z}, \qquad (1)$$

where m is the electron rest mass, e the elementary charge, and $\omega_p = \sqrt{n_e e^2/m\epsilon_0}$ is the plasma frequency. Here, n_e is the electron density, and ϵ_0 the vacuum permittivity. In the blowout 3D nonlinear regime of laser wakefield acceleration [18], $\alpha = \frac{1}{2}\sqrt{a_0}$ is the normalized accelerating field, where a_0 is the laser normalized vector potential, typically around 2 for our experiments. Equation 1 can be solved by using a 4th order Runge-Kutta algorithm to obtain the single electron trajectories for given initial conditions and fields. The electron trajectory is used to calculate the intensity radiated by the particle per unit frequency ω and solid angle Ω [19]:

$$\frac{d^2I}{d\Omega d\omega} = \frac{e^2\omega^2}{4\pi c}\left|\int_{-\infty}^{\infty} \vec{n}\times(\vec{n}\times\beta)\, e^{i\omega(t-\frac{\vec{n}.\vec{r}}{c})}dt\right|^2, \qquad (2)$$

where $\vec{n}$ is the vector corresponding to the direction of observation, and $\beta = v/c$ the normalized electron velocity. The betatron x-ray beam profile is calculated by integrating Equation 2 over frequencies. Figure 1 shows an example of electron trajectory, with its corresponding betatron x-ray spectrum and beam profile. For this particular case, the parameters are $n_e = 10^{19}$ cm^{-3}, $\gamma = 200$, x_0=1 μm, $y_0 = 0$,

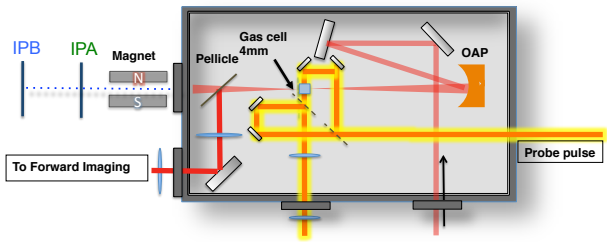

Figure 2: Experimental setup for betatron x-rays production and detection (see text for details).

and $\alpha = 0$. The trajectory was calculated using 3000 time steps (with each unit step $dt = 0.2c/\omega_p$). At each point of calculation of the trajectory, the spectrum and beam profile were calculated using frequency steps of 100 eV. For the chosen parameters, ω_c= 4.2 keV and $K \simeq 6$. The beam has a divergence of $1/\gamma$ and K/γ along the direction parallel and perpendicular to the plane of the oscillations, and the on-axis spectrum peaks at $\sim$ 2 keV. Although more computationally intensive, electrons trajectories obtained from PIC simulations can be post-processed using Equation 2 to calculate the spectrum and profile with a much better resolution[20].

EXPERIMENTAL SETUP

The experiments were conducted at the Jupiter Laser Facility (JLF) using the 200 TW Callisto laser system. Callisto can deliver up to 12 J in a 60 fs pulse (full width at half maximum, fwhm). The 13 cm diameter beam was focused by an off-axis parabola (f/8) onto the 500 μm entrance pinhole of a gas cell. The experimental setup is shown on Figure 2. The laser focal spot size w_0 was measured under vacuum at low power to be 12 μm. The back pinhole is 1 mm wide, and we have used different gas cell lengths (from 3 mm to 10 mm) as well as two-stage designs [21]. The cell was typically filled with He gas, but also with N, CO2, Ar and Ne. Electron densities ranging from 2×10^{18} cm^{-3} to 1.5×10^{19} cm^{-3} were measured for each shot with a 100 fs probe using interferometry in combination with an Abel-inversion code. The laser spot at the exit of the gas cell was imaged using a forward diagnostic, and spectrally resolved using grating and prism-based spectrometers. The electron beams were characterized using a two-screen spectrometer [22, 23]. This system provides an accurate measurement

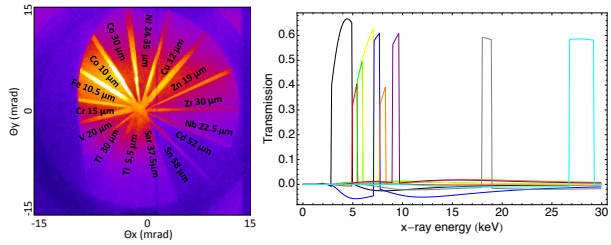

Figure 3: Betatron x-ray beam observed on IP$_a$ through the pie-shaped set of filters (left) and corresponding Ross filter pairs used to measure the spectrum (right). Each pair corresponds to the difference of signal observed through two specific filters. The nine pairs (and their respective mean energy E_n and bandwidth ΔE_n) are, from low to high x-ray energy: 5.5 μm Ti and 37.5 μm Saran (3.9 keV, 2 keV), 20 μm V and 30 μm Ti (5.2 keV, 0.45 keV), 15 μm Cr and 20 μm V (5.7 keV, 0.45 keV), 10.5 μm Fe and 15 μm Cr (6.5 keV, 1.05 keV), 10 μm Co and 15 μm Fe (7.4 keV, 0.53 keV), 24.35 μm Ni and 30 μm Co (8.3 keV, 0.52 keV), 19 μm Zn and 17.5 μm Cu (9.3 keV, 0.6 keV), 22.5 μm Nb and 30 μm Zn (18.5 keV, 0.9 keV), 58 μm Sn and 52 μm Cd (28 keV, 2.3 keV).

of the energy of the electrons, the vertical and horizontal angle that the electrons exit the plasma relative to the original laser axis, the divergence, and the electron charge. The electrons exiting the plasma are deflected in the vertical direction by a 21-cm-long, 0.42 Tesla dipole magnet. The electrons are detected by two successive image plates (IP$_a$ and IP$_b$) allowing for a unique solution to their energy and deflection, provided common spatial features can be identified on both image plates. Both the betatron x-ray beam profile and the x-ray spectrum were measured on the first image plate IP$_a$. At the vacuum/air interface, we used a 12 μm thick Al foil to block the 800 nm light from the laser as well as a 60 μm mylar window to hold vacuum. X-rays (profile or spectrum) are then measured on the image plate. To measure the x-ray spectrum from 1 keV to 30 keV, we used a set of Ross filter pairs, with transmission functions that provide narrow energy bands. The number of x-ray photons per unit energy is given by $N_{ph} = S_n/(T_n \Delta E_n)$, where S_n, T_n and ΔE_n are respectively the signal, transmission and bandwidth of a given energy band. Shown on Figure 3 is a typical x-ray beam observed on IP$_a$ through the pie-shaped sets of filters, as well as the energy bands used in the experiment.

RESULTS AND DISCUSSION

Betatron x-rays where observed in different gases. For the different profiles shown in Figure 4, observed on IP$_a$ through the filters, the x-rays where produced in a 4 mm gas cell containing mixed gases. Although these x-rays where produced in different gases, in order to make quantitative arguments it is important to note that they corre-

Copyright © 2013 CC-BY-3.0 and by the respective authors

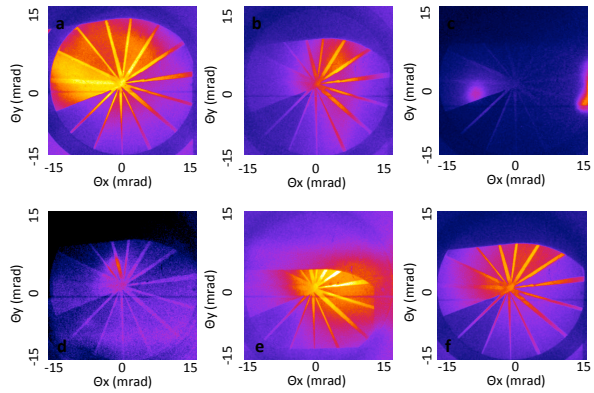

Figure 4: Betatron x-ray beam beam profiles observed on IP_a through the pie-shaped set of filters (see text for details). The gas composition for each shot was (from top left, clockwise): 100% He, 95% He and 5% Ar, 80% He and 20 % N2, 80% He and 20 % N2, 98% He and 2% Ar, 95% Ar and 5% He.

spond to different electron beam energies. The electron beam maximum energy (the largest contribution to the x-rays) is, for each of these shots: 234 MeV, 300 MeV, 385 MeV, 186 MeV, 280 MeV, 125 MeV (from top left, clockwise). Electron densities were in the 5×10^{18}- 1×10^{19} cm^{-3} range for each of these shots and $2 < a_0 < 2.5$. In some cases (Figure 4) the beam profile could be very well observed on both IP_a and IP_b with a 25% transmission from IP_a to IP_b. According to the theoretical and experimental response function and transmission curve of the image plates[24], it means that the beam contains a large amount of x-rays with energies above 20 keV. For this particular case, the electron beam peaked at $\sim$ 385 MeV, where most of the charge was located. Since the critical frequency scales with γ^2 and that in practical units, $\hbar\omega_c$[keV]=$5 \times 10^{-24} \times \gamma^2 n_e$[$cm^{-3}$]$r$[$\mu$m], it means that for $n_e = 10^{19}$ cm^{-3} and $\gamma = 750$, $r \simeq 0.7$ μm when the electrons reach their end energy. The drawback of using filter wedges in our experiments was the beam pointing jitter. As observed on Figure 4, the beam center location varies up to a few milliradians around the filter tips. Since the x-ray intensity and energy strongly depend on the angle of observation (Equation 2), making quantitative statements about the x-ray spectrum requires x-ray measurements be made at the same angular position with respect to the beam center.

CONCLUSION AND PERSPECTIVES

In conclusion we have observed betatron x-rays at energies beyond 20 keV in a collimated beam with <30 mrad divergence. X-rays have been observed in pure He, but also in He/N and He/Ar mixes, which opens several possibilities to improve and control the x-ray flux and spectrum of the source. By taking advantage of electron acceleration in the ionization-induced trapping regime, large amounts of charge can be trapped and produce bright betatron x-rays. Our preliminary measurements support betatron oscillations of $\sim$1 μm in the plasma, but also show that a simultaneous measurement of the x-ray beam profile and spectrum at a particular angle is necessary in order to make quantitative arguments about betatron x-rays production in this regime.

PARTICLE-IN-CELL MODELING OF DIELECTRIC WAKEFIELD ACCELERATOR*

C.-K. Huang#, T. J. T. Kwan, D. Yu. Shchegolkov, and E. I. Simakov, Los Alamos National Laboratory, Los Alamos, NM 87545, USA

Abstract

We explore the potential of Dielectric Wakefield Accelerator (DWA) to achieve compact high gradient acceleration of high brightness beams required by an X-ray Free Electron Laser (FEL). Particle-In-Cell (PIC) simulations of a LANL DWA experimental design utilizing a double triangle beam current profile indicate accelerating field >100 MV/m and large transformer ratio are accessible while the longitudinal wakefield phase is insensitive to beam parameters and radial offset for fixed longitudinal profile. End-to-end simulation is developed, which allows us to validate and optimize future DWA experimental design.

INTRODUCTION

The pre-conceptual design for Matter-Radiation Interactions in Extremes (MaRIE) future signature facility at LANL calls for a 12 GeV electron linear accelerator for hard X-ray FEL production. MaRIE demands a high quality electron beam with the electron bunch charges of 0.1 to 1 nC, normalized RMS emittances of 0.1 to 1 mm, and RMS energy spreads of less than 0.1%. A major deficiency of the conventional accelerator technology is the accelerating gradient that is limited to a few tens of MV/m, which put a severe restraint on the cost and future upgrade of such facility.

The wakefield which causes the dominant energy spread in beams in conventional linacs can be used in carefully designed electromagnetic structures, specifically, dielectric loaded waveguides in this study, to generate extraordinary gradients and potentially small energy spreads for electron beam acceleration. In this paper we present simulation study to assess the characteristics of DWA and its potential applications in advance of experimental validation.

THEORY ON WAKEFIELD IN DWA

Figure 1 shows the schematic of the dielectric-lined metallic waveguide. Here we confine our study to a waveguide with cylindrical symmetric geometry. The theory of wakefield generation in a cylindrical dielectric waveguide is generally formulated in frequency domain and dated back at least to 1951 in Ref. [1], where Bessel's equation for the fields is solved with boundary matching conditions at the dielectric-vacuum interface. In general, the dielectric-lined waveguide supports infinite number of discrete Hybrid EM modes. The supported EM modes have low frequency cut-off determined by the geometric

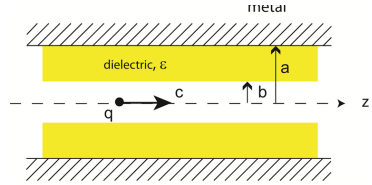

Figure 1: A schematic of the DWA consisting of a dielectric-lined metallic waveguide and an electron beam as the excitation source.

parameters of the waveguide and the dielectric constant ε of the liner materials.

However, for axial symmetric excitation (azimuthal mode number m=0), the TE and the TM modes are decoupled. For co-linear particle acceleration, the TM_{0n} modes are most useful for particle acceleration via the strong longitudinal electric field. While TE modes are detrimental to acceleration but can be used for beam deflection.

In Ref. [1], the dispersion of the TE, the TM and the HEM eigen modes are derived. Similar efforts are found in Ref. [2-4] for resonant modes driven by a moving particle. Here we adopt the notation used in Ref. [3] and summarize the key results relevant to our interests below:

(1) The conditional equation (dispersion relation) for modes with phase velocity $v_{ph} = \beta = v/c$,

$$C(s)=\frac{m^2sk^2}{a^2}\beta^2\left(\frac{\varepsilon-1}{1-\beta^2}\right)^2-s^3\left(\frac{kS_m'(sa)}{S_m(sa)}+\frac{sI_m'(ka)}{I_m(ka)}\right)\left(\frac{sI_m'(ka)}{I_m(ka)}+\frac{\varepsilon kR_m'(sa)}{R_m(sa)}\right)=0 \quad (1)$$

where $k^2=\omega^2(1-\beta^2)/v^2$, $s^2=\omega^2(\varepsilon\beta^2-1)/v^2$, $k_0=\omega/c$, and R_m, R'_m, S_m, S'_m are combinations of mth–order Bessel functions of the first and second kinds as defined in Eq. (35-38) in Ref. [3].

(2) The TM_{mn} longitudinal electric field for a single particle (Green's function),

$$E_{z,mn}(r,\theta,z-vt)=-8e\cos(m\theta)\cos\left(\frac{\omega}{v}(z-vt)\right)\times I_m(kr)I_m(kr_0)\times\frac{K_m(ka)}{I_m(ka)}\frac{T(s)}{sdC(s)/ds}\bigg|_{s=s_n} \quad (2)$$

where

$$T(s)=-\frac{m^2k^4\beta^2}{a^2}\left(\frac{\varepsilon-1}{1-\beta^2}\right)^2-s^2k^2\left(\frac{kS_m'(sa)}{S_m(sa)}+\frac{sI_m'(ka)}{I_m(ka)}\right)\times\left(\frac{sK_m'(ka)}{K_m(ka)}+\frac{\varepsilon kR_m'(sa)}{R_m(sa)}\right)$$

and s_n is the solution of Eq. (1).

To obtain the wakefield generated by a beam, one can convolve (sum) the single particle field from Eq. (2) with the beam profile. For smooth beams, this can be done

with sufficient accuracy using the first few modes excited. However, this procedure will involve more modes if the beam profile has a large Fourier content. A more efficient method is the expansion of the fields into the orthonormal modes of the dielectric waveguide [5]. In addition, evanescence modes that co-move with the beam have to be taken into account for Gauss's law to be satisfied [6].

DWA PROTOTYPE EXPERIEMENT

We attempt to combine the concepts of the dielectric wakefield acceleration and the Emittance Exchanger (EEX) [7] in a unique way to experimentally demonstrate a high-brightness DWA with an acceleration gradient exceeding 100 MV/m and with less than 0.1% induced energy spread in the accelerated beam. The designed DWA parameters are listed in Table 1. ELEGANT simulation is used to track the beam through the beam line elements to the entrance of the DWA. More detail about the beam optics to produce the double triangle drive beam current profile and a witness beam can be found in Ref. [7]. Theoretical analysis [8] indicates that a double triangle drive beam can excite a wakefield with large (>2) transformer ratio.

Table 1: DWA Parameters

Parameter	Value
Inner/Outer radius b/*a*	0.57 mm / 0.662 mm
Dielectric constant ε	3.75
TM mode cutoff freq.	298 GHz
Drive/Witness beam charge	5 nC / 250 pC
Drive/Witness beam length	2.35 ps / 100 fs

PIC SIMULATION OF DWA

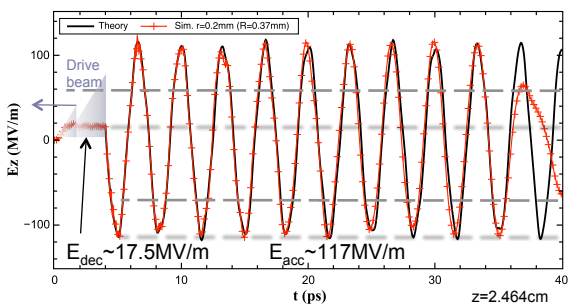

Figure 2: Comparison of theoretical prediction and MERLIN simulation result for the longitudinal wakefield driven by a double triangle beam.

We use PIC codes MERLIN [9] and LSP [10] to model the DWA in 2D cylindrical (r, z) and 3D (r, θ, z) geometries, respectively. We first conduct benchmark with analytic DWA theory presented in Ref. [3] using the same dielectric waveguide parameters defined in Table 1, but with a longer 4 ps, 5 nC, 100 MeV double-triangle beam of a temporal profile described by $f(t) = t$ for $0 \le t \le 0.85$ ps and $f(t) = t - 0.52$ (ps) for 0.85 ps $\le t \le$ 4 ps.

The MERLIN simulation uses stationary box of size 0.662 mm × 30 mm. The simulation box is divided into 133×6000 cells. The dielectric material is placed at 0.57 mm < r < 0.662 mm. The cell size is 0.00498 mm × 0.005 mm and the time step is 11.7 fs. The electron beam is injected from the boundary at z=0 mm. 1600 macro-particles per cell is used for the beam. Perfect Electric Conductor is used at the boundaries at z=0 mm and r = 0.662 mm. Transmitting boundary for particles and fields is used for the boundary at z=30 mm.

Benchmark Result

The longitudinal wakefield in the simulation and the analytical result based on the formalism described in previous section are compared in Fig. 2. The simulation lineout is taken at radius R=0.37 mm when the beam has propagated 2.464 cm into the DWA. Good agreement between the simulation and theoretical result is seen for the wakefield generated in the beam (the decelerating field) and behind (periodic accelerating and decelerating fields). Lineout on the axis shows similar agreement but is noisier. The deceleration field within the drive beam is nearly flat, which is a consequence of the double-triangle drive beam current profile and important for a high transformer ratio (in this particular example, E_{dec}≈17.5 MV/m and E_{acc}≈117 MV/m, leading to a transformer ratio of about 6.7). The difference at t >35 ps is due to the transient behavior of the wake excitation near the DWA entrance.

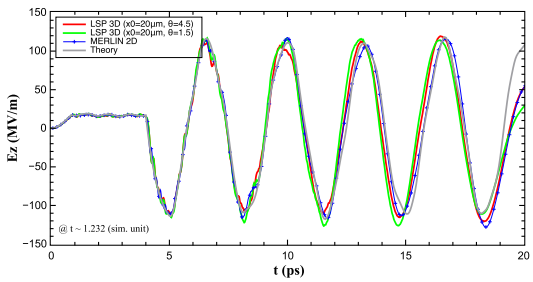

Figure 3: Comparison of the wakefield generated by on-axis beam (MERLIN) and off-axis beam (LSP, shifted by 20 μm at θ=0) at t=41 ps. The simulation lineouts are taken at R=0.04 cm and θ=1.5, 4.5.

When the transverse shape of drive beam is varied among a radial flat-top profile with radius of 0.2 mm (result shown in Fig. 2) and a Gaussian profile with spot size of 0.165 mm and 0.0825 mm respectively (not shown), the longitudinal dependence of the longitudinal wakefield shows little variation in overall shape but different noise levels (noisier for narrower beam). The former observation is consistent with Eq. (2) where the longitudinal and radial dependences are completely separate. On the other hand, higher longitudinal resolution simulation indicates that the noise is a numerical artifact, which mostly results from under-resolving the sharp edge of the double triangle beam.

Copyright © 2013 CC-BY-3.0 and by the respective authors

The wakefield of an off-axis beam in LSP simulation is compared to the MERLIN simulation and the theory in Fig. 3. The result shows that its longitudinal dependence is largely unaffected by the shift as the theory predicts.

End-to-End Simulation of DWA

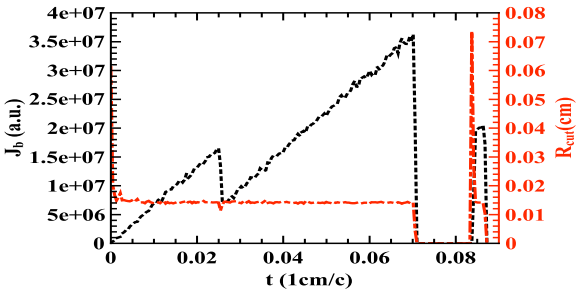

Figure 4: The on-axis beam current density (black) from the ELEGANT and the calculated cut-off radius (red) for the symmetrized Gaussian beam distribution.

Although our benchmark shows reasonable agreement between the DWA analytical theory and simulation, experiment conditions are often non-ideal, requiring more realistic simulation to validate the experimental observations and to optimize the design. It is important that this can be done in an end-to-end type simulation where beam particles are tracked through various beam-line elements and modeled self-consistently in the DWA. For this purpose, we started developing a link between the beam tracking code ELEGANT and the electromagnetic PIC codes. We have built such a prototype code for linking with the 2D cylindrical code MERLIN. The particles are taken from the ELEGANT simulation, resampled (described below) and injected into MERLIN simulation, while the transverse beam fields are first calculated in a quasi-static solver similar to Ref. [11] and subsequently imported into the MERLIN simulation as initial conditions. For relativistic beams, the beam fields are predominantly quasi-static fields and the longitudinal fields can be ignored, therefore a quasi-static solver would be sufficient (an advantage of this approach is the removal of the image charge at the DWA entrance in the simulation). Because of the cylindrical nature of the MERLIN code, we need to apply an extra step to slice and symmetrize the beam particle population (not necessary in 3D simulation). We assume the beam has a cylindrically symmetric Gaussian shape at the entrance of the DWA and calculate a cut-off radius according to the following formula for each slice,

$$Q(z) = 2\pi \int_0^{R_{cut}} \frac{J_{b0}(z)}{e} e^{-r^2/\sigma_r^2} r dr \qquad (3)$$

where $Q(z)$ and $J_{b0}(z)$ are the total charge and on axis longitudinal current density of the each beam slice from the ELEGANT data.

Figure 4 shows the calculated cut-off radius using this approach. Figure 5 shows the charge density of the beam injected into the MERLIN simulation and the longitudinal wakefield generated in the DWA.

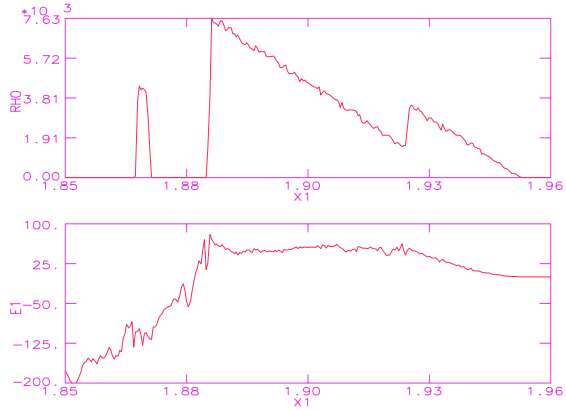

Figure 5: (Top) The on-axis beam charge density in an end-to-end simulation of DWA using MERLIN and input from ELEGANT and parameters in Table 1. Both drive and witness beams propagate to the left. (Bottom) The longitudinal wakefield generated (x_1 in cm and E_1 in MV/m). An accelerating field >100 MV/m together with a transformer ratio >3 are observed. The field noises are mostly due to the under-resolved sharp edge of the beam.

SUMMARY

We have carried out 2D and 3D PIC simulations of the DWA concept for potential application in high gradient compact accelerator. Simulations show good agreement with the analytic DWA theory for the accelerating field, the transformer ratio and the longitudinal dependence of the accelerating field with respect to the transverse beam shape and offset. End-to-end simulation shows that the LANL proof-of-principle DWA design can achieve an accelerating field >100MV/m and a transformer ratio >3.

Abstract

Dielectric wakefield accelerators (DWA) can produce high accelerating gradients and could possibly be used as afterburners for the accelerators of future free electron lasers (FELs) such as X-ray FEL of the proposed Matter-Radiation Interactions in Extremes (MaRIE) experimental facility at LANL [1]. With a double triangular drive bunch DWAs can produce a high transformer ratio. Also, by slightly customizing the time profile of the accelerated bunch it is possible to achieve high gradient uniformity along the accelerated bunch resulting in a low induced energy spread [2]. We plan to test a DWA which would incorporate all those benefits. The only way to produce the desired current profile of the main and drive bunches is to use current shaping with a beam mask. A variation of this technique is currently used at Accelerator Test Facility (ATF) at Brookhaven National Laboratory (BNL) which is available for outside users' experiments.

We report our recent beam shaping experiments at BNL for a transformer ratio test. We used a 58 MeV energy chirped electron beam and a single dogleg with a beam mask inserted in a region where the beam transverse size was dominated by the correlated energy chirp. Both measurement results and Elegant simulation data are presented.

INTRODUCTION

A demand for compact accelerators has recently resulted in an increased interest in dielectric wakefield accelerators (DWAs). The DWA is formed by one or several co-axial dielectric layers surrounded by metal cladding (Fig. 1) [3]. Wakefields in dielectric structures may reach gradients on the order of 10 GV/m [4] with 100 MV/m being demonstrated in multiple experiments [5]. They also have the remarkable property that the wakefield's axial electric field and the transverse electric field are transversely uniform and linear, respectively. This is due to the fact that the relativistic drive beam and the subsequent wakefield travel very nearly at the speed of light. If one can make the wakefield to be longitudinally constant along the bunch it will result in no induced energy spread within the bunch, leading to an extraordinary condition of preserving the main beam brightness while providing high gradient acceleration. We have realized that by a proper longitudinal customization of the accelerated beam the induced energy spread in a DWA can be made small enough (<0.1%) to satisfy tight requirements for X-ray free electron laser linac afterburner of the proposed Matter-Radiation Interactions in Extremes (MaRIE) facility at LANL [1, 2, 6].

An important characteristic of the wakefield acceleration is a transformer ratio (TR). It is the ratio of the peak accelerating gradient to the peak decelerating gradient experienced by the drive bunch, and thus it determines how long the drive bunch will be stable before some part of it decelerates to low energies. For a finite length longitudinally symmetric bunch the TR can never exceed 2 [7]. An enhanced TR can be achieved with a ramped beam or a ramp-profiled bunch train [7]. Recently a Double Triangular (DT) beam shape was proposed making possible high TRs with almost uniform drive bunch deceleration [8]. In the DT bunch the TR is approximately proportional to the beam length in wavelengths of the induced wakefield radiation and thus can be made very large.

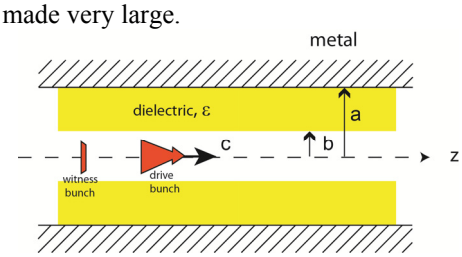

Figure 1: The schematic of a dielectric loaded waveguide with shaped electron bunches traveling on axis.

The main obstacle on the way to experimental demonstration of superior properties of the DWA with a DT drive beam is that the DT bunch shapes are difficult to produce in the submillimeter scale required for ~300 GHz DWAs using conventional methods based on direct beam current modulation. One of the actively popularized methods to shape the beam currents in such a small scale is based on an emittance exchanger technique [9]. It is easy to shape the transverse beam profile using a mask. The emittance exchanger allows to convert a transverse particle distribution into longitudinal. However this method is relatively new and not available at any user accelerator facility although it has already been verified at the Fermilab A0 Photoinjector [10]. A relatively simpler technique is used at Accelerator Test Facility (ATF) of BNL [11] which also allows current shaping on the required scale. It utilizes an energy chirped beam which is cut with a transverse beam mask placed inside of the beamline dispersive region where one transverse coordinate is linearly related to both the particle energy and arrival time.

We studied the possibility of using the ATF facility at BNL for demonstrating high gradient high transformer ratio operation of a DWA with a double triangular beam.

THE BEAMLINE SET-UP

The electron beam at the ATF is produced with an S-band RF photoinjector followed by an S-band linac. After the linac the beam can be directed to one of three different beamlines. For our experiment in May, 2013 we used the beamline #2. The system parameters relevant to the experiment are listed in Table 1. A linear energy chirp in time was produced by accelerating the beam off the crest of the RF wave.

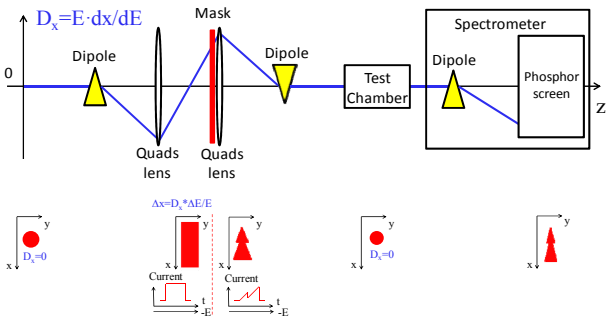

Figure 2: Principal of beam shaping: simplified scheme with only essential beamline elements pictured. Top plot shows dispersion evolution caused by the beamline elements. Bottom plots show particle distributions in different locations along the beamline.

Table 1: ATF Beamline #2 Beam Parameters.

Beam energy	58 MeV
Beam current	100 A
Pulse shape	Square
Pulse duration	5 ps
Repetition rate	1.5 Hz
Beam transverse profile	Gaussian
Normalized transverse emittances	≈ 2 mm*mrad
Typical energy chirp, ΔE/E	1.5%
Beamline dispersion, D_x	≈ 1 m

Figure 2 illustrates the principal of beam shaping employed at the ATF. Several quadrupole magnets are used inside of the dispersion region in the dogleg to minimize the beam x-beta function on the mask to make the beam size due to the dispersion strongly dominate over the beam size caused by a transverse emittance. The dogleg is followed by a zero dispersion region with a vacuum chamber where a DWA can be installed on a motorized mount. The last beamline element is a spectrometer. The spectrometer consists of a single dipole which produces dispersion, a phosphor coated metal screen and a high resolution camera. It also has a set of quadrupole magnets for minimizing the beam x-beta function on the screen. The brightness of pixels in the pictures from the camera is proportional to the density of electrons hitting the surface of the screen. There is also a number of pop-up phosphor screens with cameras along the beamline which are used to visualize the beam during a tuning of magnets process which had to be performed every day after the accelerator was warmed up. The beam parameters, including emittances, varied at the linac output quite substantially from day to day. Figure 3 shows the plots of the beam twiss parameters inside the whole beamline starting from the linac output with magnets' currents optimized in MAD-X [12] for beam shaping for some realistic set of initial beam parameters. At the top of Fig. 3 there is a scheme with all magnets, excluding weak dipole magnets used for fine beam steering, positioned along the beam path.

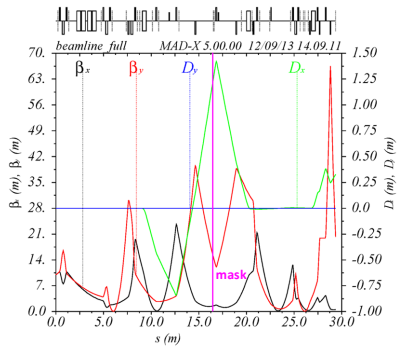

Figure 3: Twiss parameters as modeled in MAD-X vs the beam propagation distance with the mask location marked.

BEAM SHAPING EXPERIMENT

We used a mask on a motorized holder with three openings in the form of arrows, one of them being double triangular (Fig. 4). The mask was mounted on a motorized holder, its orientation corresponded to the tail of the arrows always irradiated by higher energy electrons.

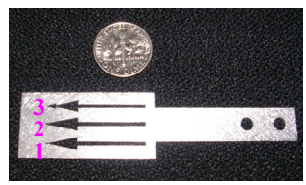

Figure 4: Aluminum mask used in the experiment.

Figures 5-7 show experimental results. The beam had a close to a Gaussian shape with no noticeable x-energy correlation left after the dogleg (Fig. 5). However the spectrometer revealed a strong energy spectrum distortion. Also, depending on the sign of the beam energy chirp the energy spectrum looked either stretched or compressed. The observed behavior was consistent with the coherent synchrotron radiation (CSR) effect making the beam tail lose more energy than the head (Fig. 6).

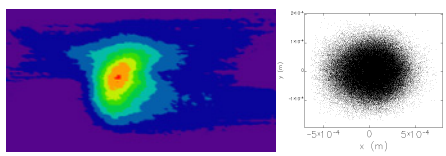

Figure 5: The beam in the test chamber: pictured with a camera using a phosphor screen (left), and simulated (right).

Copyright © 2013 CC-BY-3.0 and by the respective authors

Another evidence denoting the charge related effects was that a low charge bunch transmitted through the off beam center mask opening was reproduced on the spectrometer with minimal distortions (Fig. 7).

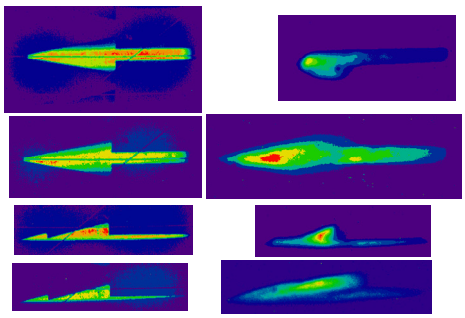

Figure 6: Left column: the beam profiles measured immediately after the mask. Right column: the beam profiles on the spectrometer, all at the same horizontal scale. Upper two rows are for a single triangular arrow mask, lower two rows are for a double triangular arrow mask (due to mechanical constraints only half of it was illuminated with the beam). For each mask the upper two pictures are for the arrow looking forward in the direction of propagation, and the lower two are for the backward arrow orientation.

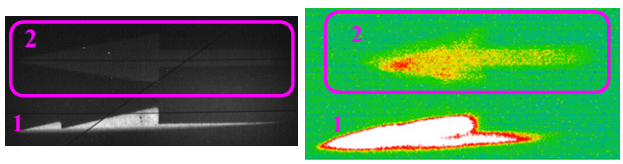

Figure 7: A low charge arrow #2 on the mask (left) is nicely reproduced on the spectrometer (right).

SIMULATIONS

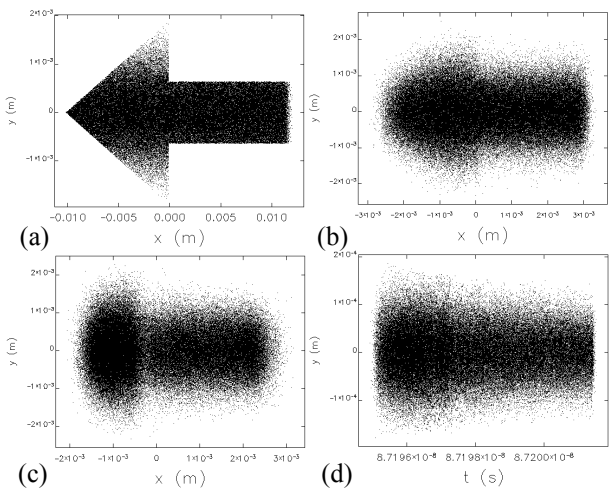

Figure 8: Simulated distribution of electrons in the beam: (a) immediately after the mask; (b) on the spectrometer obtained using the transfer matrix method; (c) on the spectrometer and (d) in the test chamber with account for the LSC effect in drift spaces & CSR in the dipole bends.

In order to confirm the nature of the effects observed in the experiment we performed simulations in Elegant [13]. We converted the MAD-X beamline model with parameters used to obtain the plot in Fig. 3 into Elegant format and wrote a script to incorporate the mask as an x-y filter element in Elegant. Elegant is a matrix code, for each beamline element it uses a transfer matrix in the form of tensors accounting for up to the 3rd order nonlinearities. It can also account for a longitudinal space charge (LSC) and coherent synchrotron radiation (CSR) by doing a specified number of kicks on the length of each beamline element. Figure 8 demonstrates the severity of the beam shape distortion inside the beamline for the initially 100 A beam. The beam energy spectrum looks different compared to its time profile (Fig. 8(c)-(d)).

CONCLUSION

We have carried out a beam shaping experiment at the ATF BNL user facility. We tried two different masks with single and double triangular shapes. For nominal current of 100 A we observed a strong CSR effect which considerably degraded the output beam energy spectrum. At the same time for a low charge beam the shaping seemed to work very well. A simple dipole-based spectrometer installed on the beamline was not helpful in characterizing the beam time profile. An RF deflecting cavity is needed to be able to resolve the beam shape in time. The deflecting cavity is going to be implemented on the beamline in the nearest future. Its addition will allow to acquire both the current shape and the energy spectrum of the beam needed for a DWA experiment with a double triangular beam. However simulations show that obtaining a perfect double triangular beam is challenging due to space charge related effects and beamline nonlinearities. Probably, some of these effects can be taken care of by customizing the mask shape.

UPDATE ON FABRICATION AND TUNING OF THE PHOTONIC BAND GAP ACCELERATING STRUCTURE FOR THE WAKEFIELD EXPERIMENT*

Evgenya I. Simakov#, Sergey Arsenyev, Randall L. Edwards, Samuel Elson, Cynthia Heath, David Lizon, and William Romero, Los Alamos National Laboratory, Los Alamos, NM 87545, U.S.A.

Abstract

We designed an experiment to conduct a detailed investigation of higher order mode spectrum in a room-temperature traveling-wave photonic band gap (PBG) accelerating structure at 11.7 GHz. It has been long recognized that PBG structures have great potential in reducing long-range wakefields in accelerators. The first ever demonstration of acceleration in room-temperature PBG structures was conducted at MIT in 2005. Since then, the importance of that device has been recognized by many research institutions. However, the full experimental characterization of the wakefield spectrum in a beam test has not been performed to date. The Argonne Wakefield Accelerator (AWA) test facility at the Argonne National Laboratory represents a perfect site where this evaluation could be conducted with a single high charge electron bunch and with a train of bunches. We describe the design of the accelerating structure that will be tested at AWA in the near future. We also report the results of fabrication and tuning of PBG cells and the initial cold-testing of the traveling-wave accelerating structure. We discuss the plan for the wakefield experiment.

INTRODUCTION

The next generation of linear colliders with multi-hundred GeV to TeV beam energies pushes the frontiers of the current beam physics and technology with the goal of obtaining high luminosity of the beam and avoiding bunch to bunch beam breakup. Thus, the aaccelerating cavities for the future linear colliders must be selective with respect to the operating mode, and higher order mode (HOM) wakefields that affect the quality of the beam must be suppressed. Photonic Band Gap [1] (PBG) cavities have the unique potential to absorb all HOM power and greatly reduce wakefields. A PBG structure or simply, photonic crystal, represents a periodic lattice of macroscopic components (e.g., rods), metallic, dielectric or both. For accelerator applications, two-dimensional PBG resonators based on arrays of metal rods are commonly employed. The first ever demonstration of acceleration in a PBG resonator was conducted at Massachusetts Institute of Technology (MIT) in 2005 [2]. Since then, the importance of PBG structures for accelerators has been recognized by many research institutions worldwide.

*Work is supported by the U.S. Department of Energy (DOE) Office of Science Early Career Research Program.

#smirnova@lanl.gov

Two attempts to experimentally study wakefields in PBG accelerators were conducted to date, but were incomplete [3,4]. The MIT team [3] cold-tested the 6-cell PBG accelerator structure of [2] in a wide frequency range and recorded the wakefield spectrum. They also ran a beam test with a train of 200 picosecond electron bunches with the charge of 1-18 pC per bunch. Radiation was observed at the output port of the PBG structure and had a quadratic scaling with current at 17 GHz and at 34 GHz. However, with the MIT setup, observation of significant wakefield radiation into other important HOMs, such as a dipole mode was impossible. A more advanced test was conducted by a team at Argonne National Laboratory (ANL) [4]. They observed wakefields in a three-cell X-band standing wave PBG structure when driven by a single electron bunch with a charge up to 80 nC. Major monopole and dipole modes were identified in the collected signal. A variable delay low charge witness bunch following a high charge drive bunch was used to calibrate the gradient. However, this test was not the test of the actual traveling-wave PBG accelerator. At this point, the full experimental characterization of the wakefield spectrum in a traveling-wave PBG accelerator is overdue.

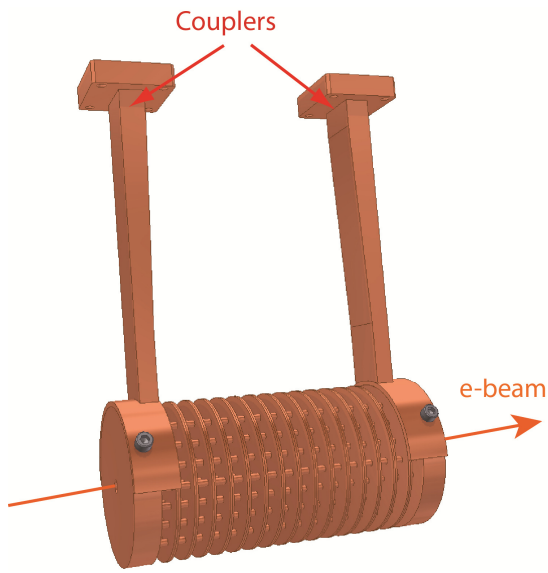

Figure 1: A 16-cell traveling-wave PBG accelerator structure with two waveguide couplers.

We have initiated a project at Los Alamos National Laboratory (LANL) to conduct the full experimental characterization of the wakefield spectrum of a traveling-wave PBG accelerator structure. We plan to put together an 11.7 GHz 2π/3-mode accelerating structure of 16 PBG

Copyright © 2013 CC-BY-3.0 and by the respective authors

cells, install it at the Argonne Wakefield Accelerator (AWA) facility and test it with a high charge (up to 100 nC) electron bunch (as shown in Figure 1) to record the full traveling-wave (TW) wakefield spectrum.

DESIGN OF 11.7 GHZ TW PBG ACCELERATOR

We designed a 16-cell traveling-wave 2π/3-mode PBG accelerator structure with characteristics similar to the 6-cell MIT PBG structure. The PBG accelerator was designed at the frequency of 11.7 GHz, which is 9 times the frequency of the AWA (1.3 GHz). The design of the traveling-wave cells was conducted with the CST Microwave Studio [5] and benchmarked with the HFSS [6]. The exact dimensions and the accelerator characteristics of the structure are summarized in Table 1. The structure has a slightly bigger beam opening and slightly larger group velocity than the scaled MIT structure to be more appropriate and attractive for higher current operations. We plan to have 14 traveling-wave and 2 coupler cells in the structure, 16 cells total.

Table 1: Dimensions and accelerator characteristics of the 11.7 GHz traveling-wave PBG accelerator.

Frequency	11.700 GHz
Phase shift per cell	2π/3
Q_w	5000
r_s	72.5 MΩ /m
$[r_s/Q]$	14.5 kΩ /m
Group velocity	0.015c
Gradient	15.4 √P[MW] MV/m
Rod radius, a (TW cell/coupler cell)	1.55 mm/1.54 mm
Lattice vector, b (TW cell/coupler cell)	10.33 mm/10.30 mm
a/b	0.150
Length of the cell	8.53 mm
Diameter of the iris	6.31 mm = 0.250 in
Thickness of the iris	1.90 mm = 0.075 in
OD of the cavity	76 mm = 3 in

The coupler cells were designed with the HFSS using a periodic voltage standing-wave ratio method. WR-90 waveguides were attached to the coupler cells, and three rods next to the waveguides were removed from the PBG structure to achieve critical coupling for the fundamental mode. The period and the diameters of the rods in the coupler cell differed slightly from the dimensions of the TW cell (Table 1) [7].

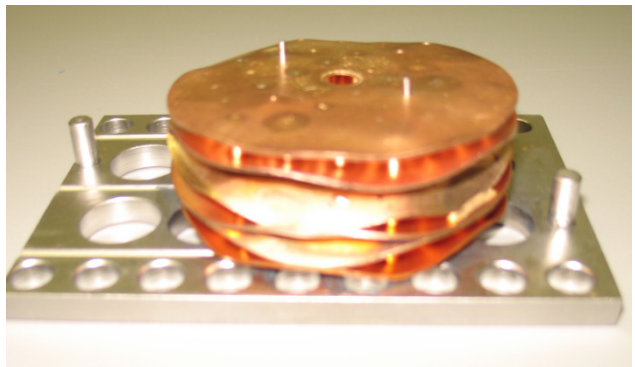

Figure 2: Photograph of the electroformed cells destroyed by brazing.

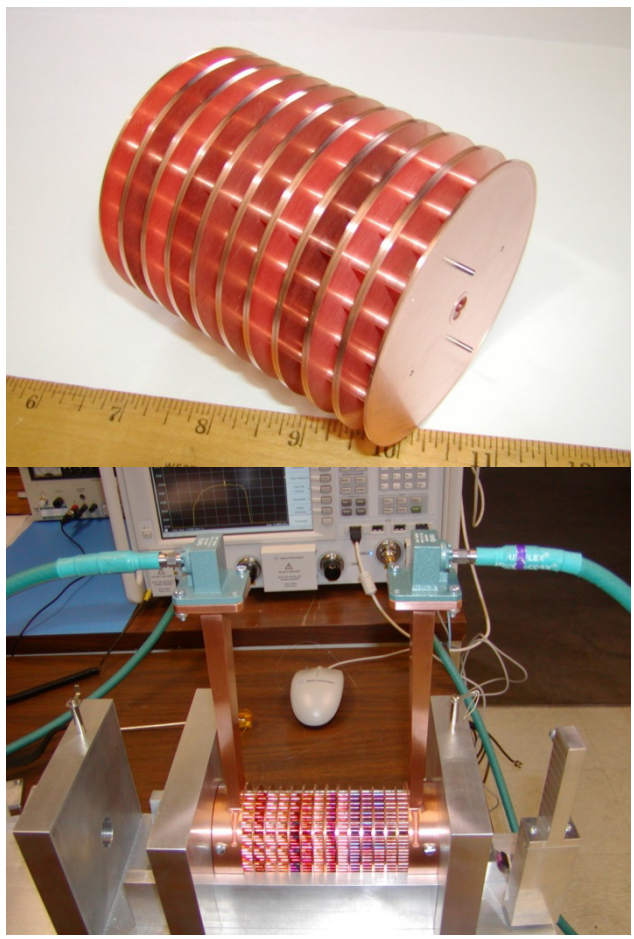

Figure 3: Photographs of the electroformed 11.7 GHz PBG cells and the assembled 16 cell PBG structure on a cold test bench.

FABRICATION AND COLD TESTS OF THE 16-CELL STRUCTURE

Three TW test cells were fabricated first in order to benchmark the tuning and brazing processes before

Copyright © 2013 CC-BY-3.0 and by the respective authors

fabricating and assembling the 16 cell structure [7]. The cells were electroformed by Custom Microwave, Inc. and then tuned at LANL with the same etching procedure as described in [7,8]. The cells were then brazed in a hydrogen furnace and this step was totally unsuccessful. The internal stresses in electroformed cells caused deformations in the structure and the cells were destroyed (Figure 2). The lesson learned was that the electroformed structures cannot be brazed and the future 16-cell structure will have to be bonded instead of brazed.

Next we fabricated PBG cells for the 16-cell structure. The total number of fabricated cells was 29, which included 25 TW cells and 4 coupling cells. The photographs of the several TW cells joined together and the assembled 16-cell PBG structure with waveguides are shown in Figure 3. The PBG cells were fabricated with small rings surrounding the beam holes which were elevated above the end surface and polished to mirror finish (Figure 3). This would ensure good electrical contact between the cells after bonding with non-conductive vacuum-compatible epoxy.

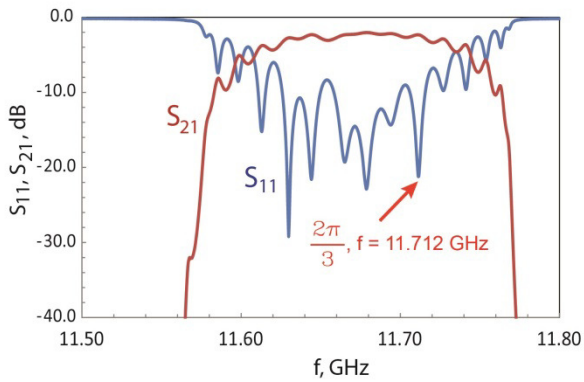

Figure 4: Transmission and reflection through the assembled 16 cell PBG structure.

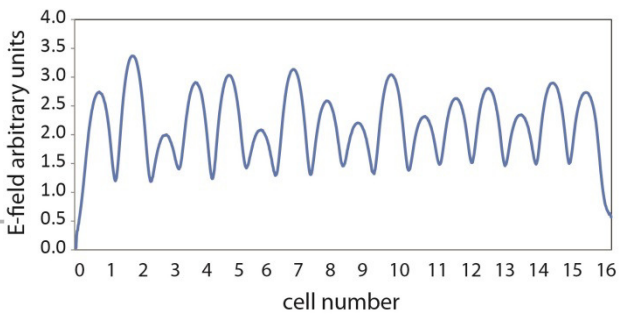

Figure 5: Bead pull field profile measurement in the 16 cell PBG structure.

The cells were tested with a network analyser and it was concluded that the frequencies of the end cells were close to the design value and the frequencies of TW cells were high. The frequencies of individual cells differed between each other all within 10 MHz frequency interval. This corresponded to approximately 0.1 thousand of an inch difference in the actual dimensions of cells. The two etching cycles were conducted to lower the frequencies of the TW cells following the procedures described in [7,8]. Each cycle removed 0.1 thousand of an inch or less off the diameter of each PBG rod. The frequencies of all PBG cells were equalized and lowered.

The transmission and reflection from the assembled PBG structure after the two etch cycles is shown in Figure 4. The $2\pi/3$-mode is the 6^{th} dip from the right on the reflection curve, at the frequency of 11.712 GHz. The reflection curve shows that the frequencies of TW cells were still higher than the target frequency and more etching cycles are needed.

The same conclusion can be made from the field profile measured with a bead pull method (Figure 5). The electric field in different cells of the structure differs slightly. The measurement of the phase shift between the cells confirms that the frequencies of the TW cells still need to be tuned down.

Another etching cycle is currently underway. Once the etching is complete, it will be followed by bonding.

CONCLUSION AND PLANS

We have planned an experiment to conduct a complete evaluation of the higher order mode wakefields in a room-temperature traveling-wave open photonic band gap accelerator structure at the frequency of 11.7 GHz. A 16-cell TW PBG accelerator structure was fabricated and is currently undergoing tuning. Once tuned, the cells will be bonded together. The structure will go on the Argonne Wakefield Accelerator beamline in 2014. We plan to drive the structure with a single 100 nC electron bunch first and look at the spectrum of the wakefields at the waveguide outputs and with antennas at the side of the structure. We might be able to conduct some experiments with a train of bunches and with a low charge witness bunch.

BEAM BRIGHTNESS BOOSTER WITH IONIZATION COOLING

V. Dudnikov#, R. Johnson, L. Vorobiev and C. Ankenbrandt, Muons, Inc. Batavia, IL, 60510 USA

Abstract

The brightness and intensity of a circulating proton beam can be increased up to the space charge limit by means of charge exchange injection or by electron cooling but cannot be increased above that limit. Significantly higher brightness can be produced by means of charge exchange injection with space charge compensation [1]. The brightness of the space charge compensated beam is limited at low level by development of the electron-proton (e-p) instability. Fortunately, e-p instability can be self-stabilized at a high beam density. By development of surface plasma sources (SPS) with cesiation and RFQ, H^- beam injectors were prepared with intensity ~0.1 A. We discuss possibilities for production of a "superintense" circulating beam with intensity and brightness far above the space charge limit. A beam brightness booster (BBB) for significant increase of accumulated beam brightness is discussed. Ionization cooling can be used for suppression of the beam brightness dilution. The superintense beam production can be simplified by development of a nonlinear nearly integrable focusing system with broad spread of betatron tunes and the broadband feedback system for e-p instability suppression [2].

INTRODUCTION

Charge Exchange Injection (CEI) was developed for increasing the circulating beam intensity and brightness above injected beam parameters by multiturn injection of beam into the same transverse phase space areas [3-5]. At that time the intensity of H^- beam from plasma source was below 5 mA with normalized emittance ~1 π mm mrad. The intensity of H^- beam from charge exchange sources was up to 15 mA, but the brightness B of this H^- beam was ~100 times less than the brightness of a primary proton beam because only 2% of the proton beam was converted into the H^- ions. In this situation the increase of the circulating beam brightness up to 100 times was necessary for reaching of the brightness of primary proton beam which can be used for one or several turn injection. The intensity and brightness of H^- ion beams were increased by orders of magnitude by adding a trace of cesium into gas discharges (cesiation effect) [6]. After development of surface plasma source (SPS) with cesiation, the H^- beam intensity was increased up to 0.1 A with emittance ~0.2 π mm mrad [7,8], so the brightness of injected beam approached the space charge limit of real accelerators such as the Fermilab Booster [9]. With such beam the further increase of circulating beam brightness is impossible, but CEI is routinely used to increase the circulating beam intensity by many orders of magnitude by injection into different parts of the transverse phase space (painting in the transverse phase space) [5, 9, 10]. Further increase of circulating beam brightness is possible by using multiturn CEI with space charge compensation by particles with opposite charge (electrons or negative ions) [1, 11, 12]

Unfortunately, such possibility is complicated by strong transverse two-beam instability driven by beam interaction with accumulated compensating particles in the circulating beam.

The strong instability with fast loss of a bunched beam was discovered at 1965 in a small scale proton storage ring (PSR) during development of charge exchange injection and was stabilized by feedback [3, 4, 5, 12, 13]. This instability was explained in [4] as an inverse variant of the strong transverse instability of circulating electron beam caused by the interaction with compensating ions (beam- ion instability) predicted in 1965 by B. Chirikov [14]. An analogue of this instability, electron-proton (e-p) instability with very low threshold was observed experimentally at the same time during accumulation of a coasting beam [1, 5, 11-13]. The e-p instability of coasting beam was in good agreement with theory [14, 15].

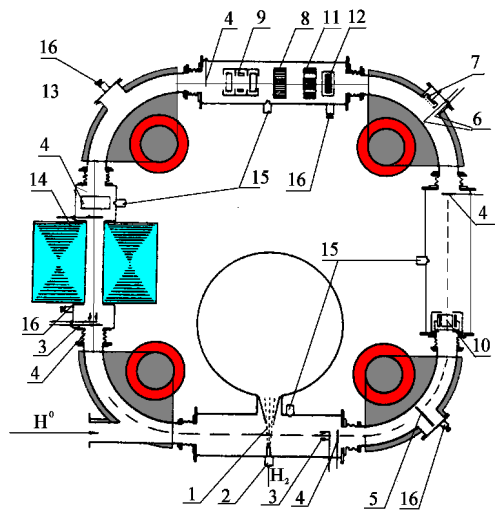

Figure 1: Schematic of storage ring with diagnostics and control. 1-stripping gas target; 2-gas pulser; 3-Faraday Cup; 4-Quartz screen; 5, 6-moving targets; 7-ion collectors; 8-current monitor; 9-Beam Position Monitor; 10-Quadrupole pick ups; 11-magnetic BPM; 12-beam loss monitor; 13-detector of secondary particle density; 14-inductor core; 15-gas pulses; 16-gas leaks.

Superintense circulating beam with intensity far above the space charge limit was produced in BINP in a simple race track ring [5,12,13,16] shown in Fig. 1.

H^0 beam with current up to 8 mA, energy 1 MeV, produced by stripping of H^- beam, is injected by CEI with electron stripping in the supersonic hydrogen jet into race track with a bending radius 42 cm, magnetic field 3.5 kG, index n=0.2-0.7, straight sections 106 cm, aperture 4x6 cm^2, revolution frequency 1.86 MHz. An inductive core was used for compensation of the ionization energy loss of ~200 eV per turn, which produces some effects of an ionization cooling [3].

A superintense proton beam with intensity ~1 A corresponding to the calculated vertical betatron tune shift ΔQ=0.85x6 =5.1 with Q=0.85 was accumulated with e-p instability self-stabilization by fast accumulation of high circulating beam current and accumulation of plasma from residual gas ionization.

This self- stabilization of the transverse e-p instability in the PSR was explained by increasing the beam density and increasing the rate of secondary particle generation above a threshold level with fast decrease of the unstable wavelength λ below the transverse beam size *a*. (i.e. the sum of beam density n_b and ion density n_i is above a threshold level):

$$(n_b + n_i) > \beta^2 / 2\pi r_e a^2 \; ; (r_e = e^2/mc^2).$$

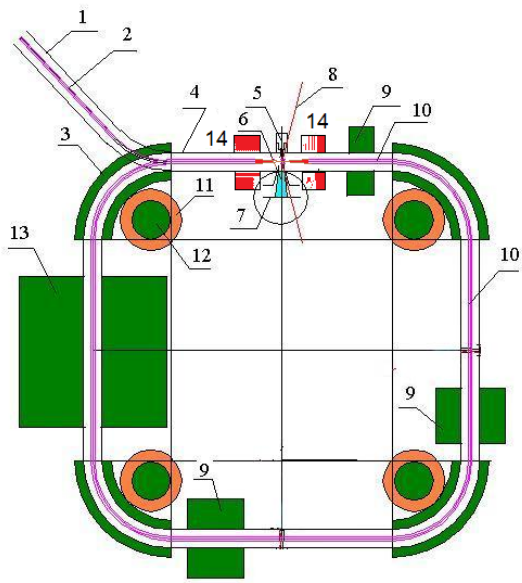

Figure 2: Schematic of BBB of circulating proton beam with thin targets accompanied by enhanced ionization cooling. 1- beam line for transportation of injecting H- beam; 2- injecting beam of H-; 3-bending magnets; 4- vacuum chamber of storage ring; 5- generator of supersonic jet- stripping, reaction target; 6- supersonic jet, stripping-reaction target; 7- pump-recirculate of target jet; 8- cone of resonant gamma rays; 9, 13- iron core for inductor for compensation of beam energy loss in first target; 10-circulating proton beam; 11- magnetic coil; 12- yoke of bending magnet; 14- magnetic lenses for beam focusing to the target.

In high current proton rings it is possible to reach this "Island of stability" by fast, concentrated charge exchange injection without painting and enhanced generation of secondary plasma as it was demonstrated in the small scale PSR at the BINP [5, 12, 13, 16]. The beam brightness loss through proton scattering and ionization loss straggling can be compensated by improved ionization cooling with beam focusing to the target by lenses (14) as shown in Fig. 2. As a prototype of magnetic system it is possible to use a round beam collier VEPP 2000 from BINP with a stron focusing of beams into the colliding point by strong solenoids [17].

The broad betatron tune and corresponding Landau damping are important for increasing the threshold of e-p instability [14,15]. This inference is supported by the increase of instability threshold with increase of bunching RF voltage, increasing of separatrix size and energy spread. With high RF voltage only the central (coherent) part of the beam is unstable and lost.

With a broad betatron tune spread it is possible to produce stable space charge compensated ion and electron beams because e-p instability (electron cloud effect, ion instability) should be suppressed by Landau damping [13, 14, 15].

We hope that production of superintense beam can be easier in BBB with a stable close to integrable nonlinear focusing lattice proposed in [2].

A possible design of such a storage ring is shown in Fig. 3. In design of the storage ring with nonlinear focusing it is good to have possibility for high brightness beam accumulation by charge exchange injection. For energy up to 10 MeV it is possible to use a supersonic gas jet as a stripping target as was done in the small scale proton storage ring in BINP [3-5]. An RFQ and small linac can be used as injector with H^- beam ~100 mA, 2-10 MeV.

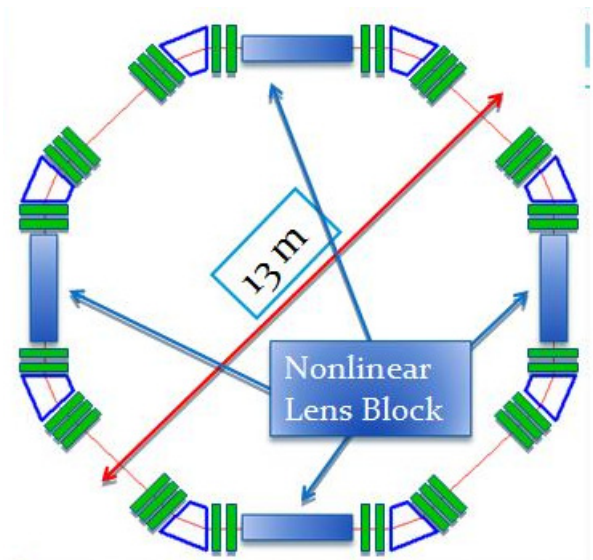

Figure 3: Schematic of storage ring with a nonlinear close to integrable focusing system from [2].

Some other methods of space charge compensation were discussed in [9, 18].

A circulating proton beam ~10 or 100 A can be accumulated. Such a beam can be used for realization of resonance reaction induced by circulating ions in a thin internal target.

The plasma accumulation during accumulation of superintense beam was discussed in [11].

A comprehensive review of e-p instability in different accelerators and storage rings was presented in [19]. Theoretical estimation of self-stabilization is presented in [20]. Practical application of space charge neutralization in advanced ion implanters is considered in [21].

With the barrier bucket acceleration, tried at the AGS in the collaboration between KEK and BNL [21], it is possible to accelerate a long uniform bunch of ions without loss of space charge neutralization. Acceleration of compensating electrons should be suppressed by magnetic field as in [12, 16].

CONCLUSION

BBB with space charge neutralized superintense ion beams with intensity far above the space charge limit can be useful in an induction Linac with recirculation and for inertial fusion, neutron, antiproton, and muon generators, resonant reaction with internal targets, high power density physics, FFAG accelerators, and inductive synchrotrons.

It is very attractive to repeat an accumulation of superintense ion beam with modern high current injectors. High current density beam should be stable without secondary ions.

The barrier bucket acceleration [22] can be used for acceleration of the long uniform bunch of ions without loss of space charge neutralization.

Now from RFQ it is possible to have H- beam with current ~100 mA and Energy ~2-3 MeV.

This can be enough for accumulation of about 1 kA of circulating proton beam in a small storage ring with R~1m.

As a first step it is possible to conduct realistic simulations of superintense beam accumulation with enhanced ionization cooling. Simulation of the self stabilization of the e-p instability can become a basis for new advanced accelerators and storage rings with intensity far above the space charge limit (by many orders of magnitude). This opens the way for new applications of accelerator technology in high energy density physics and technology. With a high injection current and with nonlinear focusing it is possible to have e-p instability self stabilization without the high density secondary plasma.

The important tasks are the development of a physical model of electron multiplication, including ion generation, slow ion dynamics, ion/electron secondary emission, and gas desorption by ion and electron impact.

An important aspect of this work is the estimation of parameters and scales for physical processes, leading to the development of a mathematical model. It is necessary to verify the proposed physical model. The system of Vlasov equations is nonlinear, requiring the use of numerical methods to solve them. As the first step it is appropriate to perform 1D and 2D simulations and compare the results of simulation with available experimental data and published results of simulations based on other codes [1-5,11-21].

TRANSVERSE BEAM DYNAMICS IN PLASMA GUIDED LASER DRIVEN ACCELERATION

D. B. Cesar, P. Musumeci, UCLA *, PBPL, Los Angeles, CA 90095, USA

Abstract

An axially modulated plasma waveguide supports slow-wave laser modes suitable for direct laser acceleration. The channel studied here supports a gradient of 2 GeV/m driven by a 1 TW laser. The transverse beam dynamics are analyzed in the context of the envelope equation and simulated by particle tracing to demonstrate the feasibility of using a photogun as the electron source. External injection promises to take advantage of the precision offered by state-of-the-art RF photogun technology to increase shot-to-shot reproducibility.

INTRODUCTION

The acceleration of electrons directly by laser fields is an attractive design for a compact accelerator because of the large gradients lasers can provide. In particular, direct laser acceleration (DLA) requires less power than laser plasma wakefield acceleration (LWFA), which enables more compact designs. In order to take advantage of the high fields of the laser it is necessary to overcome the restrictions due to phase slippage implied by the Lawson-Woodward theorem [1]. The DLA scheme pursued here overcomes these limitations by guiding a high intensity pulse through a corrugated plasma channel [2]. Analogous to a conventional disk-loaded LINAC, the corrugations introduce slow wave components phase matched to the electron beam.

Corrugated plasma channels have been created in a laser-ionized plasma [3]. Gas clusters were ionized and then heated by a 100ps pulse focused to a line by an axicon. The corrugations considered for quasi-phase matching were created by using a ring diffraction grating to introduce radial modulations in the laser pulse. The axicon maps the radial intensity pattern to the axis, and uneven heating of the plasma leads to density modulations during the shock-wave expansion. The use of the heater pulse to shape the modulations offers control over the modulation parameters.

Here we propose fixing the modulation parameters to provide focusing for an emittance dominated beam. The transverse beam dynamics in an ideal channel are studied in the context of the envelope equation. A matched solution with asymptotically damped oscillations is calculated. The input beam to match the channel can be obtained from an RF photogun. This solution bypasses the problems LWFA experiments have faced with injecting bunches from the plasma into the accelerating field.

ANALYSIS

Following previous analysis [4], the density profile of the plasma channel used for Direct Laser Acceleration experiment can be approximately described as Eq.(1), with addition of a density ramp, $n_s(z)$ to be used for phase-matching throughout the accelerator [5].

Table 1: Channel Parameters

n_0	k_m	δ	w_{ch}	λ_0	a_0
$5 \cdot 10^{19}/\mathrm{cm}^3$	232200	.9	37 μm	800nm	.2

$$n(z) = n_0 \left[1 + \delta \sin\left(k_m z\right)\right] + n_0'' r^2/2 + n_s(z) \qquad (1)$$

The parabolic density channel supports TM guided modes of radially polarized waves. The lowest order solution is expanded into slow-wave components and the transverse forces due to the resonant and non-resonant components are studied and used as the basis for an envelope calculation. Channel parameters used throughout the paper are listed in table 1 and are chosen to be consistent with experiment [3]. The channel is taken to be 1.8cm long so that the length of the accelerating pulse does not limit acceleration [4]. A laser power of $a_0 = .20$ is chosen to correspond with the TW laser in construction at UCLA's Pegasus beamline.

Guided Modes

Since we want a longitudinal field component for acceleration, we seek the radially polarized component of the laser vector potential in the slowly varying envelope approximation: $A_\perp = \hat{A}_r e^{i(k_0 z - \omega_0 t)}$, with $\hat{A}_r$ satisfying:

$$\left[2ik_0\left(\frac{\partial}{\partial z} + \frac{1}{c}\frac{\partial}{\partial t}\right) + \nabla_\perp^2\right]\hat{A}_r = \frac{\omega_p^2}{c^2}\hat{A}_r$$

where $\omega_p^2 = \frac{ne^2}{m\epsilon_0}$. This can be solved using separation of variables and expanded into harmonics using the Jacobi-Anger expansion. Palastro [4] includes discussions of the assumptions behind this model. Ignoring time dependence in the laser envelope, the lowest order solution is written in the Columb gauge as:

$$\hat{A}_r = A_0 \frac{r}{w_{ch}} e^{\frac{-r^2}{w_{ch}^2}} \sum_{q=-\infty}^{+\infty} i^q J_q(\Psi) e^{i\left(-\Psi + (\delta k + q k_m)z - \frac{\int k_{ps}^2 dz}{2k_0}\right)} \qquad (2)$$

where:

- $w_{ch} = \left(\frac{8c^2}{\omega_{p0}''^2}\right)^{1/4}$
- $k_{ps}^2(z) = \frac{e^2 n_s(z)}{m\epsilon_0 c^2}$
- $\delta k = -\frac{1}{k_0}\left(\frac{\omega_{p0}}{2c^2} + \frac{4}{w_{ch}^2}\right)$
- $\Psi = \frac{\delta\omega_{p0}}{2c^2 k_0 k_m}$

The transverse potential peaks at $r = w_{ch}/\sqrt{2}$. For our parameters $\Psi \approx .5$ is small, so that the Bessel functions limit the relevant terms in Eq(2) to small q.

The axial component of the potential is given by $\vec{\nabla} \cdot \vec{E} = 0 \Rightarrow \vec{\nabla} \cdot \vec{A} = 0$. The magnetic field is given by $\vec{B} = \nabla \times \vec{A}$ and the electric field by $\vec{E} = -\frac{\partial}{\partial t}\vec{A}$. The phase velocity of an individual harmonic is calculated by taking the derivative of the exponent of Eq.(2). The optical scale dominates $\left(k_0 >> \delta_k, nk_m, \int k_{ps}^2 dz/k_0\right)$ such that phase matched particles would have acceleration given by $\gamma = \gamma_0 + \gamma' z$. This determines v_p and allows phase matching of the largest subluminal harmonic (q=1) by using a density ramp. The density ramp asymptotically approaches $\frac{m\epsilon_0 c^2}{e^2}\left(2k0(\delta k + qk_m)\right)$ from below and rises slowly compared to both the optical and modulation periods, but quickly compared to the length of the plasma channel. The condition to keep the total density positive is:

$$km > \frac{e^2}{m\epsilon_0 c^2 2k_0}\delta n_0 + \frac{4}{k_0 w_{ch}^2} - k_0\left(1 - \frac{1}{\sqrt{1 - 1/\gamma_0^2}}\right)$$

For the small values of ψ under consideration we have the relation $E_z \propto a_0 n_0 \delta / k_m w_{ch}$. This scaling helps determine acceptable values for the parameters used.

Transverse Force

The equations of motion for a particle in the channel described above are:

$$\ddot{x_i} = \frac{e}{m_e \gamma}\mathrm{Re}[\sum_{q=-\infty}^{+\infty} f_{i,q} e^{i(n-1)k_m v_p t}] + \text{c.c.}$$

where, for $r << w_{ch}$

$$f_{z,q} = \frac{m_e c \omega_0 a_0}{eK_q}\frac{1}{w_{ch}} J_q(\Psi) e^{i\phi + ik_m \xi(q-1) + i(\frac{\pi}{2}(q) - \Psi)}$$

$$f_{r,q} = f_{z,q} K_q r\left[1 - \frac{\beta_z}{\beta_q}\left(1 + \frac{8}{(K_q w_{ch})^2}\right)\right] e^{i\frac{3\pi}{2}}$$

where $K_q = \left(k_0 + \delta k + qk_m + k_{ps}^2/2k_0\right)$, $\xi \approx z - v_p t$, and ϕ is the phase. Since ξ and ϕ are constant due to the phase matching condition the f vary in time minimally, only through the K_q's dependence on $n_s(z(t))$. The $\frac{8}{(K_q w_{ch})^2}$ is due to the finite spot size of the laser.

Following the notation of [6] the motion is separated into a slowly varying secular motion and a fast (corrugation scale) motion. In solving for the rapid motion we have used $k_0 >> \delta_k, qk_m, \kappa(z)$ and neglected terms $\kappa(z)/k0$. Averaging over the fast motion yields the secular equation of motion:

$$R''(z) = \frac{-1}{\beta^2\gamma}\frac{\omega_0 a_0}{c}\frac{R}{w_{ch}} J_1(\Psi)\left(\frac{8}{(K_n w_{ch})^2}\right) e^{i\phi + i(\pi - \Psi)} \tag{3}$$

$$+\frac{a_0^2}{w_{ch}^2(n-1)^2}\left(\frac{K_1}{k_m}\right)^2 R\sum_{q\neq 1}$$

$$\frac{1}{\beta^2\gamma^2} J_q(\Psi)^2\left(-\frac{(q-1)k_m}{k_0} - \frac{8}{(K_q w_{ch})^2}\right)^2$$

$$+\mathcal{O}\left(\frac{k_0}{k_m\gamma^2}\right) + \mathcal{O}\left(J_q(\Psi) J_{2-q}(\Psi)\right)$$

The term outside the sum is due to the resonsant force. The terms in the sum are the ponderomotive force. For our parameters the terms in big O notation are small for $\gamma >> 6$ and q> 1. For $\gamma >> 30$ the resonant term dominates the pondermotive force. To study the propagation of an electron beam through the channel we consider the envelope equation in the emittiance dominated regime:

$$\sigma_r'' + \frac{(\beta\gamma)'}{\beta\gamma}\sigma_r' + k_r^2\sigma_r = \frac{\epsilon_{nr}^2}{(\beta\gamma)^2\sigma_r^3} \tag{4}$$

The pondermotive focusing term allows for a matched beam envelope:

$$\sigma_m \approx \left(\frac{\epsilon_{nr} w_{ch}}{\sqrt{2} a_0 J_0(\Psi)}\right)^{1/2}$$

Because $\sigma_r'(0) \neq 0$ the pondermotive force will cause spot size oscillations. In addition, the resonant term will add overfocusing as γ increases. The asymptotic behavoir of this system can be be easily interpreted as $\beta \to 1$ by writing $\sigma_r(z) = \sigma_m + \delta(z)$, where it is assumed $\delta(z) << \sigma_m$. Still approximating the particles' phases as constant, and changing variables to $\hat{z} = \gamma_0 + \gamma' z$ Eq.(4) becomes:

$$\delta'' + \frac{\delta'}{\hat{z}} + \frac{1}{\gamma'^2}\left(\frac{k_{\text{res}}^2}{\hat{z}} + \frac{4k_{\text{pond}}^2}{\hat{z}}\right) = -\frac{k_{\text{res}}^2\sigma_m}{\gamma'^2\hat{z}} \tag{5}$$

where k_{res}^2 is the focusing due to the resonant harmonic, k_{pond}^2 is the focusing due to the pondermotive forces, and primes denote derivatives with respect to $\hat{z}$. In the limit where $k_{\text{res}}^2\gamma >> k_{\text{pond}}^2$ the solution is a linear combination of $J_0(2k_{\text{res}}\sqrt{\hat{z}}/\gamma')$ and $Y_0(2k_{\text{res}}\sqrt{\hat{z}}/\gamma')$. For large z this represents damped oscillations with a growing period. When still in the regime $\beta \approx 1$, but $k_{\text{res}}^2\gamma \approx k_{\text{pond}}^2$ the solution can be shown to be oscillations formed from a combination of Bessel and Hypergeometric functions.

Table 2: Beam Parameters

	γ	Espread	ϵ_n	σ_r	Q
Initial	20	.2%	0.1 mm·mrad	2.6μm	1pC
Final	90	2.2%	0.3 mm·mrad	2.6μm	.64pC

Particle Tracking

The particle tracking code General Particle Tracer (GPT) was used to test the approximations made in determining the envelope behavior. The tracing is only as accurate as the input field, Eq.(2), as the tracer does not simulate the plasma. For simplicity the laser is still assumed to be much longer than the electron beam so that the overall pulse envelope can be ignored. The solver does calculate the small contribution from spacecharge fields, but it does not account for wakefields in the plasma.

Beam parameters before and after acceleration are listed in table 2. The input parameters are similar to those obtained in UCLA's Pegasus beamline, and the final parameters are for the accelerated electrons only. Further, the

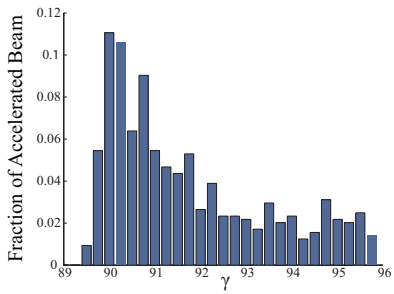

Figure 1: Energy spread of the accelerated bunch.

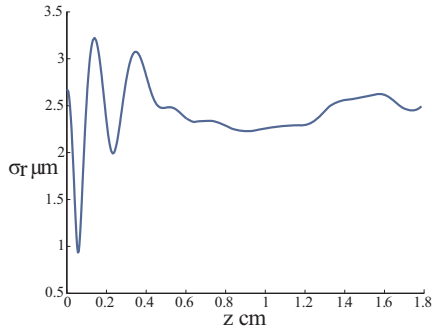

Figure 2: Envelope dynamics showing the spot size oscillations of the accelerated bunch.

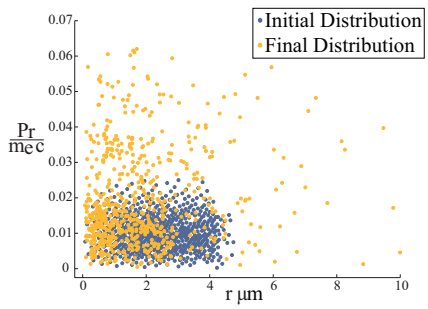

Figure 3: The inital and final phase space of the accelerated bunch. The growth in transverse momentum is due to betatron oscillations.

beam is assumed to have been previously microbunched into 20 optical length bins, with each box having a FWHM $\lambda_0/9$, as might be created by bunching in an undulator [7].

During the first millimeter of acceleration many of the particles far from the axis de-phase from the matched wave, slip into the defocusing region of the resonant harmonic, and are ejected from the channel. The remainder of the particles are accelerated with a linear gradient to $\gamma = 92$. A capture rate of as high as 64% was achieved by setting the initial phase at $\pi/6$. Because of the dephasing, the electrons fill the accelerating bucket and the final energy spread (Fig.1) is nearly 5%. The energy spread and capture rate are improved by reducing the dephasing. The capture rate is little improved by reducing the emmittance, as the dephasing is caused by betatron oscillations that are large enough to modulate γ and dephase the outer electrons. This effect would be reduced by increasing the channel width, but at the cost of the accelerating gradient. A more complex scheme may pursue a slowly changing channel width.

The envelope of a single bunch in the accelerated group of electrons is graphed in Fig.2. The beam has an input rms radius of 2.6μm, and then oscillates about the matched spot size. The oscillation magnitude is damped and the period is lengthening, consistent with the behavior predicted by the asymptotic solution to the envelope equation. The maximum spot size is 1/10 of the channel size, indicating that the forces remain linear, yet the normalized emittance triples. The increase in emittance is visually evident in the evolution of the transverse phase space (Fig.3) as an increase in the transverse momentum. Further increase in the transverse momentum is limited by dephasing due to coupling between the longitudinal and transverse momentum. Particles at the edge of the phase space are slowly dephase into the defocusing phase for arbitrarily large accelerators.

CONCLUSIONS

The transverse dynamics in an ideal corrugated waveguide have been studied and found to yield focusing forces suitable for matching a μm size beam. However, the large focusing and over-focusing forces contribute to the dephasing of electrons which leads to low capture rates, large energy spread, and emittance growth. Increasing the channel width decreases these effects and a tapered channel width may contribute to higher beam quality. Further analysis of the accelerator would benefit from modeling the plasma formation and beam-plasma interaction. Nonetheless, the analysis here suggests it would be possible to channel an externally injected beam in a proof of principle experiment.

Abstract

Particle acceleration in dielectric laser-driven microstructures, recently demonstrated at SLAC, holds the promise of providing low-cost compact accelerators for a wide variety of uses. Laser-driven undulators based upon this concept could attain very short (mm to sub-mm) periods with multi-Tesla field strengths. And since dielectric laser accelerators operate optimally with optical-scale electron bunch formats, radiation production with high repetition rate (10s of MHz) attosecond-scale pulses is a natural combination. We present preliminary analysis of the harmonic field structure for a periodic undulator based on this concept.

INTRODUCTION

The increasingly prohibitive cost and size of modern accelerator facilities has prompted interest in a variety of schemes for accelerating particles at higher gradients than traditional metallic cavity accelerators can provide, rapid fabrication techniques, and more readily available energy sources. One of the most promising of these schemes is the use of dielectric near-field structures powered by an infrared (IR) laser to produce a confined accelerating mode. Since the size of the confining beam channel scales with the wavelength of the source, the apertures of such structures are at most a few microns in transverse size. As a result, particle beam confinement requires a new operating regime with beams of low charge (10-100 fC) and ultra-low normalized emittance (1-10 nm). The bunches should ideally be short compared to the optical wavelength (10-100 fs), must be spaced at the optical period of the laser (or an integer multiple thereof), and should come in bunch trains commensurate with typical solid state laser pulse lengths (10 fs - 1 ps). The decrease in luminosity due to such small bunch charges are compensated by the fact that solid state lasers permit repetition rates 3 orders of magnitude higher than typical microwave sources. The requisite dielectric structures can be fabricated with nanometer-level precision on silicon wafers using modern solid state fabrication methods, and the first experimental demonstration of high-gradient acceleration in such structures has been recently reported [1].

The DLA concept leverages well-established industrial fabrication capabilities and the commercial availability of tabletop lasers to reduce cost, while offering significantly higher accelerating gradients, and therefore a smaller footprint. Power estimates for the DLA scenario are comparable with convention RF technology, assuming that similar power efficiency (near 100%) for guided wave systems can be achieved, 40% wall plug laser efficiencies (feasible with solid state Thulium fiber laser systems), and 40% laser to electron beam coupling (consistent with published calculations).

This research has significant near and long-term applications for energy frontier science [2, 3]. Additional applications including radiation production for compact medical x-ray sources, university-scale free electron lasers, NMR security scanners, and food sterilization are beginning to be explored. A dielectric laser-driven deflector, operating on the same basic principles as recently demonstrated accelerator devices, was proposed by Plettner and Byer [4]. The scheme uses a pair of dielectric gratings excited transversely by a laser beam and separated by a gap of order the laser wavelength where a beam of electrons would travel. By changing the sign of the excitation between successive structures (e.g. by alternating the direction of illumination) an optically powered undulator could be constructed to create laser driven micro-undulators for production of attosecond-scale radiation pulses synchronized with the electron bunch.

As a next step in exploring this concept in more detail, the commercial electromagnetic finite element code HFSS 12.0 was used to obtain realistic field profiles along the axis of an electron beam propagating in a single stage of deflection (representing half of one undulator period). These fields are analyzed with respect to the injection phase of a test electron and the deflecting forces calculated to produce a single-period model of the proposed undulator concept.

BACKGROUND

The deflector design proposed in Ref. [4] consists of a pair of coplanar gratings with a pillar height g separated by a gap of width w. If the gratings are constructed of an optically transmissive material (such as glass) an electromagnetic mode can be excited in the gap region by transverse illumination of the structure with a monochromatic plane wave. The resultant confined mode is found to produce a net deflecting force transverse on a trajectory lying in the midplane between the two gratings at an angle $\pi - \alpha$ relative to the direction of the grating lines. Consquently

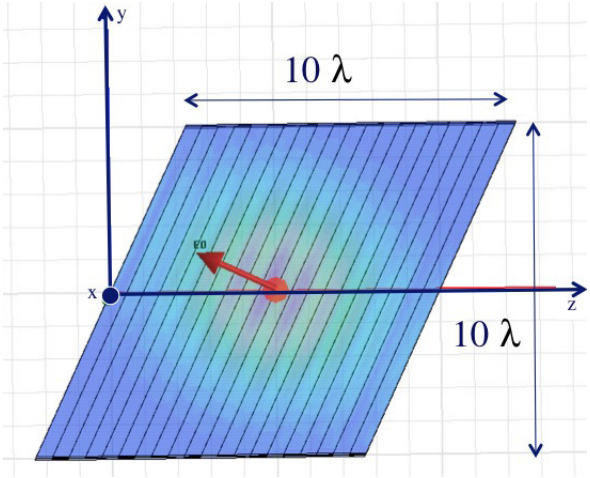

Figure 1: HFSS simulation geometry with superimposed color contour plot of the Gaussian excitation.

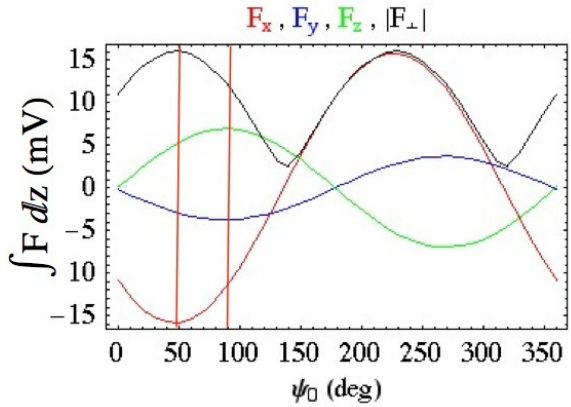

Figure 2: Computed force components as a function of particle injection phase, for an incident field E_0 = 1 V/m, integrated over half an undulator period (10λ).

by tilting the gratings at an angle α relative to the beam axis in the plane parallel to the grating surfaces a net transverse deflecting force can be imposed on a charged particle traveling between the gratings. The maximum amplitude of this deflection is found to be $F_\perp \approx qE_0 sin^2\alpha$, where E_0 is the electric field amplitude of the incident laser field and q is the particle charge, which occurs for the optimized geometrical values $w = 0.4\lambda$, $\alpha = 25°$, and $g = 0.85\lambda$. For a silicon dioxide structure with a 0.3 ps laser pulse, the corresponding peak surface electric field corresponding to the damage limit is $E_{pk} \approx 8.2$ GV/m, and the corresponding incident laser field is $E_0 = E_{pk}/3$, corresponding to an equivalent undulator magnetic deflection field $B_u = \mu_0 E_0/Z_0$ = 1.6 T.

It should be noted that the deflection has both x and y components and that there is also a significant z component of net accelerating force. To create an undulator from such structures, they can be staged, with successive stages of deflection illuminated from opposite sides so as to alternate the sign of the deflection force. Since the longitudinal extent of the deflecting force in each stage is determined by the transverse extent of the exciting laser field, in principle the period of such an undulator could be many times the laser wavelength.

SIMULATIONS

A single stage of the proposed deflector (half a period of the undulator) was simulated using the commercial electromagnetic finite element code HFSS 12.0. The computational volume includes the entire structure, with no symmetry planes, and absorbing boundary conditions on all exterior boundaries. The geometry is shown in Fig. 1. The model is excited by a Gaussian laser mode at normal incidence propagating in the negative x direction transverse to the planes of the gratings. The beam axis is taken to be the positive z direction, and the primary deflection component is in the x direction.

For the structure orientation and dimentions, we take the optimized values $\alpha = 25°$, $w = 0.4\lambda$, $g = 0.85\lambda$ as calculated in Ref. [4], with the excitation field polarized perpendicular to the lines of the gratings. The fields are then extracted along the z-axis and the integrated force on a speed of light particle is computed. The force components as a function of injection phase ψ_0 of the particle, for an incident laser field with an electric field amplitude $E_0 = 1$ V/m, are shown in Fig. 2. We see that the deflecting force $F_\perp$ is dominated by the x component. At $\psi_0 = 0$, the integrated force on the particle is entirely in the x direction, as the contributions from the other two components are zero. If the fields from the half-period are mirrored in z to produce a single undulator period, the results can be harmonically analyzed by a Fourier sine decomposition as

$$F_x(z) = \frac{a_0}{2} \sum_{n=1}^{\infty} [a_n \cos(n\pi x/L) + b_n \sin(n\pi x/L)] \quad (1)$$

The resulting harmonics at $\psi_0 = 0$ are found to have a mixture of harmonic contributions from both the cosine and sine terms. However, at an injection phase of 90°, $a_n = 0$, the accelerating (z) contribution is a maximum but the field harmonics are sinusoidal with dominant contributions at the first and third harmonics ($b_1 = 0.2E_0$, $b_3 = 0.05E_0$). The corresponding lowest-order deflection force is consistent with the analytical predictions of the prior section. The next significant harmonic contributions appear at $n = 18$ and higher, and correspond to the fast oscillation component related to the laser wavelength λ, as seen in the right-hand plot of Fig. 3. The first and third harmonic sinusoids are combined to produce the red curve superimposed upon the plot in Fig. 3. If the system is scaled to larger undulator periods (of order 100 λ), these components get pushed to higher n values and hence the undulator parameter contributions K_n from these higher harmonics become increasingly ignorable.

The significant third harmonic contribution, however, will contribute significantly to the radiation produced if

Copyright © 2013 CC-BY-3.0 and by the respective authors

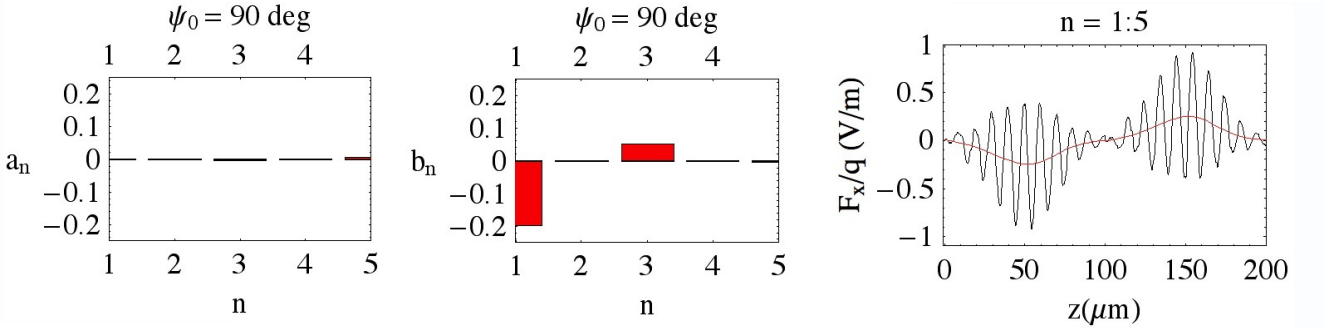

Figure 3: Harmonic analysis of a single undulator period for 90° injection phase, showing the cosine and sine harmonic terms and the dominant x force component (black curve) with superposition of the first 5 harmonics (red curve).

this device is used as an undulator for an optical-scale free electron laser. In traditional undulator designs, third harmonic field content occurs as a perturbative contribution due to the nonlinear motion of the electrons in the undulator field. However, the presence of significant inherent third harmonic has recently been studied as a mechanism to intentionally generate efficient third harmonics of the fundamental FEL radiation [5]. In addition, although we have here assumed a Gaussian laser mode for simplicity, the harmonics of the undulator fields may be manipulated (and the third harmonic contribution enhanced or reduced) by transverse shaping of the incident laser mode profile.

Unlike other electromagnetic undulator concepts, the undulator period in this scheme is set by the length of each deflection stage and can therefore be much larger than the driving wavelength. From simple 1D calculations, undulators based upon this concept could attain very short (mm to sub-mm) periods with multi-Tesla field strengths: an undulator with a 250 μm period driven by a 2 μm solid state laser would have a gain length of 4 cm and an X-ray photon energy of 10 keV when driven by a 500 MeV electron beam. Since DLA structures operate optimally with optical-scale electron bunch formats, high repetition rate (10s of MHz) attosecond-scale pulses are a natural combination.

CONCLUSIONS

The grating-based optical deflector concept presented previously by Pletter and Byer presents the possibility of creating a FEL undulator compatible with future laser-driven accelerators. We have simulated one period of such an undulator concept using an electromagnetic finite element code with a grating excited transversely by a Gaussian monochromatic mode. The axial fields extracted do show a significant integrated transverse deflecting force, as well as a net integrated acceleration, as predicted. However, while in Ref. [4], the ratio of these components is predicted to be $F_z/F_\perp \approx 2$, we find that the accelerating component is generally smaller than the deflecting force, and varies significantly with injection phase, an effect not previously noted. In addition, we find that for a Gaussian laser mode, the fields contain significant third harmonic content. The impact of these observations will be explored in future by analytical calculations as well as computational analysis using FEL codes. Prototype devices based on a modified version of the architecture reported in [1] are being developed for experimental testing at SLAC.

Abstract

Plasma wakefield studies are normally conducted as single-shot experiments. Here, single-shot means that the plasma returns to its original state before the next bunch passes through the plasma. The time scale for the plasma to return to equilibrium is 10-100 ns, which is comparable to the bunch separation in proposed linear colliders. The SLAC linac typically delivers beam at a rate of 10 Hz to FACET, but can also be operated in a manner that delivers two electron bunches per RF pulse to FACET. We explore operating modes with beam separations as small 5.6 ns so that high repetition rate plasma wakefield acceleration can be studied at FACET.

INTRODUCTION

The SLAC linac provides electron bunches with total beam charge of 3.2 nC to FACET experiments. The beam originates at Sector 0 from a thermionic cathode gun, passes through the sub-harmonic buncher for longitudinal compression, is captured and accelerated in the Sector 1 s-band linac and sent to the North Damping Ring (NDR) for beam cooling. After the emittance is damped in the ring, the beam is extracted into the Sector 2 linac, accelerated to 20.35 GeV, and delivered to Sector 20 for final compression and focusing. An overview of the linac and associated systems is given in Fig. 1. Each system imposes its own constraints on the possible bunch parameters and inter bunch spacings.

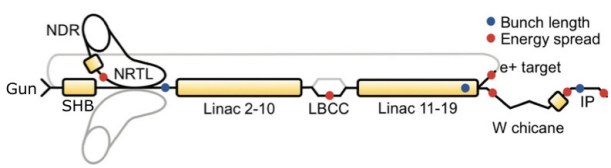

Figure 1: Overview of Linac with affected subsystems and diagnostics for multi-bunch operation.

BEAM GENERATION AND CAPTURE

Source

The electron source is a thermionic cathode driven by a multi-channel pulser. The pulser is a circuit with two planar triode amplifiers that couple into a common amplifier driving the cathode. The two triodes can be fired independently to produce electron pulses from the cathode with arbitrary separation in time. The gun can generate up to 27 nC of charge in a single pulse. We look to generate two pulses with 3.2 nC each. This can be achieved without changing the existing gun hardware [1].

Subharmonic Buncher

Immediately after the beam is generated it is captured in the sub-harmonic buncher (SHB). The SHB is operated at the $1/16^{th}$ sub-harmonic of the s-band linac. The bucket spacing for the SHB is 5.6 ns. The SHB bucket size sets the interbunch spacing in the rest of the machine. Without the SHB, most of the beam does not get captured in the linac and there is the potential for radiation damage in the injector. All of the interbunch spacings considered in this paper are multiples of 5.6 ns.

The longitudinally compressed bunches are captured in an s-band bucket at the start of Sector 1 and accelerated to 1.19 GeV before being sent to the NDR via the North Linac-to-Ring arc.

NORTH DAMPING RING

Kickers

A loaded ferrite kicker magnet with a flat-top of 30 ns kicks the bunches into the ring. This magnet was designed to have an extremely sharp rise and fall time, so as not to disturbed another bunch in the ring, which was typical during SLC operation. A second kicker magnet is located on the opposite side of the ring and is used to extract the bunches. This magnet is identical to the injection kicker except that it has a different pulse forming network that uses a Blumlein generator to produce an extremely flat pulse to the magnet [2]. The field in the magnet provides a uniform 7 mrad kick for more than 60 ns. The injection and extraction kickers set limits on the maximum separation between the two bunches. The maximum bunch spacing that is consistent with the NDR RF and SHB RF is 61.6 ns. The injection kicker would have to be equipped with a similar PFN as the extraction kicker to achieve this separation.

Instabilities

The NDR limits the bunch charge and separation in another manner due to single-bunch and coupled beam instabilities. The single bunch instability is a short range, microwave instability. With 3.2 nC per bunch, the ring is operated above the threshold for the instability. However, at this charge the instability is weak and does not degrade the bunch quality [3]. Note that having two 3.2 nC bunches

† sgess@slac.stanford.edu

Copyright © 2013 CC-BY-3.0 and by the respective authors

in the ring instead of one has no effect on this instability because it is very short range.

On the other hand, a pi-mode instability arrises in the ring due to bunch coupling to HOMs in the RF cavities. The bunches exhibit both zero mode and pi-mode oscillations with respect to the ring RF. The zero mode oscillation is damped by synchrotron radiation but the pi-mode is not. To counteract this instability, a passive cavity was added to the ring in 1992 [4]. At the time, the cavity was tuned to 1062.4 MHz, just below the 125^{th} revolution harmonic to accommodate two bunches with a bunch separation $t_i = 61.6$ ns. The cavity has a movable plunger that can be adjusted to match the frequency of the pi-mode oscillation for each of the different bunch separations tested at FACET.

MAIN LINAC

The beam is extracted from the NDR and passes to the main linac via the North Ring-to-Linac arc. The bunches pass through a compressor cavity at the zero crossing of the RF and this imprints a linear chirp on the beam. The beam is compressed down to 500 μm bunch length by the R_{56} of the chicane and then captured in an s-band bucket in the linac. Once the bunches reach the linac, the trailing bunch is affected by longitudinal and transverse wakefields of the leading bunch. Those two effects are discussed below.

Beam Loading

The leading bunch absorbs energy as it passes through the accelerating cavities. This energy cannot be replaced with additional energy from the klystron if the inter bunch spacing is very short. This effect, called beam loading, results in the trailing bunch receiving less energy after passing through the cavity as compared to the leading bunch. The voltage drop induced in the cavity by the leading bunch is given by $V_w = 2eNL\kappa_z$ where eN is the bunch charge, L is the cavity length, and $\kappa_z = 20$ V/pc/m is the fundamental wakeloss factor for the SLAC s-band cavities. The trailing bunch sees the accelerating voltage reduced by this amount.

If the cavity phase is not zero (on crest), the trailing bunch also sees a different RF phase as compared to the leading bunch. The phase the trailing bunch sees is given by Eq. 1 and explained visually in Fig. 2.

$$\phi' = \tan^{-1}\left[\frac{V_{RF}\sin\phi}{V_{RF}\cos\phi - V_w}\right] \quad (1)$$

The phase shift effect is significant at FACET because each sector in the front half of the linac is phased differently. The chirping scheme depicted in Fig. 3 was designed to minimize the effect of wakefields on the beam at low energy while still achieving the necessary chirp for compression in the Sector 10 chicane. The phase in each sector is an integer multiple of the Decker Phase, which is usually about 10^o. This rather complicated chirping scheme means that the trailing bunch will we see a different phase relative to the leading bunch in Sectors 2 though 10. The resulting phase shifts are listed in Table 1.

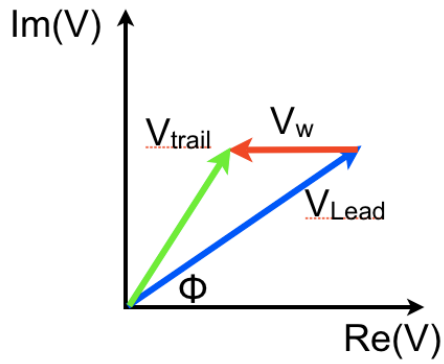

Figure 2: Phase diagram showing the RF voltage and phase difference seen by the trailing bunch.

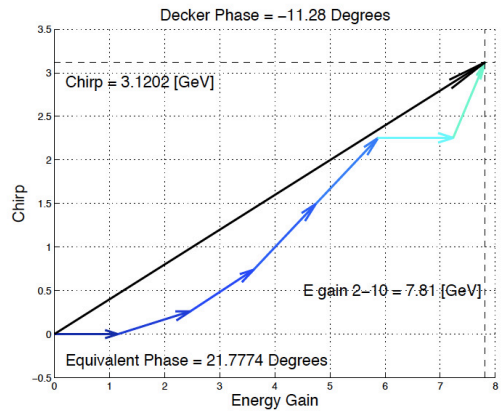

Figure 3: FACET front-end chirping scheme. Each phase arrow represents one sector and is an integer multiple of the Decker Phase.

Table 1: Sector by Sector Phase Shifts for a Decker Phase of 10^o. Note that Sectors LI07 and LI08 are omitted from the table since they are not powered.

Sect.	L [m]	$V_{RF}[GV]$	ϕ	V_w [MV]	$\Delta\phi$
LI02	75.5	1.59	0^o	9.66	0^o
LI03	96.0	1.85	10^o	12.3	0.066^o
LI04	84.0	1.72	20^o	10.8	0.12^o
LI05	97.4	1.88	30^o	12.5	0.19^o
LI06	97.4	1.88	30^o	12.5	0.19^o
LI09	97.4	1.88	0^o	12.5	0^o
LI10	67.0	1.44	50^o	8.57	0.26^o

Beam loading reduces the energy of the second bunch by 0.8% in Sectors 02-10 and 0.5% in Sectors 11-20, relative to the first bunch. This does not pose a problem because the full-width half-maximum energy apertures of the Sector 10 and Sector 20 chicanes are 5% and 4% respectively. The effective phase of the trailing bunch with respect to the

Copyright © 2013 CC-BY-3.0 and by the respective authors

leading bunch is 23.49^o compared to 23.38^o at the Sector 10 chicane. Although this effect seems small, it is amplified by the difference in compression that each bunch will see in the Sector 10 chicane, which leads to different wakefields in Sectors 11-20. Short-range longitudinal wakefields effectively chirp the extremely short beams, and therefore they will be compressed differently in the Sector 20 chicane. This extremely non-linear problem will be studied in simulation to determine the severity of the effect.

RF Pulse Compensation

For bunch separations larger 5.6 ns, RF pulse compensation can be used to correct for the beam loading effect. The SLEDed RF pulse fills the cavity over a period of several microseconds according to the parabolic form depicted in Fig. 4. Typically, the bunch is accelerated at the crest of the pulse. In order to accommodate multiple bunches per pulse, the bunches are instead accelerated on the rising slope of the pulse, with the leading bunch slightly lower on the slope and the trailing bunch slightly higher. For a bunch separation of 16.8 ns (three times the minimal separation), the effect of beam loading can be totally compensated [5].

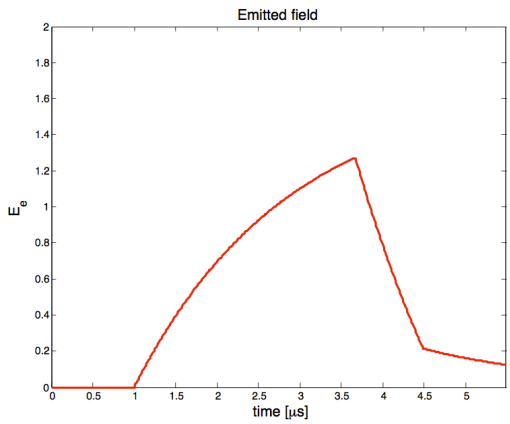

Figure 4: Temporal shape of the SLEDed pulse in the s-band cavity.

Transverse Wakefields

If the leading bunch is misaligned with respect to the RF cavities, the trailing bunch may see a significant transverse kick from the wakefields in the cavity. Fig. 5 shows that there is a minimum in the transverse wake strength at around 5 ns. For this reason, it is advantageous to choose the 5.6 ns bunch spacing for our first tests of multibunch operation. The size of the second envelope in Fig. 5 is indicative of the wake strength out to 60 ns, which is the largest bunch separation possible at FACET [6].

CONCLUSION AND OUTLOOK

The scientific merit for multibunch studies at FACET is very high considering the recent advances in plasma wakefield technology. It is critical to demonstrate that PWFA is stable and reproducible at high repetition rates before this technology can be used in light source or collider applications.

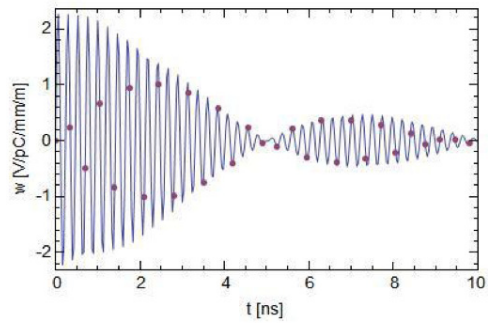

Figure 5: The time domain transverse wakefield in the SLAC s-band cavity.

Relatively few systems need to be modified in order to achieve in the multiple bunches at FACET. However, from an operations perspective, the multibunch mode is challenging because many diagnostics, including BPMs, cannot resolve the closely spaced bunches, and the timing windows are very tight for injection and extraction at the NDR. Some of these issues might be mute if the thermionic cathode is replaced by an LCLS-style photocathode. This has been proposed for FACET or FACET II. On the other hand, the phase shifts in the main linac are still an important issue, and would have to be dealt with for any high-charge, multibunch mode at FACET, regardless of the beam source.

SIMULATION OF POWER COUPLING AND WAKEFIELD IN PHOTONIC BANDGAP FIBERS FOR DIELECTRIC LASER ACCELERATION*

C.-K. Ng, R.J. England, A. Kwiatkowski, R.J. Noble, J.E. Spencer, SLAC, Menlo Park, U.S.A.

Abstract

A photonic bandgap (PBG) lattice in a dielectric fiber can provide high gradient acceleration in the optical regime, where the accelerating mode is obtained from the presence of a single defect in the lattice. In this paper, we will investigate two aspects of the PBG for acceleration. First, the excitation of the accelerating mode can be achieved by directing high-power lasers from free space. Simulation using ACE3P has demonstrated that, by appropriately shaping the end of the PBG fiber, power can be coupled into the fiber using a simple laser configuration. Second, the wakefield generated by the transit of a beam through a PBG fiber will be simulated. The radiation spectrum of the wakefield will be evaluated and corroborated with measurements from a commercial fiber.

INTRODUCTION

The photonic bandgap (PBG) structure proposed by Lin [1] has demonstrated the possibility of confining an accelerating mode in an energy bandgap existing in a periodic lattice of vacuum holes in a dielectric fiber with a central vacuum defect of larger diameter. High accelerating gradient can be achieved in such fibers in the optical regime using lasers for excitation of the accelerating mode. The mechanism of coupling power into the PBG fiber needs to be investigated to ensure efficient excitation of the accelerating mode. Previous studies have shown that a coupling scheme from free space by directly focusing laser pulses in a certain configuration into the fiber can excite the accelerating mode [2]. However, for best results the configuration requires an array of six laser beams arranged in a pattern that obeys the hexagonal symmetry of the Lin lattice. It is desirable to develop improved coupling schemes that can simplify the laser configuration by modification of the existing geometry. It will be shown in the next section that a simpler coupling scheme can be achieved by appropriately shaping the end of the PBG fiber.

While attempts to fabricate Lin-type PBG fibers that can support an accelerating mode are being explored, off-the-shelf telecom fibers are available in the commercial market place, providing samples that can be tested using high energy electron beams at the test facility at SLAC [3]. An example of these commercial fibers is the HC1060 fiber of NKT Photonics which supports the propagation of a telecom mode at the wavelength of 1060 nm. Although the HC1060 fiber does not support a strong TM-like accelerating mode, by measuring the radiated signal after the passage of an electron beam, it is possible to identify the modes that exist in the bandgap of the fiber. In order to corroborate with the measured radiation spectrum obtained from beam tests, simulations have been carried out using the 3D parallel electromagnetic code suite ACE3P [4] to model beam excitation in the HC1060 fiber to calculate wakefield effects and to compare with measurements.

POWER COUPLING IN LIN FIBER

The Lin PBG fiber consists of circular holes in a hexagonal lattice with spacing a between the centers of neighboring holes. The holes have a radius of $0.35a$. In order to introduce a defect in the lattice, one hole is replaced by another with a radius of $0.52a$. The material of the fiber has a dielectric constant of 2.13 for this glass at near IR wavelengths. A quarter of the model in the transverse plane is shown in Fig. 1, exhibiting a lattice with hexagonal symmetry and a central defect. The Lin PBG fiber supports a TM-like accelerating mode. For example, the wavelength of the defect mode is 2 μm for a = 2.61 μm. Using ACE3P's frequency domain eigensolver module Omega3P, the calculated longitudinal electric field pattern of the defect mode is shown in Fig. 1. It can be seen that a fairly uniform longitudinal electric field appears in the central circular hole and the field magnitude decays gradually at larger radial distances.

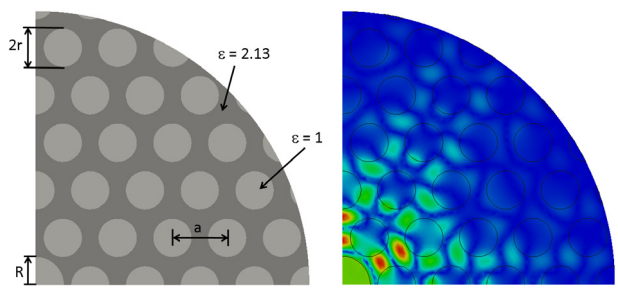

Figure 1: (Left) A quarter model of the Lin PBG fiber; (Right) The longitudinal component of the electric field of the defect mode in the Lin PBG fiber.

The study of power coupling from free space can be carried out through an inverse process by simulating the transmission and radiation of the accelerating mode through a slab of the fiber. The electric and magnetic field patterns calculated by Omega3P are loaded as an excitation at the incident port for ACE3P time domain simulation module T3P. The calculation has been reported in a previous work [2] and has shown that the radiation focuses in six hot spots, which observes the hexagonal symmetry of the Lin fiber. Figure 2 shows the model used in the simulation where a cylindrical slab of the fiber is placed in a hemisphere representing the free

Copyright © 2013 CC-BY-3.0 and by the respective authors

space. The power on the surface of the hemisphere exhibits the six-fold symmetry of the radiation pattern.

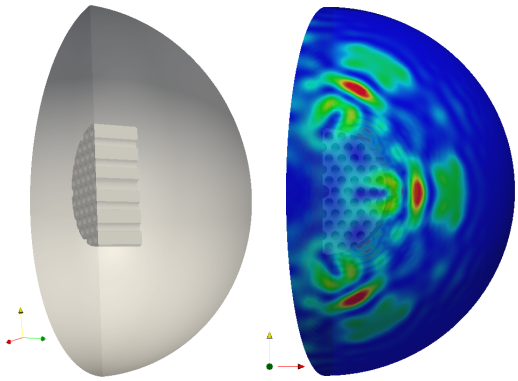

Figure 2: (Left) One half of the model for a cylindrical slab located in free space with the defect mode driven from the left end of the slab; (Right) Radiated power pattern in the forward hemisphere (after reflection at the symmetry plane in the front) with radius of 40λ.

Modification of the above scheme by cleaving the end of the fiber at a certain angle has shown that the far-field radiation pattern changes to a simpler pattern. A model with a cleaved angle of 45° is shown in Fig. 3. By varying the angle gradually, the far-field radiation pattern moves away from its six-fold symmetry without cleaving to focus into two well-defined spots in the upper hemisphere for the slab cleaved with an angle of 45° at the mode exit end. Figure 4 shows the comparison of the far-field radiation for the two cases with and without cleaving. The latter fiber geometry that produces the two hot radiated spots has the potential of simplifying the configuration of laser beams needed to excite the defect mode.

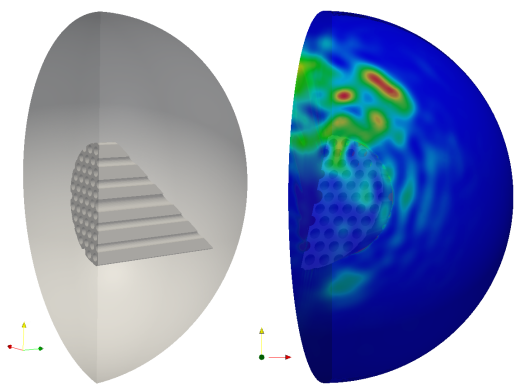

Figure 3: (Left) One half of the model for the Lin fiber slab cleaved at 45° at the exit end of the mode propagation; (Right) Radiated power pattern in the forward hemisphere (after reflection at the symmetry plane in the front) with radius 40λ.

WAKEFIELD IN HC1060 FIBER

The geometry of the commercial HC1060 fiber (KNT Photonics, Denmark) used for telecom was carefully modeled based upon scanning electron micrograph (SEM)

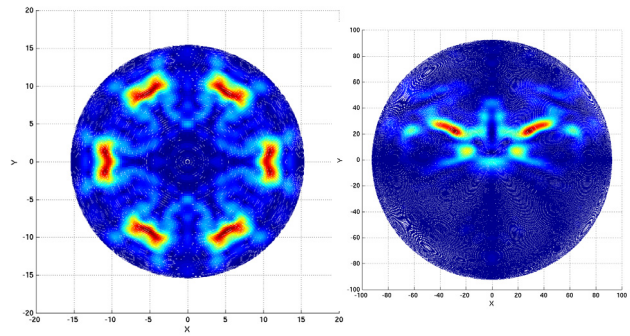

Figure 4: Far-field radiation pattern in the forward hemisphere with radius 80λ for (a) fiber without cleaving showing six-fold symmetry; (b) fiber cleaved at 45° showing two hot spots.

images taken at Stanford University. Figure 5 shows a recent SEM image of a HC1060 sample with ε = 2.13 that was used in the wakefield experiments. The core of the fiber is a circular region, which is the PBG lattice, surrounded by a cladding with a thickness about 2/3 of the diameter of the lattice region. The lattice has a central defect whose size is much bigger than the other lattice holes when compared with the Lin fiber in the previous section. The lattice holes are separated by dielectric vertices and webs whose dimensions are on the order of sub-microns. Simulation using R-Soft BandSolve shows that the web thickness determines the bandgap location with thicker web making lower bandgap frequency. The glass vertices determine the bandgap width, with more glass making wider bandgap. More detailed SEM measurements will be carried out to elucidate more accurately the vertices and web dimensions. For T3P simulation, the lattice period a 2.75 μm, the defect diameter 9.6 μm, the vertex size = 0.16a, and the web thickness = 0.036a have been used.

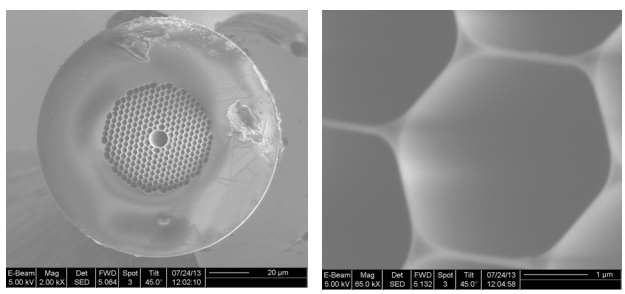

Figure 5: (Left) SEM image of a sample HC1060 commercial fiber; (Right) Close-up image showing the glass webs and vertices connecting the vacuum hexagonal-shape holes.

The T3P simulation of the HC1060 fiber assumes a perfect symmetry of the lattice, so that a 30° slice is sufficient to model the full geometry for the excitation of an axial beam. A Gaussian bunch of RMS σ = 0.3 μm enters from the left boundary and transits through the fiber with a length of 20a. The frequency content of the Gaussian bunch covers the bandgap frequency range as

Copyright © 2013 CC-BY-3.0 and by the respective authors

well as that contributed by mostly the cladding modes located near the edge of the fiber. Figure 6 shows a snapshot of the wakefield generated by the transiting beam. The trailing field inside the lattice indicates possible excitation of the fiber modes and the field in the cladding demonstrates Cerenkov radiation because of its higher dielectric constant. The simulated model has a shorter cladding width than that shown in the SEM image. This mostly affects the excitation of the cladding modes. The effect on the lattice modes is small. The radiation field is monitored as a function of time outside the HC1060 structure, from which the mode spectrum is obtained by the Fourier transform of the radiated signal.

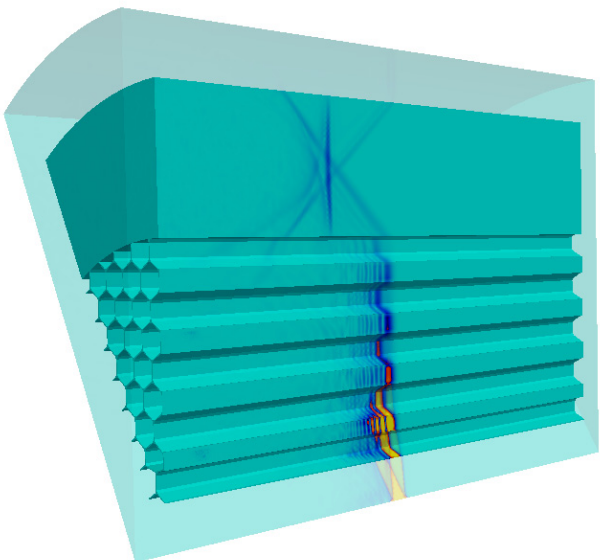

Figure 6: Snapshot of T3P simulation of beam transit through the HC1060 fiber enclosed in a vacuum region. The beam enters the structure from the left end and exits at the right.

Figure 7 shows the comparison of the radiated spectrum obtained by simulation and measurements. The spectrograph measurement in the experimental setup ranges from 550 nm to 1200 nm with 3 nm resolution step, which is comparable to the resolution of the time domain simulation. It can be seen that the simulated spectrum is in good qualitative agreement with measurements. It should be pointed out that modes of lower frequencies (or longer wavelengths) are also found in simulation. They are likely the modes generated in the cladding region of the HC1060 and will radiate away at short distances. The spectrograph measurement can be extended to the lower frequency region to determine whether the cladding modes still contribute to the signal measured at large distance from the beam excitation region.

The modes in the peaks of the spectrum can be identified by calculation in the frequency domain using Omega3P. Figure 8 shows some modes that are localized in the lattice without much field content in the cladding. In particular, a mode with significant longitudinal electric field component is found at 994 nm, which is just outside the bandgap calculated by BandSolve.

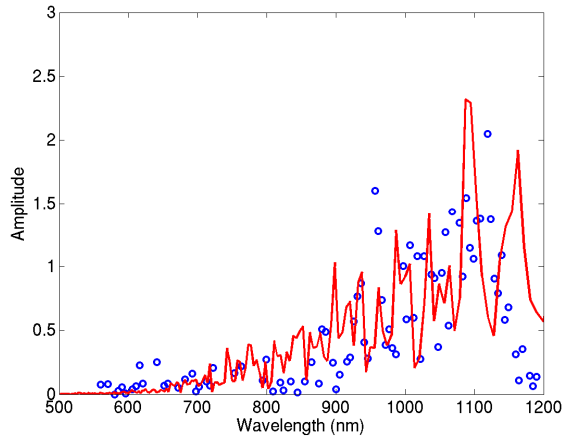

Figure 7: Comparison of simulation (red) and measurements (blue) for the radiation spectrum generated by a beam transit in the HC1060 fiber.

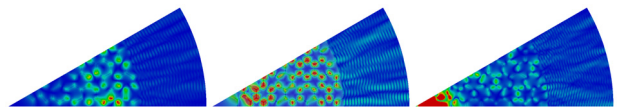

Figure 8: Field patterns of lattice modes in the HC1060 fiber. The wavelengths of these modes are 1150 nm, 1114 nm and 994 nm (from left to right).

SUMMARY

We have used the electromagnetic code suite ACE3P to simulate power coupling and wakefield in photonic bandgap fibers. A simple mechanism of coupling power into the Lin fiber for exciting the accelerating mode can be achieved by cleaving the fiber end at 45° where the laser pulses are directed as indicated in Fig. 4. For the HC1060 commercial fiber for telecom applications, simulation results corroborate well with wakefield experiments, showing that modes in the bandgap can be excited by the transit of a beam through the fiber.

Abstract

Rapid progress in the development of laser technology and in the sophistication of semiconductor manufacturing has enabled the realization of the first dielectric laser-driven particle accelerator (DLA) on a chip [1]. Since the accelerating channel in DLA structures typically have dimensions in the sub-micron range, the ability to precisely control particle position within these structures will be critical for operation. A number of beam deflection and focusing schemes have been devised, but without the ability to measure the position of the particle beam to nanometer accuracy, these schemes will be extremely difficult to implement.

We present a new concept for a beam position monitor with the unique ability to map particle beam position to a measurable wavelength. Coupled with an optical spectrograph, this beam position monitor is capable of sub-nanometer resolution. We describe one possible design of this device, and present the current status of the structure fabrication and experimental demonstration.

INTRODUCTION

Recent success at SLAC and Stanford have demonstrated the proof-of-principle of the dielectric laser-driven accelerator (DLA) [1]. These dielectric accelerator structures are fabricated using commercially developed lithographic fabrication methods and can be mass produced on conventional dielectric wafers. The accelerator structures are powered using commercially available laser systems, rather than specialized klystrons, and can support peak electric fields well beyond those found in traditional accelerator components. Therefore, DLAs have the advantage of requiring a three-order of magnitude smaller footprint, while boasting significantly higher acceleration gradients than those achievable in traditional accelerator structures. With its inherent advantages, DLAs have the potential to revolutionize the concept of particle accelerators, moving the technology from expensive grand-scale machines to low cost printed microstructures. The applications of compact particle accelerators are numerous and extensive, spanning everything from radiation therapy to x-ray microscopy. While the recent proof-of-principle demonstration is a momentous occasion, the road to a complete particle accelerator-on-a-chip is still an arduous journey. A complete particle accelerator will require the staging of hundreds or thousands of individual dielectric accelerator microstructures, as well as beam focusing and beam deflecting elements – with submicron alignment tolerances. And although nanometer-class alignment of structures within a single wafer is inherent through well-established lithography methods, alignment from wafer-to-wafer does not have a corresponding process. For this reason, beam monitoring elements will necessarily be a critical component for DLA devices.

We present experimental demonstration towards a novel beam position monitor (BPM) which has the ability to map beam position to a measurable wavelength [2]. Coupled with a commercial optical spectrograph, this novel BPM device is capable of sub-nanometer resolution. Additionally, this BPM device can be easily fabricated alongside the DLA accelerator structures, using the same mass-producible lithographic processes; thereby ensuring nanometer-class alignment.

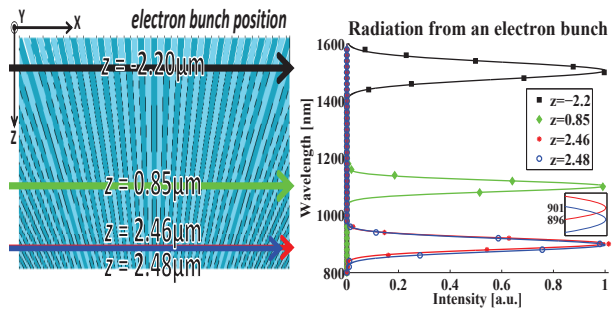

Figure 1: A top-down view of the grating BPM geometry (left), and the predicted normalized radiation spectrum from an electron bunch traversing the grating BPM at four unique positions (right). The markers on the plot represent simulation data, whereas the solid lines depict a Gaussian fit. The inset highlights the distinct radiation spectrum generated by two closely separated bunches.

The geometry of the proposed beam position monitor is shown in Fig. 1. The structure operates on the principles of an inverse-accelerator structure. If a grating accelerator structure can accelerate electrons with a laser pulse, then by reciprocity an electron beam traversing an unpowered grating structure will decelerate (slightly) and radiate. Based on the operating principles of the grating structure as an accelerator, we expect the generated wakefield radiation to be polarized in the direction of beam propagation. Additionally, from the phase-synchronicity condition ($\lambda_{laser} = \lambda_{grating}$), we expect a traversing electron beam to generate wakefield radiation with a center wavelength matching the observed structure periodicity. By varying the periodicity of the grating structure as a function of position, we create a structure which generates position-dependent

radiation. We can then deduce the position of a traversing electron beam by simply observing the color of the radiation.

We have begun fabrication of a grating beam position monitor with a periodicity varying continuously from 800 nm to 1600 nm. A lithographic mask has be produced, and initial analysis of the exposure of resist on a fused silica wafer look promising, as shown in Fig. 2a. In anticipation of a complete grating BPM structure, we have begun beam-based experiments to demonstrate the proof-of-principle of the BPM device concept. In the following experiments, we verify the operating principles of the grating BPM using a single period grating structure as a stand-in, shown in Fig. 2b. Namely, we verify a polarization dependent radiation, as well as a geometry dependent radiation wavelength.

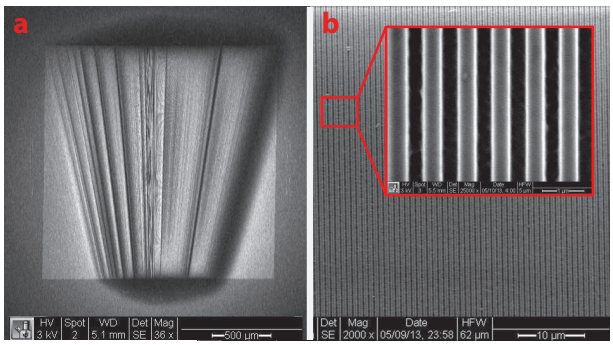

Figure 2: SEM images of (a) the in-progress grating BPM structure and (b) the uniform single period grating accelerator structure.

EXPERIMENT

The experiments were performed at the Next Linear Collider Test Accelerator (NLCTA) at SLAC. The NLCTA beamline is capable of generating a 60 MeV relativistic electron beam, with a bunch length of 130 μm and 5 pC of charge. This electron beam is then focused through a high-field strength permanent magnet quadrupole triplet, which produces a typical beam r.m.s. spot size of 30 x 30 μm^2 at the entrance of our test structure. The test structure itself is mounted on a four-axis stage, allowing for micrometer-precision control of the structure's vertical, horizontal, tip, and rotation with respect to the beam. The structure used in this experiment was the uniform binary dual grating structure optimized for the laser-driven acceleration experiments [1]. In this experiment, a drive laser source was not used to power the structure. Instead, a photomultiplier tube (PMT) was used to monitor the coupling port, along with either a polarizer or a spectrograph to filter the radiation. A simplified schematic is shown in Fig. 3.

In the first experiment, we monitored the strength of the radiation signal filtered by a polarizer. The physics of the grating accelerator predicts a strong wakefield polarization in the direction of the beam trajectory. In our experiment, this will manifest as a cosine-squared pattern in the wakefield intensity versus polarization. We find that our experimental results are in strong agreement with theory, as shown in Fig. 4. This agreement verifies that the nature of the radiation is an inverse-acceleration effect, rather than Cherenkov or optical transition radiation.

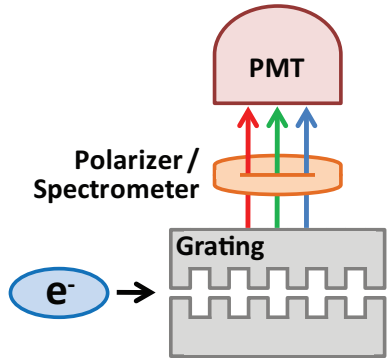

Figure 3: A simplified schematic of the primary components in the wakefield radiation experiment.

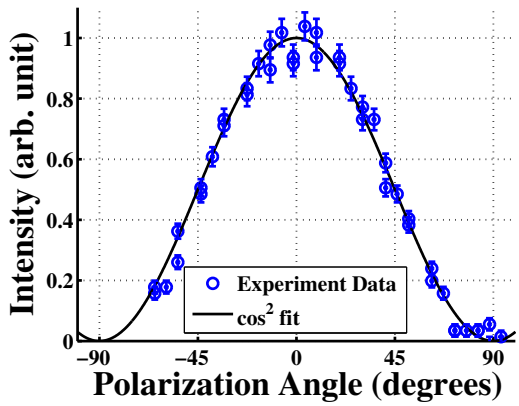

Figure 4: Experimental data (blue markers) showing highly polarized wakefield radiation, which is in strong agreement with theory (black line).

In the second experiment, we monitored the strength of the radiation signal filtered by an optical spectrograph (10 nm slit width). From the electron-laser phase synchronicity condition of the grating accelerator, we expect to observe wakefield radiation with a periodicity matching that of the grating accelerator. A wavelength versus intensity scan of the emitted wakefield radiation reveals a distinct peak in radiation near the design periodicity of the grating structure. We extract the wavelength peak and bandwidth by fitting the recorded wakefield spectrum with an asymmetric Gaussian, as shown in Fig. 5, where we find a center radiation wavelength at 782.5 $\pm$ 9.5 nm. This is in close agreement with the 800 nm design period of the grating structure. The wide bandwidth of the radiation signal is likely due to the 10 nm slit width of the spectrograph.

In the third and final experiment, we varied the rotation of the grating structure relative to the electron beam,

Copyright © 2013 CC-BY-3.0 and by the respective authors

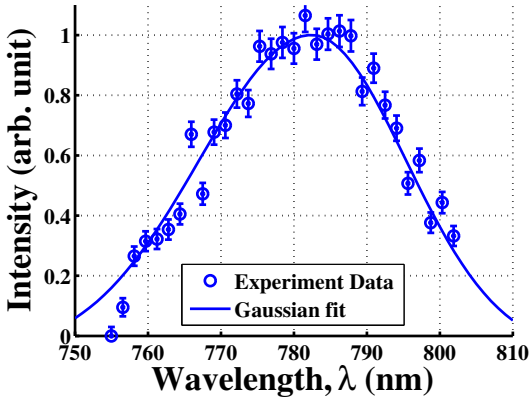

Figure 5: Spectrum of the wakefield radiation as measured by a spectrograph (blue markers). An asymmetric Gaussian fit (blue line) predicts the center wavelength at 782.5 nm with a bandwidth of 9.5 nm.

thereby effectively modifying the grating period observed by the electrons. For a grating structure rotated at an angle ϕ relative to the electron trajectory, the effective grating period λ_e is given by,

$$\lambda_e = \frac{\lambda_0}{\cos\phi} \tag{1}$$

where λ_0 is the nominal grating period. At each grating rotation position, we measured the wakefield spectrum using an optical spectrograph, in the same manner as the previously mentioned experiment. A comparison of the extracted peak wavelength for five unique rotation positions reveals the trend described by Eq. 1. This comparison is shown in Fig. 6.

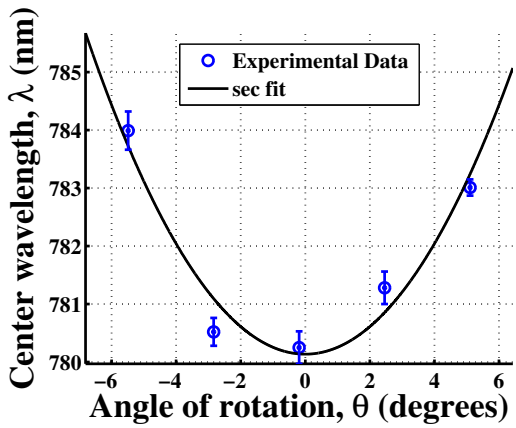

Figure 6: The observed center wavelength (blue markers) at five distinct grating rotation angles. A secant fit to the data (black line) verifies that the radiation wavelength is dependent on the structure geometry.

From these three experiments, we demonstrate the operating principles of the grating beam position monitor. We observed a wakefield radiation signal generated by the inverse-acceleration effect, we measured the spectrum of the wakefield radiation, and we show that the spectrum of the wakefield radiation signal is highly dependent on the geometry of the radiating structure. Future work include the complete fabrication of the continuously variable grating beam position monitor, as well as the beam testing of this device.

SILICA ROD ARRAY FOR LASER DRIVEN PARTICLE ACCELERATION*

Abstract

Here we describe a structure of double-row silica rods array for laser driven acceleration. Similar to the dual-layer rectangular grating structure, the periodic arrangement of the rods alongside the beam channel provides the necessary phase modulation of the electromagnetic fields, and therefore required phase synchronicity for laser acceleration of charged particles. Resonances among adjacent rods could enhance the near-fields in the gap region to achieve high gradient operation. Simulation has been carried out to optimize the structure dimensions for high accelerating gradient or high acceleration factor. Results show that acceleration factor up to 0.45 could be achieved from this rod array structure. One advantage of this structure is that all the rods are fabricated on one single substrate, therefore positioned and aligned with photolithographic level precision. Several prototype samples have been fabricated for potential laser acceleration experiments.

INTRODUCTION

To utilize the extraordinary electric field available from the state-of-the-art laser systems for charged particle acceleration has long been attractive in the advanced accelerator research. Laser driven dielectric accelerator structures possess advantages over conventional metallic RF structures in their miniaturized dimensions, greatly reduced manufacturing cost, larger breakdown threshold, and higher accelerating gradient [1]. Several resonant or waveguide based structures have been proposed theoretically [1-3]. Recently, near-Infrared laser induced electron energy modulation has been demonstrated for the first time on a fused silica near-field grating structure [4], with larger than 250 MV/m gradient observed.

The dual-layer rectangular grating structure [2] is advantageous for its structural simplicity and convenience of excitation (direct side illumination). However, on-chip power network of an integrated accelerator or accelerator-based light source usually employs a high-index-material waveguide sitting upon a planar low-index substrate, where laser light travels inside the waveguide parallel to the substrate. Side illumination then implies that grating teeth needs to stand up straight with respect to the chip substrate. Direct lithographic fabrication of these vertical teeth up to tens of micron tall is challenging. To vertically assemble a dual-layer, pre-bonded grating accelerator to the chip substrate also demands much fabrication and alignment effort.

Meanwhile, deep etching of silicon to form long cylinder array on a substrate has been demonstrated feasible. Oxidation process after etching is also demonstrated to transfer these rods to fused silica. This rod array may essentially serve as the phase-resetting dielectric mask just as well as the rectangular grating structure, but already integrated since it can share the same substrate with the on-chip waveguide network. This paper explores this possibility, by looking into achievable acceleration gradient from a silica rod array structure. Parametric study results of the structure dimensions will be shown, aiming for either optimal acceleration factor or large field enhancement. Following that will be an introduction to the manufacture of the structure.

DESIGN AND SIMULATION

Figure 1 below illustrates the proposed rod array accelerator structure. Two rows of dielectric rods with radius r and length l are laid on a substrate. The two lines are separated in the z direction by a gap width w, forming the electron accelerating channel. Rods across the gap have their centre positions aligned along the y direction. Within each row, the centre-to-centre periodicity between adjacent rods is p. Laser light is incident along the z direction to power this accelerator structure.

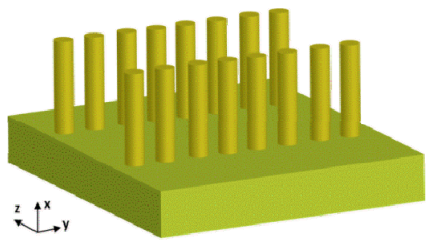

Figure 1: Layout of the rod array accelerator structure.

Silica Rod Array for Acceleration

The structure is modelled in Ansoft HFSS [5] to look for possible phase modulation for net acceleration gradient. Figure 2 shows the single-period structure simulated, with its geometrical parameters denoted on the schematic. Its y-direction periodicity is reflected by assigning master and slave boundary conditions to its left and right xz plane boundaries, with zero-degree phase delay. A plane wave excitation propagating towards the positive z direction is launched, with two perfect-matching-layer boundaries terminating the front and back xy planes to simulate infinite open spaces. The incident plane wave has its e-field polarized in the y direction, with magnitude of 1V/m. The top and bottom yz planes of the model are terminated by perfect magnetic boundary

Copyright © 2013 CC-BY-3.0 and by the respective authors

conditions, so that the rods (1 um long in the model) are effectively infinitely long in the x direction. The rods are made of silica with a dielectric constant of 2.40 and assumed no material loss. The periodicity p is set to 3 um, and so is the simulation wavelength. Note that the gap width $w = p/6$ is defined as the nearest rods edge distance along z, so that the centre-to-centre rod distance is $w+2r$ as marked in the figure. The rod radius is initially set to $0.456p$ in order for the plane wave to experience π extra phase shift per rod along its longest dielectric path in the z direction, so that the wave front can be recovered past the rods [2]. The inset in Fig. 2 plots the real part of the E_y component on the bottom yz surface. One can observe that the incident plane wave recovers its phase front well behind the rods. Also an enhanced field and modulated phase distribution occur in the gap between the rods, which are necessary for net acceleration after integration over one period.

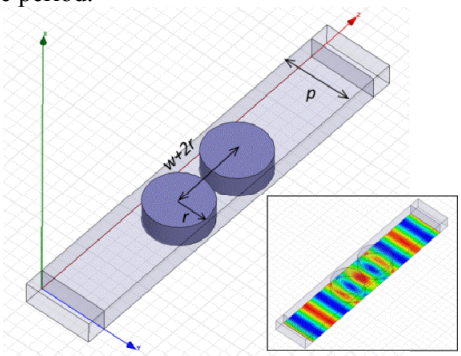

Figure 2: Simulation model of one period of the silica rod array accelerator structure. Inset is the colour map of its longitudinal y component with a plane-wave illumination.

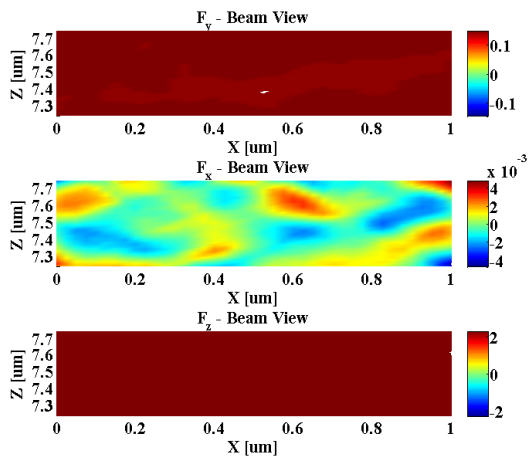

Figure 3: Integrated accelerating force F_y, and deflecting forces F_x and F_z over one rod array period, at a particle injection phase optimized for maximum F_y.

To evaluate the accelerating and deflecting forces a charged particle traversing the channel experiences, the three components E_x, E_y, and E_z in the gap region are sampled and exported. E_y at the centre of the xz cross-sectional area, offset by an extra phase Φ denoting the particle injection phase with respect to the optical phase, is then integrated over the y coordinate for one period to get $F_y(\Phi)$ as the integrated kick a particle of unit charge will encounter. Φ is then scanned over the 2π optical cycle to determine its optimal value to maximize the net acceleration F_y. E_x and E_z are then offset by this optimal injection phase, and integrated as the net deflecting kicks. Calculation results of the model in Fig. 2 are colour-mapped over the gap transverse area in Fig. 3 below. Net acceleration is indeed feasible, with quite uniform F_y of around 0.145 V/m over the whole cross-section of the channel. F_x is almost three orders of magnitude smaller, thus negligible. However, F_z is quite large – about 2.253 V/m over the transverse area, therefore this structure mainly deflects the particle in the z direction.

Elliptical Rods to Optimize Acceleration

From the inset of Fig. 2, it is clear that the dielectric path length along the longitudinal y direction needs to be further shortened to approach one half of the full sinusoidal cycle, so that ideal for maximum net acceleration [2]. With the z dimension size of the rods fixed still for the purpose of the wave front recovery, it implies that the rods need to be elliptically shaped, whose major axis radius R_z will be equal to $r = 0.456p$, and minor axis radius R_y being a variable.

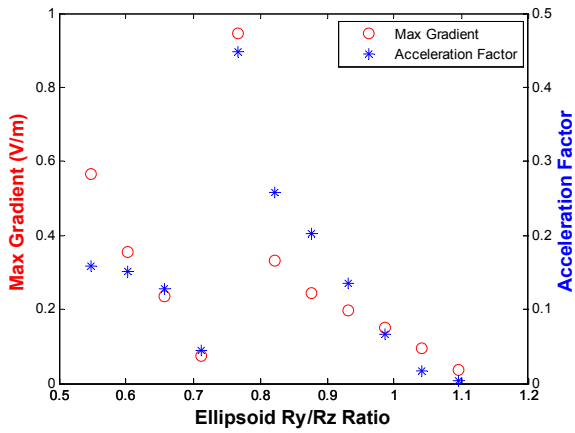

Figure 4: Maximum longitudinal gradient (red circle) and the corresponding acceleration factor (blue star), as the minor axis length of each rod in an elliptical rod array accelerator varies.

Parametric study of R_y (with $p/6$ gap width) has its results plotted in Fig. 4. The maximum gradient value is still the integrated acceleration gradient F_y at optimal injection phase. The acceleration factor (AF), as another important figure of merit (FOM) for dielectric laser acceleration, is defined as the acceleration gradient divided by the maximum e-field magnitude in the dielectric material. It measures the practical achievable gradient before the material breaks down at certain threshold field intensity. The plot shows coincident peaks of both FOMs at $R_y = 0.767R_z$, where the maximum gradient F_y is greatly improved, reaching 0.945 V/m. The optimal acceleration factor on the right ordinate is

Copyright © 2013 CC-BY-3.0 and by the respective authors

roughly 0.45. It is worth mentioning that in this case F_z is about 1.05 V/m and F_x remains negligible. Thus the longitudinal kick is of comparable magnitude with the deflection kick, also a great improvement over the circular rod array design.

Resonant Structure to Enhance Gradient

When doing the same parametric study of R_y, however with doubled gap width $w = p/3$, the elliptical rod array structure shows strong field resonance at $R_y = 0.658R_z$. In this case, with the same incident field magnitude of 1 V/m, the scattered fields from one rod and its adjacent rods interfere constructively, enhancing the longitudinal field in the middle of the gap up to 42 V/m from simulation. Figure 5 illustrates this sharp resonance, and the resultant extraordinary gradient of 17.9 V/m at the peak of the resonance. The inset figure depicts the colour map of the E_y component on the bottom surface of the model, much stronger in magnitude than the excitation plane wave. However, the inset also shows enhanced fields at spots inside the silica rods, normalizing the large gradient to mediocre AF values of 0.311 maximum and 0.267 at the resonance peak.

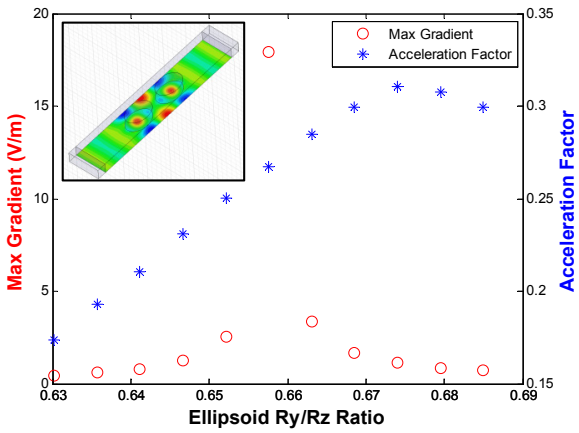

Figure 5: Maximum gradient (red circle) and the corresponding AF (blue star) of a resonant elliptical rod array design.

Despite the fact that its AF is not outstanding, with much smaller excitation field this resonant design could yield the same accelerating gradient as that of non-resonant designs. Therefore it could be operated at low laser power level. Also, at resonance the other two components E_x and E_z remain unenhanced, and the integrated deflecting kick F_z is only 1.8 V/m, almost one order of magnitude lower than the longitudinal kick. F_x is three orders of magnitude lower than F_y. This resonant design deflects charged particles much less, and uses laser energy more efficiently on acceleration.

FABRICATION

The adopted strategy to make this silica rod array structure is to first fabricate the rods in silicon and then convert the rods into silicon dioxide. It takes advantage of the available deep etch chemistry for silicon while avoiding the difficulty in fabricating high-aspect ratio silicon dioxide rods. A 600 nm thick negative tone resist, Hydrogen SilsesQuioxane (HSQ), was spun on a silicon wafer and subsequently exposed by an electron-beam lithography tool at 100 kV acceleration voltage. After development the pattern was transferred to silicon in a high-density plasma etching tool using chlorine chemistry. The etched depth was about 10 micrometers. The conversion into silica rods was achieved through wet oxidation at around 900 degree C.

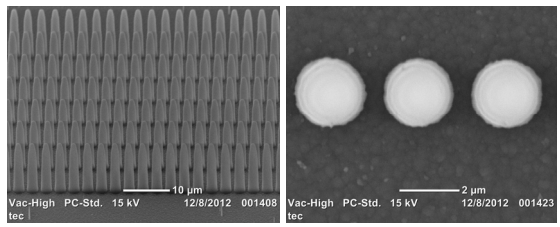

Figure 6: Side-view and top-view SEM images of a fabricated silica rod array structure.

SEM images of some prototype samples of a silica rod array structure are shown in Fig. 6. From the top view on the right, the circular shapes are well defined, and the centre-to-centre spacing of the rods is roughly 3 um. From the side view on the left, the rods have consistent heights of around 10 um. However, instead of a uniform cylinder, each rod exhibits a tapered down diameter along its long axis. A silicon-made rod array may provide net acceleration just as well, whose manufacture then avoids the oxidation process and may lead to better control on the rod cross-sectional uniformity. Fabrication of elliptical shaped rods array is also under exploration.

CONCLUSION

In this work, a new accelerator structure of double-row silica rod array is studied. Net acceleration is found achievable with circular shaped rods, and elliptical shaped rods improve its performance in terms of optimized acceleration factor and reduced deflecting forces. Acceleration factor as high as 0.45 can be realized with an ellipse aspect ratio of 0.767. Of certain dimensions the structure also exhibits strong longitudinal e-field enhancement in the accelerating channel, therefore useful for achieving large gradient with low laser power, and for suppressing beam deflection. Preliminary fabrication of a circular shaped rod array has been done. Samples appear promising, and show room to improve with respect to the uniformity of the rod cross-section, as well as possibility to fabricate elliptical shaped rods.

Abstract

Laser driven ion acceleration has been the focus of considerable research efforts since multi-MeV energies were first demonstrated. Most experiments use solid state laser pulses focused onto thin foil targets. However, recent progress in CO_2 laser technology allows for the creation of intense pulses at lambda $\sim$10 μm. The longer wavelength permits the use of low density targets. In these conditions ion acceleration is primarily driven by a shock wave due to the radiation pressure of the laser. This acceleration mode has the advantage of producing narrow energy spectra while scaling well with laser intensity. New improvements to the CO_2 laser at the Accelerator Test Facility allow for the unique production of a single picoseconds-scale pulse with 1TW peak power. We report on the interaction of an intense CO_2 laser pulse with overdense hydrogen and helium gas jets. Using a two pulse optical probe, we are able to obtain real-time density profiles at different times during the interaction, allowing for the characterization of shock wave velocities and peak density conditions. Ion energy spectra are measured using a Thomson spectrometer and scintillating screen.

INTRODUCTION

Acceleration of protons by intense laser pulses has become an increasingly active area of study amongst nuclear, plasma, and accelerator physicists. Considerable progress has been made using thin foils as targets for high intensity lasers at optical wavelengths [1] [2] . These experiments utilize the highest intensity lasers to reach the highest proton energies, but at the expense of beam quality and energy spread.

An alternative is to use the radiation pressure of the laser to drive hole-boring or shock wave acceleration of ions from a low density target. The ponderomotive force of the laser can drive plasma electrons in an underdense plasma further into the target, forming a critical surface. For a cold electron population, hole-boring acceleration takes place. The plasma critical surface recedes at the hole-boring velocity, v_{HB}, reflecting ions at a velocity of $2v_{HB}$. Recent experiments with intense, circularly polarized, CO_2 laser pulses have demonstrated hole-boring acceleration by producing collimated bunches of protons with energies greater than 1 MeV and narrow energy spread [3] [4].

* Work supported by the United States Department of Energy, Grant DE-FG02-07ER41488.

† ncook@bnl.gov

In the case of a hot electron population, the strong charge separation at the critical surface launches a shockwave into the plasma, which reflects ions at nearly twice the shockwave velocity [5]. This mechanism requires a high electron temperature to reach high shock velocities. Collisionless shockwave acceleration has been shown to similarly produce quasi-monoenergetic proton beams [6].

Improvements to the CO_2 laser system at Brookhaven National Laboratory's Accelerator Test Facility have allowed for the production of ps-scale single pulses with TW peak power [7]. We report on the acceleration of protons using intense linearly polarized CO_2 pulses. With two pulse optical probing, we measure peak densities and shock wave velocities, while ion spectra are measured using a scintillator and Thomson spectrometer. Observed profiles correlate with 1D PIC simulations predicting declining shockwave velocity immediately following the laser plasma interaction (LPI).

EXPERIMENTAL METHOD

Utilizing a isotopic CO_2 mixture in a regenerative amplifier, we amplify a 10.2 μm CO_2 pulse centered on the R-branch of vibrational transitions. The pulse passes through a 10 bar amplifier resulting in a single 5 ps pulse providing a maximum of 1 TW power [7]. The pulse is then focused with an $f/3$ off-axis parabolic mirror to a focal spot of $w_0 = 50$ μm, providing a maximum on-target intensity of $I \sim 3 \times 10^{16} W cm^{-2}$ corresponding to $a_0 = 1.5$. The laser contrast is $> 10^5$ as measured by an infrared power meter.

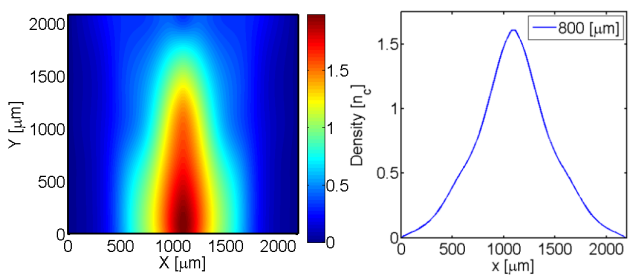

Figure 1: H_2 neutral density from a 1 mm nozzle at 15 bar backing pressure. Right, the density profile 800 μm above the nozzle.

We use 1 mm and 2 mm cylindrical nozzles to produce high density gas jets. Figure 1 shows the neutral density for H_2 gas with a backing pressure of 15 bar. A lineout is taken at 800 μm from the nozzle, showing a peak density

Copyright © 2013 CC-BY-3.0 and by the respective authors

of $1.5 \times 10^{19} cm^{-3}$ along the laser axis, with an underdense absorption region upstream of the laser focus. The critical density for a 10.2 μm laser is $1.06 \times 10^{19} cm^{-3}$.

A frequency-doubled 532 nm YAG pulse is split into two 14 ps probe channels for plasma diagnostics, as shown in Figure 2. Each pulse interacts with the plasma transverse to the laser axis, with a variable delay of 50 ps to several ns achievable between pulses. One beam is used for shadowgraphy; the resulting image provides highlights areas of rapidly changing density, due to the dependence on the 2nd-derivative of refractive index. The other is sent through a Mach-Zehnder interferometer, providing a density dependent fringe pattern.

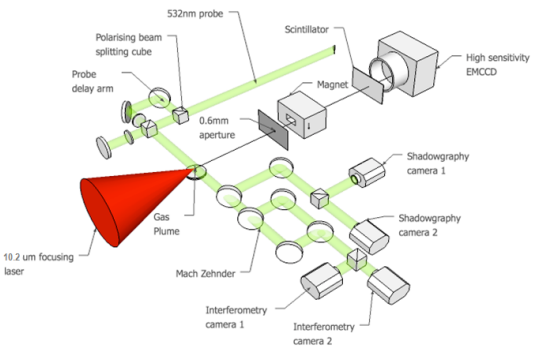

Figure 2: Optical probing arrangement.

The accelerated ion beam is filtered through a 600 μm pinhole before being dispersed by a Thomson spectrometer. The corresponding solid angle seen by the pinhole is 1.2×10^{-5} sr. The beam is dispersed according to momentum by a 5 cm magnet, while a 6.4 cm long electrode provides an adjustable electric field for displacing different ion charge states, if needed. The dispersed beam strikes a 0.5 mm thick sheet of BC-408 polyvinyl toluene (PVT) based scintillator. Photon yield calibrations have been performed using low energy protons at the Stony Brook Tandem Van de Graaf [8]. Scintillation light is imaged by a Princeton ProEM+ EMCCD camera.

PROTON ACCELERATION WITH NARROW ENERGY SPREAD

The ion beam profile is near Gaussian in both spectral and transverse directions, the latter of which is caused by passage of the beam through the pinhole along the laser axis. We can deduce the instrument function of the pinhole from this transverse spread, allowing us to calculate a true spectral profile of the beam. The obtained spectrum is shown in Figure 3. The central energy of the beam is measured at $\sim$ 1.6 MeV with a 12% FWHM energy spread. Using our calibrated BC-408 yields, we observe $\sim 8 \times 10^9$ protons/MeV/sr.

For this particular shot, the H_2 backing pressure is 12 bar, leading to peak neutral densities of $1.5 \times 10^{19} cm^{-3} \simeq 1.4$ n_c. We measure a laser pulse energy of 4.34 J on target, corresponding to $a_0 = 1.25$. The predicted hole-boring velocity at this intensity and density is $v_{hb} \approx 8 \times 10^6 ms^{-1}$, resulting in a kinetic energy of 1.3 MeV, less than the observed proton energies. We also measure the proton density using interferometry taken 132 ps after the beginning of the LPI. By performing an inverse Abel transform on the target's phase map, we obtain electron density profiles of the plasma, as shown in Figure 4.

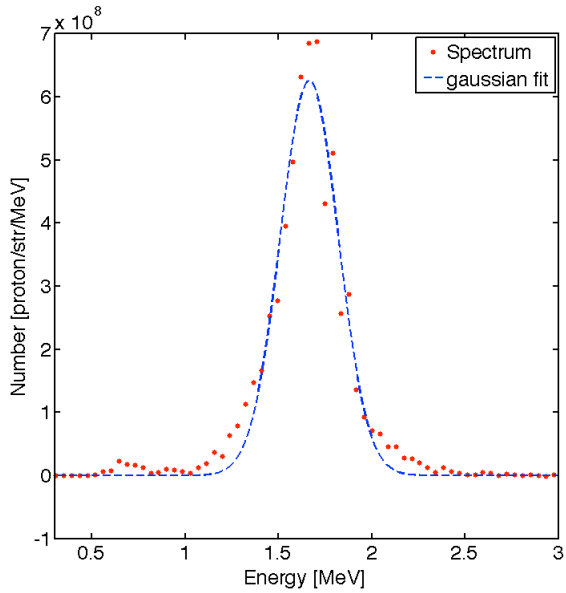

Figure 3: Proton energy spectrum shows a well defined peak at 1.6 MeV with a 12% FWHM energy spread.

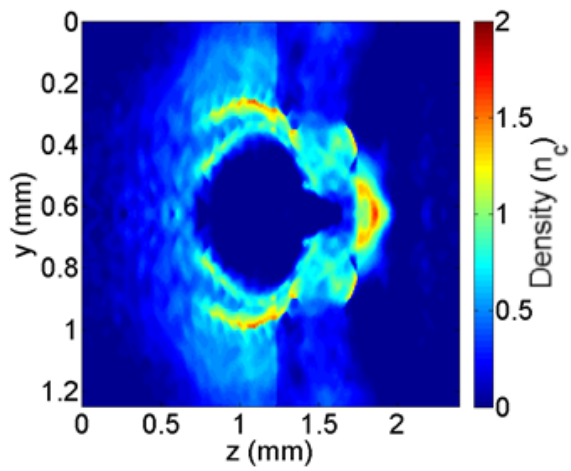

Figure 4: Time resolved interferometry reveals the plasma density distribution at 132 ps after the LPI begins. The laser travels left to right.

SHOCKWAVE VELOCITY EVOLUTION

We observed many instances of accelerated protons possessing a broad energy spectrum under the same experimental conditions as described above. Figure 5 shows a combined spectra of protons accelerated by similar laser intensities. Single shot outcomes are strongly sensitive to

Copyright © 2013 CC-BY-3.0 and by the respective authors

target conditions [9]. In particular, the laser pre-pulse has a significant effect on the ion spectrum by tailoring the density profile prior to the arrival of the main pulse. This effect will be discussed in detail in a future publication.

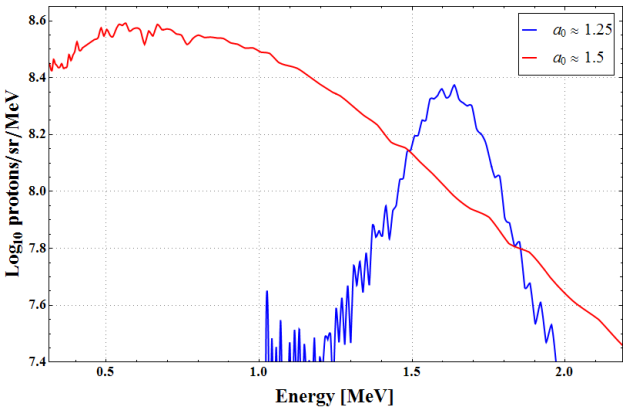

Figure 5: A comparison of measured proton spectra with listed laser intensities.

We performed 1D PIC simulations using EPOCH to investigate time dependence of shockwave velocity. Simulations were performed using 1300 cells at 100 particles per cell within a 500 μm simulation box. Figure 6 shows the proton density evolution through an infinite slab of cold plasma with density $2n_c$ after irradiation by a 1 TW pulse. Collisions are included in the simulation processes.

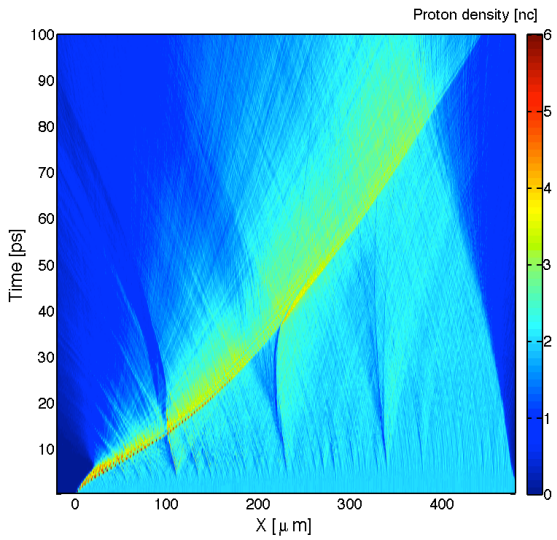

Figure 6: Particle density plotted from 1D PIC simulations.

These simulations show a clear decline in shockwave velocity beginning within the first few ps beyond the LPI. A significant reduction in peak ion density is also predicted by the simulation. The decay of the shockwave velocity modifies the accelerated proton spectra as protons are reflected at lower energies. The resultant spectra are highly dependant upon the duration in which ion reflection occurs. Energy spectra predicted by PIC simulations document the degradation of ion spectra with time and are shown in figure 7. A lengthened ion reflection period would suggest an increase in the total number of ions accelerated, which is consistent with observed spectra in figure 5.

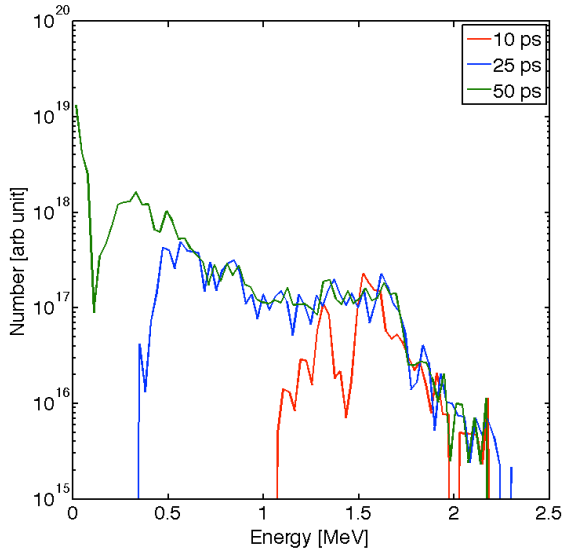

Figure 7: Simulated ion spectra extracted at different times after the LPI.

CONCLUSION

We have reported the production of high purity proton beams from the interaction of a single, linearly polarized 10.2 μm CO_2 pulse with near critical density Hydrogen gas. Peak proton energies correlate well with those predicted by radiation pressure models. Interferometry taken immediately following the LPI show the creation of a high density shock which propogates into the plasma. However, a broad swath of proton energy spectra are measured, providing evidence of rapid decline of shockwave velocities. These findings are corroborated by 1D PIC simulations with comparable experimental parameters. Our results emphasize the importance of target profile and LPI timeframe in accelerating ions with a narrow energy spread.

A BETATRON-ANALYSIS TECHNIQUE FOR IDENTIFYING NARROWBAND TRAPPED CHARGE WITHIN A BROADBAND ENERGY TAIL IN PWFA EXPERIMENTS AT FACET*

Chris Clayton#, Weiming An, Chan Joshi, Kenneth Marsh, Warren Mori, Navid Vafaei- Najafabadi (UCLA, Los Angeles, California), Patric Muggli (MPI, Muenchen), Erik Adli, Christine Isabel Clarke, Sebastien Corde, Jean-Pierre Delahaye, Robert Joel England, Alan Stephen Fisher, Joel Frederico, Spencer Jake Gessner, Mark Hogan, Selina Zhao Li, Michael Dennis Litos, Dieter Walz, Ziran Wu (SLAC, Menlo Park, California), Wei Lu (TUB, Beijing)

Abstract

Plasma accelerators driven by ultra-relativistic electron beams have demonstrated greater than 50 GeV/m acceleration gradients over a distance of a meter [1] though the accelerated particles typically have had a 100% energy spread when a single drive bunch was used. However, it is known that by locally producing electrons via ionization within the beam-driven plasma wake, they can become trapped and accelerated so that high-energy, mono-energetic electron bunches can be produced [2]. Prior experiments and the associated simulations [3] suggested that, by augmenting the usual He buffer gas in the heat pipe oven plasma source [4] with a moderate ionization potential (IP) gas such as Ar or Ne, local injection can indeed occur. In a recent experiment associated with the E-200 plasma wakefield accelerator (PWFA) experiment at the Facility for Advanced Accelerator Experimental Tests (FACET) [5] at SLAC, the expected energy gain of these injected electrons (initially at rest) puts them within the energy range of the accelerated tail electrons of the FACET beam. We propose a technique to help identify bunchlets of electrons at the 10's of pC level arising from the ionization injection of Ar/Ne electrons that may otherwise be lost or overlooked as part of the discrete betatron-focusing maxima or the maxima inherent the chromaticity of the imaging electron spectrometer.

OBJECTIVES OF THE EXPERIMENT

For most applications of high-energy beams, narrow energy spreads are desired. By employing spatially localized ionization to produce and inject new electrons within the plasma wake, a PWFA can produce high-energy, mono-energetic electron "bunchlets".

When these bunchlets appear at the image plane of the imaging spectrometer, there are two other types of distinct features that may mask the bunchlets having only 10's of pC of charge. First is the fact that the highly chromatically aberrated electron imaging spectrometer has a very narrow energy range for which a stigmatic focus–a focus that is simultaneous focusing in x and in y (or energy) at the same spot–is located and thus there is always a "bright feature" in the spectrum due to this. Secondly, even with a broadband spectrometer, the electrons (both the FACET beam electrons and any injected electrons; i.e., the bunchlet) exit the plasma with an energy-dependent phase advance of their betatron envelope oscillations [6] that leads to an energy-dependent divergence of the electrons at the plasma exit. This fact also puts structure onto the final spectrum, as discussed below.

Let ζ_k represent the local (within the wake) longitudinal location of the k^{th} slice of the accelerated electrons. Suppose further that this k^{th} slice exits the plasma as a nearly parallel beam having undergone $N = N_k$ betatron oscillations. Due to the finite angular acceptance of the spectrometer coupled with the strong focusing force of the ion column within the wake in the blowout regime, and the finite bit-depth of the recording CCD cameras, this slice will appear relatively bright on the spectrometer. There will be another slice, the k+1$^{\text{th}}$ slice at a lower energy that has undergone $N = N_{k+1} = N_k + 1$ betatron oscillations and will likewise appear relatively bright at the spectrometer. In fact, for each final slice energy such that $N_{k,m} = N_k \pm m$ where $m = \pm1, \pm2$, etc., there will be a corresponding bright spot on the spectrometer. We call this series of spots the "betatron ladder". This ladder was clearly visible in the E-167 energy-doubling experiment of Ref. [1].

In the following Sections we will describe the experimental setup, derive the energy-locations of the betatron ladder, and finally suggest a strategy for identifying the bunchlets within the other structures appearing at the image plane of the spectrometer. Specifically, by placing the stigmatic focus on one "rung" of the ladder after another over a series of data aquistion runs, we can optimize our chances of observing accelerated bunchlets, especially if they lay between or straddle the rungs on the aforementioned betatron ladder.

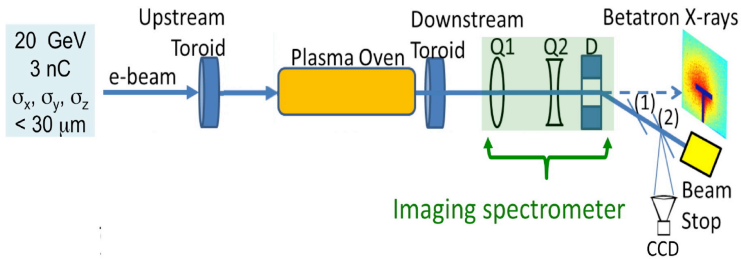

Figure 1: Schematic of portions of the E-200 experimental setup. A 20.35 GeV, 3 nC, compressed (σ_z ~ 30 μm) electron beam is focused ($\sigma_x = \sigma_y$ ~ 30 μm) near the entrance of a Li-vapor column contained in the plasma oven. Toroids measure the incoming and outgoing electron charge. Betatron X-rays excite a phosphor screen located behind 1 mm of copper; the emitted light is captured by a CCD camera (not shown). The imaging spectrometer (quadrapole doublet Q1 and Q2 plus dipole D), discussed further in the text, sends the electrons to the beam stop prior to which is the Cherenkov air gap. The gap is composed of the two Si wafers (1) and (2) which are in laboratory air, thus emitting a Cherenkov-light cone that is subsequently reflected by wafer (2) to a pair of CCD cameras (two cameras for a wide vertical or energy field of view).

EXPERIMENTAL SETUP

A rough schematic of the FACET setup for the E-200 experiments is shown in Fig. 1. The fully compressed FACET beam (σ_z ~ 30 μm) is focused to a nearly round spot of $\sigma_x = \sigma_y$ ~ 30 μm near the front edge of the Li vapor column which has a length of about 39 cm FWHM. The Li is contained in an oven at a temperature of nearly 1000°C, giving a Li neutral density of 2.5 x 10^{17}cm^{-3}. At each end of the oven is the buffer gas composed of He alone or He with an admixture of an intermediate IP gas such as Ar or Ne. This closed system is in pressure balance. The cooler buffer gas confines the Li by collisionally forcing the escaping Li atoms to the walls where a wick returns the (now liquid) Li back towards the oven's center. The length of the boundary region is about 10 cm on each side of the ~ 29 cm-long constant-density portion of the vapor column. The Li is easily field-ionized by the radial electric field of the (vacuum-size) FACET beam while the He is not. To obtain a mono-energetic beam from the accelerated ionization-injected electrons—the goal of this experiment—fine-tuning of the focal position of the FACET beam and the longitudinal distribution of the admixture is required. Ideally, the FACET beam would have a betatron pinch localized to where the flat-topped region of Li begins and where the availability of the admixture element nearly ends thus terminating injection.

The imaging spectrometer consists of a quadrapole doublet, a dispersing dipole magnet, a pair of Si wafers tilted at 45° to the beam, and two CCD cameras to record the Cherenkov light emitted in the air gap between the wafers and reflected to the lenses of the cameras. As mentioned before, the energy-bandwidth for which a stigmatic focus is obtained is very small.

Examples of the spectra recorded by the spectrometer cameras are shown for three different experimental conditions in Figs. 2(a)-(c). As can be seen especially in Fig. 2(b), the local brightness of the spectrum increases at an energy for which the spectrometer was set to produce a stigmatic focus. The magnification of the spatial imaging from the plasma exit to the Cherenkov air gap is about nine times larger in the *x*-direction than in the *y*- or energy-direction.

Figure 1(a) shows the aforementioned betatron ladder; the few bright spots beginning at ~ 24 GeV and up, as well as a rung near 17 GeV as evidenced by the bulge in this (purposely) saturated portion of the image. For this shot, the final focus quadrapoles were set to put the main interaction point waist about 20 cm upstream of the Li column, twice the β^*_x (= 10cm) of the vacuum waist. Since β^*_y = 100 cm, the beam had a larger *x*-size when it began to field-ionize the Li and hence the amplitude of the betatron oscillations was large in the *x*-direction. This allowed for a clear analysis of the betatron features that is discussed in the following Section.

BETATRON ANALYSIS

For a given plasma density, the number N_k of betatron oscillations experience by the k^{th} slice of the beam is related to the *initial* energy of the beam slice E_0 (which we will approximate as independent of ζ), the effective length L of the plasma and the *final* energy of that slice E_k ($z = L$).

Number of betatron envelope oscillations

A simple definition of N_k is the ratio of L to the betatron period for the k_{th} slice. The betatron period is given by [6] $\pi / k_\beta(\zeta_k, z) = \omega_p(z)/(\pi c)/\left(2\gamma(\zeta_k, z)\right)^{0.5}$. The general expression for N_k at the plasma exit is given by

$$N_k(\zeta_k)\big|_{z=L} = \int_0^L \frac{k_\beta(\zeta_k, z)}{\pi} dz = \frac{\omega_p}{\pi c\sqrt{2}} \int_0^L \gamma(\zeta_k, z)^{-\frac{1}{2}} dz = \frac{\omega_p}{\pi c\sqrt{2}} \int_0^L \left[\gamma_0 + \frac{eG(\zeta_k) z}{mc^2}\right]^{-\frac{1}{2}} dz \quad (1)$$

Copyright © 2013 CC-BY-3.0 and by the respective authors

where we have assumed a constant density along z and a non-evolving electric field of the wake $G(\zeta)$. The final form of Eq. (1) reduces to

$$N_k(\zeta_k)\big|_{z=L} \approx L\frac{\sqrt{2}\omega_p\left(mc^2\right)^{\frac{1}{2}}(\pi c)^{-1}}{E_k^{0.5}(\zeta_k)+E_0^{0.5}} \qquad (2)$$

where $E_k(\zeta_k)$ is again the *final* energy of the k_{th} slice.

Building the betatron ladder

As mentioned before, integer changes in N define the betatron ladder. Thus, taking $N_{k+1} - N_k = 1$ and solving for L we have

$$L = \frac{\pi c}{\sqrt{2}\omega_p\left(mc^2\right)^{0.5}}\left(\frac{1}{E_k^f(\zeta_k)^{0.5}+E_0^{0.5}}-\frac{1}{E_{k+1}^f(\zeta_{k+1})^{0.5}+E_0^{0.5}}\right)^{-1} \qquad (3)$$

where $E_{k+1} < E_k$. After substituting L from Eq. (3) into Eq. (2), and replacing N_k with $N_{k,m} = N_k \pm m$ ($m = \pm1, \pm2$, etc.) the expected energy-locations $E_{k,m}$ of all the other rungs on the betatron ladder are obtained. The dashed lines in Fig. 2 show this calculated ladder lying nicely on the experimentally identified locations of the betatron features.

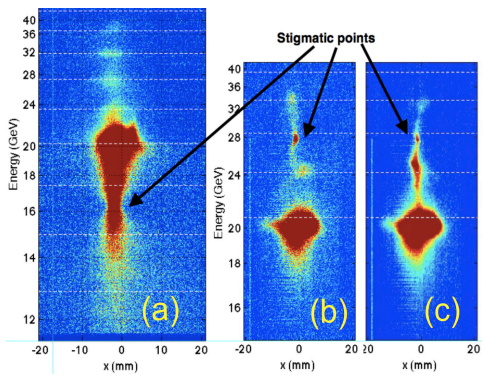

Figure 2: Three electron spectra with betatron ladders overlaid (white dashed lines, see text). (a) Buffer gas: He only, FACET waist 20 cm upstream of Li. (b) Buffer gas 50% He, 50% Ar, FACET waist 0 cm upstream of Li. (c) same as (b) but shot - by - shot difference: potential candidate shot.

The value of L is determined numerically by the measured energies of two of the rungs of the ladder; E_k and E_{k+1}. If there are multiple betatrons spots as in Fig. 2(a), one can take E_k and E_{k+2} while taking $N_k - N_{k+2} = 2$. The same value for L should obtain.

STRATEGY

To distinguish the ionization-injected and accelerated bunchlets from the other structures due to the betatron ladder as in Fig. 2(a) and the narrowband stigmatic focusing of the imaging spectrometer as seen in Fig. 2(b), it is best to place the stigmatic point on a rung of the ladder in order to reduce the complexity of the structred spectrum and thus make the identification of a bunchlet more obvious. Since the energy of the bunchlet is initially unknown, this process would be repeated over a series of data acquisition runs, each run with the stigmatic point dialed onto one of the ladder's rungs. In this way, charge that appears between rungs of the ladder or widely stradling them may possibly be attributable to the bunchlets.

It is important to note that, even if a bunchlet and accelerated FACET tail electrons in some longitudinal slice have the same energy, they will not have the same number of betatron oscillations since the initial energy $E_{0,\text{trapped}}$ of the trapped charge is zero. Thus, the bunchlets could very well be focused or badly defocused at any given output energy. This is why scanning the energy-imaging point is important.

A co-called "candidate shot" for a bunchlet is shown in Fig. 2(c) where there appears to be charge both away from the stigmatic point and straddling rungs the betatron ladder; i.e., it appears that this charge is a new feature not seen in Fig. 2(b).

Although a full analysis of existing data using this strategy has only now begun, looking forward to future runs at SLAC, the plasma length L at FACET is designed to be increased by several times over the current length. While this could in principle simply scale the bunchlet-identification issue to higher energies on the one hand, on the other hand, it may result in a much cleaner measurement of these bunclets. Simulations show that the bunchlet is trapped in the high-field spike at the back of the wakefield, giving it an inherent energy-gain advantage over the FACET tail electrons. Thus, the density of the plasma can dropped to depopulate the high-gradient portion of the wakefield of FACET-beam tail electrons, potentially isolating the ionization-injected and accelerated charge on the spectrometer screen.

UCLA, Los Angeles, CA 90024, USA

Abstract

In plasma based acceleration (PBA), the methods of injecting high quality electron bunches into the accelerating wakefield is of utmost importance for various applications, including next generation light sources and high energy colliders. Numerous simulations are being conducted in order to study various methods of injection and to optimize the beam parameters. Particle-In-Cell simulations using codes such as OSIRIS are used to model PBA. 3D simulations are possible in some cases but are computationally expensive. 2D simulations are computationally less expensive, but 2D simulations in cartesian coordinates only provide qualitative agreement and 2D simulations in cylindrical coordinates cannot model laser wakefield acceleration (LWFA) at all and cannot include important physics such as hosing and low mode azimuthal mode asymmetries for particle beam drivers (PWFA). Here we discuss one method for reducing the computational load of a 3D simulation into those comparable to a 2D simulation that can model LWFA and include hosing. It utilizes a truncated azimuthal mode expansion. We describe how this expansion has been included into the OSIRIS simulation framework and show preliminary results.

INTRODUCTION

Simulations have played an essential role in the development of plasma based acceleration from the seminal work of Tajima and Dawson to the very present. Simulations are used to model both laser wakefield acceleration (LWFA) and plasma wakefield acceleration (PWFA). These simulations have evolved from 1D simulations to demonstrate the feasibility of new ideas to full 3D simulations that model current experiments one to one and that model parameters out of reach of current experiments. Although 3D simulations are now possible they are still computational expensive, therefore, when simulating LWFA and PWFA using we often begin with a series of 2D simulations over a range of parameters. The parameters are either for an ongoing experiment, for a future experiment, or for understanding a new theory or concept. We then have to perform a few large-scale 3D simulations to determine in what manner and to what degree the 2D simulations replicate a more realistic result.

*This work was supported by DOE awards DE-FC02-07ER41500, DE-SC0008491, DE-FG02-92ER40727, and DE-SC0008316, and by NSF grants NSF PHY-0904039 and NSF PHY- 0936266. Simulations were carried out on the UCLA Hoffman 2 Cluster, and Dawson 2 Cluster.

DIFFERENCES IN 2D AND 3D SIMULATIONS

One topic that is receiving much theoretical, computational, and experimental attention is how to best inject electrons into a plasma wave wakefield. One concept is to use field ionization to create electrons inside the wake. An important question is how do the 2D simulation results compare to those from otherwise identical 3D simulations. When using a laser, it is not possible to use 2D azimuthally symmetric simulations as such simulations only allow radially polarized modes. Therefore, 2D cartesian geometry are used and in such simulations both structure of the wakefield and the evolution of the laser can be very different. We provide examples of the differences by showing results from a a series of 2D and 3D simulations that were performed to model experiments conducted using the Callisto laser at LLNL. These simulations highlight some of the differences we see and the importance of the including full 3D physics. In these simulations a linearly polarized, 60 fs laser was focused into an "Injection Section" that is composed of 99.5% He and 0.5% N. After the laser propagates 1.5 mm in the injection section, it enters an "Acceleration Section" composed entirely of He. The total plasma density is $n_p = 1 \times 10^{18}$ cm^{-3} aside from the 0.5 mm up ramp at the beginning. Simulations were conducted with a 100 TW and a 500 TW laser beam. The spot size was 20.0 μm for the 100 TW case, and 26.2μm for the 500 TW simulation.

As can be seen from Table 1, the peak energy of the trapped electrons can be significantly different between the 2D and 3D simulations. Another notable difference is that in the two 2D simulations, a comparable number of particles are trapped whereas in the 3D simulations 3.9 times more particles are trapped for the 500TW laser than for the 100TW laser. And in the 2D cartesian simulations only the charge per unit length that is trapped can be obtained. These differences illustrate that if one uses 2D simulations to optimize the process one can be led very far astray.

There is another notable qualitative difference in the 2D and 3D 500 TW simulation. If you look at the particle energy spectrums about 3 mm into the plasma (Figures 1 and 2), you see that there is a large, lower-energy peak exclusively in the 3D simulation. Although this peak eventually falls out, it dynamically affects the shape and the evolution of the wake. The 2D simulation fails to capture this process. Although not shown the evolution of the laser is also very different.

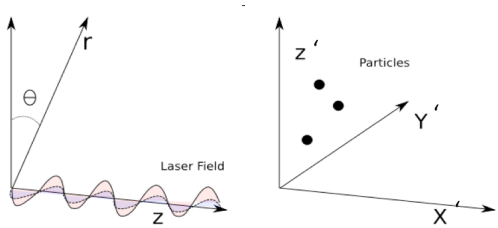

Figure 3: Coordinates of the cylindrical mode simulation.

AZIMUTHAL MODE EXPANSION

There are various possible ways to reduce the computational requirements for capturing the 3D physics including using boosted frames, the ponderomotive guiding center approximation, and the use of the quasi-static approximation. Another recent idea proposed by Lifshitz et al. [1] is to expand the electromagnetic fields into a truncated Fourier expansion along the poloidal direction in cylindrical coordinates. The idea is to provide key 3D physics for situations where only low mode azimuthal asymmetry exists (a linearly polarized laser can be described by the m=1 mode). Such simulations will have a similar computational load to 2D r-z simulations. Here we describe how this algorithm has been implemented into OSIRIS and present some preliminary results. We can keep an arbitrary number of m modes. As noted in [1] a linearly polarized laser propagating along x, as described in Figure 3, can be expressed in cylindrical coordinates as

$$\mathbf{E}(\mathbf{r},\mathbf{x},\theta,t) = E_y(r,x,t)(\cos(\theta)\hat{r} - \sin(\theta)\hat{\theta}) \quad (1)$$

$$\mathbf{B}(\mathbf{r},\mathbf{x},\theta,t) = B_z(r,x,t)(\sin(\theta)\hat{r} - \cos(\theta)\hat{\theta}), \quad (2)$$

which are first order terms in the expansion

$$\mathbf{F}(r,x,\theta) = \Re\left(\sum_{m=0} \hat{\mathbf{F}}^m(r,x)e^{-im\theta}\right),$$

where $\mathbf{F}$ is any vector field and the index m is the mode number. The zeroth order mode contains the cylindrically symmetric fields that are already incorporated in the 2D cylindrical coordinate simulation in the OSIRIS framework. Therefore, a linearly polarized laser can be modeled by only keeping the $m = 1$ mode. PWFA can be modeled in an r-z code, however, while very useful it is limited as it cannot include hosing or spot size asymmetries.

Algorithm

Therefore, as suggested above, the vector fields ($\mathbf{E}$, $\mathbf{B}$, and $\mathbf{J}$) are calculated as a series of modes truncated at a number specified at the input. Each mode is stored on a different 2D grid. Due to the linearity of the Maxwells equations they each evolve independently[1], according to Equations 3-8.

$$\frac{\partial \mathbf{B}_r^m}{\partial t} = \frac{im}{r}\mathbf{E}_x^m + \frac{\partial \mathbf{E}_\theta^m}{\partial x} \quad (3)$$

$$\frac{\partial \mathbf{B}_\theta^m}{\partial t} = -\frac{\partial \mathbf{E}_r^m}{\partial \mathbf{x}} + \frac{\partial \mathbf{E}_x^m}{\partial \mathbf{r}} \quad (4)$$

$$\frac{\partial \mathbf{B}_x^m}{\partial t} = -\frac{1}{r}\frac{\partial}{\partial r}(r\mathbf{E}_\theta^m) - \frac{im}{r}\mathbf{E}_r^m \quad (5)$$

$$\frac{\partial \mathbf{E}_r^m}{\partial t} = -\frac{im}{r}\mathbf{B}_x^m + \frac{\partial \mathbf{B}_\theta^m}{\partial x}\mathbf{J}_r^m \quad (6)$$

$$\frac{\partial \mathbf{E}_\theta^m}{\partial t} = \frac{\partial \mathbf{B}_r^m}{\partial \mathbf{x}} + \frac{\partial \mathbf{B}_x^m}{\partial \mathbf{r}} - \mathbf{J}_\theta^m \quad (7)$$

$$\frac{\partial \mathbf{E}_x^m}{\partial t} = \frac{1}{r}\frac{\partial}{\partial r}(r\mathbf{B}_\theta^m) - \frac{im}{r}\mathbf{B}_r^m - \mathbf{J}_x^m \quad (8)$$

The mode mixing occurs when there is a presence of macro-particles, which are followed in cartesian space (x, y, z, p_x, p_y, p_z) and pushed according to the Lorentz Force Law (Equation 9). This requires transforming the fields in cylindrical coordinates to cartesian coordinates before pushing the particles.

Copyright © 2013 CC-BY-3.0 and by the respective authors

$$\dot{\mathbf{P}} = q(\mathbf{E} + 1/cv \times \mathbf{B}) \qquad \dot{\mathbf{x}} = 1/(m\gamma)\mathbf{P} \quad (9)$$

The current density (or charge density) for each cylindrical modes at each r-z grid point i and j is obtained according to the equation

$$\rho_{ij}^{m} = \frac{1}{\pi} e^{im\theta} S_{ij} q/\Delta V,$$

where S_{ij} is the area-weighing coefficient (subject to the interpolation scheme), and $\Delta V = 2\pi r \Delta r \Delta x$. The cylindrical angle θ is calculated from the particle's x and y values. Looping over field evolution, particle advance, and charge deposition, we have a complete PIC algorithm.

Laser-Driven Field

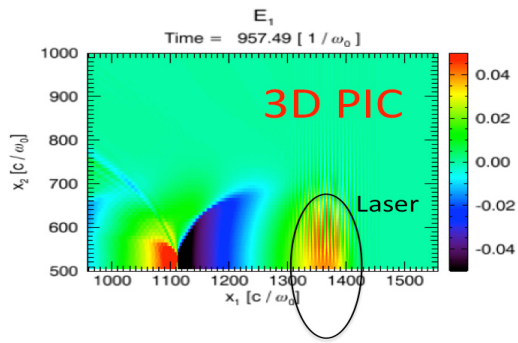

Figure 4: A full 3D PIC simulation of a laser propagating through a pre-ionized plasma. E_1 in units of $[m_e c\omega_o/e]$.

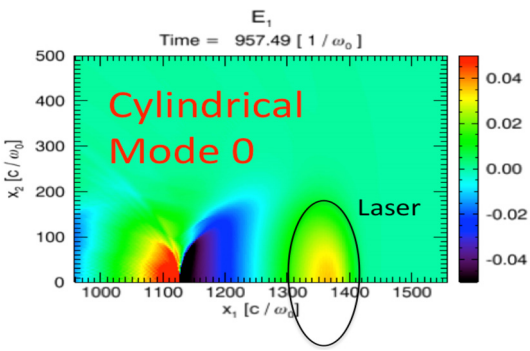

Figure 5: The 0th mode of the cylindrical mode simulation.

The above algorithm was implemented into the development version of OSIRIS, and tested using the parameters modeled after the LWFA simulation described by Lu et al [2]. Here a linearly polarized 200 TW,30 fs laser pulse is shot into a fully ionized $n = 1.5 \times 10^{18}$ cm^{-3} plasma, with a spot size of 19.5 μm. The computational window is of dimension $76.4 \times 127\mu\text{m}^3$, with the number of grid points 3000×256. Figures 5 and 6 show the E_1 field formed after the laser propagates 0.1 mm. A clear bubble is formed. In this simulation only the zeroth and first modes of the fields have been included.

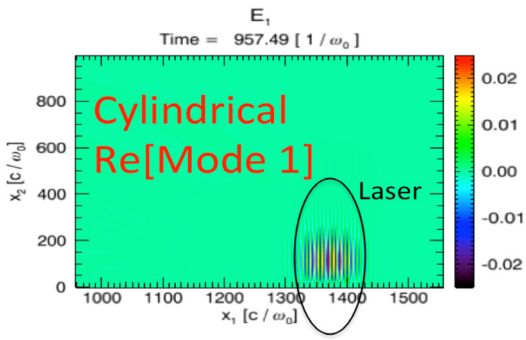

Figure 6: $\Re[E_1]$ of mode 1 of the cylindrical modes.

The full 3D PIC simulation is shown in Figure 4 for comparison (the plot is sliced in the middle for better comparison with the cylindrical simulations). Since in this simulation the wake is nearly perfectly cylindrical, it appears in the plot of the zeroth order mode of E_1 as shown in Figure 5. The oscillations in the real part of the first mode, however, are directly produced by the laser. You can see in the full 3D simulation that ordinarily these two modes of electric fields are solved together.

Since in this case the full 3D simulation requires another 256 grids along the third dimension, it is necessarily at least 256 times slower then the equivalent 2D simulation. With the cylindrical modes truncated at $m = 1$, we only need to solve three 2D grids (two for the real and imaginary parts of the 1st nonzero mode). By design this algorithm is magnitudes faster then the 3D simulation while capturing much of the 3-dimensionality of the laser-plasma interaction. It is the ideal tool for wakefield accelerators.

CONCLUSION

We have illustrated though simulations of a two stage ionization injection LWFA concept that there are both qualitative and quantitative differences between 2D and 3D simulations on injection and acceleration of electrons in LWFA stages. Because 3D simulations are often computationally intensive, it is important to be able to conduct simulations whose computational requirements is comparable to a 2D simulation, and yet includes the physics that makes the 2D simulations unreliable for accurate predictions. We describe how a new algorithm proposed by [1] has been successfully implemented into OSIRIS. This algorithm expands the EM fields into a truncated number of azimuthal mode numbers (often just 2). Preliminary results were also presented that show that using only 2 modes provides good agreement with full 3D simulations.

LASER-PLASMA INTERACTION STUDIES USING ABOVE CRITICAL DENSITY GAS JET PLASMAS AND A MULTI-TW CO_2 LASER*

C. Gong, S. Tochitsky, J. Pigeon, C. Joshi, Neptune Laboratory, Department of Electrical Engineering, University of California Los Angeles, CA, 90095, USA

Abstract

CO_2 laser-plasma interaction provides a unique parameter space for particle acceleration in a gas jet plasma taking place at a critical plasma density $n_{cr} \sim 10^{19}$ cm^{-3} and even at higher densities (3~10 n_{cr}) of 10μm radiation. Here we report the latest results of our study of electron acceleration in a wide range of plasma densities 1~10 n_{cr} using a multi-TW CO_2 laser system at the UCLA Neptune Laboratory. To gain insight into plasma density profile evolution during ~120 ps long CO_2 laser-plasma interaction, we used laser interferometry with two 1 ps, 532 nm probe pulses with variable delay of 5~120 ps. The knowledge of spatial distribution of accelerated electron beam transported through the overdense gas plasma is critically important for minimizing laser beam filamentation and for understanding influence of other laser-plasma instabilities. This should allow for optimization of CO_2 laser driven shock wave acceleration of low-divergence monoenergetic ion beams [1].

INTRODUCTION

The interaction of short high-intensity laser pulses with an overdense plasma can produce forward directed multi-MeV ions and electrons. Electrons heated/accelerated by the laser pulse can drag ions with them due to the space charge separation. Studying the spatial distribution of accelerated electrons can help to optimize the quality and yield of ion beams and is also important for understanding laser-plasma instabilities.

At the UCLA Neptune laboratory, a ~120 ps CO_2 laser train of 3ps pulses separated by 18ps with a peak intensity up to ~4×10^{16} W/cm^2 is used to study overdense laser plasma interaction in a helium gas jet. One of our goals is to optimize the ion acceleration by collisionless shock waves [1]. In order to gain an insight into the plasma density profile evolution during the CO_2 laser pulse train, a two-frame interferometry using 1ps, 532nm light has been developed. An adjustable temporal delay 5~120ps between pulses allows for optical probing of the laser/plasma interaction region. Through a careful analysis and comparison of the two-frame interferogram, the hole boring speed of the above critical density layer pushed by the radiation pressure along the laser propagation axis can be measured. Also, forward directed electron and ion beam is recorded on the LANEX phosphor screen to analyse its spatial distribution and divergence. A permanent magnetic dipole with ~600 Gauss magnetic field is placed before the LANEX phosphor screen to estimate the energy of particle beams.

EXPERIMENTAL SETUP

Target Chamber

The CO_2 Master Oscillator Power Amplifier system having a multi-terawatt peak power is used in the experiment. Due to a modulated gain spectrum of the CO_2 molecule, a ~3ps CO_2 laser seed pulse evolves into a ~120ps long pulse train after amplification. Each individual pulse within the pulse train preserves the original pulse width and is separated from the adjacent pulse by ~18ps.

The experimental arrangement in a target chamber is shown in Fig. 1.

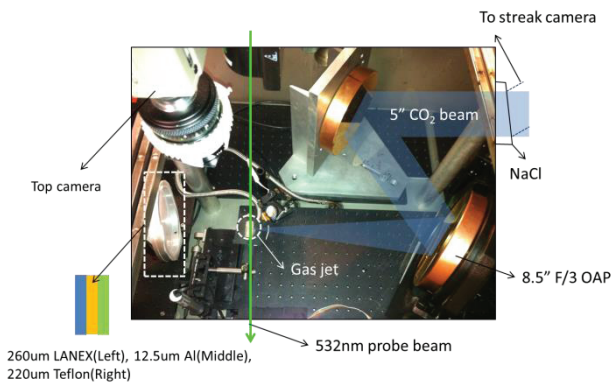

Figure 1: Experimental setup in the target chamber.

A 5" diameter CO_2 laser beam with an energy of ~60J is coupled into the target chamber through an 8" NaCl window mounted on a 4° wedged flange. The back reflection of the beam from the salt window is combined with a red diode laser beam in a CS_2 Kerr modulator. The red pulse modulated by the high intensity 10μm CO_2 laser is analysed by a Hamamatsu streak camera (Model: C5680-21) for the temporal structure measurement of the CO_2 pulse. The beam inside the chamber is focused in a 2mm diameter gas jet by an 8.5" F/3 off-axis parabolic mirror. Using an IR camera, we have characterized the spatial profile of the unamplified CO_2 laser beam by scanning along the laser axis (Z-scan) which is shown in Fig. 2. The measured spot size is w_o = 48μm. Using this spot size and an estimate of the energy contained in the most intense of the 3ps pulses (~20%) in the train of pulses, we estimate that a peak a_o of >1 can be achieved in these experiment. Here a_o is the normalized vector

potential with a_o~1 corresponding to 10^{16} W/cm^2 for a CO_2 laser.

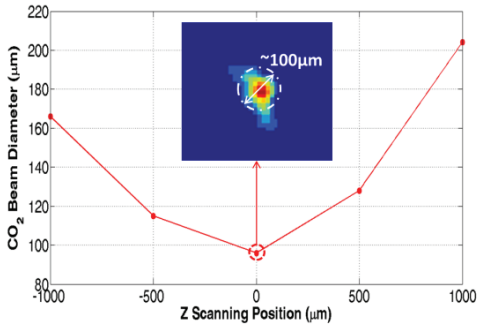

Figure 2: Spot size measurement of 10 μm CO_2 laser beam.

The laser beam interacts with a pulsed supersonic gas jet which allows for the peak plasma density around 0.1 to 10 times of the critical density for the 10μm light (10^{19} cm^{-3}).

As shown in Fig. 1, a detector consisting of a 260 μm LANEX phosphor screen (Left), 12.5 μm Al foil (Middle) and 220 μm Teflon (Right) layer is put 150mm away from the gas jet. The LANEX phosphor screen imaged by a COHU analog camera outside the target chamber is used to detect the forward directed electron beams with energy above 220keV. A permanent magnetic dipole (600 Gauss) capable of resolving energy in the range of 0.3-4 MeV is placed between the gas jet and the LANEX phosphor screen. A top COHU analog camera is installed to determine the focal position of the high power CO_2 beam relative to the center of the gas jet. A 1ps, 532nm, green probe with energy of ~20μJ is delivered to the interaction point (IP) for the two-frame interferometry and schlieren diagnostics.

Two-Frame Interferometry and Schlieren Diagnostics

The two-frame polarization based interferometry and schlieren optical scheme is depicted in Fig. 3.

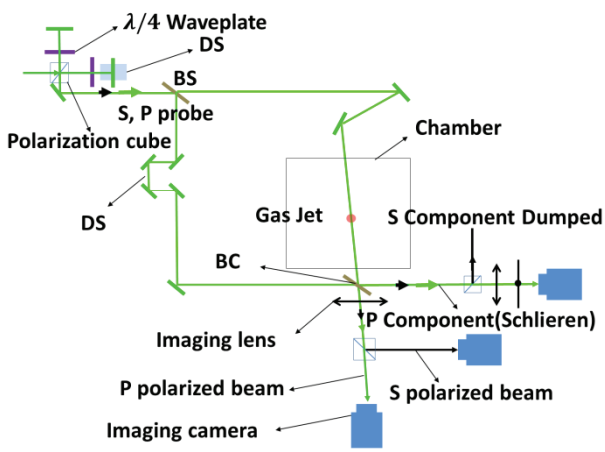

Figure 3: Schematic of the 1ps, 532nm two-frame interferometry and Schlieren diagnostics setup. Beam Splitter (BS), Delay Stage (DS), Beam Combiner (BC).

The 1ps, 532nm elliptically polarized probe beam enters the narrowband polarization cube and is separated into P (60%) and S (40%) components. This is a classical Michelson scheme in which an arbitrary delay can be introduced for the S polarized component. Then, each of them goes through a quarter wave plate twice and changes their polarization. A translational delay stage of the S probing arm is used to control the temporal delay relative to the P arm. The adjustable temporal range is 5~120ps with the P probe arriving at the IP earlier. After switching the polarization, P and S probes follow the same beam path and enter into the Mach-Zehnder interferometry system. Another narrow band polarization cube is placed behind BC to separate the polarized beams into two orthogonal directions. The imaging lens transfers the image plane of the plasma to the two CCD cameras. The measured spatial resolution of interferograms is ~20um. In addition to the interferometry, part of the beam probing the plasma is reflected off BC for a Schlieren diagnostic. The reflected beam contains P and S components and we use another polarization cube to select P component for the Schlieren image. A dark field schlieren technique [2] is used to analyse the plasma density gradient. A ~250um diameter ink dot deposited on a 2" transparent plastic disc is used as a beam stopper. The green probe passing through the plasma without refraction is attenuated by the dot by a factor of 10^5. The measured resolution of the schlieren images is ~40um.

EXPERIMENTAL RESULTS

At the Neptune laboratory, the 10um short pulse and the 532nm probe pulse are both produced using the same 1μm pulse [3], so inherently they are deterministically synchronized with each other. However, due to the different transport length, they arrive at the IP at different times and need to be temporally re-synchronized with a picosecond accuracy. Also as mentioned earlier, our structured CO_2 pulse train contains multiple ~3p micropulses separated by ~20ps. We are interested in observing the interaction between the overdense plasma and different micropulses in the pulse train and to learn how the plasma density profile will evolve temporally. To synchronize CO_2 laser pulse envelope and green probe with better than 20ps accuracy, a cross-correlation measurement in Si was used [4]. The probe timing of P arm is adjusted such that the probe pulse arrives approximately at the peak of the CO_2 pulse train. And the relative delay of the S arm can be changed using a delay stage in order to cover a chosen micro-pulse that arrives at a later time.

One of the most important mechanisms in laser overdense plasma interaction is hole boring or pushing of the density steepened plasma layer by radiation pressure of the laser field. Two frame interferometry allows for accurate measurement of the hole boring speed. For example, for interferogram shown in Fig. 4, we can extract this information by comparing how the overdense plasma layer is pushed by the radiation pressure at two different times.

Copyright © 2013 CC-BY-3.0 and by the respective authors

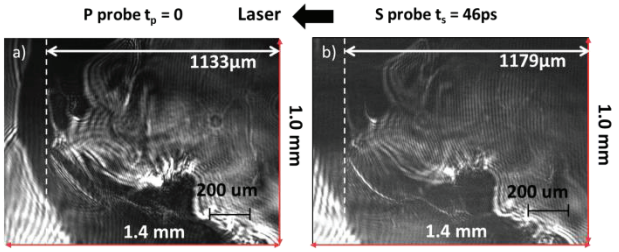

Figure 4: Two-frame interferogram at different times. a) shows P probe. b) shows S probe with 46ps delay. White dashed line shows the instantaneous position of the overdense plasma layer pushed by the radiation pressure.

For this shot our CO_2 laser beam is focused into a helium gas jet target and the laser intensity is above the ionization threshold of He^{2+} (~8.5×10^{15} W/cm^2). According to our neutral density calibration data of the gas jet, a backpressure of 1000psi corresponds to ~$6n_{cr}$ for a fully ionized He gas. Analysis of two interferograms of P and S arms (S is 46ps later) reveals that the pushed layer is moving forward with a hole boring velocity of 0.0037c (c is the speed of light).

Using the formula $\frac{v_h}{c} = [\frac{n_{cr}}{2n_{pe}}\frac{Zm}{M}\frac{I\lambda_L^2}{1.37\times10^{18}}]^{1/2}$ [5], where v_h is the hole boring velocity, n_{cr} the critical density for 10μm light, n_{pe} the plasma density and Z is the charge state of the ionized atoms, one can extract the laser intensity in the hole boring process which is 1.5×10^{16} W/cm^2. However, this formula assumes a constant radiation pressure and not directly applicable for the case of CO_2 laser 3ps pulses separated by 18ps. Thus, the intensity 1.5×10^{16} W/cm^2 corresponding to the measured v_h is a lower estimate of the laser intensity in the experiment.

Another shot, shown in Fig. 5, corresponds to the case when neutral density of the gas jet was reduced. We observed a nicely formed plasma channel. Analysis of the fringe shift in the interferogram gives us the plasma density in the channel of P probe time equal to 1×10^{18} cm^{-3} and S probe equal to 5×10^{17} cm^{-3}, which indicates a drop in plasma density over 46ps delay. Schlieren image in Fig. 5(c) shows a piled up plasma upstream of the plasma channel.

For this shot, a well-confined, beam-typed signal was detected on the LANEX screen with a divergence angle of 2°. Currently, we are studying the nature and energy of this forward directed beam.

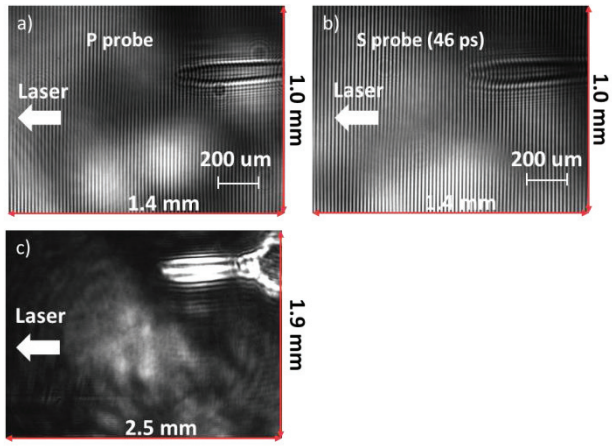

Figure 5: Two-frame interferogram and dark field schlieren images. a) Shows the channel formation as seen by P probing arm. b) Shows the channel expansion probed by S arm (46ps later). c) Shows the schlieren image for P polarized probe with a larger field of view.

CONCLUSION

In this paper, we describe the current status of the experiment being carried out in the Neptune laboratory at UCLA. Two-frame interferometry and dark field schlieren technique have been demonstrated to be very critical plasma interaction diagnostics. Hole boring velocity has been measured by comparing two interferogram images taken at different time. A channel guided propagation of laser light is observed at the underdense plasma condition and the corresponding signal on the LANEX phosphor screen requires further investigation.

Abstract

The results of the LLNL/UCLA inverse free electron laser (IFEL) experiment are presented. A 500 mJ 120 fs Ti:Saph laser pulse interacts with a short electron beam in a planar undulator tapered both in magnetic field strength and period to accelerate the electron beam. The tapering of the undulator maintains resonant energy exchange between the laser and electron beam while the electron beam's energy increases. We observe an energy modulation from 77 MeV to 120 MeV. Through use of simulations that are consistent with the observed data, we report a peak acceleration gradient of at least 180 MeV/m.

INTRODUCTION

The growing expense of high energy electron accelerators has produced a demand for increasingly compact, high gradient accelerators than traditional rf accelerators. Because of breakdown which occurs at around 100 MeV/m for traditional rf structures, shorter wavelengths must be used to drive the acceleration. The inverse free electron laser (IFEL) [1] is a laser driven electron accelerating scheme that has the advantage of taking place in vacuum.

In this acceleration scheme, a high intensity laser copropagates with a relativistic electron beam through an undulator. As the electron beam oscillates in the periodic magnetic field, it's transverse velocity allows for coupling to the laser's transverse electric field. If the laser's frequency, electron beams energy, and the magnetic field's strength and period are set such that the electron beam slips one laser wavelength per undulator period, energy is maximally transferred between the laser and the electron beam. As the electron beam becomes accelerated by this period averaged effect, the undulator must be tapered in order to maintain the resonance condition and facilitate efficient energy exchange.

This concept was demonstrated at Neptune at UCLA [2], as well as STELLA at Brookhaven National Lab (BNL) [3]. Renewed interest in IFEL has allowed experiments to be performed at Lawrence Livermore National Lab and BNL. While BNL's Rubicon [4] focused on use of a helical undulator to give stronger coupling to a circularly polarized CO_2 laser at low rep rate (.05Hz), the LLNL IFEL Project focuses on exploiting the high repetition rate of TW class Titanium Sapphire laser systems (10 Hz) and achieving high gradient acceleration with a sub picosecond driving laser. This paper covers the preliminary results of the LLNL IFEL experiment.

THEORETICAL BACKGROUND

If we define a pondermotive phase as $\Psi = (k + k_w)z - \omega t - \Phi_G$, we can use this phase as the coordinate of an electron in the period averaged pondermotive field. Here k and k_w are the radiation wave number and undulator wave number, respectively, and ω is the radiation frequency, and Φ_G is the Guoy phase shift.The electron's conjugate momentum then can be described by γ, the electron's energy normalized by it's rest energy. The longitudinal equations of motion then can be described by:

$$\frac{d\gamma}{dz} = \frac{1}{2\gamma} k K_L K J J sin\Psi \tag{1}$$

$$\frac{d\Psi}{dz} = k_w - k\frac{1+\frac{K^2}{2}}{2\gamma^2} - \frac{1}{z_r(1+\frac{z}{z_r}^2)} \tag{2}$$

Where K_L is the radiation parameter equal to eE_0/kmc^2 and E_0 is the peak radiation electric field, m is the electron mass, and c is the speed of light. K is the undulator strength parameter and is equal to $eB_w/k_w mc^2$ and B_w is the peak undulator magnetic field. JJ is the coupling factor, which is a result of using a planar undulator. z_r is the Rayleigh range, and the final term in the pondermotive phase evolution is due to the Guoy phase shift.

If we allow the left hand side of Eq. 2 to go to zero, this gives the condition for which the pondermotive phase does not evolve. γ_r is then resonant electron's normalized energy. Plugging into Eq. 1 we have a description of evolution of a resonant particle as it is accelerated with a stationary phase. Expanding about the resonant phase,Ψ_r, we have a pondermotive potential that goes like $cos\Psi + \Psi sin(\Psi_r)$. This potential creates a stable accelerating bucket whose width in phase is dependent on the resonant phase. If the resonant phase is near zero, the bucket is wide and traps many particles at the cost of reduced accelerating gradient whereas if the resonant phase is near $\pi/2$ then the gradient is maximum but only a single point in phase space can be accelerated. If the laser intensity is not matched to the design, the injected electrons can fall out of the pondermotive bucket and resonant acceleration ceases. Non trapped particles interaction increases the energy spread of the non-captured distribution. Beyond the 1-D equations of motion, the particle tracking code cbeam [5] was used together with

Parmela [6]and Elegant[7] to model the evolution of the electron beam in a start-to-end simulation. The results of the integration of the equations of motion in the pondermotive phase description matched the start-to-end simulation well.

EXPERIMENTAL DESCRIPTION

A layout of the interaction area can be seen in Fig 1. The electron beam approaches from the left of the diagram after being accelerated to injection energy and acquiring longitudinal chirp appropriate for compression. The electron beam is then compressed by the chicane and put on axis for the final focus quadrupole magnets that focus that electron beam at the center of the undulator to a spot size of 100 µm. The laser approaches from the right of the diagram and Spatial overlap between the electron beam and laser is achieved using DRZ fluorescent screens before and after the undulator, as well as a finger at the center of the undulator. Synchronicity to 2 ps between the electron beam and laser pulse is achieved by observing the optical transition radiation and laser in a streak camera. A micrometer on the delay arm on the interaction laser is then slowly scanned until electron beam modulation is observed. Experimental parameters can be seen in Table 1.

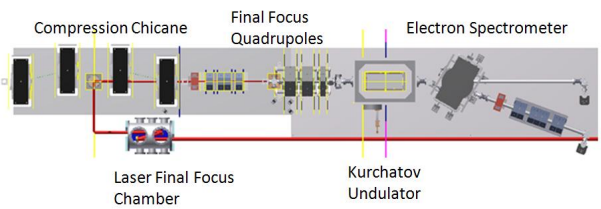

Figure 1: CAD Model of IFEL Interaction Region.

The LLNL BLDG 194 beamline consists of a SLAC/UCLA/BNL 1.6 Cell S-Band photogun, acceleration by three 3 m SLAC style accelerating sections, chirped for compression by a final accelerating section compressed through a chicane, and focused into the undulator. With the radius of 1 mm a 120 fs laser pulse applied to the cathode, the electron beam is produced in the photoinjector blowout regime, in which the electron beam expands nonlinearly into a near uniformly filled ellipsoid, helping to preserve transverse and longitudinal emittance during initial acceleration.

The KIAE-2p hybrid planar undulator was used in this experiment. Built by the Kurchatov Institute and originally designed for the UCLA Neptune IFEL experiment[2], the aggressively tapered undulator was designed for a 3.5 cm Rayleigh Range. It is nonlinearly tapered in both field strength and undulator period.

The Ti:Saph laser was purchased from Amplitude Technologies [8]. The laser consists of an SHG fiber oscillator, a regenerative amplifier 4 pass amplifier, and compressor. The spot size which is larger than the diffraction limited case, is a result of higher order modes acquired in the main amplifier, resulting in an M^2 value of approximately 1.3. The laser waist parameters shown in Table 1 were measured by attenuating it at low power and putting it directly into a CCD camera. The camera was moved along a linear stage and the Rayleigh range, minimum spot and a degree of astigmatism were measured.

Determination of energy modulation for the high gradient IFEL requires a broadband spectrometer. The spectrometer was made by placing a DRZ fluorescent pop-in within the tank of the dipole magnet. Such a broadband spectrometer has a nonlinear calibration, which was determined by sweeping the magnetic field for a fixed momentum electron beam and determining the various bend radii. A simple geometrical model was developed to ensure accuracy of the spectrometer. The method of calibration data was well matched with the model.

Table 1: IFEL Experimental Parameters

Beam Parameters	
Average Injection Energy	55-77 MeV
Charge	50 pC
Undulator Parameters	
K_0	0.2
K_f	2.8
λ_{w0}	1.5 cm
λ_{wf}	5.0 cm
L_w	50 cm
Laser Parameters	
λ	785 nm
τ	150 fs
Pulse Energy	500 mJ
z_r	12 cm
w_0	200 µm

EXPERIMENTAL RESULTS

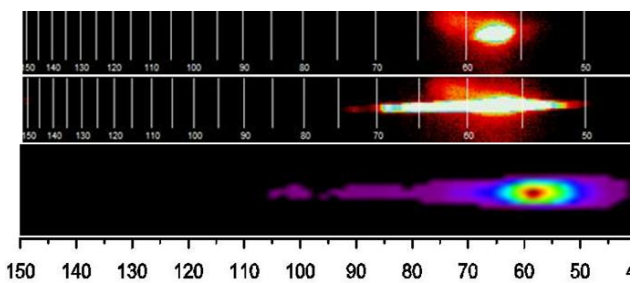

Figure 2: 57 MeV IFEL Interaction Results. a. Electron beam without laser. b. Electron beam with laser applied, IFEL interaction. c. 2D histogram binning of comparable simulation results. Horizontal Scale is Energy in MeV, measured data has nonlinear scaling.

We placed the waist of the laser approximately 2 cm upstream of the center of the undulator and used 57 MeV injection energy into the IFEL. Placing the waist further up-

Copyright © 2013 CC-BY-3.0 and by the respective authors

stream allows for capture earlier in the undulator at the cost of dropping off of the resonant energy curve faster. The energy modulation can be seen in Fig. 2. For both sets the images data has a nonlinear scale by nature of the spectrometer while the simulation data has a linear scale.

We then placed the waist at the center of the undulator and injected at 77 MeV, the highest energy our chicane compressor will allow, injecting into the undulator at above initial resonant energy. The results from this interaction can be seen on Fig. 3. In both cases simulations were run with the measured laser waist parameters. The simulation spectra matched the observed spectra fairly well, justifying the examination of the simulation data as acceleration occurs in the undulator.

Figure 4 shows the average energy evolution for the particles gaining the most energy in three simulations: the design case with a 3.5 cm Rayleigh range 100 µm laser waist is used, and the two cases for our measured waist parameters at the two observed energies. The lower bound energy cuts were 180, 110 and 70 MeV for the design, 77 and 57 MeV cases, respectively. The peak gradient of the 77 MeV injected energy curve shows a maximum gradient of 180 MeV/m. While the design curve shows resonant gain throughout the undulator, the 77 and 57 MeV cases show the electron beam accelerated up to a point where there is a sharp change in slope as the electrons fall out of the pondermotive bucket in the first half of the undulator. After the electrons fall out of the pondermotive bucket nonresonant energy modulation occurs to further increase the energy spread, showing mild gain based upon the selection of the highest energy particles.

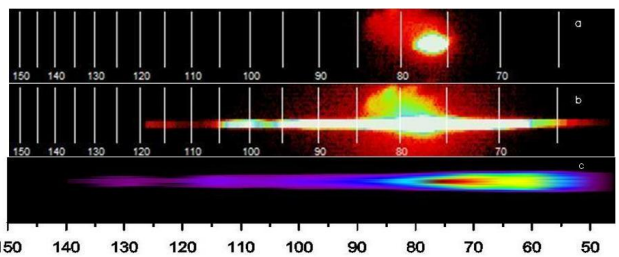

Figure 3: 77 MeV IFEL Interaction Results.a. Electron beam without laser. b. Electron beam with laser applied, IFEL interaction. c. 2D histogram binning of comparable simulation results. Horizontal Scale is Energy in MeV, measured data has nonlinear scaling.

CONCLUSION AND FURTHER STUDY

The IFEL interaction has been demonstrated and has produced high peak gradient acceleration (180 MeV/m) and a record maximum energy produced by the IFEL acceleration mechanism of 120 MeV. Further improvement of the laser waist should yield a higher gradient over the entire undulator with acceleration to the design energy. The short pulse nature of the Ti:Sapphire IFEL is planned to be investigated over the next few months with an electrooptic

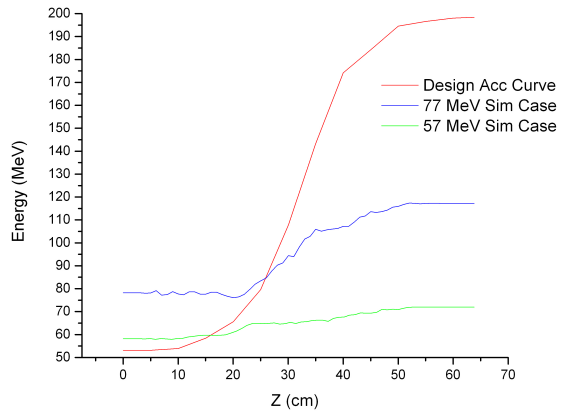

Figure 4: Acceleration curves for the design laser and injection at 50 MeV, The 57 MeV case, and the 77 MeV case.

sampling based time of arrival diagnostic discussed in previous work.[9]. The electrooptic sampling diagnostic will allow for relative time of arrival measurements to be correlated with the observed energy modulation so that the time of arrival jitter can be unfolded from the temporal overlap tolerance.

DEVELOPMENT OF A HIGH-REPETITION RATE TW CO_2 LASER DRIVER FOR A COMPACT, VARIABLE SPECIES ION SOURCE

J. Pigeon, S. Tochitsky, C. Joshi, UCLA, Los Angeles, CA 90095, USA

Abstract

CO_2 laser-driven ion acceleration has been used to generate monoenergetic, MeV proton beams from a gas jet plasma. Use of a gas jet is advantageous because it offers interactions at a density around the critical plasma density for 10 μm pulses (10^{19} cm^{-3}) and can be run at a repetition rate of 1-100 Hz. This opens the possibility to create a variable species ion source easily switchable from protons to light ions (*e.g.* He, N and Ne). A TW class high repetition rate CO_2 laser driver is required for implementing such a source. At the UCLA Neptune Laboratory we have built a 1 Hz CO_2 laser system and demonstrated the amplification of 20 GW, 3 ps laser pulses. However, peak powers on the order of 0.2-1 TW are required for producing ~ MeV proton beams. Here we report progress on an ongoing project in which the peak power of our laser system will be increased by nonlinear chirping and broadening followed by pulse compression. We also discuss a possible strategy for generating 300 mJ, 300 fs CO_2 laser pulses for driving a 1 – 10 Hz laboratory ion source.

INTRODUCTION

There are applications in material science, radiation biology and medical physics [1] that would benefit from a MeV class, multiple species ion accelerator. The cost of such a machine, if built using conventional accelerator technology, is prohibitively expensive for most universities and hospitals. Laser driven ion acceleration (LDIA) may be one avenue for reducing this cost, either as a stand-alone accelerator or as an injector for a conventional accelerator.

Recent experiments have demonstrated monoenergetic, MeV ion acceleration from over-dense ($\omega_{plasma} \geq \omega_{Laser}$) laser plasma interactions (LPI) [2]. High power CO_2 lasers are an attractive candidate for LDIA because, at a wavelength of 10 μm, the critical plasma density can be achieved using a gas jet or cell. In contrast, the majority of high power lasers operate at wavelengths from 0.8 – 1 μm and must use solid targets to study over-dense LPI. Due to the potential ease in targetry, 10 μm drivers are the most technological option for a multi-species, laser driven ion accelerator.

CO_2 LDIA studies have been limited to single shot experiments even though optimization of the laser-plasma interaction may only be possible at a high repetition rate. Although gas jet technology can be scaled up to 100 Hz, experiments have suffered due to limitations in the repetition rate of the driver. At the UCLA Neptune Laboratory we have recently developed a 20 GW, 3 ps CO_2 laser system which operates at 1 Hz [3]. Peak power on the order of 0.2 TW is required for acceleration of ~ 3 MeV protons from a H_2 plasma. In this paper we investigate a method to increase the peak power of our system by using nonlinear chirping and broadening followed by compression. Further we propose a path to a 300 mJ, 300 fs CO_2 laser to be used as a 1 – 10 Hz driver for a compact, multi-species ion source.

STATUS OF THE 1 HZ, PICOSECOND CO_2 LASER SYSTEM

CO_2 lasers have some technological advantages that cannot be matched by solid state laser systems. The gas medium can withstand intensities up to the ionization threshold, $\geq 10^{12} \frac{W}{cm^2}$, which allows for direct amplification of short pulses. Further, gas discharge technology can be scaled in repetition rate and provides high wall plug efficiency. Despite these advantages, high peak power amplification in CO_2 is difficult due to the relatively narrow bandwidth present in gaseous media. Gas lasers typically provide a bandwidth of 3.5 GHz/atm such that, at 1 atm of pressure, a CO_2 laser can only produce pulse lengths greater than 1 ns. Unfortunately, pulse lengths on the order of picoseconds or less are necessary to reach the relativistic intensities required for LDIA.

At the UCLA Neptune Laboratory we achieve broad band CO_2 laser amplification by relying on two broadening mechanisms: pressure and field broadening. Figure (1) shows simulated gain spectrums of the CO_2 medium at 1, 10 and 25 atm of pressure. At 1 atm of pressure the gain spectrum consists of a family of 3.5 GHz, rovibrational lines.

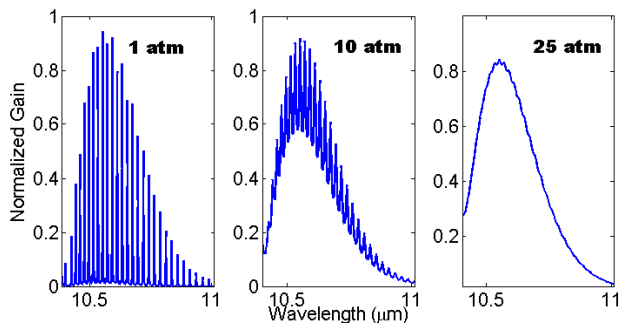

Figure 1: Simulations of the CO_2 gain medium at 1, 10 and 25 atm of pressure for the 10P branch.

At high pressures the collisional time becomes comparable to the radiative transition time which results in line broadening. At 25 atm of pressure the gain spectrum is a continuum across the entire 1.2 THz branch. In practice modules with 10 atm of pressure are used as it is difficult to obtain stable discharge at pressures greater than this. The presence of residual modulation in the gain

Copyright © 2013 CC-BY-3.0 and by the respective authors

spectrum at 10 atm results in the amplification of a pulse train as depicted in figure 2. The resulting pulse train consists of 5 – 7, 3 ps pulses separated by 18 ps.

After the pulse reaches intensities on the order of GW/cm^2 the lasing transition can be broadened by the field of the pulse itself. This broadening manifests in a way similar to the ac Stark effect and can be estimated by $\Delta\nu_{Field} \approx \mu\sqrt{I}$ where μ is the dipole moment in Debye and I is the peak intensity of the pulse. For CO_2 $\mu = 0.0275$ such that, at intensities of $10\frac{GW}{cm^2}$, a 1 atm amplifier has the bandwidth of a 10 atm machine [3]. The total broadening is the sum of the pressure and field dependent terms, $\Delta\nu_{Total} = \Delta\nu_{Pressure} + \Delta\nu_{Field}$.

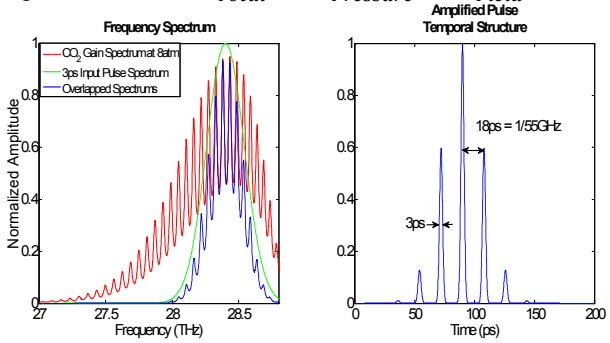

Figure 2: Simulations showing the production of a ps pulse train after amplification of a single ps pulse in a 10 atm CO_2 laser.

Figure 3 is a block diagram of the Neptune Laboratory's CO_2 master-oscillator power-amplifier chain where amplification is realized in two stages. In the first stage the pulse is amplified from nJ to mJ in two 8 atm CO_2 lasers where the pressure sustains the bandwidth for ps pulse amplification. The first module is used as a regenerative amplifier while the second module is used as double pass booster. In the second stage the seed is sent for final amplification in a 1 meter, 1 atm CO_2 laser where the field from the pulse sustains the bandwidth for final amplification.

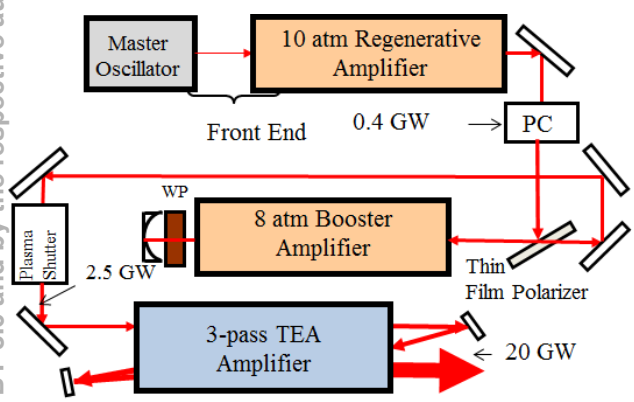

Figure 3: Block diagram of the Neptune Laboratory's high repetition rate system. The orange and blue blocks refer to amplifiers which use pressure and field broadening to sustain ps bandwidth, respectively.

Figure 4 is a plot of the temporal structure of our output pulse train as measured by a streak camera. As simulations predict, the pulse train consists of 3 ps pulses separated by 18 ps, a time scale related to the 55 GHz modulation in the gain spectrum.

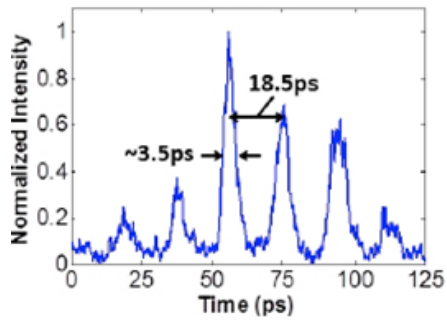

Figure 4: Temporal profile of the ps pulse train

As reported in [3] we extract 200 mJ out of our final amplifier which results in a peak power of 20 GW for the most intense pulse in the train. The amount of extracted energy is limited by saturation and could be increased if the 1 atm final amplifier was replaced by a larger aperture, 2 – 3 atm TE CO_2 module.

NONLINEAR SPECTRAL BROADENING IN A NOBLE GAS FILLED HOLLOW GLASS WAVEGUIDE

A peak power beyond one defined by the CO_2 bandwidth can be obtained via self-phase modulation in a nonlinear optical medium. Nonlinear spectral broadening and subsequent compression of guided waves is a technique which has been successful in the near-IR but has not been explored at 10 µm. Hollow glass waveguides (HGW) which are coated with Ag/AgI are commercially available and have been used in our laboratory to guide GW, 10 µm pulses with a throughput of 95% in the air [4].

Figure 5 illustrates our scheme to use a Xe filled HGW to broaden and chirp our pulses through self-phase modulation. After the HGW the pulses will be compressed via propagation through NaCl, a material with negative group velocity dispersion at 10 µm. The plots of figure 5 depict simulated time and frequency domain representations of our pulse train before and after the pulse compressor.

We have modelled this process by numerically solving the nonlinear Schrödinger equation [5] for our pulse parameters. We have assumed a waveguide radius of 500 µm which corresponds to a peak intensity of 6 TW/cm^2 when the beam is coupled into the EH_{11} mode of the waveguide. The pulse is broadened by a factor of 5 in 200 cm of Xe gas. The length of NaCl to compress the output pulse train was approximately 35 cm which results in 100 GW, 650 fs pulses on the output of the Brewster angled salt plate. Currently the set-up for pulse compression is being built.

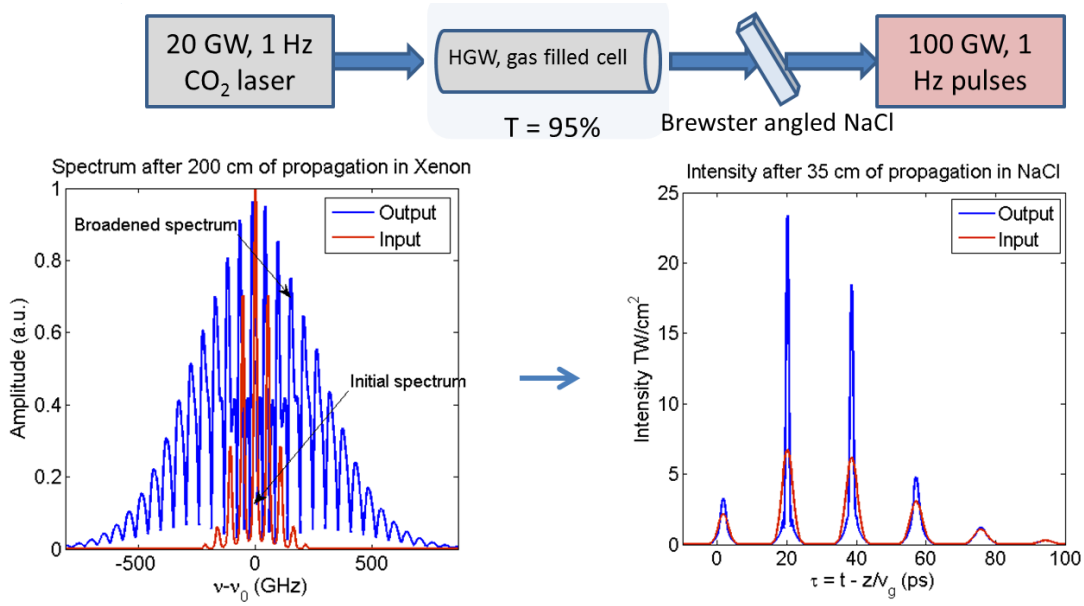

Figure 5: Top: Proposed set-up to use self-phase modulation followed by compression in NaCl to produce 100 GW CO_2 laser pulses. Bottom: Simulated frequency and time domain representations of our pulse train before and after the pulse compressor.

Based on this technique we envision the development of a 1 TW, 1-10 Hz CO_2 laser system by using the strategy described here. In order to extract the energy required to produce a TW class driver we must first replace the 1 atm final amplifier with a 100 cm length, 3 atm CO_2 laser. With this final amplifier we can extract 3 J of energy which can be sent through the same nonlinear pulse compressor of figure (5) to produce 300 fs, 300 mJ pulses.

CONCLUSION

We have presented the status of an on-going project to develop a 100 GW CO_2 laser driver for a variable species ion source at the UCLA Neptune Laboratory. If nonlinear broadening in 200 cm of a noble gas filled HGW followed by pulse compression is successful then we will scale the interaction to generate >0.1 TW CO_2 laser pulses. This power will be sufficient to study CO_2 LDIA with a gas jet target. The capability to study LDIA at a high repetition rate is critical for understanding and optimizing the laser plasma interactions responsible for ion acceleration. Such a system would be an ideal driver for a multi-species, MeV class ion accelerator.

TECHNIQUE FOR DETERMINING THE MAXIMUM ENERGY OF A DISPERSED ELECTRON BEAM FROM LASER WAKEFIELD ACCELERATORS*

J. Shaw#, N. Vafaei-Najafabadi, K.A. Marsh, C. Joshi, UCLA, Los Angeles CA 90024, USA

Abstract

We present a new curve-fitting method based on asymptotically fitting transverse size contributions to the measured electron spectrum that is capable of determining the maximum energy of a dispersed electron beam from a laser wakefield accelerator regardless of its transverse size. This method is applied to experimental spectra obtained in the characterization of a new injector stage to show that Direct Laser Acceleration may be an additional acceleration mechanism in laser wakefield accelerators where the laser pulse is long enough to overlap the trapped electrons.

INTRODUCTION

The energy of electron beams from an accelerator is typically measured by magnetically dispersing the electron beam onto a detector. Because the magnetic dispersion is highly nonlinear, the lower-energy charge generally experiences higher deflection and is well dispersed on the detector, whereas the higher-energy charge is deflected less and therefore is less dispersed. This small spatial separation leads to reduced resolution at higher energies and makes it challenging to accurately determine the maximum energy of an electron beam in the 10s to 100s of MeV energy range using a non-imaging but dispersive magnet. The issue of determining the maximum energy of an electron beam is further complicated when that beam has a large transverse size at the detection plane. In such a case, it is difficult to determine whether the signal at high energies on the detector is actually high-energy electrons or if it is an artifact of the transverse size of the beam. This proceedings describes a curve-fitting method to determine the maximum energy of an electron beam regardless of its transverse size.

EXPERIMENT

This curve-fitting method was developed to accurately characterize a newly-designed laser wakefield acceleration (LWFA) injector, which could produce ~100 MeV electron bunches in gas cells with lengths of 400 μm to 1100 μm [1, 2]. The Ti:Sapphire laser used to do this characterization had a pulse width of 45 fs FWHM and an a_0 of ~2. During the characterization, the injector was tested over a range of plasma densities from 8.1 x 10^{18} cm^{-3} to 2.5 x 10^{19} cm^{-3}. For these laser and plasma parameters, the LWFA is not operating in the ideal blowout regime [3]. Therefore, self-trapping of electrons in the wake will not occur without significant laser pulse evolution. To eliminate the need for laser pulse evolution and thus devote the length of the injector to acceleration, the ionization injection technique [4] was employed. As a result, the spectrum of the accelerated electrons was typically continuous with an exponentially decreasing tail as shown in Figure 1(a). To demonstrate that the injection stage was capable of producing ~100 MeV electrons as designed, it was critical to accurately measure the maximum energies of these electron beams even though they have exponentially decreasing tails. The method described here was found to converge on many real data sets and enabled us to determine the maximum energy of an electron beam regardless of its transverse size, its energy spread, or its exponentially decreasing tail.

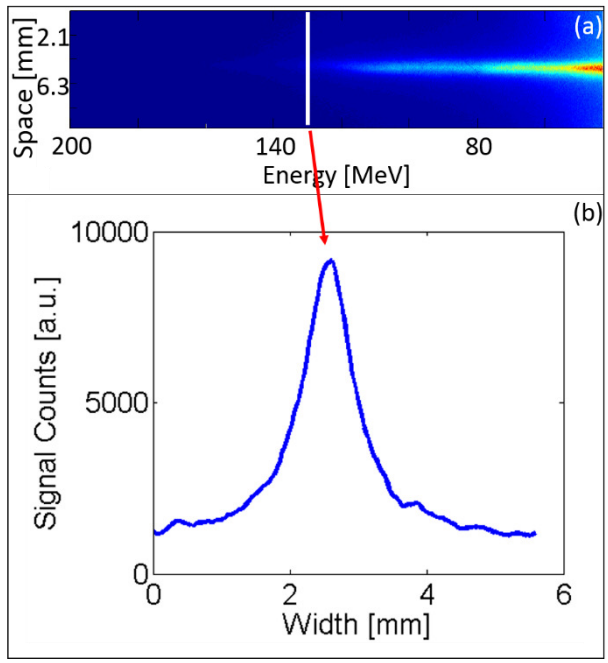

Figure 1: (a) Linearized electron spectrum showing the location of the transverse lineout taken at 130 MeV. (b) Typical raw transverse lineout of the electron spectrum taken at 130 MeV before being rotated and linearized.

DETAILS OF THE METHOD

The method separates out the transverse size contribution by comparing the signal in the dispersed plane to the signal in the transverse (undispersed) plane. In the dispersion plane, the lineout of the electron spectrum has the combined effects of energy dispersion and transverse size. The transverse lineout, however, only

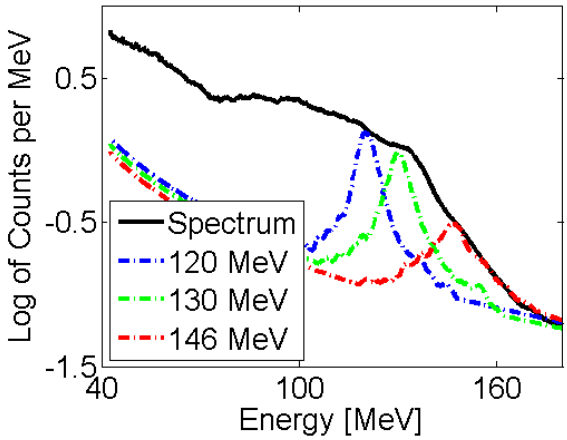

Figure 2: Process of comparing the rotated and linearized transverse lineouts (dashed lines) against the central lineout of the electron spectrum (solid black line). The converted transverse lineout at 146 MeV (red dashed curve) is asymptotic with the central lineout; therefore the maximum electron energy is 146 MeV.

shows the effects of the transverse size. Therefore, by comparing the transverse and longitudinal lineouts of the electron spectrum at a particular energy, it is possible to determine if the signal at that point is due to electrons of that energy or if the signal is from the transverse size contribution of lower-energy electrons.

To compare the transverse lineout of the signal at a particular energy to the actual spectrum, the transverse size contribution of the transverse lineout must first be converted into a dispersed signal. This process is best illustrated on an actual electron spectrum. The raw electron spectrum is first linearized as shown in Figure 1(a) to correct for the energy dispersion of the spectrometer. Based on the energy scale of this linearized spectrum (Figure 1(a)), the maximum electron energy appears to be between 110 MeV and 160 MeV. Therefore, transverse lineouts of the raw spectrum are taken for a series of energies between 110 MeV and 160 MeV. A typical transverse lineout is shown in Figure 1(b).

Each transverse lineout contains the transverse size contribution from the electrons at the energy where it was taken. Assuming that the transverse size effects are radially symmetric, this transverse lineout also includes the contributions of any lower-energy electrons whose transverse sizes are large enough to overlap the chosen energy. The selected transverse lineouts are rotated 90^0 to orient them in the dispersion plane. They are then linearized using the same process used to linearize the dispersed spectrum. Again, because the transverse lineout has no dispersion effects and therefore only accounts for the transverse size contribution, by rotating it into the dispersion plane and linearizing it, the transverse size contribution is converted into a linearized signal in the dispersion plane. This converted transverse lineout thus only shows the portion of the total signal at a given energy that is due to the transverse size. Each converted transverse lineout can then be compared to the central lineout of the actual dispersed signal as shown in Figure 2. In this figure, the solid black curve is the central lineout of the dispersed electron spectrum, and the blue, green, and red dashed curves are the converted transverse lineouts from 120 MeV, 130 MeV, and 146 MeV, respectively. If the tail of the longitudinal lineout has a greater magnitude than the tail of the converted transverse lineout, then the longitudinal signal cannot be caused by the transverse size of the energy of interest alone. There must be a contribution from higher-energy electrons. However, if the tail of the converted transverse lineout at a given energy has a higher signal, then the longitudinal signal at that energy can be attributed to the transverse size contributions of electrons at energies less than the energy being compared. Therefore, the comparison must be repeated with the transverse lineout at the next lowest energy.

To illustrate this comparison, in Figure 2, the tail of the blue curve (the transverse lineout at 120 MeV) is below the dispersed signal. Therefore, 120 MeV is not the maximum measured electron energy; there must be a contribution to the measured electron spectrum from higher-energy electrons. The tail of the red curve falls on the dispersed lineout. Therefore, the tail of the actual dispersed signal can be attributed to the transverse size contribution of the 146 MeV electrons. Therefore, 146 MeV is the maximum energy of this electron spectrum. Note that this method does not account for errors in the measurement of the maximum electron energy due to the electron bunch leaving the plasma at an angle relative to the laser axis. However, if this method is used with a two-screen spectrometer [5, 6], both the transverse size and the exit angle of the electron bunch can be taken into account when calculating the maximum electron energy.

EXPERIMENTAL FINDINGS

Using the curve-fitting method just described, the maximum energy of the electron beams produced in the characterization of the injector cell [1, 2] were determined. Figure 3 shows typical electron spectra obtained at low ($<1\text{x}10^{19}$ cm^{-3}) and high ($>2\text{x}10^{19}$ cm^{-3}) plasma densities.

The performance of LWFAs operating in the blowout regime ($a_0>2$) is commonly benchmarked against the scaling equation for the dephasing-length-limited energy gain [3]:

$$\Delta E \cong \frac{2}{3} mc^2 \frac{\omega_0^2}{\omega_p^2} a_0 \qquad (1)$$

where ω_0 is the frequency of the drive laser and ω_p is the plasma frequency. Equation 1 predicts a maximum energy gain of 126 MeV for the typical low-density shot (Figure 3(a)) and of 48 MeV for the typical high-density shot (Figure 3(b)). Though the parameters of the UCLA injector characterization are not rigorously in the blowout

Copyright © 2013 CC-BY-3.0 and by the respective authors

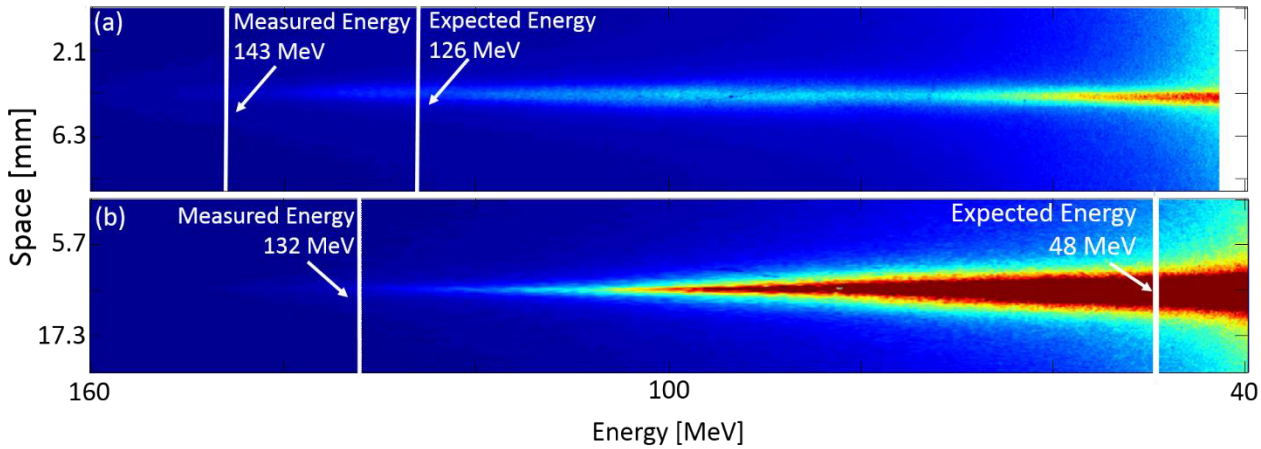

Figure 3: (a) Typical low-density electron spectrum. The cell length l_{cell} was 1100 μm, the plasma density n was 9.1 x 10^{18} cm^{-3}, and a_0 was 2.00. (b) Typical high-density spectrum. l_{cell} was 430 μm, n was 2.2 x 10^{19} cm^{-3}, and a_0 was 1.86.

regime, the measured energy for the low-density spectra agree relatively well with the energies predicted by Equation 1. However, for the typical high-density spectrum shown in Figure 3(b), there is a 175% difference between the maximum measured energy (132 MeV) and the energy predicted by Equation 1 (48 MeV).

DIRECT LASER ACCELERATION

Through a detailed study and a series of OSIRIS [7] particle-in-cell simulations (future publication), it was determined that the source of the additional energy gain produced in high plasma densities is Direct Laser Acceleration (DLA). In LWFAs, the electrons that are trapped in the wake therefore undergo betatron oscillations in response to the field of the ion column formed behind the drive laser. In the UCLA work, the laser had a fixed pulse length of 45 fs and an approximately constant a_0 of 2. Because the length of the bubble formed in LWFAs decreases for increasing plasma densities [3], when the injector was operating at low densities, only the tail of the 45-fs pulse overlapped the electrons trapped in the back of the first bubble, but when the injector ran at high densities, the bubble length was short enough that the higher-intensity portions of the 45-fs pulse overlapped the electrons trapped at the back of the bubble. When the pulse overlaps the trapped electrons that are oscillating in the ion column, the transverse field of the laser will increase the transverse momentum of the electrons that are at the correct phase. This increased transverse momentum can then be transformed into longitudinal momentum through the **v** x **B** force due to the magnetic field of the laser. This process of enhancing the transverse momentum of an electron and then converting that increase to longitudinal momentum is known as DLA [8]. DLA can lead to increased energy gain in LWFAs operating in a regime where the pulse overlaps the electrons trapped in the first bucket and is the source of the additional energy gain seen at UCLA when the injector was operating at high densities.

CONCLUSION

This proceedings details a newly-developed curve-fitting method for determining the maximum energy gain of a dispersed electron beam regardless of its transverse size. This method was applied to experimental work at UCLA to find that DLA is an additional acceleration mechanism at work in LWFAs where the laser pulse overlaps the trapped electrons.

Abstract

Evidence of beam loading due to distributed injection in Plasma Wakefield Accelerator experiments carried out at the FACET facility at SLAC during the year 2012 is presented. The source of the injected charge is tunnel ionization of Rb^+ inside the wake, which occurs along the length of the interaction at each minima of envelope betatron oscillation. Rb was used specifically to mitigate the problem of head erosion, which limited the energy gain in earlier experiments using Li that were carried out at FFTB in SLAC. In the present experiment however, electrons produced via secondary ionization of Rb were injected in the wake and led to a severe depletion of the accelerating wake, i.e. beam loading, which is observed as a reduction of mean, i.e. measured, transformer ratio. This "dark current" limitation on the maximum achievable accelerating gradient is also pertinent to other heavier ions that are potential candidates for high-gradient PWFA.

INTRODUCTION

A Plasma Wakefield Accelerator (PWFA) uses a short, dense, high current electron beam to drive a high amplitude wake [1], which can accelerate electrons with gradients that are orders of magnitude larger than the conventional accelerators [2]. When the beam density (n_b) is higher than the plasma density (n_p), the electron beam expels all of the plasma electrons locally and creates a blowout region, a structure of uniform ion density that accelerates and focuses electrons [3]. The FACET Facility at SLAC [4] is currently used for further research on PWFA.

Two particular physics problems that have to be addressed are the problems of head erosion [5] and ion motion [6]. Head erosion is a physical effect limiting the length of the acceleration. Briefly, if the plasma is generated by the beam via field ionization, as was the case in [2], the part of the beam that ionizes the medium into plasma is not in the blowout region and therefore continues to expand at a rate that is dependent on its emittance. The expansion then causes the ionization front to recede back in the frame of the beam. The rate of this "head erosion" effect is dependent on $1/\gamma$, ϵ_n, and $\mathrm{IP}^{1.73}$ [7], where ϵ_n is the normalized emittance and IP is the ionization potential of the element that is being ionized. Ion motion is a problem because it leads to distortion of the linear focusing force in the blowout regime, and it occurs for $n_b/n_p > m_i/m_e$.

Both of these problems can be addressed by switching Li (used previously [2]) to a higher Z element, such as Rb. With an ionization potential that is 23% smaller than Li, the application of the scaling equations for head erosion implies that the interaction length in Rb would be 40% longer, leading to a proportional increase in maximum achievable energy. Additionally, with an atomic mass of over 12 times larger than Li, Rb ions are an order of magnitude less mobile. On the other hand, the ionization potential of the second Li electron is so high (75.6 eV) that it is not exceeded during the experiment. This is not the case with Rb. The second ionization potential of Rb is 27.3 eV, which could be reached during the experiment. Here, we show that this secondary ionization of Rb is responsible for significantly reducing the energy gradient. The suppression of the accelerating gradient is diagnosed in this experiment by monitoring average transformer ratio $\langle T \rangle$, which can be measured in experiments as $\Delta W^+/\Delta W^- = \int E^+ dz / \int E^- dz$.

EXPERIMENTAL SETUP

The 3 nC, 20.35 GeV electron beam from the FACET facility at SLAC was focused on the rising edge of a column of Rb vapor at the neutral density of 2.7×10^{17} cm^{-3} in a heat pipe oven [8] (Fig. 1). Rb gas was contained in the oven using Ar as buffer. Therefore, the density of Ar rose as the density of Rb fell in such a way that the total pressure stayed the same. The bunch length of the beam was monitored for every shot using the integrated transition radiation signal, which was generated as the beam traversed a 1 μm thick Ti foil and was measured by a pyroelectric detector (pyro). This signal correlated with a THz Michelson interferometer (Fig. 1) and was the main diagnostic of the bunch length. Two absolutely calibrated toroids before and after

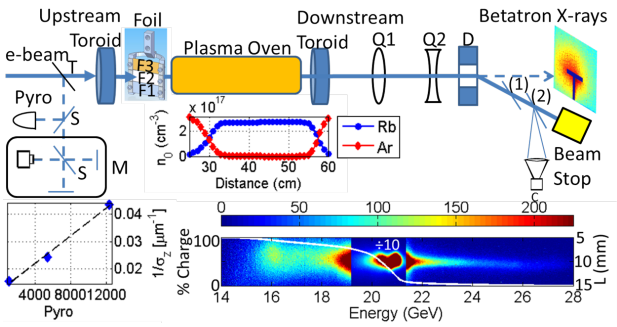

Figure 1: Experimental setup. The electron beam enters from the left. Transition radiation generated as the beam traverses the 1 μm Ti foil is observed simultaneously by a pyroelectric detector (Pyro) and a THz Michelson interferometer (M). Correlation of the two signals is shown beneath the setup. Foils can be inserted in the path of the beam before it enters the plasma oven to change its emittance from $\epsilon_{n0} = 250 \times 50\,\mu$m (see Table 1 for details). Underneath the schematic of the oven, the density profiles of neutral Rb and Ar are shown in blue circles and red diamonds, respectively. The quadrupole magnets Q1 and Q2 along with the dipole magnet D form the spectrometer. The Cherenkov radiation emitted between silicon wafers (1) and (2) is detected by camera C. An example of the energy spectrum with the white curve showing the integrated charge is shown below the camera C. The charge near 20.4 GeV observed not to lose any energy has been attenuated by a factor of 10. The Lanex screen, shielded by a 1mm copper foil, detects the betatron x-rays.

the plasma oven were used to monitor the incoming and outgoing charge. Excess charge generated during the interaction was calculated by subtracting the upstream toroid from the downstream one. To vary the beam emittance, a set of foils of various thicknesses and compositions (F1-F3, see Fig. 1 and Table 1) were placed in to path of the beam. An imaging spectrometer containing two quadrupole magnets and one dipole magnet are used to measure the energy spectrum of the beam after the plasma. After being dispersed by the dipole, the electrons traveled in air and generated Cherenkov radiation, which was imaged onto a 12 bit CCD. An example of such image is shown in Fig. 1. X-ray photons of 50-200 keV are observed using a Lanex film, which is shielded from low energy x-rays using a 1 mm copper mask [9].

Table 1: Composition, Thickness, and Emittance Contribution [10] of the Foils F1-F3 in Fig. 1

Foil	Thickness	Metal Composition	ϵ_n/ϵ_{n0}
F1	25.4 μm	71.15 Ag/28.1 Cu/0.75 Ni	1.2
F2	50.8 μm	25.57 Au/74.43 Cu	1.3
F3	38.1 μm	81.1 Au/16 Cu/2 Ni	1.4

METHODS AND ANALYSIS

The energy gain and energy loss are needed to calculate the average transformer ratio. To calculate these values, a plot of the integrated charge (white curve shown in spectrometer image in Fig. 1) is first produced by integrating the counts on the spectrometer image first in the non-dispersive dimension and then in the dispersive dimension. Energy gain and loss in this experiment are defined as the energies where this curve exceeds 2% and 98%, respectively. For example, in the spectrometer image shown in Fig. 1, the maximum energy is 24.4 GeV and minimum energy is 15.1 GeV, leading to values of 4 GeV and 5.3 GeV for energy gain (ΔW^+) and energy loss (ΔW^-), respectively.

From the same spectrometer image, it is clear that a significant portion of the charge has not moved from the initial energy. This portion of the beam is the unaffected charge and is dependent on where the ionization occurs in the frame of the beam. Modeling the ionization with the ADK model [11, 12], we can plot an ionization contour for the beam and calculate the amount of unaffected charge at a certain ionization contour based on the element and beam characteristics. This measurement can also be applied in reverse, inferring the initial size of the beam as it enters the plasma. The insertion of foils F1-F3 causes an increase in the beam size [13], reducing the beam density and field, leading to an increase in the unaffected charge for increasing foil number. Typical value of the unaffected charge as a function of total charge were 38% for the case of no foil, 43% for F1, 43% for F2 and 51% for F3. These values are for a pyro reading between 3000 and 6000 or $\sigma_z \sim 40\,\mu$m. Subtracting the unaffected charge from the total charge yields the amount of charge that participated in driving the wake and forming the accelerating structure.

Once the Rb vapor was ionized, the experiment quickly evolved into the blowout regime, where the electron beam traveled in a uniform ion column. The evolution of the electron beam in this ion cavity can be illustrated by the envelope evolution model [14]. If the initial beam radius is larger than the matched radius, given by $\sigma_r^2 = \epsilon_n(c/\omega_p)\sqrt{2/\gamma}$ [15], the envelope radius of the beam decreases in the up-ramp of the plasma and then oscillates along the entire length of the interaction. As the envelope of the beam oscillates, the electrons generate x-rays that will be observed by the x-ray diagnostic. To calculate the x-ray yield resulting only from the beam-plasma interaction, background data is obtained by sending the electron beam through neutral Ar. This yields a background emission region, which is independent of the plasma interaction, and is then selected and blocked in the experimental results. Furthermore, since the number of electrons participating in the oscillations varies from one experiment to another, the x-rays yield is normalized to the participating charge. In this manner, the x-ray yield per electron can be compared in different experiments.

The envelope oscillation of the beam has another signif-

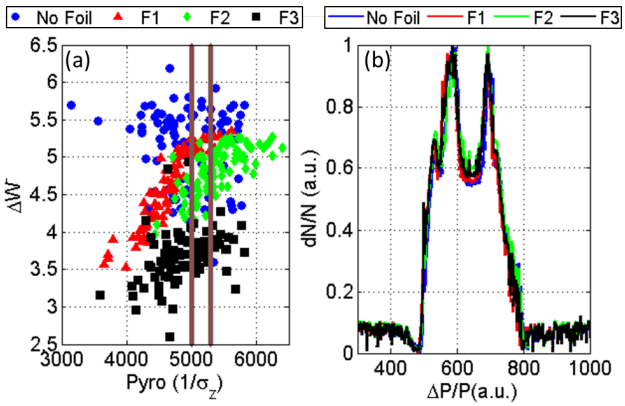

Figure 2: (a) Energy loss as a function of inverse bunch length ($\propto$ pyro). Data with 5000<pyro<5300 is marked. (b) Projection of phase space for data with 5000<pyro<5300. Current profiles are nearly identical.

icant consequence. As the envelope radius decreases, the radial electric field of the beam increases. For a participating charge of $N = 1.3 \times 10^{10}$ electrons, $\sigma_z = 40\,\mu$m and $\sigma_r^* = 3\,\mu$m, where σ_r^* represents the minimum value of the envelope radius, the electric field can be calculated from $E_r^{max} = 17.3\,\text{GV/m}(N/10^{10})(10\mu\text{m}/\sigma_r^*)(30\mu\text{m}/\sigma_z)$, which yields an E_r^{max} of 56 GV/m. The peak electric field strength required to ionize Rb^+ by 10% for the same σ_z is 53 GV/m. Therefore, Rb^+ electrons are ionized at the lowest point of the radius oscillation, released inside the wake, accelerated by the wake structure [14], and observed as excess charge on the toroids.

To minimize the effect that different current density profiles can have on the results, ΔW^-, ΔW^+, and excess charge data were filtered to a narrow range of pyro reading with nearly identical current densities (Fig. 2). This specific range of pyro (5000 <pyro< 5300) was selected because the data contained in this region spanned a large range of values. For instance, ΔW^- shown in Fig. 2(a) varied by more than a factor of 2. This variation allowed for meaningful study of the correlation between different parameters. The current density profiles were inferred from the projection of the electron beam's phase space, which is recorded on every shot. This projection is obtained using a vertical half period wiggler magnet, which reroutes electrons through two small bends [16]. The resulting radiation illuminates a scintillating crystal of YAG:Ce, which is imaged onto a CCD camera. These profiles confirm that experimental data points in the narrow range of pyro selected indeed have a beam current profile that is nearly identical to one another (Fig. 2(b)). Using this dataset selected for their similar current density profile, it is observed that excess charge is almost linearly correlated with both the x-ray yield and energy loss [17]. In other words, for every betatron oscillation contributing to x-ray yield, the excess charge increases as well. Furthermore, the correlation between excess charge and the energy loss strongly implies that this distributed trapping occurs over the length

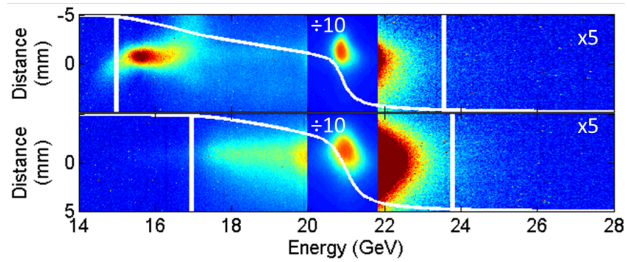

Figure 3: Electron energy spectra. Top: Excess charge was 770 pC and $\langle T \rangle = 0.6$. Bottom: Excess charge was 510 pC and $\langle T \rangle = 1.1$; Foil F3 was also inserted in the beam path. $\langle T \rangle$ decreases as the excess charge increases.

of the interaction. This distributed injection of charge in turn beam loads the wake, reducing the accelerating gradient and the transformer ratio. As stated earlier, this effect is observed in the experiment by measuring the average transformer ratio $\langle T \rangle$. The spectrum corresponding to the two data points with the highest and the lowest excess charge from the narrow range of pyro selected in Fig. 2 is shown in Fig. 3. It is evident that while the energy loss increases significantly, the energy gain is nearly the same between the two as the result of the heavy beam loading.

In summary, secondary ionization of heavy ion species in the blowout region is a significant limiting factor for the accelerating gradient in PWFA. In our experiment, Rb^+ ionization led to beam loading and a reduction in $\langle T \rangle$ by a factor of two. Other heavy elements considered as candidates to mitigate head erosion and ion motion in PWFA experiments may be limited in their accelerating gradient by the same effect.

Abstract

Simulating Laser wakefield acceleration (LWFA) in a Lorentz boosted frame in which the plasma drifts towards the laser with v_b can speedup the simulation by factors of γ_b^2, where γ_b is the Lorentz factor of the boosted frame. To eliminate the high frequency numerical instability induced by relativistic plasma drift in these simulations, we develop a fully parallelized, multi-dimensional, particle-in-cell code that uses a spectral solver to advance the Maxwell's equations. This new EM-PIC code is called UPIC-EMMA and it is based on the components of the UCLA PIC framework (UPIC). It is shown that using UPIC-EMMA, LWFA simulations in the boosted frames with large γ_b can be conducted without any notable numerical instability. We also benchmark the UPIC-EMMA results with OSIRIS in the lab frame, an EM-PIC code with a finite difference time domain (FDTD) Maxwell solver, and good agreements are found.

INTRODUCTION

Laser wakefield acceleration [1] offers the potential to construct compact accelerators that has a numerous potential applications, and the last ten years has seen an explosion of theoretical and experimental results. Due to the strong nonlinear effects in the laser plasma interaction involved, numerical simulations, in particular particle-in-cell (PIC) simulation, are critical in exploring the physics of LWFA. Recently, it was shown that by performing the simulation in an optimal Lorentz boosted frame with velocity v_b, the time and space scales to be resolved in a numerical simulation may be minimized [2, 3, 4]. The basic idea is that in the boosted frame the plasma length (the laser propagation distance) is Lorentz contracted while the plasma wake wavelength and laser pulse length are Lorentz expanded, which lead to savings of factors of $\gamma_b^2 = (1 - v_b^2/c^2)^{-1}$ as compared to a lab frame simulation using the so-called moving window [5].

However, in the boosted frame simulations noise from a numerical instability can be an issue. As discussed in [6, 7, 8, 9, 10], the noise results from a numerical Cerenkov instability induced by the plasma drifting with relativistic speeds on the grid. According to the dispersion relation this numerical instability is attributed to the coupling between the wave-particle resonances with EM modes (including aliased modes) in the numerical system. The pattern of the instability in Fourier space can be found at the intersections of the EM dispersion relation of the solver used in the simulation algorithm, and the wave-particle resonances [8, 9, 10].

In order to mitigate this instability, it is preferable to use an EM solver that eliminates the numerical instability at the main beam resonance [10]. When using a spectral solver that spatially advances the EM fields in Fourier space, its EM dispersion curve assures no instability pattern at the main beam resonance. In addition, the pattern at the first space aliasing beam mode is found to be located at high $|\vec{k}|$ values that are far away from the interested physics. For the spectral solver the numerical Cerenkov instability of the first aliased beam mode is located at a predicted pattern in $\vec{k}$ space so it can be conveniently eliminated by applying simple filters directly in $\vec{k}$ space.

We developed a fully parallelized three-dimensional electromagnetic spectral PIC code called UPIC-EMMA that was built using components of the UCLA PIC Framework called UPIC [11]. A spectral EM-PIC code has the same basic flow chart as a finite-difference-time-domain (FDTD) PIC code. In a spectral EM-PIC code both the charge and current are deposited on the mesh from the particles; the forces exerted on the particles are interpolated from the mesh points, and particles are advanced using the Lorentz forces. The main difference between the spectral PIC code and FDTD PIC code is the solver used to advance the electromagnetic field and that all field quantities, including the charge and current densities, are defined at the same locations on a cell (no Yee mesh [12] is needed). In a spectral PIC code the charge and current are directly deposited, and a strict charge conserving current deposit is not needed because Gauss's law is solved at each time step using the charge density.

There are no dispersion errors for light waves due to the grid (however there are errors from the finite time step). This is a significant advantage of the spectral solver, whereas a FDTD code describes the $[k]_i$ operator to $\mathcal{O}(k_i\Delta x_i)^3$, the spectral code has no errors in the finite $[\vec{k}]$ operator. In addition, when including time step errors, the numerical dispersion of a spectral PIC code is superluminal, while that of the FDTD code is sub-luminal. The more accurate and superluminal aspect of the EM dispersion relation provided by the spectral solver (together with the simple filters) is crucial for eliminating the numerical Cerenkov instability. This ensures no non-physical interaction between waves and particles in the first Brillouin zone for the spectral PIC code.

LAUNCHING LASER AND ELECTRON BEAM

To model LWFA stages including beam loading it is necessary to have an antenna and a cathode in the boosted frame. Next, we discuss how these are implemented in UPIC-EMMA.

Moving Antenna

As discussed in [3] and [13], the effective spot size of the laser increases by a factor of $\gamma_b^2(1+\beta_b)$ because the Rayleigh length of the laser contracts by γ_b and the pulse length expands by $\gamma_b(1+\beta_b)$. To prevent the need for using a simulation box with transverse size $\sim \gamma_b^2$ times that is needed in the lab frame, we utilize a thin slice of grids at the plasma boundary as an antenna to drive the laser pulse into the plasma. The antenna moves backward together with the plasma boundary in the boosted frame.

In the spectral code, the transverse and longitudinal components of the fields are solved for separately. Therefore, on the antenna we set ρ equal to zero so there are no longitudinal fields on it. When launching a laser from the antenna, we assign current (in the direction of the laser polarization direction) at every point inside the antenna such that $\vec{E}$ has the desired form and polarization. The other components and the magnetic field follow naturally from Maxwell equations. The antenna has a finite width of around $\lambda/2$ where λ is the wavelength of the laser in vacuum to eliminate any backward propagating signal. The current for generating the laser is added after the current is deposited for all the particles in the system is finished.

Beam Cathode

Similarly to the initialization of laser, when initializing a particle beam in the Lorentz boosted frame the effective β^* contracts, which greatly enhances the effective spot sizes of the beam. We implement a beam cathode in UPIC-EMMA which, similarly to the moving antenna for laser, launches beam particles from a thin slice moving together with the plasma boundary. The corresponding EM fields produced by the beam are likewise initialized within the slice. The beam cathode also enables UPIC-EMMA to be used to simulate loading a particle beam into a wake driven by a laser and simulate plasma wakefield acceleration (PWFA).

BENCHMARK WITH OSIRIS

To benchmark the boosted frame simulation results from UPIC-EMMA, we performed extensive simulations. Here we present simulations of a 1 GeV LWFA stage with both UPIC-EMMA in a boosted frame and OSIRIS [14] in the lab frame. OSIRIS uses a FDTD solver, e.g. Yee solver, to push the EM field. The parameters for the OSIRIS simulations are listed in table 1, and the results for the $a_0 = 8.0$ cases are shown in figure 1. From the plasma density plot and wakefield plot in the Lorentz boosted frame, we can see clean physical results with no evidence of the numerical Cerenkov instability. Good agreement for the on-axis wakefield is found between OSIRIS lab frame and UPIC-EMMA boosted frame simulation. More comparisons can be found in Ref. [15].

Table 1: Simulation Parameters for the Simulations Shown in Figure 1 and 2 – ω_0 is the Laser Frequency and k_0 is the Laser Wave Number in the Lab Frame

2D LWFA boosted frame simulation	
Plasma	
plasma column length L	0.9 cm
density n_0	2×10^{18} cm^{-3}
Laser	
pulse length τ	30 fs
norm. vector potential	$a_0 = 8.0$
pulse waist W	15 μm
Simulation	
grid size $(k_0\Delta x_1, k_0\Delta x_2)$	$(0.0982, 0.0982)$
time step $\omega_0\Delta t$	0.0225
number of grid in box	16384×512
boosted frame γ_b	14
particle shape	quadratic
3D PWFA lab frame simulation	
Plasma density n_0	5×10^{16} cm^{-3}
Beam	
pulse length τ	113.7 fs
spot size W	10 μm
beam energy	22.5 GeV

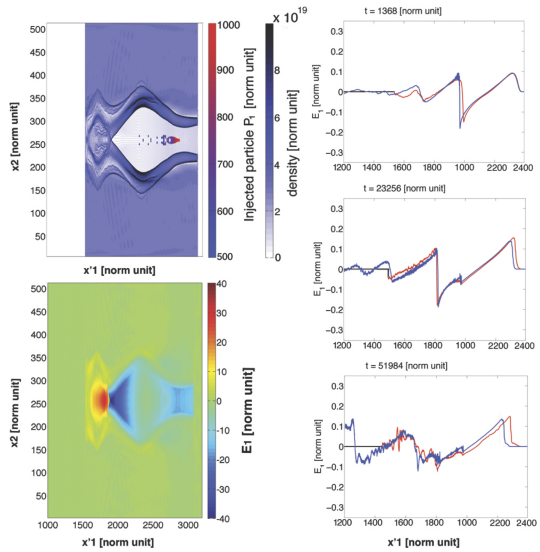

Figure 1: Highly nonlinear case at $a_0 = 8.0$. Left column shows the 2D plots of plasma electron density, and the corresponding E_1 at $t = 221$ [norm unit] in the boosted frame ($\gamma_b = 14$). The second column shows the on-axis E_1 comparison between OSIRIS lab frame, and UPIC-EMMA boosted frame simulation ($\gamma_b = 14$).

BOUNDARY CONDITIONS

Currently, in UPIC-EMMA there are 3 types of EM boundary conditions (b.c.) available: (i) 3D periodic boundary; (ii) 3D conducting boundary; and (iii) mixing boundaries with conducting boundary in x_1 and x_2, and periodic boundary in x_3. The particles are specularly reflected from the conducting boundary. The conducting b.c. is particularly useful when modeling beam loading or PWFA. This is due to the fact that when all the three directions are periodic, the charge neutrality in the simulation box is enforced, while in the PWFA simulation the system is non-neutral because of the electron beam. To illustrate this issue we show UPIC-EMMA results from a lab frame simulation where only one driving particle beam is modeled (no trailing beam). In figure 2 we present the results of a 3D PWFA simulation in the lab frame, using 3D periodic b.c. (first row), and mixing b.c. (second row), and the comparison in the on-axis wakefields are shown in figure 2 (c) and (d). The QUICKPIC results are also shown in figure 2 (c). In figure 2 (d) we plot the transverse lineout of the wakefield in the bubble, to illustrate the differences in the wakefield due to the different b.c.

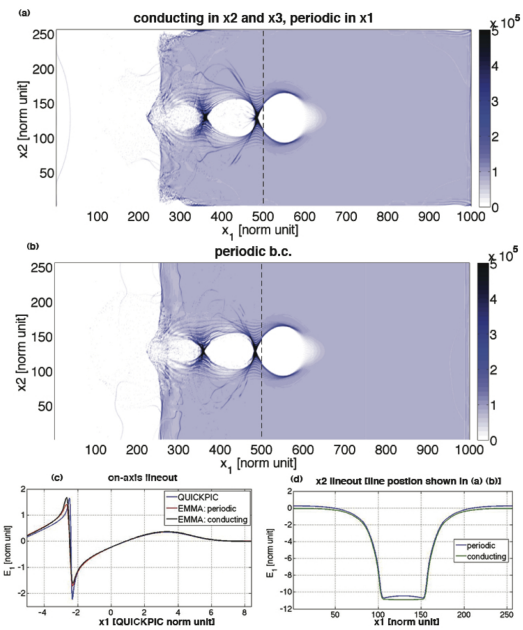

Figure 2: (a) and (b) show the 2D plasma density plot of a 3D PWFA lab frame simulation using the parameters shown in table 1. (a) uses the conducting b.c. in the transverse directions of the propagating driving beam, while (b) uses 3D periodic b.c. In (c) the on-axis wakefields are compared between the mixing b.c. and 3D periodic b.c., and also compared with the QUICKPIC results. In (d) we plot the transverse lineout of the wakefield in the bubble for the two types of b.c; the position of this cross section is shown in (a) and (b).

CONCLUSIONS

In this paper we briefly described a new simulation code called UPIC-EMMA that can model LWFA stages, including beam loading from an injected particle beam, at very high gammas γ_b. UPIC-EMMA uses a spectral solver to mitigate the numerical instability induced by the relativistic plasma drift. The spectral solver together with a band-pass filter conveniently mitigates the numerical instability.

We have also implemented a moving antenna to launch a laser and a moving cathode to launch a particle beam. The moving cathode allows beam loading as well as PWFA studies. The implementation of a mixing boundary condition is shown to give correct results for the wakes from the driving particle beams.

We presented details of LWFA parameters for simulating LFWA stages using UPIC-EMMA in the Lorentz boosted frame. The γ_b of the boosted frame is chosen such that the laser frequency is in the same order as the plasma frequency so neither of these two characteristic lengths are over-resolved. We compared the transformed boosted frame data in UPIC-EMMA with the lab frame data from OSIRIS, and good agreements are found.

This work is supported by DOE awards DE-FC02-07ER41500, DE-SC0008491, DE-FG02-92ER40727, and DE-SC0008316, and by NSF grants NSF PHY-0904039 and NSF PHY- 0936266, and by NSFC Grant 11175102, thousand young talents program. Simulations were carried out on the UCLA Hoffman 2 Cluster, and Dawson 2 Cluster.

POSSIBILITY OF CONFIRMING SMI THROUGH ENERGY SPECTRUM WITH THE 1 nC ATF ELECTRON BUNCH

Abstract

In this paper, we demonstrate numerically the possibility of measuring the energy gain/loss experimentally to confirm the self-modulation instability (SMI) development with electron bunch parameter available at Accelerator Test Facility (ATF) of Brookhaven National Laboratory (BNL). The results also show that due to plasma wakefield dephasing during the SMI development, the actual energy gain/loss by drive bunch particles is lower than deduced from maximum accelerating fields. All the simulations are performed with the 2D-cylindrically symmetric partilcle-in-cell code OSIRIS [1].

INTRODUCTION

We have successfully demonstrated the excitation of multiple-periods plasma wakefields by a 50 pC bunch with square current profile available at the Accelerator Test Facility of Brookhaven National Laboratory (BNL-ATF) [2]. These wakefields act as the seed for self-modulation instability (SMI). The experimental data is in excellent agreement with the linear theory and OSIRIS-2D [1] simulation results. With this low 50 pC charge, the SMI does not grow within the 2 cm propagation distance in the plasma density range available in the experiment (10^{15}-10^{17} cm^{-3}), and therefore periodic energy modulation measurements were possible. However, simulations have shown that the SMI of the 1 nC bunch grows significantly and reaches saturation over the 2 cm propagation distance (see Fig. 1 b)). Note that for 1 nC bunch, the beam-plasma interaction is still in the linear regime of the PWFA for the plasma density range as indicated above, i.e., n_b/n_p <0.06. According to linear theory, the initial wakefield amplitude is 20 times higher for 1 nC bunch than that of 50 pC bunch, and this has been confirmed by previous simulations [3]. We here further analyze the simulation results of 1 nC bunch to examine the possibility of measuring the energy spectrum experimentally to confirm the development of SMI. As an example, we take the plasma density of $n_e = 4.85 \times 10^{15}$ cm^{-3} such that $L_{\rm beam}/\lambda_{pe} = 2$. It has been demonstrated that during the development of SMI, the plasma wave phase velocity becomes smaller than the beam velocity, resulting in dephasing between the bunch particles and the wakefields [4, 5]. The following results show that due to such dephasing, the actual energy gain/loss by drive bunch particles is $\approx 25\%$ lower than deduced from maximum accelerating field plots, i.e. assuming the wakefield on the particles do not dephase. However, the resulting energy gain is approximately 2.4 times larger than the case without SMI development. It is therefore still possible to confirm the SMI development through the measurement of resulting energy spectrum in the experiment.

ENERGY GAIN/LOSS

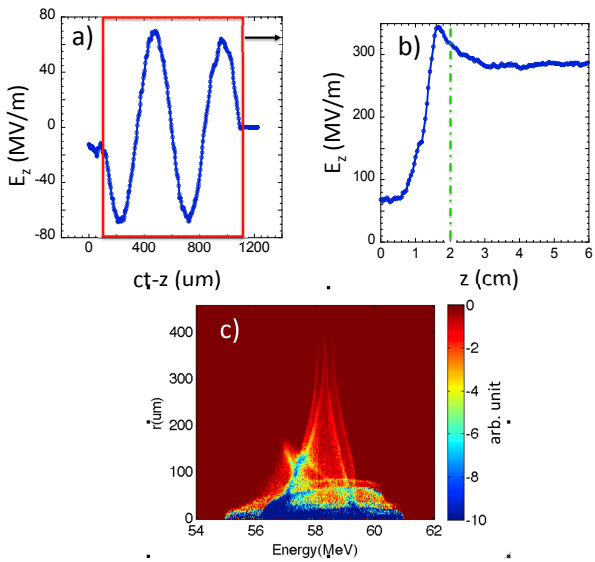

Figure 1: a) The longitudinal wakefield E_z on the axis ($r = 0$) at plasma entrance ($z = 0$) within the bunch. The red rectangle indicates position of the electron bunch. b) The evolution of maximum E_z on the axis ($r = 0$) along the propagation distance. The green line indicates the plasma length in the experiment. c) Electron bunch density in the r, E space, showing the energy spectrum of the beam at plasma exit ($z = 2$ cm). Results are obtained from OSIRIS 2D.

We first assume that there is no SMI growth during the 2 cm propagation for the 1 nC bunch, and therefore the energy gain/loss at the plasma exit can be estimated by multiplying the initial E_z amplitude (at $z = 0$) with 2 cm. Figure 1 a) shows the initial longitudinal wakefield E_z on the axis ($r = 0$) at the plasma entrance ($z = 0$) obtained from simulation, with an acceleration amplitude $E_{z0} \approx 67$ MV/m, which is within $\%5$ difference with the estimation of linear theory (≈ 64 MV/m). Therefore, assuming no SMI growth and hence no E_z amplitude evolution, the energy

* yunf@usc.edu

Copyright © 2013 CC-BY-3.0 and by the respective authors

gain/loss at the plasma entrance would be $\Delta E_{\mathrm{no-growth}} = E_{z0} \times 2$ cm$\approx$ 1.33 MeV. Figure 1 b) shows the evolution of maximum longitudinal field on the axis E_{zmax} along the propagation distance. The exponential growth and saturation of E_{zmax} indicate the development of SMI with the 1 n bunch. Since the SMI is a convective instability, the maximum E_z is expected to be at the back of the bunch, e.g. at the acceleration peak of the second wakefield bucket in this case. Assuming no dephasing of the plasma wave with respect to the square bunch during the propagation, the maximum energy gain can be estimated as the integral of E_{zmax} over the propagation distance, resulting in $\Delta E_{\mathrm{growth-integration}} \approx 3.52$ MeV. Figure 1 c) shows the energy spectrum of the electron bunch particles at the plasma exit, obtained from the OSIRIS-2D simulation. With the mean incoming energy of 58.35 MeV, the maximum energy gain is estimated as $\Delta E_{\mathrm{growth-spectrum}} \approx 60.98 - 58.35 = 2.63$ MeV, more than 2 times larger than the value obtained assuming no SMI growth. We hence conclude that it is experimentally possible to confirm the development of SMI through the measuring of the energy gain/loss at the plasma exit. It is also worth noting that the particles' actual maximum energy gain/loss $\Delta E_{\mathrm{growth-spectrum}}$ is 25% smaller than the integration of the maximum E_z result $\Delta E_{\mathrm{growth-integration}}$. This clearly indicates the occurrence of dephasing during the development of SMI, which will be further examined in the following section. Note that the conclusion also applies to energy loss, although the figures are not shown here.

DEPHASING OF THE WAKEFIELD

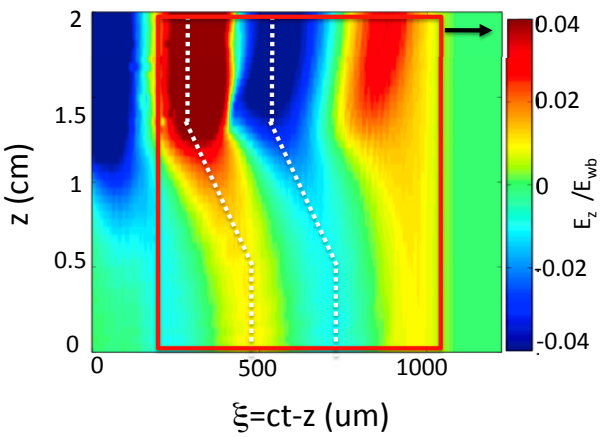

Figure 2: Evolution of the accelerating wakefield structure E_z within the bunch(es) along the propagation distance z. The red rectangle shows the longitudinal position of the bunch and the white dotted lines show the "trajectory" of the peak accelerating and decelerating field in the $z - \xi$ plane, respectively.

To confirm the dephasing of the plasma wave with respect to the electron bunch during the propagation, Fig. 2 shows the evolution of accelerating wakefield structure E_z. The phase velocity of the longitudinal plasma wave v_ϕ can be deduced from the slope of maximum E_z in the z and $\xi(= ct - z)$ plane (as shown schematically by the dotted line in Fig. 2), yielding $v_\phi = c \times (1 + \frac{1}{\delta z/\delta\xi})$ [6]. Consequently, a smaller negative slope ($\delta z/\delta\xi$) means a smaller phase velocity. Figure 3 d) shows the fitting to obtain the phase velocity. During the first 0.5 cm propagation, there is no significant growth of SMI (as can be observed in Fig. 1 b)) , and therefore the wakefield phase velocity is close to the beam velocity $v_b(\approx c)$. Between $z = 0.5 - 1.5$ cm, the beam density becomes modulated due to the periodic focusing/defocusing field and hence SMI develops, resulting in a lower wakfield phase velocity v_ϕ. Its value is estimated as 0.986 c according to Fig. 3 d). For $z = 1.5 - 2.0$ cm, the SMI saturates and the wake phase velocity almost reaches c again.

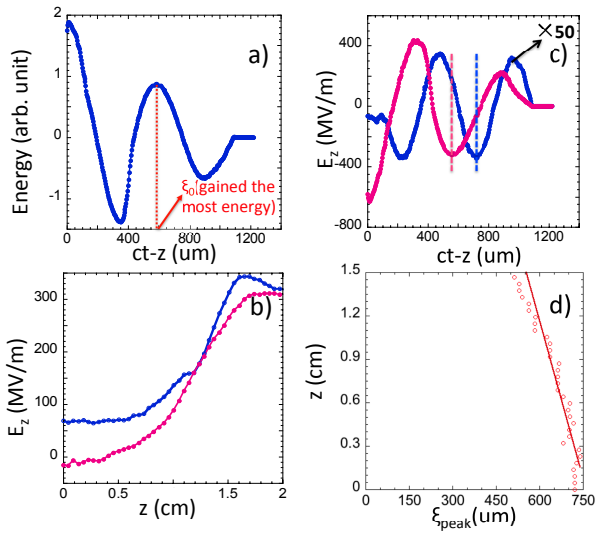

Figure 3: a) Energy gain/loss by particles along the bunch (ξ) after 2 cm plasma, obtained by integrating the acceleration field (as shown in Fig. 2 c)) over the propagation distance z. ξ_0 indicates the position in the bunch where particles gain the most energy; b) the accelerating field on the axis at position ξ_0 of the bunch ($E_z(\xi_0, r = 0)$) along the propagation distance z (red line) and the maximum E_z field on the axis along z (blue line); c) Longitudinal wakfield E_z on axis ($r = 0$) at plasma entrance $z = 0$ (blue line) and plasma exit $z = 2$ cm (red line). Note that E_z at $z = 0$ (blue line) is multiplied by 50 in order to make it visible on the same scale. The dotted lines show the accelerating peaks of the respective fields, and the distance between the two dotted lines directly shows the wakefield dephasing; d) the shifting of the position ξ of the peak accelerating field along the propagation distance z, and the fitted line is given as: $z(\mathrm{cm}) = 5.5467 - 0.0072932 \times \xi(\mathrm{cm})$, yielding $v_\phi = c \times (1 + \frac{1}{\delta z/\delta\xi}) \approx 0.986c$.

Figure 3 a) shows the energy gain of the beam particles along ξ, obtained by integrating the acceleration field in Fig. 2 over the propagation distance z, yielding the ap-

Copyright © 2013 CC-BY-3.0 and by the respective authors

proximate energy gain/loss of the bunch particles during the 2 cm propagation ($\int E_z dz \approx \sum E_z \Delta z$). We can therefore identify the ξ_0 position where the bunch particles gain the most energy. This is indicated by the dotted line in the Fig. 3 a). Figure 3 b) shows the evolution of the accelerating wakefield experienced by the the particles at ξ_0 (red curve), compared to the maximum accelerating wakefield (blue curve) along the bunch. The fact that the former amplitude is smaller than the later one explains the energy difference between the integration from maximum E_z and the actual energy spectrum of the particles at the plasma exit, as mentioned above. Fig. 3 c) shows the longitudinal field E_z on the axis along ξ at the plasma entrance $z = 0$ (blue line, $\times 50$) and at the plasma exit $z = 2$ cm (red line). The shift of the peak accelerating field between $z = 0$ and $z = 2$ cm clearly confirms the dephasing. It is worth noting that the dephasing occurs mostly over the first plasma period.

CONCLUSION

In conclusion, simulation results presented here demonstrated that the SMI grows significantly over the 2 cm propagation distance for 1 nC bunch at ATF with a plasma density such that $L_{beam} = 2\lambda_{pe}$. Due to dephasing between the bunch particles and the plasma wakefield, the actual energy gain is $\approx 25\%$ smaller than the integration of the maximum E_z over the propagation distance. However, the resulting energy gain is still approximately 2 times larger than the case without SMI development. It is therefore possible to confirm the SMI development through the measurement of resulting energy spectrum in the experiment.

CURRENT INDUCED IN VACUUM CHAMBER DURING NSLS-II BOOSTER RAMP*

S. Gurov#, V. Kiselev, S. Sinyatkin, BINP SB RAS, Novosibirsk, Russia

Abstract

Fields that arise in the booster magnets during a ramp induce currents in the vacuum chamber, including currents through the "ground". These induced currents produce magnetic fields, which influence the beam. Calculations and simulations for the NSLS-II booster are discussed.

INTRODUCTION

Budker Institute of Nuclear Physics has built the booster for NSLS-II. The booster has been designed [1, 2], produced [2], delivered, assembled and tested [3]. The booster is intended for continuous and reliable acceleration of electron beam from a minimum 170-MeV injection energy to a maximum energy of 3.15 GeV at an average beam current of 20 mA and a 2 Hz repetition rate.

The combined-function dipole magnets have magnetic fields with quadrupole and sextupole components. The basic parameters of the dipoles are given in Table 1.

Table 1: Specification of the Dipoles

Dipole parameters	BF	BD
Number	28	32
Effective magnetic length	1.24 m	1.30 m
Angle	3.2673°	8.3911°
Vertical gap	±14 mm	±13 mm
Field injection	0.03068 T	0.07516 T
Field extraction	0.46021 T	1.12734 T
Quadrupole K1, extraction	0.82 m^{-2}	-0.55509 m^{-2}
Sextupole K2, extraction	3.6 m^{-3}	-4.3 m^{-3}
Good field region	±12 x ±20 mm	
Field quality in the good field region, ΔB/B0	± $1\cdot10^{-3}$	

During a ramp, the fields arising in the booster magnets induce currents in the vacuum chamber, including currents through the "ground".

CURRENT THROUGH THE "GROUND"

The current through the "ground" is the total current I_{total} through the vacuum chamber:

$$I_{total} = \oint\!\!\iint \sigma E_z(r,\varphi,t)\,dS \qquad (1)$$

The integrating is done over the entire vacuum chamber cross-section with the conductivity σ.

The induced electric field can be found from the Maxwell-Faraday equation,

$$rot\vec{E} = -\frac{1}{c}\frac{\partial\vec{B}}{\partial t}, \qquad (2)$$

with $B_z = 0$ and $\frac{\partial\vec{E}}{\partial z} = 0$ taken into account.

We have the following equations:

$$\frac{1}{r}\frac{\partial E_z}{\partial\varphi} = -\frac{1}{c}\frac{\partial B_r}{\partial t} \quad \text{and} \quad \frac{\partial E_z}{\partial r} = \frac{1}{c}\frac{\partial B_\varphi}{\partial t} \qquad (3)$$

A magnet with symmetry in its median plane has the following magnetic field in the aperture:

$$B_r(r,\varphi,t) = \sum_{n=1}^{\infty} B_n(t)\cdot r^{n-1}\sin(n\varphi)$$
$$B_\varphi(r,\varphi,t) = \sum_{n=1}^{\infty} B_n(t)\cdot r^{n-1}\cos(n\varphi) \qquad (4)$$

As result,

$$E_z(r,\varphi,t) = E_{0z}(t) + \frac{1}{c}\sum_{n=1}^{\infty}\frac{\partial B_n(t)}{\partial t}\cdot\frac{r^n}{n}\cos(n\varphi) \qquad (5)$$

Here we get a component $E_{0z}(t)$, which is independent from the coordinates r and φ. This component depends on some external conditions.

If the vacuum chamber is isolated, I_{total}=0 and we get $E_{0z}(t)$ from Eq. (1) and Eq. (5).

If the vacuum chamber is grounded on the both sides of magnet, we can find $E_{0z}(t)$ in the following way. There is a field line that divides the magnetic field flow into two parts (see Fig. 1). This line crosses the magnet median plane at the point x_o. Let the circuit consist of the ground circuit and a line which is parallel to the beam axis and cross x_o. Then, the magnetic field flow through this circuit does not change during a ramp. Therefore, $E_z(r = x_o, \varphi = 0, t) = 0$, and from equation (4)

$$E_{0z}(t) = -\frac{1}{c}\sum_{n=1}^{\infty}\frac{\partial B_n(t)}{\partial t}\cdot\frac{x_0^n}{n}. \qquad (6)$$

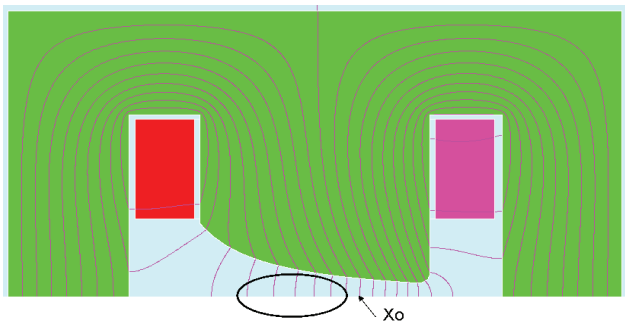

Figure 1: Magnetic field distribution in a BF dipole. The ellipse denotes the vacuum chamber. The "zero shift" is x_o = 30.7 mm for the BF dipole and x_o = 4.4 mm for the BD dipole.

If we neglect the effects related to the steel properties of the magnetic yoke,

$$B_n(t) = Bm_n \cdot f(t). \quad (6)$$

Here Bm_n is the field harmonics at the maximum magnet current and $f(t)$ is a function that describes the ramp of the magnets, such that $f(t) = 1$ at the maximum magnet current.

Consequently

$$E_{0z}(t) = -\frac{1}{c}\frac{\partial f(t)}{\partial t}\sum_{n=1}^{\infty} Bm_n \cdot \frac{x_0^{\,n}}{n}$$

or

$$E_{0z}(t) = -\frac{1}{c}\frac{\partial f(t)}{\partial t}\int_0^{x_0} Bm_y(x)dx \quad (7)$$

MAGNETIC FIELD

Since the current induced in the vacuum chamber has symmetry in the median plane, the induced magnetic field $Bc(t)$ in the vacuum chamber looks similar to that Eq. (4) with the field harmonics $Bc_n(t)$. This harmonics can be found in the following way. On the one hand, the magnetic field in the median plane is

$$Bc_y(x,t) = \sum_{n=1}^{\infty} Bc_n(t)\cdot x^{n-1}. \quad (8)$$

On the other hand,

$$Bc_y(x,t) = \frac{2}{c}\iint \frac{(r\cos\varphi - x)}{R^2}\cdot j(r,\varphi,t)\cdot r\,d\varphi\cdot dr \quad (9)$$

The integrating is done over the entire vacuum chamber cross-section; r is a function of φ; R is the distance from the current dI to x:

$$R^2(\varphi, x) = (r\cos\varphi - x)^2 + r^2\sin^2\varphi. \quad (10)$$

Since $\frac{x}{r} < 1$ in the vacuum chamber, we can use the following expression:

$$\frac{\cos\varphi - x/r}{(\cos\varphi - x/r)^2 + (\sin\varphi)^2} = \sum_{m=0}^{\infty}\left(\frac{x}{r}\right)^m \cos(m+1)\varphi \quad (11)$$

Therefore,

$$Bc_n(t) = \frac{2\sigma}{c}\iint \frac{E_z(r,\varphi,t)\cos(n\varphi)}{r^{n-1}}d\varphi\cdot dr \quad (12)$$

In case of round vacuum chamber, there is no induced magnetic field. In case of elliptical vacuum chamber, the main component of the induced field is a quadrupole harmonics.

SIMULATION

Dynamical effects arising during an energy ramp were simulated with the help of the computer code ANSYS for a stainless steel dipole vacuum chamber 1 mm thick with a 41×24 mm cross-section.

Simulated were the "through-ground" currents of the BD (see Fig. 3) and BF dipoles (see Fig. 4) during a ramp (see Fig. 2).

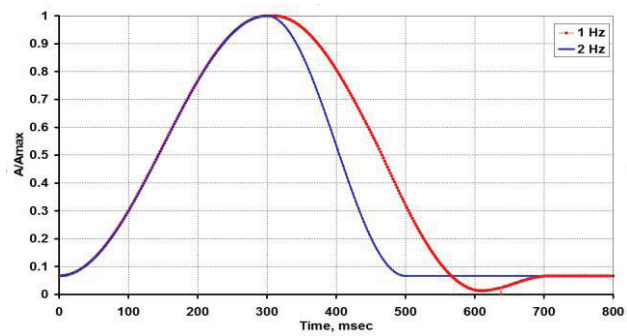

Figure 2: Dipole field ramp for 1 Hz and 2 Hz.

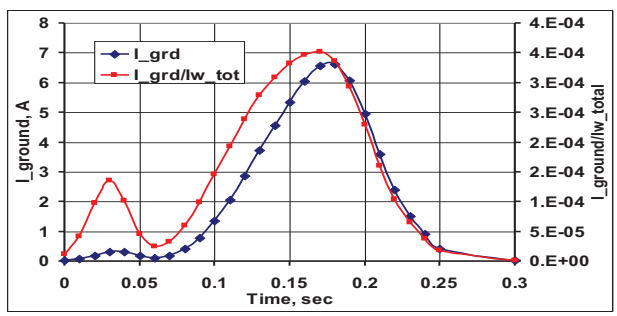

Figure 3: "Through-ground" current of the BD dipoles (red); the same normalized to the dipole current in Ampere-turns (blue).

Copyright © 2013 CC-BY-3.0 and by the respective authors

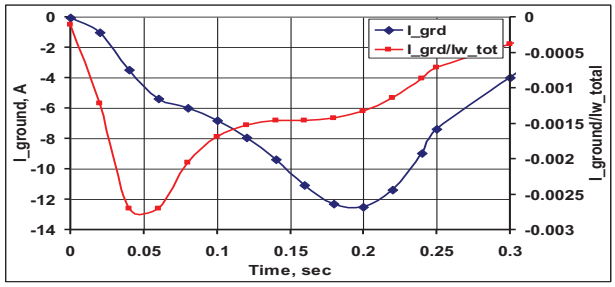

Figure 4: "Through-ground" current of BF dipoles (red); the same normalized to the dipole current in Ampere-turns (blue).

Figures 5 and 6, respectively, show the deviation of magnet parameters for the BD and BF magnets. The eddy current effect results in an equal relative deviation of the magnetic field and gradient magnitudes (Fig. 5 and Fig. 6, ΔB/B_eddy, ΔG/G_eddy). The eddy current in the vacuum chamber induces a strong sextupole component of the magnetic field (ΔS/S_eddy). The "through-ground" currents through the vacuum chamber induce an additional large gradient of the field (ΔG/G_eddy+ground) and give a small contribution to the field and sextupole strength (ΔB/B_eddy_ground, ΔG/G_eddy_ground).

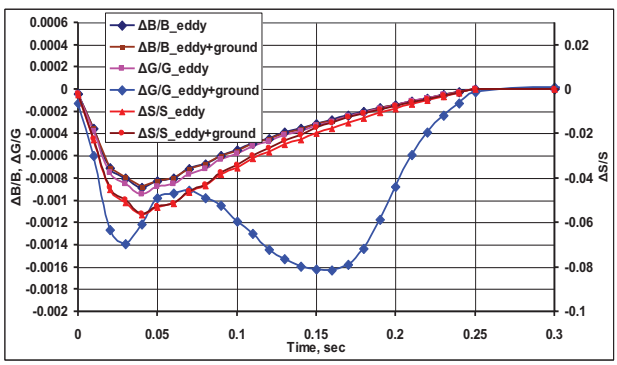

Figure 5: Deviation of the magnet parameters of the BD dipoles due to the eddy current effect.

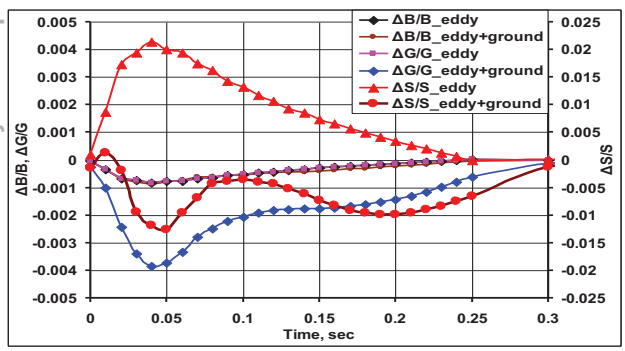

Figure 6: Deviation of the magnet parameters of the BF dipoles due to the eddy current effect.

MEASUREMENTS

The dipoles were measured with Hall probes at DC currents [4]. In addition, one BF dipole and one BD dipole were measured during a ramp with an assembly of long coils [5]. This coil assembly allows measuring integrated fields with and without the vacuum chamber.

When the vacuum chamber was grounded on both sides, the through-ground current (see Fig. 7) was measured with a current probe. This current produces the measured quadrupole and sextupole components (see Fig. 8).

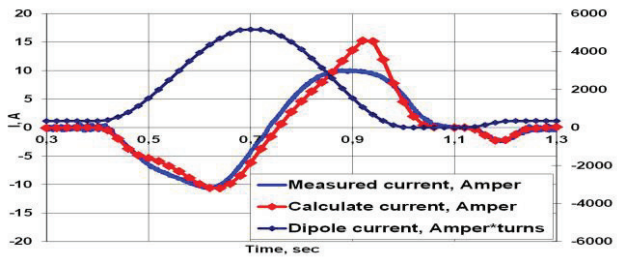

Figure 7: Through-ground current for the BF dipole. Calculated current (red); measured current (blue); dipole current in Ampere-turns (black).

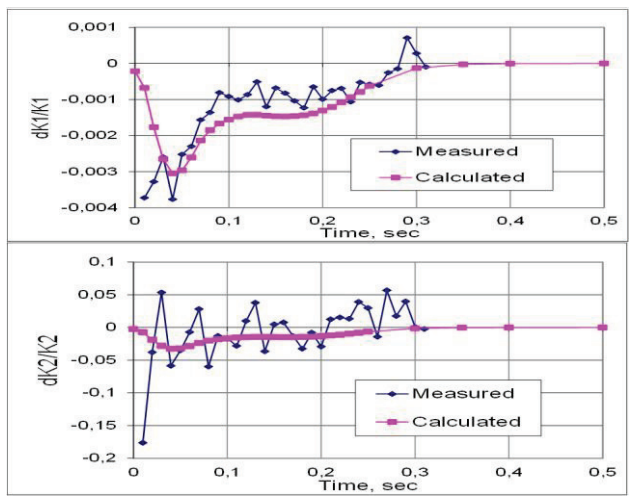

Figure 8: Influence of the vacuum chamber grounding on the quadrupole (top) and sextupole (bottom) field components of the BF dipole.

SELF-CONSISTENT SIMULATIONS OF PASSIVE LANDAU CAVITY EFFECTS*

G. Bassi†, A. Blednykh, S. Krinsky, J. Rose, BNL, Upton, NY 11973-5000, USA.

Abstract

We discuss passive Landau cavity effects for arbitrary fill patterns. We present a new algorithm for the self-consistent calculation of the long-range multibunch interaction and implement it in the parallel OASIS code. As an application, we show numerical simulations with parameters of the passive Landau cavity system of the MAX-IV storage ring, which consists of normal conducting cavities. Together with with the uniform filling case, which is planned for nominal operations of the MAX-IV storage ring, we discuss the case with a gap in the fillings.

EQUATIONS OF MOTION

We assume M bunches, each with N electrons, circulating in a ring with circumference C and revolution period T_0. According to the steady state beam loading compensation scheme shown in Fig.1, for self-consistent simulations of passive Landau cavity effects, the dynamics of the particles in bunch m ($m = 0, .., M-1$), under the one-turn map approximation, is governed by (without radiation damping and quantum fluctuations)

$$\begin{aligned} \delta_{n+1} &= \delta_n \\ &+ \frac{e}{E_0}\Big[V_{gr}\cos\Psi\sin(\phi_s+\theta_L+\Psi-\omega_{rf}\tau_n) \\ &- V_m(\tau_n) - V_{rf}\sin\phi_{s0}\Big], \\ \tau_{n+1} &= \tau_n - \eta T_0\delta_{n+1}, \end{aligned} \tag{1}$$

where n is turn number, e the electron charge, δ is the relative energy deviation with respect to the nominal energy E_0, τ is arrival time and η the momentum compaction. Here V_{gr} (generator voltage) V_{rf} (rf voltage), ϕ_s (synchrotron phase), Ψ (detuning angle) and θ_L (load angle) are the parameters of the main cavity and $\sin\phi_{s0} = U_s/(eV_{rf})$, where U_s is the energy loss per turn. $V_m(\tau_n)$ is the collective voltage induced by the passages of the M bunches through the main and Landau cavities.

The self-consistent calculation of $V_m(\tau_n)$ for a narrow-band resonator wake can be done efficiently by computing averages, via a MonteCarlo integration, of trigonometric functions with respect to the "history" of the bunch densities [3]. For the case of an arbitrary long-range wakefield interaction, see [2], where the collective voltage is calculated via a Taylor series expansion. The algorithm is implemented in OASIS, a self-consistent parallel code for efficient simulations of instabilities driven by short and long-range wakefields [3], and allows the study of passive Landau cavity effects for normal conducting cavities. The case with superconducting cavities is at the moment computationally too expensive. However, we are planning to extend the capability of the algorithm to cover the superconducting case, since our ultimate goal is the study of the passive Landau cavity system of the NSLS-II storage ring, which is planned to operate with superconducting cavities. Notice that Eq.(1) provides Robinson damping of the 0 mode by properly detuning the main cavity. This is crucial vhenever the longitudinal radiation damping is not strong enough to suppress the Robinson instability induced by detuning the Landau cavity for bunch lengthening.

UNIFORM FILLINGS

As an application of our current algorithm, we study passive Landau cavity effects with parameters of the MAX-IV storage ring [1] (see Table 1), which will be operated with normal conducting cavities (see Table 2). In our simulations we include only the fundamental mode of the main and Landau cavity. The optimal bunch lengthening can be estimated by calculating the collective voltage induced by equally spaced stationary bunches [4]. According to the parameters of MAX-IV the optimal bunch lenghtening for uniform fillings is ≈ 200ps.

In Fig.2 we show self-consistent simulations of Eq.(1) with the OASIS code. OASIS is based on a Vlasov approach and implements a particle tracking method to solve the Vlasov equation, therefore uses $\mathcal{N}$ simulation or representive particles to sample the underlying phase space density, and its number is not necessarily related to the actual number of particles in the bunch N. The simulations of M bunches, each with $\mathcal{N}$ simulation particles, are done in parallel using M processors, by assigning $\mathcal{N}$ of each bunch to a single processor. Eq.(1) is integrated up to 300K turns. The parameters (per cavity) used to solve Eq.(1) are $V_{gr} = 0.495$MV, $\phi_s = 2.728$rad, $\Psi = -1.137$rad and $\theta_L = 0$. The detuning frequency of the Landau cavity is 47.53kHz and the number of simulation particles used is $\mathcal{N} = 100$K. In Fig.2 (left) we plot the bunch length of the bunch train after 300K turns. The red curve represents the numerical result with Landau cavities. The bunch length is roughly constant across the bunch train and approximately equal to 210ps. The curve in blue shows the nominal bunch length of 40ps without Landau cavities. In Fig.3 (top left) we plot the longitudinal density of the bunch train. We clearly see that for uniform fillings the Landau cavities induce roughly the same bunch lenghtening across the train without displacing the bunch centroid.

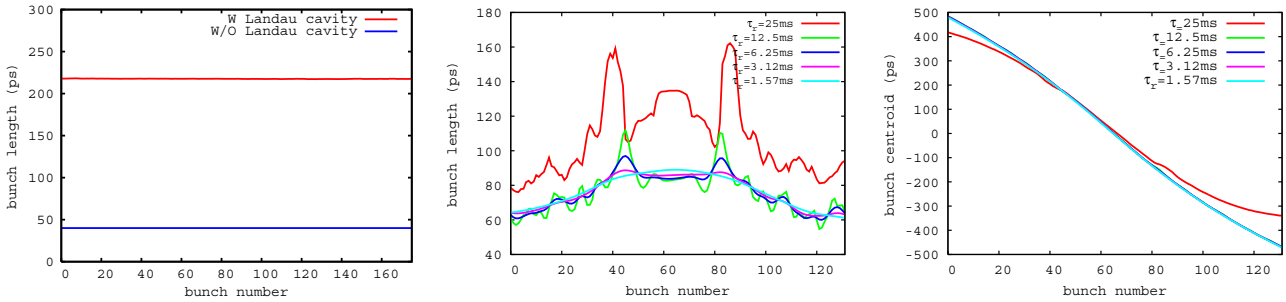

Figure 2: Numerical simulations with OASIS. The number of simulation particles used is $\mathcal{N} = 100$K. Bunch length vs bunch number after 300K turns for uniform fillings and maximum bunch length equal to 210ps (left) and for a gap of 44 bunches in the fillings and several values of the radiation damping time (center). Right: same as center for the bunch centroid.

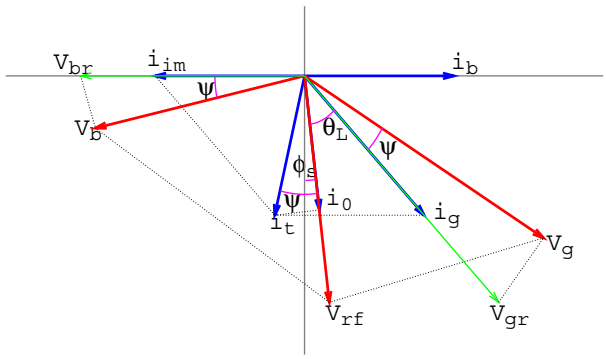

Figure 1: Phasor plot for steady state beam loading compensation according to Eq.(1). Per cavity (main) parameters: V_{gr} is the generator voltage, V_{rf} the rf voltage, ϕ_s the synchrotron phase, Ψ the detuning angle and θ_L the load angle.

Table 1: MAX-IV Storage Ring Parameters (Bare Lattice)

Parameter	Symbol	Value	Unit
Beam energy	E_0	3	GeV
Average current	I	500	mA
Number of bunches	M	176	
Harmonic number	h	176	
Circumference	C	528	m
Bunch length w/o HC	σ_τ	40	ps
Energy spread	σ_p	7.7×10^{-4}	
Energy loss per turn	U_s	364	keV
Momentum compaction	η	3.07×10^{-4}	
Long. radiation damping	τ_r	25	ms

NON-UNIFORM FILLINGS

We now discuss the case of a gap in the fillings. We assume 44 empty buckets and 132 filled buckets, with the same average current $I = 500$mA. The per cavity parameters used are $V_{gr} = 0.491$MV, $\phi_s = 2.729$rad, $\Psi = -1.139$rad and $\theta_L = 0$. The detuning frequency

Table 2: Main (4 Cavities) and Landau ($m = 3$) Cavity

Per cavity parameter	Symbol	Value	Unit
RF frequence (main)	ω_{rf}	$2\pi\times99.93$	MHz
RF frequency (Landau)	$m\omega_{rf}$	$2\pi\times299.793$	MHz
RF voltage (main)	V_{rf}	0.255	MV
Shunt impedance (main)	R_L	2.6	MΩ
Shunt impedance (Landau)	R_H	2.3644	MΩ
Quality factor (main)	Q_L	21000	
Quality factor (Landau)	Q_H	21000	

of the Landau cavity is 47.53kHz. The bunch centroid and bunch length vary accross the bunch train as shown in Fig.2 and Fig.3. For the nominal radiation damping $\tau_r = 25$ms we observe a dipole instability (as shown in Fig.4, center) as well as an increase of the bunch length vs bunch number, as shown also in Fig.2 (center) by the red curve. This instability is not present for smaller values of the radiation damping. We observe also that the bunch length shows two spikes around bunch number 40 and 85. These spikes weaken when reducing τ_r, disappearing at $\tau_r = 1.57$ms, as shown by the cyan curve in Fig.2 (center) and by the longitudinal density across the bunch train shown in Fig.3 (bottom right). We are investigating the nature of this effect. Notice that the bunch centroids for $\tau_r < 25$ms are roughly the same, as shown in Fig.2 (right). The numerical results discussed in this paper are preliminary and will be subject to further analysis.

POLARIZATION PROFILE AND SPIN DYNAMICS SIMULATIONS IN THE AGS USING THE ZGOUBI CODE*

Y. Dutheil, L. Ahrens, H. Huang, F. Méot, V. Schoefer
BNL, Upton, Long Island, New York, USA

Abstract

Polarization transmission during the AGS acceleration cycle is critical for the RHIC polarized proton program.Thus drives a strong interest on the exploration of the polarization losses in the AGS. Intrinsic spin resonances are the main source of depolarization in the AGS. This results in the formation of a polarization profile since the strength of such depolarizing resonance depends on the Courant-Snyder invariant of each particle. The Zgoubi code and the AGS Zgoubi on-line model now allow exploration of the formation of the polarization profile during the acceleration cycle using multi-particle trackings with realistic beam and machine conditions. This paper introduces the specifics of these simulations and compares some of the latest simulated and experimental results.

INTRODUCTION

Acceleration of polarized protons in a synchrotron requires particular schemes to conserve the polarization. Two main types of depolarization resonances can reduce the overall polarization of the beam. The imperfection resonances are driven by vertical closed orbit distortions and occur when $Q_s = I$ with Q_s the spin tune and I an integer [1]. The intrinsic resonances are driven by the vertical betatron motion and occur when $Q_s = I \pm Q_y$ with Q_y the vertical tune.

The AGS uses two partial Siberian snakes to overcome the spin resonances [2], usually called *warm* and *cold* snakes. While in a regular synchrotron $Q_s = G\gamma$ (G is the anomalous gyromagnetic g-factor of the proton), the complex helical dipole fields of the Siberian snakes open forbidden bands in the spin tune around the integer values of $G\gamma$, the spin tune gap. The imperfection resonances are avoided since the integer values of Q_s are now forbidden. The vertical intrinsic resonances are overcome by keeping the vertical tune in the spin tune gap, typically around $Q_y = 8.98$.

Despite the use of Siberian snakes polarization losses are observed in the AGS and while the polarization profile at injection is negligible, measurements show significant profiles of polarization in both vertical and horizontal planes after the acceleration. We will present the main candidates that can explain the observed profiles then some simulation methods and results will be compared to measured polarization profiles.

Sources of Polarization Profile

The strength of an intrinsic spin resonance depends on the *Courant-Snyder* invariant, hence the depolarization experienced by a particle across such a spin resonance also depends on the single particle emittance. The crossing of such resonance can result in the particles at larger amplitude being depolarized while the center of the beam remains polarized.

The injection in the AGS occurs at $G\gamma = 4.5$ and the vertical tune needs to be placed in the spin gap before the first vertical intrinsic resonance, around $G\gamma = 5$. Figure 1 shows the vertical tune crossing the spin tune around $G\gamma = 5$. Due to the strong optical distortions caused by the Siberian snakes it is not possible to push vertical tune high enough at low energy. We expect that the crossing of vertical intrinsic resonances in this region depolarizes part of the beam and induces a polarization profile in the vertical plane.

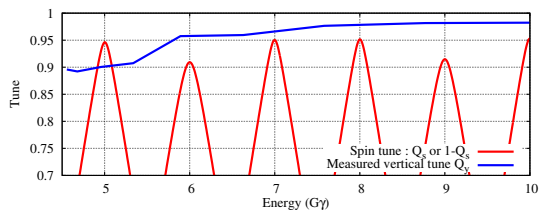

Figure 1: Fractional part of the vertical tune and spin tune at low energy.

While the partial Siberian snakes configuration avoid depolarizations caused by the imperfection and vertical intrinsic resonances, it can also induce depolarization through horizontal intrinsic resonances when $Q_s = I \pm Q_x$ with Q_x the horizontal tune. The stable spin direction is never perfectly vertical with partial snakes and therefore the non-zero horizontal component of the spin can resonate with the horizontal betatron tune. The strength of these resonances depends on the horizontal emittance and horizontal component of polarization. The crossing of these resonances builds up an horizontal polarization profile.

Other sources of depolarization can contribute to the polarization profile. For instance linear betatron coupling or high order partial snake resonances [3] can increase the polarization profile but will not be discussed here.

SIMULATIONS

Extensive development of the AGS Zgoubi on-line model provides a realistic model of the polarized proton

machine [4][5][6]. Measured currents of the power supplies along the acceleration cycle are used by the Zgoubi on-line model to generate corresponding optics of the AGS. The Siberian snakes were represented by 3-D OPERA field maps to exploit the precision of the stepwise ray-tracing code Zgoubi and achieve the high accuracy required for long term spin tracking.

Simulations Conditions

Due to the lack of a reliable field map to simulate the warm snake, a cold snake map has been scaled down to achieve the same snake angle as the warm snake and is used as the warm snake in this model. This provides a realistic spin dynamics and a better behavior of the beam dynamics at low energy. This is the solution adopted while a new field map of the warm snake is being developed.

Measurements are used to constrain the model and achieve realistic machine parameters. Modeled tunes have been modified around $G\gamma = 10$ and $G\gamma = 35$ to avoid resonant lines during the tracking but the modeled and measured tunes are very close elsewhere (Fig. 2). The measured chromaticity has been smoothed before being used to tweak the model in order to avoid fast variations of the chromaticity during the tracking.

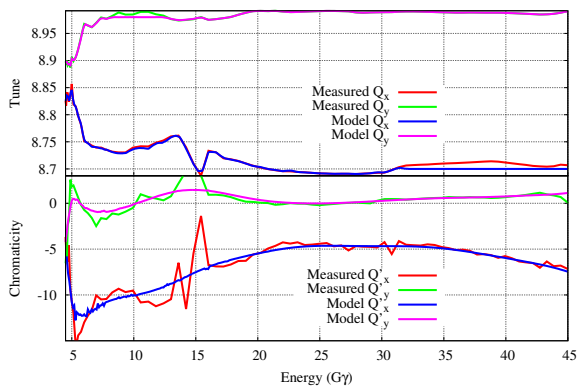

Figure 2: Comparison of tune and chromaticity used in the model and measured in the machine.

The simulations also include the tune jumps, used in the AGS to reduce the polarization losses across the horizontal intrinsic resonances [7].

No dipole error is added to the lattice, hence the modeled orbit coincides with the design orbit of the AGS. Longitudinal dynamics is naturally handled by the Zgoubi code. The model uses a single RF cavity and the synchrotron motion is determined by the characteristics of the lattice and the RF parameters. A harmonic number of $h = 8$ and a realistic RF voltage are used, synchronous phase is computed from measured acceleration rate. This results in a tracking of 150 000 turns to go from the injection energy $G\gamma = 4.5$ to the AGS flat-top at $G\gamma = 45.5$.

The beam is formed by 5000 particles picked in a 6D Gaussian distribution, cut at 3σ. The transverse emittances were chosen at $\epsilon_x^{N,95\%} = 10\,\pi$·mm·mrad and $\epsilon_y^{N,95\%} = 10\,\pi$·mm·mrad, values slightly lower than the measured values at extraction but still realistic. A longitudinal emittance of $\epsilon_l^{95\%} = 0.8$ eV·s is used, leading to a realistic bunch length of $l^{95\%} = 28$ ns at extraction. The spin of the particles is randomly chosen with the condition $\vec{S} \cdot \vec{n}_0 = 0.82$ with $\vec{S}$ the spin vector of the particle and $\vec{n}_0$ the stable spin direction, such that the initial polarization is realistic with 82 % without profile. These simulations require huge amount of computation power and are carried on the supercomputer of the NERSC but the tracking of a single particle on a single CPU for the full acceleration cycle takes one to two hours.

Beam Dynamics

In order to simulate the full AGS cycle the main challenge was to introduce the gamma transition optics and RF gymnastics. The gamma transition quadrupoles were naturally handled by the Zgoubi On-line model, the same way as the other magnets [4][5][6]. Figure 3 shows the behavior of the momentum spread across the transition region during a tracking of 1000 particles, with realistic momentum spread. Despite the perfectly timed jump of the synchronous phase, the transition induces a quadrupole oscillation of the beam but likely due to the non-linear momentum compaction factor of the lattice it is unavoidable.

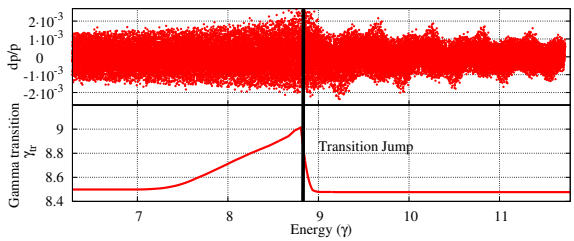

Figure 3: Momentum distribution of the particles and gamma transition of the lattice as a function of the energy around the gamma transition region.

The transverse emittance is estimated by using the variance of the particles coordinates after removing the effect of the chromatic orbit. Figure 4 shows important variations of the estimated emittance when particles are lost during the tracking. Some particles are lost during the transition around $G\gamma = 15$ but also at lower energy ($G\gamma = 6$) when the vertical tune is brought very close to the integer. Beam dynamics behavior is clearly smoother than using the warm snake map but losses during the tracking remains, likely due to the crossing of resonant lines.

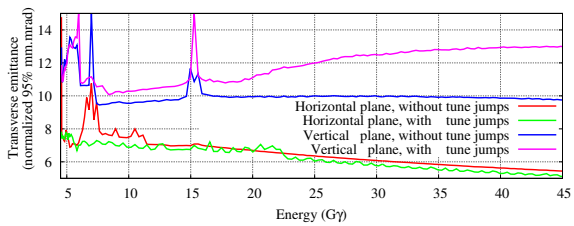

Figure 4: Evolution of the estimated emittances with or without tune jumps.

POLARIZATION PROFILE

The polarization measurement in the AGS uses a thin carbon foil target plunged into the circulating beam. One of the operation modes moves the target across the beam during the measurement and determine the polarization of the beam as a function of the target position. Measured intensity and polarization as a function of the target position are fitted to a Gaussian function to extract σ_P and σ_I respectively the standard deviations of the polarization and beam intensity. Then the polarization profile is defined by P_{max} the maximum polarization at the center of the profile and $R = \sigma_I^2/\sigma_P^2$ to characterize the steepness of the profile.

Simulations and Measurements

The particles coordinates at the end of the tracking are transported to the location of the polarimeter and binned, along with the polarization. The top plot on figure 5 shows the binned beam profile in grey and the average polarization in each beam in blue. The polarization is fitted to a Gaussian and the number of particles in each beam is used as weight for the fit. The process is very similar to the measurements analysis and lead to a similar figures.

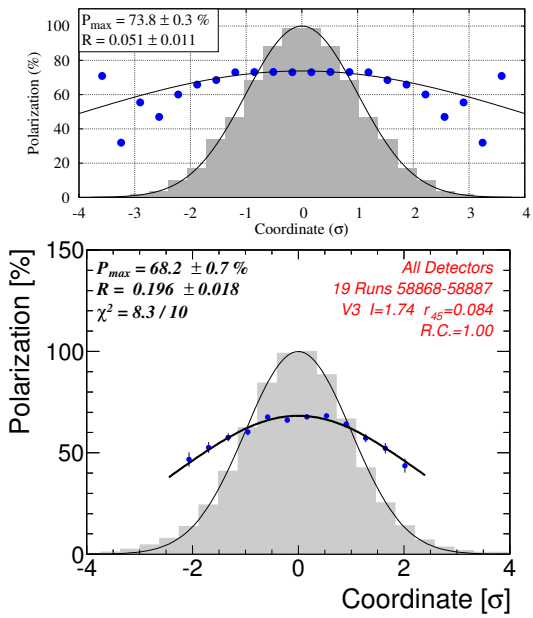

Figure 5: Polarization profile in the horizontal plane without tune jumps along with the beam profile for the simulation (top plot) and for a measurement (bottom plot).

Table 1 summarizes the simulation results and compares them to measured data. The simulated profiles are not as big as the measured ones but it is expected since the emittance used in the simulations is smaller than the usual emittance in the AGS. The simulated horizontal profile is greatly reduced when the tune jumps are used, which is expected and consistent with the measured data.

CONCLUSION

The Zgoubi on-line model provides variable and realistic optics of the polarized proton AGS for tracking. In addition, recent developments allow tracking with realistic longitudinal dynamics around the injection and transition regions.

Table 1: Polarization Profiles Simulated (Sim.) and Measured (Meas.), With or Without Tune Jumps (TJ)

	Horizontal	Vertical
No TJ Meas.	$P_{max} = 68.2 \pm 0.7\,\%$ R $= 0.196 \pm 0.018$	$P_{max} = 66.5 \pm 0.9\,\%$ R $= 0.190 \pm 0.022$
No TJ Sim.	$P_{max} = 73.8 \pm 0.3\,\%$ R $= 0.051 \pm 0.011$	$P_{max} = 72.2 \pm 0.2\,\%$ R $= 0.015 \pm 0.006$
TJ Meas.	$P_{max} = 73.8 \pm 0.6\,\%$ R $= 0.109 \pm 0.012$	$P_{max} = 71.6 \pm 0.7\,\%$ R $= 0.080 \pm 0.014$
TJ Sim.	$P_{max} = 76.3 \pm 0.1\,\%$ R $= 0.012 \pm 0.004$	$P_{max} = 77.3 \pm 0.2\,\%$ R $= 0.035 \pm 0.006$

The model of the AGS currently uses a replacement for the warm snake field map while a new warm snake map is being developed. While this model does not allow us to draw definite answers for now, it still provides good indications about depolarization sources. Polarization profiles and maximum polarization are not comparable to the measured values but the evolution of the profiles when the tune jumps are used is consistent with the measurements. More work is needed to refine the model in view of improved comparison with measured beam and polarization data.

The Zgoubi model of the AGS is a unique and extremely accurate tool to simulate the polarized proton acceleration in the AGS. Ongoing work based on the Zgoubi code aims to develop new and original schemes to reduce polarization losses at low energy using, for instance, the tune jumps.

DESIGN OF THE INJECTION INTO THE 800 MeV/amu HIGH POWER CYCLOTRON*

M. Haj Tahar, Y. Dutheil, A. Morgan, F. Méot, N. Tsoupas
BNL, Upton, Long Island, New York, USA
L. Calabretta†, INFN/LNS, Catania, Italy; A. Calanna, MIT, Cambridge MA, USA

Abstract

We present the design of the injection into a separated sector cyclotron (SSC) aimed at the production of a high power beam of 800MeV/amu molecular H_2^+ for ADS-Reactor applications. To work out the beam line parameters and beam dynamics simulations, including the first accelerated turns, we used the ray-tracing code Zgoubi and the OPERA magnetic field map of the cyclotron sector. We simulated the injection path of the H_2^+ and evaluated radial injection scheme in order to evaluate the parameters so derived. The paper details and discusses various aspects of that design study and its outcomes.

INTRODUCTION

The present paper addresses an attempt to find an appropriate injection design for our SSC: the cyclotron complex consists of an injector cyclotron accelerating H_2^+ molecules from 50 KeV/amu up to 60 MeV/amu. The beam is then injected to our 6-sector cyclotron by means of electrostatic and magnetic elements, and accelerated up to 800 MeV/amu. In order to do so, 6 RF cavities, 4 single-gap and 2 double-gap are used, which are PSI-like. A plot of the OPERA magnetic field map in the median plane, for one sector is shown in Fig. 1. There are many considerations that explain the magnetic field shape [1]:

- The azimuthal variations show that the field is decreasing in the central region which ensures more focusing of the beam.
- The superconducting coils of each sector, which are wound around the hills, and the iron of the sector, produce the magnetic field that has to follow the γ(r) law in order to keep the isochronicity, where γ stands for the Lorentz factor.
- The isofield lines show that one edge of the sector has spiral shape while the other is quite straight: even though it is better to have spiral edges to increase the vertical focusing, the design of the magnet becomes problematic when it comes to using superconducting coils, because of the expansion radial force exerted from the inner region of the coil towards the outer radii. A superconducting magnet with a convex shape of the coil would be very difficult to build.

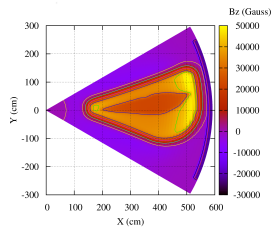

Figure 1: Plot of the z-component of the magnetic field in the median plane for one sector, with the isofield lines.

BEAM DYNAMICS AT INJECTION

Orbits at various energies from injection to nearby extraction are shown in Fig. 2. These orbits were obtained by Zgoubi [2] . It can be easily seen that the distance between consecutive turns (that have the same step size in energy) decreases quickly. In fact, the transverse separation of the turns is very important to consider in our design because it has to be maximized in order to allow clean injection. The step width per turn can be described by the formula [3]:

$$\frac{dR}{dn_t} = \frac{U_t}{m_0 c^2} \frac{R}{(\gamma^2 - 1)\gamma} \quad (1)$$

where U_t denotes the energy gain per turn. However, this assumes that the condition of isochronicity is perfectly satisified. It can be deduced from Eq. 1 that both the energy gain per turn and the injection radius should be made as big as possible in order to increase the step width per turn at injection as well. The transverse separation of the turns as a function of the kinetic energy is shown in Fig. 3.

The first orbit suitable for acceleration is the first closed orbit shown in Fig. 2. This orbit is very important to study in order to match the injected beam properly. Paraxial rays were generated around this orbit in order to compute the transfer matrix of the sector. From that, the betatron functions of the sector ensuring the 6-fold symmetry were computed. The beam envelope of the entire cyclotron was then obtained by multi-turn tracking of a set of particles generated around the eigen ellipse. Both axial and radial beam envelopes are shown in Fig. 4 and 5 respectively. All the results obtained here assume a H_2^+ beam energy of 60 MeV/amu and a normalized emittance of 13.5 π mm.mrad.

INJECTION LINE

The injection system needs to transport the beam from a point outside the cyclotron ring to the first orbit suitable for

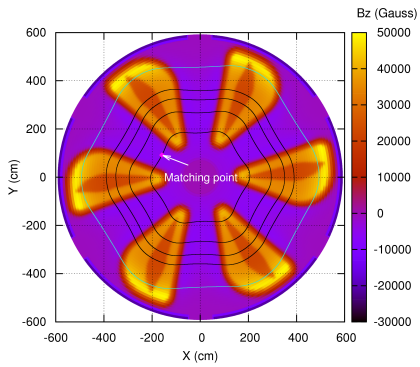

Figure 2: Plot of the closed orbits: the first closed orbit at injection which corresponds to an energy of 60 MeV/amu is shown in black, the next ones, still in black, correspond to a constant step size of energy of 80MeV/amu with respect to each other. The blue one however shows the closed orbit near the extraction, at 700 MeV/amu. The point marked with a pink color is the matching point inside the first closed orbit that will be used to match the beam properly.

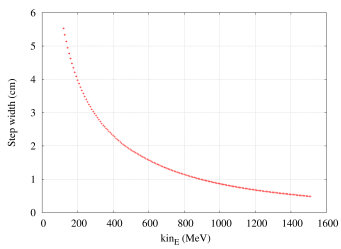

Figure 3: Plot of the transverse separation of the turns as a function of the kinetic energy: this result was obtained from tracking by searching for the closed orbits assuming a constant energy gain per turn of 4 MeV/amu.

acceleration. The main constraints of the design are:

- The beam has to match the equilibrium orbit at a reference azimuth that in our simulations is $\theta = 150°$. This position is referred to as the matching point (see Fig. 2): the beam machine functions (betatron functions) as well as the beam coordinates have to be matched at this point.
- The beam envelope has to be kept small along the injection trajectory: in our case, the maximum beam

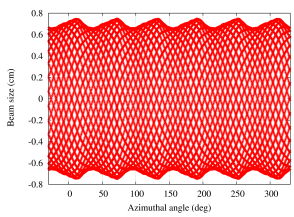

Figure 4: Axial beam envelope vs θ along the 1st closed orbit.

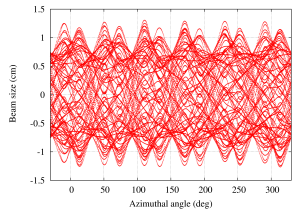

Figure 5: Radial beam envelope vs θ along the 1st closed orbit.

size allowed in both the vertical and horizontal plane is 4 cm in the region where 150 cm <R< 500 cm.

An easy and straightforward solution to the injection problem is to track backwards (≡ clockwise) starting from the matching point. So the field map had to be flipped. Then, to insert the injection elements, the magnetic field was recalculated by adding the equivalent magnetic field to, either electrostatic or magnetic devices. The solution obtained is shown in Fig. 6.

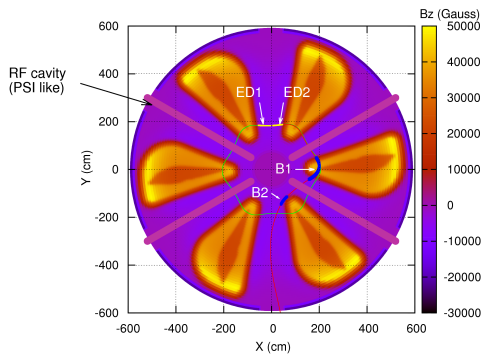

Figure 6: Layout of the injection system for the Superconducting Ring Cyclotron.

NB: The effect of the two RF cavities along the injection trajectory was neglected in the current study.

Electrostatic Deflectors (ED): Design Considerations

According to a design study of the RF cavities [4], it was shown that the voltage at injection should not exceed 500 kV for each single gap cavity instead of 1 MV. This implies that the step width was even smaller at injection. Taking this into account, as well as the radial dispersion of the beam, it was found that we have ≈ 1 cm available space (in the radial direction) at the location of the matching point. The choice then was to place an electrostatic deflection channel at this location. In fact, there are many reasons that explain this choice:

1. The small step size which is of about 1 cm here;

2. The neighbouring turns would not be affected by such a thin electrode while a magnetic element would need much more material to be placed between the turns;

Copyright © 2013 CC-BY-3.0 and by the respective authors

3. Avoid arcing problems by placing the septum in the free space between two magnets: for each material, there is a critical magnetic field beyond which the spark damage is severe [5]. The upper limit here is 60 kV/cm inside the drift.

4. The ED was divided into two pieces as shown in Fig. 7 in order for the electrodes to be tailored to the trajectory of the beam.

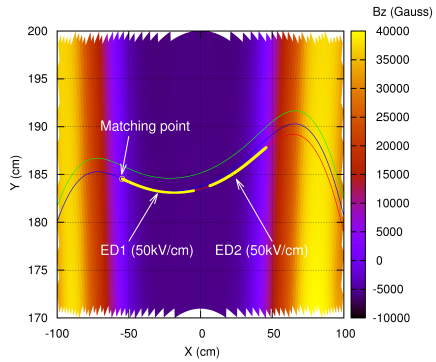

Figure 7: Plot of the beam trajectory inside the eletrostatic deflectors (red curve): the blue curve shows the first closed orbit (that has to be matched) while the green one represents the first accelerated orbit at the location of the septum.

Magnetic Channels (MC)

The choice then was to use two magnetic channels B1 and B2: B1 was placed inside the gap of the main magnet for two reasons:

1. It was preferred to avoid the RF cavity which will occupy most of the space inside the drift.

2. While tracking backwards, it was noticed that we gain at least 1 cm more at this location.

The next step was to focus the beam properly. For that, a gradient was applied to magnet B2. Figure 8 and Fig. 9 show the axial and radial beam envelope respectively. A conservative value of 0.68 kG/cm was found which ensures that the beam size does not exceed 4cm inside the pole gap.

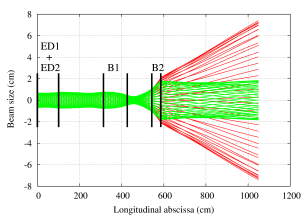

Figure 8: Axial beam envelope vs the longitudinal abscissa along the injection trajectory: the green and red curves show the result when a 0.68 kG/cm or 0 kG/cm gradient is applied to the magnet B2, respectively. The difference between the two envelopes is observed after dipole magnet B2.

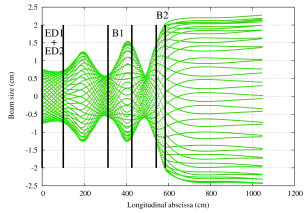

Figure 9: Radial beam envelope vs the longitudinal abscissa along the injection trajectory: there is almost no change in the beam envelope before and after applying the gradient to the dipole B2. However, the beam size exceeds 4 cm outside the pole gap which is fine especially that the radial inter-turn separation at the location of B2 is not limiting any more.

The specifications for the magnetic and electrostatic elements required are summarized in Table 1. It is important to point out that the solution proposed has the merit to avoid us using quadrupoles inside the cyclotron ring to focus the beam.

Table 1: Magnetic and Electrostatic Elements Required for the Proposed SRC Injection System

Element Label	Type	Strength	Effective Length
ED1	Electrostatic septum	50 kV/cm	0.55 m
ED2	Electrostatic septum	50 kV/cm	0.39 m
B1	Magnetic septum	9 kG	1.13 m
B2	Magnetic channel	18 kG	0.42 m

Abstract

A code called SPACE for the simulation of beam-induced plasma in gas-filled RF cavities has been developed. The core code uses the particle-in-cell (PIC) method for the Maxwell equations coupled to the dynamics of particles. In the SPACE code, the electromagnetic PIC methods are coupled with probabilistic treatment of atomic physics processes. The aim of the project is to demonstrate the feasibility of the RF cavity with muon collider beams. The most critical part is investigating how intense muon beams influence the plasma dynamics. Initial phase of simulations demonstrating the plasma generation and its short time dynamics in the high pressure hydrogen filled RF test cell has been performed.

INTRODUCTION

A dense hydrogen gas filled RF cavity has been proposed for muon beam phase space cooling and acceleration. The aim of the simulation program is the development of mathematical and numerical models and parallel software for the simulation of processes occurring in gas-filled RF cavities. An important issue in high-pressure gas filled cavity is a RF power loading due to beam-induced plasma [1]. Incident particle beam interacts with dense hydrogen gas and causes significant ionization level. Due to high frequency of collisions with neutrals, electrons reach equilibrium within picosecond time scale and move with a slow drift velocity. The recombination processes occur on the millisecond time scale. In order to induce the three-body electron capture, electronegtive gas has been tested in the test cell. This is the most critical process in the final cooling stage and should be modeled accurately in simulations. Other important processes include the interaction between positive and negative ions and the interaction of the beam with wakefields. A parallel electromagnetic PIC code with atomic physics, called SPACE, has been developed at Stony Brook University / BNL. It implements new mathematical models and numerical algorithms for the interaction of high-energy proton and muon beams with neutral gas and plasmas.

NUMERICAL METHODS

PIC method for Maxwell's equations

The system of Maxwells equations is discretized using the finite difference time domain (FDTD) method on a staggered mesh [2] that achieves second order accuracy in space and time. Electric charges are represented by discrete macroparticles coupled with electromagnetic fields by the action of Lorentz forces and electric currents. When one solves Maxwells equations analytically, solving two equations describing the Faraday and Ampere laws is sufficient as the equations expressing the Gauss law and the divergence-free constraint for the magnetic field are invariants of motion. The numerical method of Yee [2] for electromagnetic fields in vacuum also preserves the divergence-free properties of the electric and magnetic fields. To deal with the last two equations in the presence of charges and currents, the rigorous charge conservation method was developed within the PIC framework in [3]. The method calculates electric currents along computational grid edges by solving a geometrical problem of sweeping the computational mesh by finite volumes associated with each macroparticle. By using this method, we find first a set of initial conditions consistent with the Maxwell equations by either solving the Poisson problem for the electric potential or by a superposition of electric fields and changes created by each particle. Then only the first two Maxwell equations and the Newton-Lorentz equation are solved numerically thus avoiding solving the Poisson problem at each time step.

A schematic of processes computed at each time step is depicted in Figure 1. We would like to note that the conservative Leapfrog time discretization scheme for the Newton-Lorentz equations of particle motion becomes implicit. We use the Boris scheme for the time update [4], which is a modification of the Leapfrog scheme resulting in an explicit and conservative scheme. We also implement modifications of the Boris scheme proposed in [5] for dealing with rapidly accelerating particles for which the relativistic factor is not constant.

For accurate simulations of electromagnetic fields in geometrically complex structures, we have implemented the embedded boundary method [6] in a stand-alone Maxwell equation solver. The coupling of algorithms for complex boundaries with the main electromagnetic PIC code will be performed in the next phase.

Code Structure and Properties

The code is developed in C++ utilizing the advantages of Objected-Oriented Programming. The code is composed of three major parts. The first part, the FieldSolver class, contains FDTD solvers of the Maxwell equations. The second part, the ParticleMover class, contains solvers for the Newton-Lorentz equation. This class also includes various physics models describing particle interactions and trans-

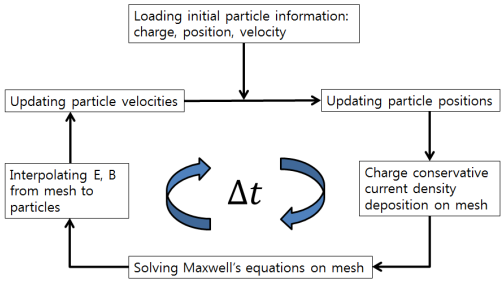

Figure 1: Interaction of muons with plasma in cooling absorbers. Negative (top) and positive (bottom) muons (red dots) interacting with ions (green) and electron (blue dots). Semi-transparent iso-surfaces represent electric field intensity.

formations by atomic physics processes. The code is capable of tracking numerous particle species. Finally, the third, TimeController class, controls the above classes and any miscellaneous classes such as classes performing the visualization of electromagnetic fields and particle data. The visualization is done using the visualization software called VisIt developed at LLNL for the remote parallel visualization on distributed memory supercomputers. Since the main classes of the code are connected via the interface classes, the code can easily be extended by implementing additional functions and physics models. For convenience of a new problem setup, the initialization routines use XML (eXtensible Markup Language).

Parallelization Methods

The electromagnetic PIC code is parallelized using a hybrid MPI / tread programming for distributed memory multicore supercomputers. The FieldSolver uses a three-dimensional domain decomposition for solving Maxwell's equations. The ParticleMover uses a decomposition of particles that is independent of the FieldSolver domain decomposition. Namely, particles in a parallel computing node can be distributed in the whole computational domain whereas Maxwell's equations are solved in a local domain of a parallel computing node. As the distribution of particles is usually very non-uniform in the space, such a decomposition maximizes the load balance.

In the electromagnetic-PIC code, computations performed by the ParticleMover are more time consuming compared to computations by the FieldSolver. The described parallel decompositions minimizes the CPU computing time but requires a large amount of communications between the FieldSolver and ParticleMover. We have adopted ideas from the sparse matrix storage to minimize the amount of communications and send field data to ParticleMover from only those computational cells that contain macroparticles.

Verification and Validation

The electromagnetic PIC code has undergone a V&V program and its accuracy and parallel scalability has been

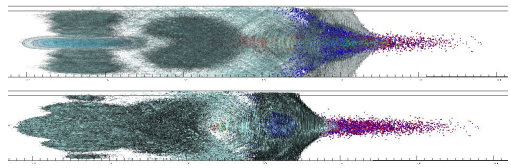

Figure 2: Example of simulation using SPACE code. Interaction of muons with preset plasma in cooling absorbers. Negative (top) and positive (bottom) muons (red dots) interacting with ions (green) and electron (blue dots). Semi-transparent iso-surfaces represent electric field intensity.

estimated. The FieldSolver has been verified using analytical solution for electromagnetic fields in a rectangular cavity. The FieldSolver achieves the second order accuracy and achieves close to linear weak scalability on thousands of processors. The embedded boundary solver has also been verified using analytical solutions for rectangular cavities initialized under some angle to the computational mesh. While the stair-case approximation of boundaries results in a zero-order accuracy, the use of the embedded boundary method restores the accuracy to the order of 1.4 1.5. The ParticleMover has been verified using space charge problems and problems with special distributions of particles.

ATOMIC PHYSICS EFFECTS

In this section, we describe the implementation of probabilistic models for atomic physics processes in gases under the influence of high energy particles and high gradient electromagnetic fields. As each macroparticle passes through the absorber, it ionizes the medium in real time by creating electron - ion pairs. The motion of ions and electrons is explicitly tracked, and their recombination and other atomic physics transformation are resolved as described below. The code supports the dynamics of multiple particle species.

Consider a high-energy particle entering an absorber medium. The energy loss of this particle by ionization can be described by the Bethe-Bloch formula [7]

$$\frac{dE}{ds} = 4\pi N_A r_e^2 m_e c^2 \rho \frac{Z}{A}\left(\frac{1}{\beta^2}\ln\frac{2m_e c^2\gamma^2\beta^2}{I} - 1 - \frac{\delta(\beta)}{2\beta^2}\right), \quad (1)$$

where N_A is the Avogadro number, ρ, A, and Z are the density, atomic weight and number of the absorbing material, and m_e and r_e are the mass and the classical radius of the electron. Numerically,

$$4\pi N_A r_e^2 m_e c^2 = 0.3071\, MeV cm^2/g.$$

The ionization constant I is approximately $16Z^{0.9}$eV, and δ is the density effect factor that arises from the screening of remote electrons by close electrons and results in a reduction of energy loss for higher energies.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Implementation of Atomic Physics Processes

While various atomic physics transformations are supported in the code, we currently resolve the following processes that are most essential for the problem of interest:

$$p + H_2 \rightarrow p + H_2^+ + e^-, \quad (2)$$

$$H_2^+ + 2H_2 \rightarrow H_3^+ + H_2 + H, \quad (3)$$

$$H_3^+ + e^- \rightarrow 3H. \quad (4)$$

The implementation using macroparticles is as follows. The energy loss of each proton macroparticle is calculated by integration the Bethe-Bloch formula along the particle trajectory

$$\Delta E = N_p \int f(v) ds,$$

where $f(v)$ denotes the right hand side of the Bethe-Bloch formula and N_p is the number of real protons represented by one macroparticle. At each time step,

$$(int)\frac{\Delta E}{I N_H}$$

of ion – electron pairs are created along the proton macroparticle path by assigning them random direction velocities corresponding to their initial energy. Here N_H is the number of real H_2 molecules represented by one macroparticle. The initial time is recorded for each new ion and electron macroparticles and they are then tracked in the code. (int) stands for the rounding-off to integer as only integer number of ion-electron pairs can be created. The rounding-off error is saved and used in the next time step to satisfy the energy balance.

When the macroparticle of H_2^+ propagates the distance equal to the mean free path of the second atomic transformation (2.3), it is transformed into the H_3^+ ion. This simply requires changing the mass of the ion macroparticle and resetting its internal time in the data structure. As there is no need to track neutral particles, the molecule H_2 and atom H in (2.3) are ignored. The error due to the fact that the atomic weight of neutrals in the left and right sides of (2.3) differ by one atomic mass is negligible in terms of changing properties (density and pressure) inside of the RF cavity.

Finally, when the ion H_3^+ macroparticle propagates the distance equal to the mean free path of the transformation (2.4), it captures the closest electron and neutralizes into $3H$. In the code, the corresponding H_3^+ and e^- macroparticles are simply eliminated from data structures.

The interaction of electrons and ions with neutrals is modeled in the code using theory and available experimental data. For instance, electrons equilibrate on the picosecond time scale due to high frequency collisions with neutral molecules. The experimental measurements [8] suggest that the electron drift velocity in the conditions of the HPRF experiment is very low, 2.9×10^4 m/s.

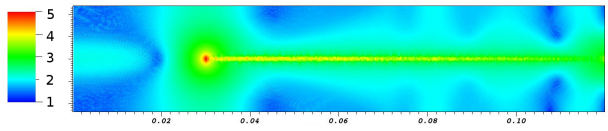

Figure 3: Logarithm of the electric field magnitude [log V/m] in the longitudinal slice of HPRF test cell during the propagation of the proton beam.

RESULTS AND DISCUSSION

We have performed simulations of the entrance of 200 MeV proton beam into the HPRF test cell filled with the hydrogen gas with the density of $10^{21}\ 1/cm^3$ at the pressure of 200 bar and the generation and short time scale dynamics of plasma. Each proton generates on the order of 1000 electron-ion pairs per 1 cm travel distance. Accelerated by the external field, electrons and ions practically instantaneously reach the equilibrium drift velocity defined by their collisions with neutral molecules. Unlike in simulations with preset initial distributions of positive and negative charges in vacuum shown in Figure 2, the self consistent simulation of the plasma formation and evolution in high density gas demonstrates very weak wake fields induced by the proton pulse. The 2D distribution of the magnitude of the electric field is shown in Figure 3.

CONCLUSIONS AND FUTURE WORK

We have developed a parallel electromagnetic code SPACE that combines the PIC method for particles with atomic physics. Simulations of the generation of plasma by the 200 MeV proton beam in the hydrogen filled RF test cell and the short time scale dynamics of plasma and induced wake fields have been performed. Simulations demonstrated insignificant strength of wake fields. In the future, we will perform simulations involving electronegative ions using the SPACE code. We will complete implementation of a multiscale approach in SPACE that allows simulations of both short (picosecond) and long (microsecond) time scale processes in plasma, and conclude on plasma effects in a practical RF cavity.

MULTIPLE SCATTERING EFFECTS IN A STRONG MAGNETIC FIELD*

P. Snopok, J. Ellison, Illinois Institute of Technology, Chicago, IL 60616, USA
T. Roberts, Fermilab, Batavia, IL 6051, USA

Abstract

New computational tools are essential for accurate modeling and simulation of the next generation of muon-based accelerator experiments at the energy and intensity frontiers. There is a long list of crucial physics processes specific to muon accelerators that have not yet been implemented adequately. One of the long-standing entries on that list is multiple scattering in the presence of strong magnetic field. Earlier studies showed significant discrepancies depending on the models used and step sizes when stepping through the field. A liquid Hydrogen (LH2) absorber in a strong longitudinal magnetic field is analyzed using G4beamline to study and mitigate the effects of step size, and compared to a past study. The updated results and an algorithm to limit step size depending on the field strength are presented.

INTRODUCTION

Though accelerator simulation codes have been steadily improving over the years, there is still much room for improvement. Many single-particle processes and collective effects in vacuum and matter, such as space charge, beam-beam effects, plasma effects from ionized electrons and ions, etc. have not been studied thoroughly or implemented. In order to ensure proper accuracy of simulations, these effects have to be either deemed negligible or taken into account.

One of the processes that is a source of concern is multiple scattering in a strong magnetic field. In a paper by P. Lebrun [1] scattering of muons through a 32 cm length of LH2 is compared between a Moliere (GEANT3) model and a Discrete Scattering model for both a zero field and a several Tesla magnetic field arrangement, showing significant discrepancies, especially in the tails of the distributions. This paper attempts to recreate the simulations of Lebrun as best as possible in G4beamline [2] based off the GEANT4 package. Several problems presented themselves during the recreation, and a complete recreation was not possible, however we believe it to be accurate enough for our purposes. Since [1], the PDG value for the radiation length of LH2 has been updated. Attaining a perfect match to the magnetic field profile in [1] was also not possible. Overall, GEANT4 shows a much better agreement with a Discrete Scattering model studied by Lebrun.

Another issue is that scattering in a strong magnetic field as simulated in G4beamline will yield different results for different step sizes as shown in the first plot in Fig. 4. Consistent results are achieved at very small step sizes, so an algorithm is required that will reduce step size in matter according to the field strength, so that the performance of tracking of particles in vacuum or in a relatively weak magnetic field is not affected.

OVERVIEW OF ALGORITHMS

The main difference in multiple scattering algorithms between GEANT3 and GEANT4 (and as a result G4beamline) was the change from the Moliere formalism to Lewis theory. In GEANT3, Moliere theory was used. This has a few limitations [1, 3]:

- the angular deflection is small;
- the theory applies only in semi-infinite homogeneous media;
- the absorber is not a very low Z material, as the Thomas-Fermi model could be inaccurate here;
- there is no energy loss built into the theory.

GEANT4 is based on the more complete Lewis theory. Like Moliere theory, this simulates the scattering of a particle after a step, but Lewis Theory also computes the path length correction and the lateral displacement, along with the moments of spatial distribution as well [4].

WITHOUT MAGNETIC FIELD

The simulation presented in Lebrun's paper was recreated as close as possible using G4beamline 2.14. A pencil beam of 180 MeV/c muons are scattered through a 32 cm length of LH2 in and out of an intense magnetic field. The magnetic field comes from the 2 m long Alternate Solenoid cooling channel [5] which reaches a peak field of 15 T. The 32 cm length of LH2 begins where the field is at peak. Ref. [1] makes a comparison between a Discrete Scattering model for LH2 and the Moliere model used in GEANT3 at the time, while we compare these to the current G4beamline 2.14 based on the GEANT4 package. The step sizes of the simulations were discussed in [1] and are set to 4 mm in the Moliere results and G4beamline results, and to a micron in the Discrete Scattering results.

Table 1 shows the compared results for the case with no magnetic field. Extensive track cuts were made by insisting on an aperture cut of 2.5 cm and angle cut of 250 mrad and maximum $r \cdot \theta$ of 500 mm·mrad.

WITH MAGNETIC FIELD

In recreating the coils, the data from [5] was used and is summarized in Table 2. The Z offsets were adjusted to

* Work supported by DOE.

$\sigma_{r \cdot r'}$ (mm·mrad)	76.5	58.9	63.23

reflect the positions of the centers of the coils rather than their front faces. Actual current densities were calculated from the relative densities, scaled down by a constant factor. The constant factor was determined by trial and error, such that the maximum field in the configuration was 15 T, and found to be 1/1015.6. For symmetry and to alleviate fringe effects, five identical cells of coils were used. In Lebrun's work, the field decreases from its 15 T maximum to 10.9 T after 32 cm of LH2. It was found in our simulation that the field dropped to 11.2 T instead. That is consistent with a difference in radiation length of LH2 between the previous and current simulations. Figure 1 shows the arrangement of the simulation. Table 3 shows the comparison of the first and second moments in the case with magnetic field.

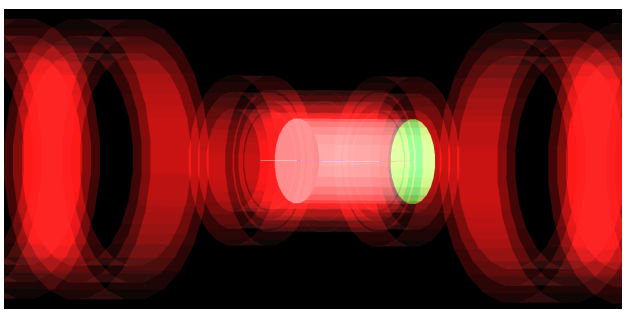

Figure 1: Arrangements of solenoids. The muon beam enters from the left. The 32 cm length of LH2 ends where the detector (green) is.

Figures 2 and 3 show the r and r' distributions, respectively, for the different models used. The data points were obtained using a digital graph analyzer for the points in [1]. It is argued in [1] that although the overall shape of the distributions is similar, the Moliere model did not simulate properly the tail end of the spectrum, while the Discrete Scattering model did. It is seen here that the current scattering model implemented in G4beamline 2.14 (based on GEANT4) follows the tail of the Discrete Scattering distributions much more closely than GEANT3.

EFFECTS OF STEP SIZE

As mentioned in the introduction, scattering in a strong magnetic field as simulated in G4beamline depends strongly on the tracking step size as per Fig. 4. Consistent

results are achieved at very small step sizes, so an algorithm is required that will automatically control step size in matter according to the field strength.

In a G4beamline simulation, a pencil muon beam with a momentum of 200 MeV was passed through 30 cm of LH2 in various uniform magnetic fields, and the beam widths were recorded. Ideally, there should be no variation in results from altering the step length used, but as the magnetic field was increased, it was found that a smaller step size was needed to maintain accuracy. The number of steps taken have a great impact on computing time, therefore it

$\langle r' \rangle$ (mrad)	16.9	14.3	15.349
$\sigma_{r'}$ (mrad)	12.0	8.4	10.043
$\langle r \cdot r' \rangle$ (mm·mrad)	23.0	16.1	16.247
$\sigma_{r \cdot r'}$ (mm·mrad)	32.6	19.6	22.747

would be good to find an optimal way to balance accuracy and load.

To less than one percent difference of the value at a step size of one millimeter, it was found empirically that the step size should be scaled with magnetic field as $Step(\text{mm}) \leq 1/(0.004 * Field(\text{T}) + 0.01)$. The results before and after automatic step limiter is implemented are shown in Fig. 4. Similar simulations for Al, Be, LHe, Li and LiH show the same scaling. It was found that in addition, the step length should be shorter than one third the length of the material, to allow for at least 4 steps to take place. This allows for good accuracy with as little CPU time lost as possible.

Note that the step sizes obtained by using the limiting algorithm are consistent with those used for the purposes of comparison with Lebrun's work.

ACKNOWLEDGMENT

Authors would like to thank Paul Lebrun for fruitful discussions and for providing the relevant code decks of the original GEANT3 simulation.

PROGRESS OF THE MATTER-DOMINATED MUON ACCELERATOR LATTICE SIMULATION TOOLS DEVELOPMENT FOR COSY INFINITY*

P. Snopok†, J. Kunz, Illinois Institute of Technology, Chicago, IL 60616, USA

Abstract

COSY Infinity is an arbitrary-order beam dynamics simulation and analysis code. It can determine high-order transfer maps of combinations of particle optical elements of arbitrary field configurations. For precision modeling, design, and optimization of next-generation muon beam facilities, its features make it the ideal code. The one component that needs to be included in COSY is the algorithm necessary to follow the distribution of charged particles through matter. Muon beams are tertiary production particles and high-intensity collection necessitates a large initial phase space volume. Therefore, accurate modeling of the dynamics and correction of aberrations is imperative. To study in detail some of the properties of particles passing through material, the transfer map approach alone is not sufficient. The interplay of beam optics and atomic processes must be studied by a hybrid transfer map–Monte-Carlo approach in which transfer map methods are used when there is no material in the accelerator channel, and Monte-Carlo methods when particles pass through material. Progress on the development of the hybrid algorithm is reported.

INTRODUCTION

Muon beams are tertiary production particles and high-intensity collection necessitates a large initial phase space volume. The resultant spray of muons must be collected, focused, and accelerated well within the muon lifetime (2.2 μs in the rest frame). The only technique fast enough to reduce the beam size within the muon lifetime is ionization cooling. Muons traverse a certain amount of material in order to lose energy in both longitudinal and transverse direction due to ionization. The energy is then restored in the longitudinal direction only, leading to an overall reduction in the transverse direction (cooling). In order to achieve cooling in the longitudinal direction, emittance exchange is used, usually involving wedge-shaped absorbers.

In order to carefully simulate the effect of the absorbers on the beam, one needs to take into account both deterministic and stochastic effects in the ionization energy loss. The deterministic effects in the form of the Bethe-Bloch formula with various theoretical and experimental corrections fit well into the transfer map methods approach, where the effect of the lattice on the particles is evaluated first by producing the so-called transfer map, and then applied to a given initial distribution of particles. The arbitrary-order simulation code COSY Infinity [1] is a key representative of the transfer map codes. COSY was chosen because of its built-in optomization tools, speed, its ability to produce high-order transfer maps, and its ability to control individual aberrations.

However, the stochastic effects are not easy to take into account in the framework of the transfer map paradigm. To compensate, we are interfacing COSY with select parts of another code, ICOOL [2], which was written specifically to study the ionization cooling of muon beams. The implementation of the stochastic effects due to various geometries and materials into COSY is reported with the most recent results.

CODE SELECTION PROCESS FOR STOCHASTIC PROCESSES

A variety of codes exists which would complement COSY. Initially, it was hoped that the implementation of a fragment separator into COSY that used a Monte-Carlo approach [3] could be repurposed; however, the libraries were heavily oriented towards electrons, protons, and heavy ions, with no muon data. Other codes that were considered included MUSIC [4], MARS [5], and GEANT4 [6], but were discarded either due to the code focusing on cosmic ray muons, difficulty in interfacing, or sheer bulk.

ICOOL was eventually chosen due to its modularity, compactness, and the fact that, like COSY, is written in FORTRAN. ICOOL's main purpose is to simulate particle-by-particle propogation through electromagnetic fields and matter, with roughly twenty built-in materials to call. The processes included are decays, delta rays, multiple scattering, energy loss, and straggling. Although built for muons, ICOOL can also keep track of other relevant particles such as electrons, pions, kaons, and protons. Additionally, ICOOL can either generate a beam with uniform or Gaussian distribution, or it can read particle information from an input file. This is advantageous since COSY also has a similar input/output file method, which makes direct comparison between the two codes simple.

INTERFACING DETAILS

While ICOOL has routines to calculate particles through, for example, an RF cavity, those were not used since there are corresponding routines in COSY that work faster since the transfer map is only calculated once and then applied to simultaneously to all particles. Therefore, only the routines that directly dealt with absorbers were interfaced. Currently, the following routines have been implemented into COSY: flat absorber (a cylindrical block of arbitrary thickness and radius), radially-symmetric wedge (where

* Work supported by the Department of Energy.
† psnopok@iit.edu

the thickness of the wedge dz is given by the third order polynomial $dz = a_0 + a_1 r + a_2 r^2 + a_3 r^3$), and an arbitrary-order polynomial absorber (a symmetric or asymmetric absorber of order n such that thickness dz is given by $dz = a_{10}x + a_{01}y + a_{11}xy + \ldots + a_{nn}x^n y^n$). The polynomial absorber is of the most significance, as there exists a routine in COSY (WA) with similar functionality and could be used to account for the deterministic effects. This will further limit the use of the slow particle-by-particle tracking using ICOOL routines to only account for stochastic effects. The ultimate goal is to have COSY do the deterministic part, propagate the beam through a negative drift back to the beginning of the absorber again, and then call the stochastic ICOOL routines that would do multiple scattering and energy straggling for the particles without the loss of energy due to ionization.

As previously mentioned, both ICOOL and COSY are written in FORTRAN. Therefore, the initial task was to gather the relevant subroutines from ICOOL and compile them with COSY which would allow COSY to call ICOOL subroutines. Next, ICOOL and COSY had to exchange information about the same beam. For that, $(6 \times n)$ arrays were used, where the six columns held coordinates and n was the number of particles. When COSY runs its polynomial absorber subroutine it constructs a transfer map based on the absorber, runs the vector through the map (which includes the negative drift), and write the vector to a temporary file. ICOOL would then read this temporary file, run the particles through the stochastic processes, and write a second temporary file with the updated particles. In turn, COSY would read this new file, assign the particle coordinates back to the vector, and delete both of the temporary files. Observe that this process can have anything before or after the wedge, as well as repeat the wedge any number of times. Ultimately, those temporary files will be replaced by direct interaction of the codes.

Additionally, it was mentioned that ICOOL only has 20 materials through which to propagate particles. Its routines read strings, such as 'GHE' (gaseous helium), and then read its libraries to find parameters that match (i.e. Z-number, A-number, ionization potential, etc.). However, COSY takes the parameters themselves as arguments, and as such is not limited to a certain list of materials. To alleviate this, subroutines were placed in COSY and ICOOL such that any absorber routine could accept a string or vector argument for the "material" argument. If, for example, the polynomial absorber was given an argument 'LH' (liquid hydrogen), ICOOL would give the parameters to COSY from its library. If the argument given was a vector containing Z-number, A-number, ionization potential, etc. (as is customary in COSY routines), then ICOOL would read a dummy material named 'XXX' and associate it with the vector contents. In this manner, all relevent information that was needed by either program could be stored into one input variable and be read by both COSY and ICOOL subroutines.

In the interest of benchmarking, it should be noted that at this point it is possible to "turn on" the deterministic processes in ICOOL and run it by itself. Indeed, at this point it is possible to have any combination of (ICOOL, COSY) with (deterministic, stochastic), except for COSY+stochastic of course.

SIMULATION RESULTS

The following compares pure ICOOL and the COSY-ICOOL hybrid with one another. All simulations were done using a flat liquid hydrogen absorber of length 32 cm. The absorber is preceded and followed by a drift of 10 cm. The initial beam consists of 1000 muons with a mean momentum of 200 MeV/c. Beam parameters are summarized below in Table 1 for both initial and final distributions.

Table 1: Distribution Parameters and Simulation Results (Stochastics on)

Parameter	Initial	ICOOL	COSY-ICOOL
avg(x) (mm)	0.157	-1.673	-1.641
std(x) (mm)	96.71	100.24	100.36
avg(y) (mm)	1.817	1.165	1.097
std(y) (mm)	103.48	105.16	105.23
avg(p_x) (MeV/c)	-0.703	-0.641	-0.650
std(p_x) (MeV/c)	10.09	9.81	10.33
avg(p_y) (MeV/c)	-0.325	-0.187	-0.221
std(p_y) (MeV/c)	9.91	9.58	10.21
avg(p_z) (MeV/c)	200.0	188.6	188.6
std(p_z) (MeV/c)	0.0	0.96	0.98

It is clear from Table 1 that there is a good agreement between the two codes. The source of discrepancy is the stochastic treatment of multiple scattering as evidenced by Figs. 1–3. These plots were produced by a different simulation with a beam emanating from a single point with a 5% spread in momentum.

SUMMARY AND FUTURE DIRECTIONS

Interfacing of COSY and ICOOL was successful. It is now possible to simulate realistic matter-dominated lattices in COSY. However, further investigation is in order: the hybrid method has only been shown to work for simple absorber configurations; the interaction between the codes as well as the overall performance of the hybrid code can be optimized significantly; interaction with the end-user can be streamlined.

For the future, it is anticipated that COSY will make use of a one-time analysis of the absorber for faster simulations. When turning on stochastic processes, the simulation can easily take up to 400% longer, and in a realistic cooling channel a beam may have to pass through several absorbers of the same geometry. To that end, it has been proposed that when COSY encounters an absorber, it will propagate the beam through using both deterministic and stochastic processes as previously described. It will then produce a trans-

fer map taking into account all the effects, which will then be re-used for future absorbers of the same geometry in the beamline. How this map depends on various properties of the beam will be determined and then approximated (i.e. if the map depends linearly on total momentum, etc.). Using this method would greatly reduce the computation time involved in realistic simulations of muons through matter.

SPACE CHARGE SIMULATION IN COSY USING FAST MULTIPOLE METHOD

B. Loseth*, M. Berz*, K. Makino*, H. Zhang*, P. Snopok**
* Michigan State University, East Lansing, MI 48824, USA
** Illinois Institute of Technology, Chicago, IL 60616, USA

Abstract

A method is presented that allows the computation of space charge effects of arbitrary and large distributions of particles in an efficient and accurate way based on a variant of the Fast Multipole Method (FMM). It relies on an automatic multigrid-based decomposition of charges in near and far regions and the use of high-order differential algebra methods to obtain decompositions of far fields that lead to an error that scales with a high power of the order. Given an ensemble of N particles, the method allows the computation of the self-fields of all particles on each other with a computational expense that scales as O(N). Using remainder-enhanced DA methods, it is also possible to obtain rigorous estimates of the errors of the methods. Furthermore, the method allows the computation of all high-order multipoles of the space charge fields that are necessary for the computation of high-order transfer maps and all resulting aberrations. This method has been implemented in COSY Infinity, and the progress of applying it to simulating the 6D cooling channel for the Muon Collider is reported.

FAST MULTIPOLE METHOD

The fast multipole method for the Coulomb interaction between many charged particles divides an arbitrary charge distribution into small boxes with a hierarchical structure. It then computes the multipole expansions and local expansions of charges far from the observer to achieve a computation efficiency that scales with the number of particles, N, and computational errors scaling with a high power of the differential algebra order. The FMM algorithm is especially suited for beam dynamic simulations because of the efficiency and low computational error compared to other spacecharge algorithms.

Other methods, such as the particle-particle interaction (PPI) and the particle in cell (PIC) method, while computationally efficient, incur excess error due to modeling and statistics. The PPI method uses macroparticles and assumes a particular distribution. The PIC method places the charge distribution onto a mesh, solves the Poisson equation on mesh points and interpolates between mesh points to find the field on each particle. Both of these methods suffer from an inability to precisely handle complicated charge distributions. This difficulty is overcome in the FMM by decomposing the charge distribution into boxes according to the charge density such that there are a pre-specified number of particles in each box to efficiently and accurately compute the multipole expansions.

FMM Algorithm

The principle of the FMM is to determine the potential of groups of source particles sufficiently far from the observer in terms of expansions in $1/r$, utilizing the fact that far away, high powers of $1/r$ become less significant. These multipole expansions can be translated and combined, and again locally expanded to determine the field on a group of nearby observer particles.

First, all of the charges are enclosed in a cube box called the zero-level box. A box is defined to be a parent box if the number of charges inside is larger than s, which we select. If a box is a parent box, it will be split into eight equal square boxes which are its child boxes and form a new level. If any of the child boxes have more than s charges, they will in turn be split into eight child boxes which form the next level. This process is iterated until no box has more than s charges. At each subdivision, we keep only the nonempty boxes, so the empty boxes are ignored by the subsequent field calculation.

Analytic Considerations

For a distribution of n particles of charge q_i located at $\mathbf{r_i}(x_i, y_i, z_i)$, the potential at a point $\mathbf{r}(x, y, z)$ can be expressed as

$$\phi = \sum_{i=1}^{n} \frac{d_r \cdot q_i}{\sqrt{1 + r_i^2 d_r^2 - 2x_i d_x - 2y_i d_y - 2z_i d_z}} \qquad (1)$$

with

$$d_x = \frac{x}{x^2+y^2+z^2} \quad d_y = \frac{y}{x^2+y^2+z^2}\ , \qquad (2)$$

$$d_z = \frac{z}{x^2+y^2+z^2} \quad d_r = \frac{1}{\sqrt{x^2+y^2+z^2}}\ . \qquad (3)$$

In COSY Infinity [1,2] we apply the DA techniques [3,4] to express ϕ as a DA vector by choosing d_x, d_y, and d_z as our DA variables. This DA vector is essentially the Taylor expansion of ϕ with respect to $1/d_x$, $1/d_y$, $1/d_z$, $1/d_r$, and can be translated into another multipole expansion at an arbitrary point and converted into a local expansion with a simple composition operation on the DA vector. Using the domain decomposition to determine near and far regions, the field in a box is computed using a combination of far multipole expansions and local expansions.

LINEAR COOLING CHANNEL IN COSY

The demonstration of muon ionization cooling is one of the key challenges for the Muon Accelerator Program

Copyright © 2013 CC-BY-3.0 and by the respective authors

hosted at Fermilab [5]. A linear cooling channel consists of solenoids, RF cavities, and wedge absorbers designed for the transverse cooling of a muon beam (Figure 1). Longitudinal emmitance is not reduced in this channel; slower particles lose more energy in absorbers than their faster counterparts, leading to an increase in longitudinal emittance. As the overall beam size is reduced, the density of particles is increased which leads to space charge effects becoming significant. Studying these space charge effects requires developing tools in COSY that are coherent with the FMM.

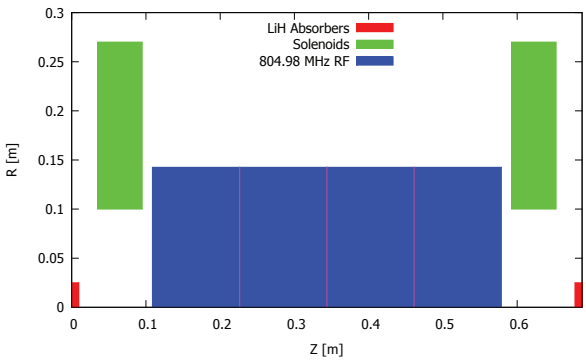

Figure 1: R vs. Z geometry of 1 cell.

Ionization Cooling

Muons are produced by sending proton bunches into a target in order to create pions, which in turn decay into muons. As a consequence of this production, the muons are quite 'hot' by having a large momentum spread. The beam must be cooled significantly, within the muon lifetime, in order ensure a high luminosity muon collider. Beam emittance is reduced via ionization cooling; the beam is strongly focused with magnetic fields and subsequently sent through an absorber material to reduce overall momentum. The beam regains longitudinal momentum in RF cavities, resulting in a net loss in perpendicular momentum and thus beam emittance [6].

Solenoids

The cooling channel is divided into 10 cells with two solenoids of opposite polarity per cell. These solenoids are placed on either side of the absorber wedges that divide the cells in order to increase transverse focusing at the absorber, which in turn minimizes the heating due to multiple scattering.

To implement these solenoids in COSY, a 2-dimensional fieldmap with sufficient range was produced using a Taylor Model based integrator. For a thick solenoid with uniform azimuthal current and finite length, the field at an arbitrary point in space $\mathbf{r}$ is given by the Biot-Savart Law

$$\mathbf{B} = \frac{\mu_0}{4\pi} \int \frac{(\mathbf{J}dV) \times (\mathbf{r} - \mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|^3} \,. \qquad (4)$$

To perform this integral, the domain is subdivided into small cylindrical boxes centered at $\mathbf{r}'$, and the taylor model of the integrand is computed. If the remainder bound of this taylor model is larger than a predefined error bound, the box at $\mathbf{r}'$ is subdivided into 8 equal boxes and the taylor model is computed again for the child boxes. This process is repeated until the remainder bound criterion is met, and integrated over the entire domain of current. Integrating the domain in this manner is computationally efficient because the areas of the domain that are far from the observation point are not subdivided as finely, so less time is spent on the domain compared to a uniform domain decomposition.

To generate the field on a particle in the ring:

- The particles are translated, rotated, and tilted into the first solenoid's frame of reference
- Using linear interpolation between field map points, the magnetic field on each particle is determined in each direction
- The resulting magnetic field in the solenoid's frame is then tilted and rotated back into the global frame and added to the total field
- This process is repeated for each solenoid in the channel
- For this channel, the solenoids have no rotation or tilt, so a 2D fieldmap for an entire cell was produced to take advantage of the cylindrical symmetry

RF Cavities

Each cell in the ring contains four closely spaced RF cavities which fit inside the solenoids. Similar to the solenoids, a fieldmap is used to determine the electric and magnetic fields on the particles inside the cavity. The timing of the $\omega = 804.98$ MHz cavities is determined by the time the reference particle is tracked through the center of the cavity. In order to achieve the correct RF phase (φ_0) at the center of the cavity, the tuning process proceeds as follows:

- Stop the reference particle at the boundary of the cavity and create an identical tune particle
- make a crude guess of the offset time: $t_0 = RFlength/2v$
- propagate the tune particle to the center of the cavity using the crude offset time for the RF fields
- update the offset time: $t_0' = t + 0 + dt$, where $dt = (\varphi - \varphi_0)/\omega$
- reload the tune particle at the beginning of the cavity with the updated offset time
- exit the tuning loop once dt is sufficiently small

Absorber Wedges

The absorber wedges are placed at the boundary of each celll. The energy loss of a particle over a distance ds in the absorber is determined by the Bethe-Bloch formula

$$\frac{dE}{ds} = -K\rho\frac{Z}{A}\frac{z^2}{\beta^2}(log(\frac{2m_e c^2\beta^2\gamma^2 T_{max}}{I^2}) - 2\beta^2 - \delta), \qquad (5)$$

Copyright © 2013 CC-BY-3.0 and by the respective authors

for the parameters

- $K = 15.35375(MeV \cdot cm^3)/(m \cdot g)$,
- Z is the atomic number of the absorber material (LiH),
- A is the atomic mass of the absorber material,
- ρ is the density of the absorber material,
- I is the ionization potential in MeV,
- δ is the density correction parameter,

where the maximum kinetic energy transferred to a single electron in the absorber in a collision is

$$T_{max} = \frac{2m_e c^2 \beta^2 \gamma^2}{1 + 2\gamma m_e/m_\mu + (m_e/m_\mu)^2}. \quad (6)$$

SIMULATIONS IN COSY AND G4BEAMLINE

With all of the lattice elements previously discussed implemented in COSY, we proceeded to compare simulations of a 10-cell cooling channel in both COSY Infinity and G4beamline [7] with and without space charge effects. G4beamline is one of the de-facto codes for muon beam simulations and provides a space charge calculation algorithm and is useful to benchmark for the new COSY functionality. Stochastic effects and particle decays were turned off in both codes to ensure an accurate comparison; these processes are not yet implemented in COSY.

We start with the same beam of 1000 particles in both codes and compare the average orbit excursion, average momentum (Figure 2) and finally, transverse and longitudinal emittance (with and without spacecharge; Figures 3, 4). As mentioned previously, longitudinal cooling is not achieved in this linear channel; this region of the Bethe-Bloch function has a negative slope (ie slower particles lose more momentum). The behavior of the emittances is noticeably different between the codes although the form of the emittance graphs is similar.

Conclusions

In conclusion, we have gained a lot of insight into cooling channel simulations. We can simulate various lattice elements and compare meaningful figures between the codes with and without spacecharge. As this is a work in progress, some of the issues and differences evident during the cross-check with other codes are not resolved yet and require further investigation. There is still a lot of effort to be made on a detailed result comparison in order to obtain consistent results upon comparing the codes, as well as general improvment to efficiency and functionality in COSY.

MITIGATION OF NUMERICAL NOISE FOR SPACE CHARGE CALCULATIONS IN TRACKING CODES

L.G. Vorobiev, C. Ankenbrandt, T.J. Roberts, Muons, Inc., Batavia, IL 60510, USA
F. Schmidt, CERN, Geneva, Switzerland

Abstract

Modern tracking codes have very stringent requirements concerning space charge calculations. They should combine speed of calculations, in order to track particles for many turns (e.g. the LHC injection chain), with numerical accuracy while maintaining symplecticity. Grid solvers and modified Green's function algorithms have been compared, and upgrades were suggested.

INTRODUCTION

Multiple-particle tracking allows for accurate space charge (SC) beam simulations and design. However, in the particle-in-cell (PIC) formalism [1], spatial non-physical grid effects may jeopardize the validity of modeling in accelerator rings and colliders, especially during multi-turn particle tracking. To remedy artificial grid noise, PIC codes increasingly use more macro-particles, denser grids, and more SC kicks per bunch, requiring massive parallelization. Even so, numerical errors persist. The split operator method itself (unlike the general PIC paradigm) decouples three-dimensional (3D) SC forces and dynamics, possibly resulting in additional errors and faulty estimates of instabilities, dynamic aperture, emittance growth, etc. Recent numerical experiments demonstrated artificial noise due to mesh effects and interpolation, leading to micro-scale beam instability [2].

The situation can be improved in two ways. First, we perfect the components of the PIC formalism itself. We will develop a grid density module, suppressing numerical noise to upgrade the accuracy of Poisson solvers. Secondly, we avoid spatial grids entirely, because despite precautions the grid-related noise will always persist. The known grid-free SC solvers are based on the classic Green's function or direct Vlasov solvers (we are aware only of axi-symmetric ones) [3], but they are too slow for multiple particle tracking in rings and work only in free space without boundaries. Instead, we introduce hybrid SC solvers based on "space-charge templates", which represent macro Green's functions for macro-elements [4-5], from which a large family of beam distributions can be built. These SC templates calculate the 3D self-forces of a beam in the presence of conducting boundaries.

There is a gap in terms of generality and performance between fast but over-simplified "frozen" models and standard PIC codes. The proposed hybrid SC solvers fill that gap: they are more flexible than "frozen" models and approach the accuracy of PICs while being much faster. Template-based solvers can simulate rather arbitrary beam distributions within conducting boundaries and may be parallelized, boosting their performance even further.

ACCURACY OF MULTIPLE-PARTICLE TRACKING BY PICS

The computational flows of multiple-particle tracking codes are similar, and our analyses of the accuracy and performance of their components have much in common.

PIC Computational Modules

Each macro-particle in a 3D beam has six phase space coordinates, and a step-by-step evolution of the ensemble of N macro-particles $\mathbf{X}=(x_1, x'_1, y_1, y'_1, z_1, z'_1,\ldots, x_N, x'_N, y_N, y'_N, z_N, z'_N)$ looks like the following:

$$\mathbf{X}_{\text{old}} \rightarrow \underbrace{\rho_{3D}}_{\text{Space}}, \underbrace{u_{3D}}_{\text{Charge}}, \underbrace{\mathbf{E}_{3D}}_{\text{module}} \rightarrow \left[\begin{array}{c}\text{Trajectory}\\ \text{Integrator}\end{array}\right] \rightarrow \mathbf{X}_{\text{new}} \quad (1).$$

Here the trajectories are integrated either by multi-step (2nd order leap-frog, or higher order) schemes, or symplectic maps, which are more customary for multi-turn modeling in the rings. These higher order maps take into account non-linearities of the lattice and SC forces, and they trace particles with any prescribed accuracy in the framework of the single particle approximation [6].

Contemporary Poisson solvers are able to derive nearly exact grid solutions by multi-grid techniques, assuming that the input, i.e. the grid density, is known exactly. The interpolation between grid nodes is also very accurate. Unfortunately, the grid density is evaluated only approximately, and moreover, it represents the main source of numerical noise in (1). We need to find remedies to manage this.

Space Charge Density on the Grid

The Cloud-In-Cell (CIC) technique was developed decades ago (see [1] and references therein). If a spatial grid has dimensions of $N_x \times N_y \times N_z$ and meshes $h_x \times h_y \times h_z$, then the macro-particle sizes are $\delta_{x,y,z}=\Delta \times h_{x,y,z}$ ($\Delta \geq 0.5$). A redistribution of elementary space charge among grid nodes must satisfy a conservation of space charge and should converge for higher order interpolations. A linear scheme is used in ORBIT, WARP, and Synergia codes. A quadratic interpolation is also possible.

Using finite clouds with bell-like shape functions is beyond linear/quadratic interpolation. One needs an infinite polynomial series to represent them. For example, Fig. 1 shows a family of one dimensional (1D) clouds:

$$S_2(\xi)=\frac{q}{2\Delta}, S_3(\xi)=\frac{3q}{4\Delta}\left[1-\frac{\xi^2}{\Delta^2}\right], S_4(\xi)=\frac{q}{2\Delta}\left[1+\cos\left(\frac{\pi\xi}{\Delta}\right)\right],$$

$$S_5(\xi)=\frac{q}{3\Delta}\left[1+\cos\left(\frac{\pi\xi}{\Delta}\right)\right]^2, S_6(\xi)=\frac{15q}{16\Delta}\left[1-\frac{\xi^2}{\Delta^2}\right]^2 \text{ for } |\xi| \leq \Delta.$$

Copyright © 2013 CC-BY-3.0 and by the respective authors

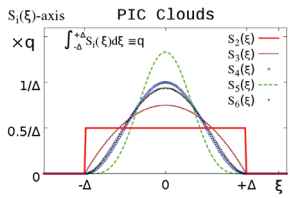

Figure 1: Macroparticle clouds in CIC scheme. All clouds have different ramps, but carry the same space charge "q".

As shown in [7], the integrals $\Phi_k=\int_a^\eta S_k(\xi)d\xi$ are:

$$\Phi_2(\eta,a)=q\frac{\eta-a}{2\Delta},\quad \Phi_3(\eta,a)=q\frac{3(\eta-a)}{4\Delta}-q\frac{\eta^3-a^3}{4\Delta^3},$$
$$\Phi_4(\eta,a)=q\frac{(\eta-a)}{2\Delta}-q\left(\sin\frac{\pi\eta}{\Delta}-\sin\frac{\pi a}{\Delta}\right)/2\pi\ ,$$

and so on for $\Phi_{5,6}(\eta\, q)$. In our algorithm, the choice of the cloud may vary from the beam center to the edges. Figs. 2 illustrate SC density of 10^5 macro-particles within 40cm×40cm boundary, N_x=N_y=128 and different sizes of macro-particles for the cloud $S_3(\xi)$.

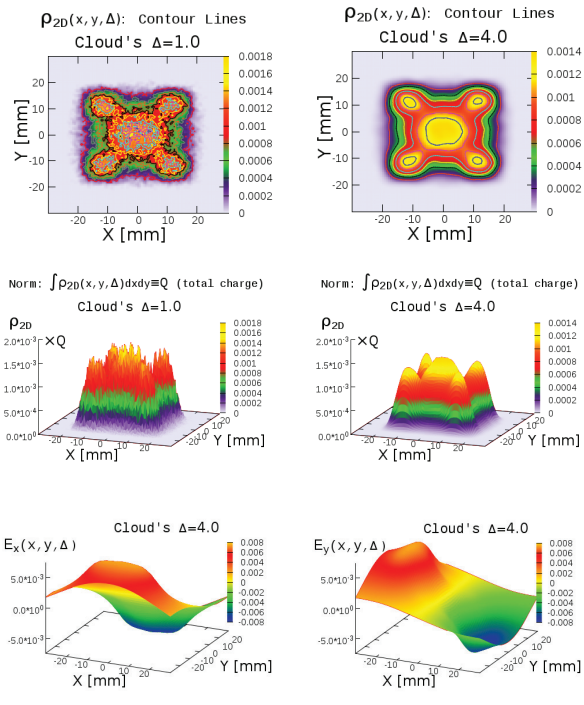

Figure 2: Contour plot (top), 3D space charge densities (middle) for Δ=1, 4; and corresponding fields $E_{x,y}$ (bottom) for Δ=4.

For Δ=1 and 4, contour lines and 3D plots are very different (~15%). The potentials, as integrals of densities differ by < 0.01%. The field differences drop from 3% to less than 0.01% for Δ=1 and 4 respectively [8].

SPACE CHARGE TEMPLATES

A concept of space charge templates was introduced in [5,9]. The templates are macro-elements reproducing an original beam; their fields are derived from the library of template fields via superposition. A family of beam distributions built by templates is rather general but always has elliptical cross-sections along "z". See Fig. 3.

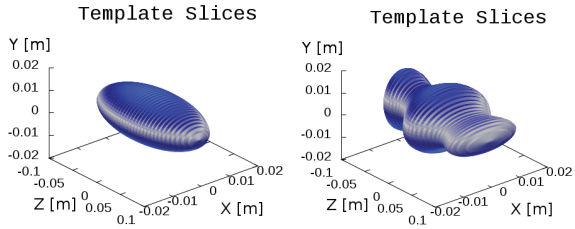

Figure 3: 3D beam bunches within a round cylindrical pipe of 4 cm in diameter (not shown). An ellipsoid 1cm×1cm×10cm (left) and an arbitrary 3D beam (right). Both bunches are "sliced" longitudinally by templates.

In earlier versions of space charge templates, the fields of a 3D beam were calculated, using a library of charged disks/slices with pre-assigned density distributions.

A more universal way to model a composite structure of real charge distributions is to use template-rings [10,8].

The 3D potential in free space $\Re$ is

$$u_{tmp}(\mathbf{x})=\iiint_{\Re}\rho(\tilde{\mathbf{x}})d\tilde{\mathbf{x}}\,/\left|\mathbf{x}-\tilde{\mathbf{x}}\right|.$$

For the particular case of a round ring of the outer radius R_{tmp} and the inner radius R_{tmp}-dR (dR_{tmp} stands for the thickness) with constant surface density σ_{tmp}, the potential becomes:

$$u_{tmp}(\mathbf{x})=2\pi\sigma_{tmp}\left[\sqrt{R_{tmp}^2+z^2}-\sqrt{(R_{tmp}-dR)^2+z^2}\right]\quad(2),$$

leading to analytical formulae for the longitudinal field on the axis [10]. We used this equation along with successive over-relaxation (SOR 3D) technique, which solves the Poisson equation with and without boundaries.

For illustration, the potentials of a positively charged disk of R=0.01 m, a negatively charged disk of R=0.007 m, a ring, as a superposition of these disks and a ring field are plotted in Fig. 4 (left). Template fields, representing a beam from right part of Fig. 3 are plotted in Fig. 4 (right).

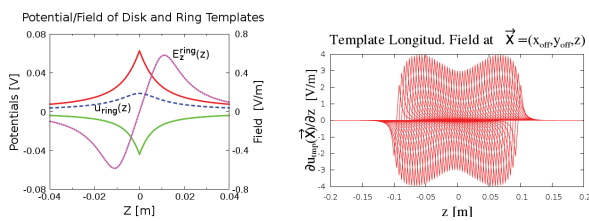

Figure 4: Potentials and a field of disks/ring in free space (left). Template potentials of a beam from right part of Fig. 3 (right).

We benchmarked the results for a 3D 1cm×1cm×10cm ellipsoid, carrying a uniformly distributed space charge of Q=10^{-11} C, placed into a conducting pipe of 4 cm in diameter. The results obtained for disk and for ring templates agreed very well. Figs. 5 shows the same potential and fields as in [11, p.407] at x_{off}=y_{off}=0, obtained by SOR 3D, for distributions from Figs. 3. For longer bunches with semiaxes 1cm×1cm×50cm, the field flattens in the middle and "ear-fields" appear at the edges.

Copyright © 2013 CC-BY-3.0 and by the respective authors

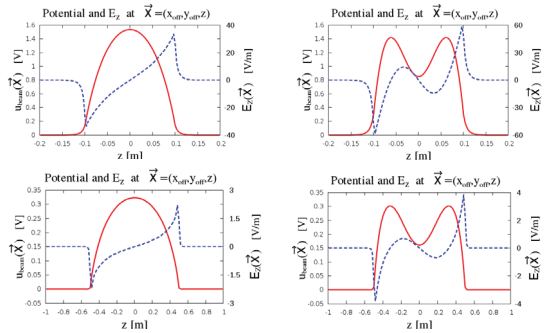

Figure 5: Potentials and fields of 3D ellipsoids with 1cm×1cm×10cm (top), and 1cm×1cm×50cm (bottom).

Fig. 5 suggests that non-linear behavior of longitudinal field becomes very strong due to image forces (in free space, a uniformly charged 3D ellipsoid has linear fields).

A Gaussian 3D beam of ellipsoidal shape in free space has an analytical form of $E_{x,y,z}$ fields (the so-called "frozen" SC model). The presence of a boundary changes them dramatically, limiting their applicability in tracking codes. We refer especially to the longitudinal field E_z, which is most affected by image forces.

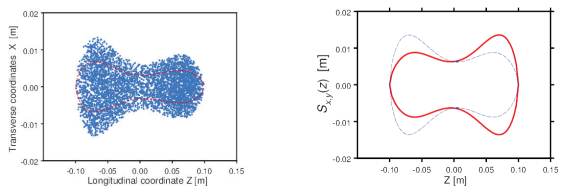

Figure 6: Transverse rms profiles $\langle x^2\rangle^{1/2}(z)$, $\langle y^2\rangle^{1/2}(z)$ (left) and shape functions $S_{x,y}(z)$, defining the template shell (right).

The number of templates for accurate space charge calculations is a free parameter. For a beam depicted in Figs. 3, one needs 15-20 templates. "Thick" slices may also be helpful to deal with very long bunches.

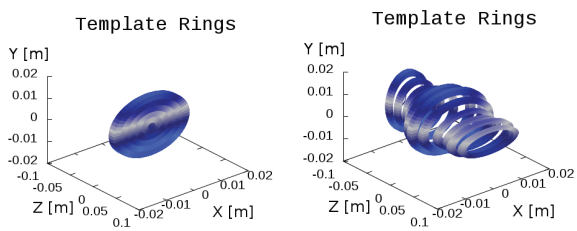

Figure 7: Disk templates (left), built from rings. Ring templates for the outer layer of beam bunch (right).

For a real 3D bunch consisting of macro-particles, Figs. 6 demonstrate the procedure to find shape functions $S_{x,y}(z)$, determining the shell containing all templates, and Fig. 7 illustrates how ring templates reproduce the beam.

Halo and Hollow Beams

For high-brightness accelerators (HL-LHC, ESS), beam loss control is critical, and generally must obey "the 1W/m rule" [12]. While losses may be less than 0.1%, the halo (from which most losses come) may contain a much larger fraction of a beam, and fields from halo particles can't be neglected. Numerical noise from halo particles in a regular grid-based PIC may well be unacceptable.

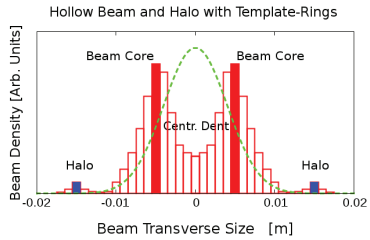

Figure 8: A transversal cross-section of an arbitrary "made-up" hollow beam with a halo, represented by a library of ring templates. An ideal Gaussian beam distribution is a dashed line.

Ring templates are quite appropriate for halo as well as hollow beam field calculations, as shown in Fig. 8. Having disk templates, a special distribution like that would be difficult to reproduce.

DISCUSSION

The goal of this paper is to evaluate accuracies of SC tracking codes for rings, to develop a strategy to suppress artificial numerical effects, and ultimately, to improve code performance. The errors in SC fields will always persist due to granularity of space charge distribution, and inaccuracies of grid density calculations will dominate other errors: a grid Poisson solver and field interpolation and of course those of higher order tracking engines.

A decrease of grid dimensions (larger meshes) damps density fluctuations. The same is valid for larger CIC clouds. However, these fluctuations may be physical, and such a brute force remedy simply eliminates them. A beam halo requires special treatment.

The split operator paradigm is valid for very long bunches (a coasting beam approximation, as in PSR, SNS). For shorter bunches, a more accurate approach is required, based on templates and hybrid technique [5,8].

OPTIMIZATION OF THE MULTIPOLE TO LOCAL TRANSLATION OPERATOR IN THE ADAPTIVE FAST MULTIPOLE METHOD

Abstract

The Fast Multipole Method (FMM) is an accurate and fast way to calculate potentials/fields created by a very large number of particles. The runtime of the FMM is significantly less than that of the pairwise calculation if the particle number, N, is sufficiently large. Two major parts in the FMM are the upward pass and the downward pass. The upward pass calculates multipole expansions and then performs multipole-to-multipole translations. The downward pass calculates multipole-to-local expansions and local-to-local expansions. The multipole-to-local translation in the downward pass is the most time consuming translation in the FMM. In order to make the FMM more efficient, we sought to minimize the time taken by the multipole-to-local translation. The promising and practical strategy to minimize the multipole-to-local translation time is to replace the 3D multipole-to-local translation with a 1D multipole-to-local translation in conjunction with rotations of the coordinate axes. In this paper we show how to perform the 1D multipole-to-local translation and the time comparisons between the two FMM variants.

INTRODUCTION

The traditional method to calculate the Coulomb interaction between charged particles is pairwise calculation. The computational power needed for this method is of the order $O(N^2)$ and it is not practical if the number of particles is very large. The FMM can reduce the computational power to $O(N)$.

The details of the two major components of the FMM, data structuring [1, 2] and calculation of the potential/field [3], are discussed in our previous papers. If the number of particle is large, the data structuring time scales linearly [2]. We have also shown that the total runtime, the addition of data structuring time and the time taken to calculate the potential, scales linearly with the number of particles, if the number is large enough [3].

The major components of runtime with optimized settings are the time taken by upward pass (~3%), the downward pass (~50%) and the direct calculation in the final summation (~47%). To decrease the runtime we need to decrease the downward pass time or the direct calculation time. As the direct calculation time solely depends on the optimum q (the parameter q has its usual meaning, the maximum number of sources allowed in the neighbourhood of a given target), it is no longer possible to reduce the direct calculation time. Hence, we focus on reducing the downward pass time. Further analysis showed that the multipole-to-local translation (M2L) used in the downward pass is the bottleneck. This paper places emphasis on the M2L operator and shows that the FMM runtime can be significantly reduced if the 3D M2L translation is replaced by the 1D M2L translation.

ALGORITHM

In the data structuring we create the C-forest (the collection of trees) and the D-tree (parent-child relations of all boxes which contain target particles) [1, 2] at the optimum q. Once the octree-type data structure is created we can implement the FMM proper to calculate the potentials/fields.

The FMM implementation consists of two key components, the upward pass and the downward pass [3]. The downward pass starts at level two and it has three steps. The first step is the M2L translation of the multipole expansions of the boxes in the interaction list of a particular box or leaf node, b. In the second step, we move to the next finer level and compute the local expansion of child nodes of b around their centers from the multipole expansions of the boxes in the interaction list of child nodes. In the third step, we re-expand the result in the first step to evaluate the contribution from the local expansion of the parent box and add that to the result obtained in the second step. In order to complete the downward pass the above three steps must be repeated until we reach the finest level.

After the upward pass and downward pass we move to the final summation [3]. In the second step of the final summation we calculate the potential at each target in b due to the sources in the neighbourhood of b. This is a pairwise calculation. We have noticed that the M2L translation in downward pass and direct calculation in final summation take a considerably longer amount of time compared to all the other operations in the FMM process. Since this pairwise calculation is unavoidable and we cannot reduce that time it becomes apparent that the FMM runtime can be further reduced by optimizing the M2L translation operator. At higher orders M2L translation takes more than 50% of the total FMM runtime.

In this translation, we perform a 3D M2L translation in all three directions, x, y and z. In 3D, the number of boxes in the interaction list varies from 27 to 189. Therefore, the M2L translation takes a longer time. If we rotate the coordinate system of the box with the multipole expansion to be translated in such a way that the z-axis of the box aligns with the line joining the centers of the box and the interaction list boxes, the 3D transformation of the M2L becomes a 1D transformation. Hence, the time taken

Copyright © 2013 CC-BY-3.0 and by the respective authors

for M2L translation can be considerably reduced as shown in Table 1 and 2.

1D M2L TRANSLATION

There are four coordinate systems involved in changing 3D M2L translation to 1D.

- Original multipole expansion in $(X, Y, Z)_{m,\,o}$
- Rotated multipole expansion in $(X, Y, Z)_{m,\,r}$
- Original local expansion in $(x, y, z)_{l,\,o}$
- Rotated local expansion in $(x, y, z)_{l,\,r}$,

where the subscripts *l*, *m*, *o*, and *r* denote local, multipole, original, and rotated, respectively.

The rotation about any arbitrary axis $\hat{\boldsymbol{\omega}}$ by an angle θ can be described by the matrix *R*,

$$R = \begin{pmatrix} t\omega_x^2 C & t\omega_x\omega_y - S\omega_z & t\omega_x\omega_z + S\omega_y \\ t\omega_x\omega_y + S\omega_z & t\omega_y^2 C & t\omega_y\omega_z - S\omega_x \\ t\omega_x\omega_z - S\omega_y & t\omega_y\omega_z + S\omega_x & t\omega_z^2 C \end{pmatrix}.$$

C, *S* and *t* denote cos θ, sin θ and (1- cos θ), respectively.

In order to make a 1D translation we need to rotate the coordinate system of the interaction list box such that the z axis lies along the line joining the center of an interaction list box and the center of a D-tree node, which is denoted by **r** (Fig. 1). In our implementation, we avoid this rotation if the z axis is already aligned with **r.** The unit vector along the axis of rotation, $\hat{\boldsymbol{\omega}}$, is then given by the cross product between **z** and **r**.

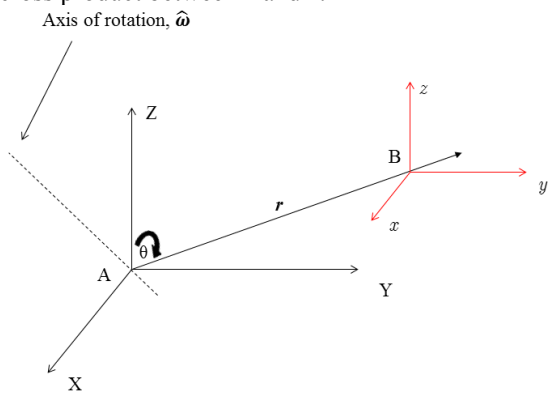

Figure 1: Rotation of the coordinate system.

If $\boldsymbol{r} = (\boldsymbol{r_x}, \boldsymbol{r_y}, \boldsymbol{r_z})$, $\hat{\boldsymbol{\omega}} = (\boldsymbol{\omega_x}, \boldsymbol{\omega_y}, \boldsymbol{\omega_z})$ and $\boldsymbol{z} =$ (0,0,1), then $\omega_x = -\frac{r_y}{r}$, $\omega_y = \frac{r_x}{r}$, $\omega_z = 0$.

Once the coordinate system is rotated, we transfer the multipole expansion into a local expansion. Finally, this rotated local expansion must be rotated back to the original coordinate system. This process is explained below.

The relationship between rotations can be given as follows:

$$\begin{pmatrix} X \\ Y \\ Z \end{pmatrix}_{m,r} = R \begin{pmatrix} X \\ Y \\ Z \end{pmatrix}_{m,o} \text{ and } \begin{pmatrix} x \\ y \\ z \end{pmatrix}_{l,r} = R \begin{pmatrix} x \\ y \\ z \end{pmatrix}_{l,o}.$$

The translation of the multipole expansion M_o to local expansion L_o can be expressed as a composition between M_o and M2L.

$$L_o \begin{pmatrix} x \\ y \\ z \end{pmatrix}_{l,o} = M_o \circ M2L_o \begin{pmatrix} x \\ y \\ z \end{pmatrix}_{l,o}.$$

Since *r* is the distance between the centers of the boxes (invariant under *R*), we can establish the following relationships:

$$\frac{1}{r^2} \begin{pmatrix} X \\ Y \\ Z \end{pmatrix}_{m,o} = M2L_o \begin{pmatrix} x \\ y \\ z \end{pmatrix}_{l,o};$$

Similarly, the new operator $M2L_n$ can be introduced as,

$$\frac{1}{r^2} \begin{pmatrix} X \\ Y \\ Z \end{pmatrix}_{m,r} = M2L_n \begin{pmatrix} x \\ y \\ z \end{pmatrix}_{l,r},$$

where the subscript *n* stands for *new*.

The two operators, $M2L_o$ and $M2L_n$, must give the same local expansion around centers of the nodes. Hence,

$$L_n \begin{pmatrix} x \\ y \\ z \end{pmatrix}_{l,o} = L_o \begin{pmatrix} x \\ y \\ z \end{pmatrix}_{l,o}.$$

By further simplification, it can be shown that

$$L = M \circ R^{-1} \circ M2L_o \circ R,$$

where $L_o = L_n = L$ and $M_o = M$. Since the rotation matrix is orthogonal $R^{-1} = R^T$.

PERFORMANCE ANALYSIS

The 3D M2L translation requires a dense function composition operator in three variables while the 1D M2L translation requires a sparse function composition operator in the variables *x* and *y* and a dense operator in *z*. The 3D translation is computationally more expensive compared to the 1D translation. Both translations are order-dependent and hence the difference in cost between these translations becomes order-dependent. The two rotations needed for the 1D translation are considered order-independent overhead. Empirically, we notice that the time saving by employing the 1D operator instead of 3D operator becomes significant around order five, independent of the type of distribution. Therefore, based on our results, it is clear that below order five 3D M2L translation is advantageous, while above order five 1D translation is advantageous, independent of the distribution (Figs. 2 and 3). In order to achieve high accuracy, it is essential to perform calculations at higher orders [3, 4].

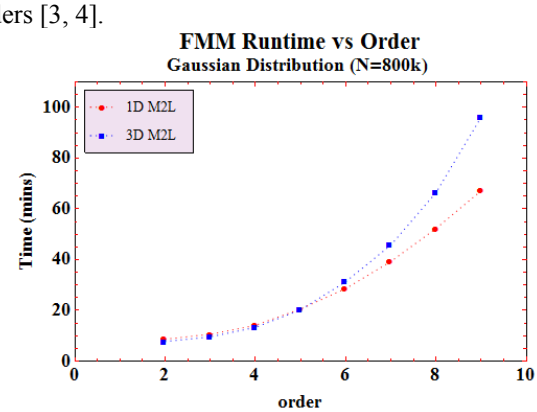

Figure 2: Runtime measured for normally distributed particles using 1D and 3D M2L operators.

Copyright © 2013 CC-BY-3.0 and by the respective authors

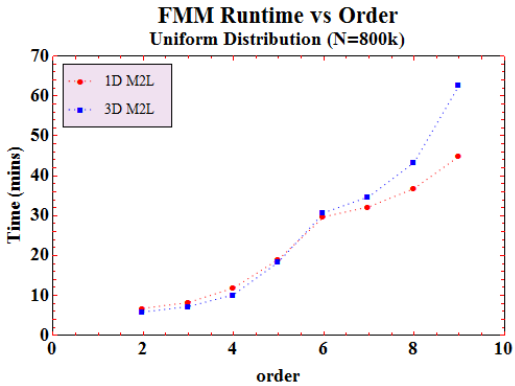

Figure 3: Runtime measured for uniformly distributed particles using 1D and 3D M2L operators.

Tables 1 and 2 summarize the runtime measured for normally and uniformly distributed particles, respectively, at different orders at optimum q (in each case identical sources and targets are used).

We studied the relationship between the FMM runtime (t) and the expansion order (p) in the region where the order is greater than five. For normally distributed particles (N=800k), t is proportional to the nth power of p and the value of n is 3.4 and 2.4 for 3D M2L and 1D M2L, respectively. For uniformly distributed particles (N=800k), the corresponding values are 7.2 and 5.5.

Table 1: Runtime measured for normally distributed particles using 1D and 3D M2L operators.

Order	Time(mins)	
	1D	3D
2	8.724	7.765
3	10.589	9.621
4	14.155	13.314
5	20.582	20.235
6	28.620	31.342
7	39.294	45.760
8	52.292	66.442
9	67.178	96.185

Table 2: Runtime measured for uniformly distributed particles using 1D and 3D M2L operators.

Order	Time(mins)	
	1D	3D
2	6.800	5.886
3	8.265	7.236
4	11.900	10.204
5	19.107	18.450
6	29.732	30.752
7	32.240	34.767
8	36.809	43.323
9	44.926	62.701

The runtimes are machine dependent. All the tests were run on a single core Intel® Core™ i5-2410M @ (2.30GHz) computer (no SSE). The machine had 8GB of RAM. The code for data structuring is written in C++ and compiled under Cygwin on Windows 7, and used the g++ compiler with optimization flags –O3 and –funroll-loops. The FMM is implemented in COSY Infinity [4].

SUMMARY

In this paper, we showed that the use of 1D M2L operator (for expansion orders greater than five) in the downward pass to calculate the potentials/fields reduces the overall FMM runtime in both normally and uniformly distributed particles. As shown in Table 3, when run at optimum q, 1D M2L operator saves the downward pass time by 40% for uniformly distributed particles and by 35% for normally distributed particles. Hence, the overall FMM runtime is reduced by 30% and 29% for normal and uniform distributions, respectively.

Table 3: Downward pass times at order 9 (N=800k).

Distribution	Dimension	Optimum q	Time (mins)
Uniform	1D	6000	9.40
	3D	6000	15.70
Normal	1D	12000	31.08
	3D	20000	47.75

Abstract

The trajectories of protons interacting through Coulomb forces were computed using a numerical integrator based on Picard's iteration method. This is a variable order, adaptive integrator with dense output. We show different cases by varying some parameters such as the impact parameter, the relative velocity of the protons and the order of the differential algebraic (DA) vector. The accuracy of the trajectories was tested by changing the order of the DA vector while fixing the other parameters. The impact parameter between the protons and the velocity of the incident proton has the most impact on the trajectories. The maximum time step is determined by the radius of convergence of the expansions, while a fixed accuracy is attained by varying the order.

INTRODUCTION

Many physical phenomena involve N bodies (particles) interacting with one another by long range forces which decrease inversely as the square of the distance. Examples include the gravitational interaction among the stars in a galaxy, and the Coulomb forces between charges. Many particle systems have wide range of applications in different areas such as biophysics, chemistry, astrophysics [1], etc.

This work includes the two-body problem, in which two charges interact through Coulomb forces. Coulomb's law describes the force between two point charges by the following equation:

$$\overrightarrow{F} = \frac{1}{4\pi\varepsilon_o}\frac{q_1 q_2 \vec{r}}{|\vec{r}|^3},$$

where $\overrightarrow{F}$ is the force, q is the charge, $\vec{r}$ is the radial distance between the two charges, and ε_o is the permittivity of free space.

It is complicated to solve the N-body problem numerically due to the singularity of very close encounters where $|\vec{r}| \to 0$ (very strong interaction $\overrightarrow{F} \to \infty$), and the requirements of high precision with violently varying time steps that are necessary to reduce errors to acceptable levels.

We consider the interaction between two protons in two dimensions. The first proton is initially at rest, and the second proton is moving horizontally towards the first one with a specific vertical distance between them. According to Coulomb's law, the electrostatic force between two similar charges is repulsive.

The integrator has applications in electron cooling of heavy ion beams, and any other beam dynamics problem where individual collisions need to be resolved.

ALGORITHM

To compute the trajectories of both of the protons, we used a code developed by us via COSY INFINITY [2]. The code is a numerical integrator based on Picard's iteration method (see [3] for details). Picard's method uses the initial conditions of the system and gives a sequence of functions that converge to the solution. This method can compute completely algebraically the Maclaurin polynomial (Taylor series expansion of a function about zero).

In this program, the Maclaurin polynomial of the solution is represented by DA vectors. The DA vector is an array of elements that describe a multi-variable function when given its value and derivatives at a specific point [4]. The integrator order is equivalent to the DA order, and we can vary this order to the one that we want to truncate the Taylor series at. At each time step, the program evaluates the change of the radius between the particles and compares it with the one at the next time step. Whenever the convergence radius is exceeded, the program will display an error message.

The maximum velocity (β_{max}) used for the incident proton is 0.283. Different fractions of this velocity were used as well. The initial horizontal distance between the protons was varied from 10^{-15}-10^{-9} m. The impact parameter (vertical distance between the particles) was varied from 10^{-15}-10^{-11} m. It is possible to use larger distances (horizontal or vertical), but the strong interactions are localized within these distances. Hence, larger distances would result into very small changes in the positions of the protons that would be hard to see.

EXAMPLES

The parameters of the system will be denoted as follows: d = horizontal distance (m), b = vertical distance (m), δt = time interval ($1/c$ s), N = number of time steps, and the DA order was set to be 4 unless specified otherwise.

Example 1

The impact parameter and the moving proton's velocity are fixed at 10^{-15} m and 10% β_{max}, respectively. The other parameters are varied in two instances:

- The parameters are: d = 10^{-15} m, N =10^4, δt = 3.6 × 10^{-17} $1/c$ s. The trajectories are shown in Fig. 1.
- Fig. 2 shows the protons' paths with the parameters: d = 10^{-10} m, N = 5.5 × 10^4, δt = 10^{-13} $1/c$ s.

The resulted trajectories in this example are as one would expect due to the Coulomb's interaction.

Copyright © 2013 CC-BY-3.0 and by the respective authors

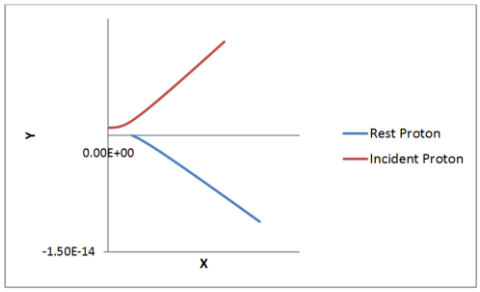

Figure 1: The paths of the protons from Ex. 1 where d = 10^{-15} m and the trajectories are as predicted by the Coulomb interaction.

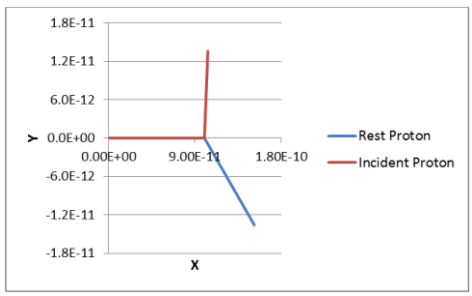

Figure 2: Ex. 1 paths of the protons when d is relatively large (10^{-10} m). The incident proton moves straight horizontally until very close to the rest proton where they start to interact.

Example 2

The horizontal distance is fixed at d = 10^{-12} m and the incident proton has high velocities in the two cases included here:

- The parameters are: b = 10^{-14} m, β = β_{max}, N = 5 × 10^4, δt = 3 ×10^{-16} 1/*c* s. In this case, the rest proton follows a parabolic path for a very short time, and then moves downward (see Fig. 3). This could be a result of the incident proton having a very high velocity such that it knocks the other proton down while its path deviates upward.

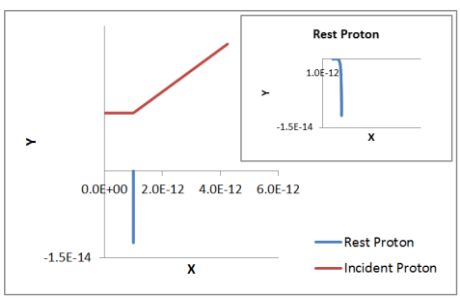

Figure 3: The rest proton moving downward when the moving proton has very high velocity (Ex. 2). The inset shows the parabolic path of the rest proton.

- In this example: b = 10^{-12} m, β = 50% β_{max}, N = 7 × 10^4, δt = 10^{-13} 1/c s. This is one of the cases in which the rest proton exhibited unexpected behavior. It moves downward for a very short interval, and then it starts to recoil and goes backward (as shown in Fig. 4). However, this behavior is very un-noticeable such that it appears like the proton is just going vertically down (as shown in Fig. 5).

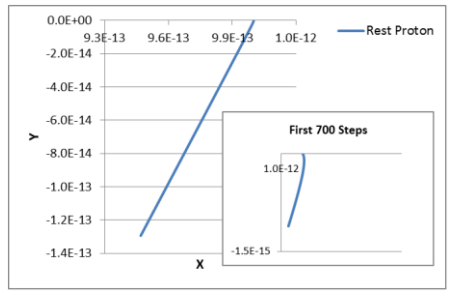

Figure 4: The path of the rest proton going backwards. In the small box, the first 700 steps shows the recoiling.

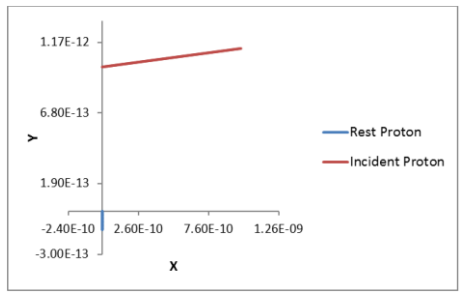

Figure 5: The proton at rest going downward with the un-noticeable recoiling when the moving proton has a relatively high velocity.

ACCURACY TESTS

To check the accuracy of the computed trajectories, we varied the order of the DA vector and the time interval in two ways, as described next.

Fixing the time interval

We used a small δt and different orders of the DA vector. If the trajectory of a low DA order is the same as the trajectory of a higher DA order, then the chosen time interval is sufficiently small to get accurate paths. The other parameters in this example are: d = 10^{-12} m, b = 10^{-13} m, β = 10% β_{max}, N = 6 × 10^4. Fig. 6 shows this accuracy for δt on the order of 10^{-15} 1/*c* s, in which the trajectory with the DA order of 4 is exactly the same as the one with the DA order of 20.

Changing the time interval

We used various time intervals with a specific order of the DA vector. We increased δt until the new trajectory diverges from the accurate one (with small δt) of the same order. We fixed the other parameters at: d = 10^{-12} m, b = 10^{-13} m, β = 10% β_{max}. The number of time steps was changed according to the change of δt.

Since the code we are using tests for errors of the radius of convergence, we include two cases:

Copyright © 2013 CC-BY-3.0 and by the respective authors

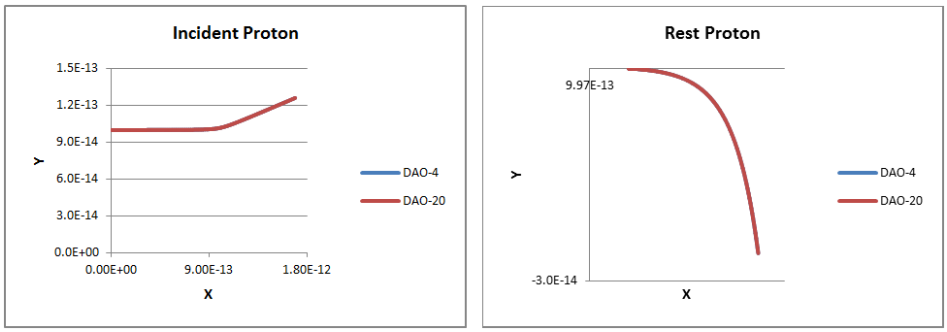

Figure 6: The accuracy test by fixing the time interval and varying the DA order. The paths of the incident proton and the rest proton are illustrated in the left and right pictures, respectively.

- δt is large, but not such that we get errors. Here are two examples with DA order = 4 and 20. In both examples, the trajectory of the moving proton was not affected by changing δt. Therefore, we show only the paths of the rest proton in Fig. 7. For DA order = 4, the paths with large δt start to diverge from the ones with small δt. For DA order = 20, both paths are almost the same.

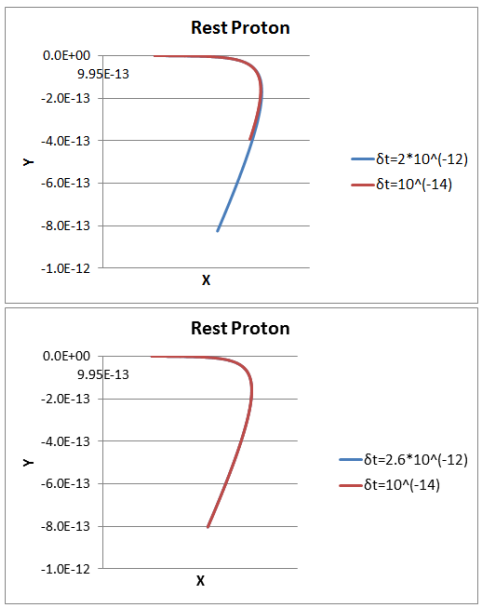

Figure 7: The paths of the rest proton with large δt (in blue), and with small δt (in red). The DA order is 4 in the top box, and 20 in the bottom one.

- Beyond the radius of convergence errors. The resulted trajectories are unphysical and inaccurate. It is hard to explain these results, and the only reason might be the errors of the radius of convergence. Fig. 8 is an example where the DA order is 18.

SUMMARY

Using a numerical integrator based on Picard's iteration method, we computed the trajectories of two protons interacting through the Coulomb force. Our main interest was in close encounters of the protons. We showed different examples by changing different parameters in the problem. The results are in agreement with the theory: to obtain certain accuracy most efficiently, a maximum step size is determined by the region of convergence, and the desired accuracy is achieved by increasing the DA order with the given maximum time step. Also, these results will enable us to automatically adjust the time step adaptively, as needed. More studies are needed to get better understanding of the results. A future work is to apply similar studies for the attracting case (proton-electron interaction).

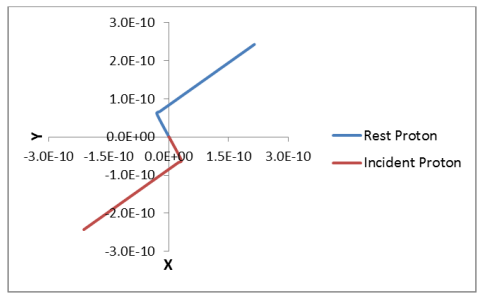

Figure 8: The unphysical results from having large time interval such we get radius of convergence errors.

Abstract

Strong space charge is a significant impediment in charged particle beam physics, particularly at the high intensity frontier. For future applications, where particles must occupy the smallest region possible, quickly and accurately and efficient modeling space charge modeling is essential, for instance, to minimize the space charge contribution to beam dispersion. In this paper, we study and compare the performance for the method of moments (MoM) and the single-level fast multipole method (SLFMM) in 2D. The method of moments has been widely used to solve computational electromagnetic problems but assumes a series-expandable smooth distribution function, limiting its reliability in some cases. The fast multipole method was more recently developed and shows remarkable accuracy with difficult beam distributions. We demonstrate these methods using a simplified version of the University of Maryland electron ring (UMER). We present some multi-particle tracking results obtained using these methods. Future work will study the space charge inclusive transfer maps calculated from these methods.

INTRODUCTION

The general N body problem, although simple in principle, is computationally very challenging. The simplest method uses direct pair-wise interaction computations, where the complexity behaves like $O(N^2)$, and gives a machine precision solution for each pair. The mean field methods almost always involve some kind of numerical approximation. Two methods in particular were developed that approximate our solution to a significant degree of accuracy and reduce the scaling to $O(NlogN)$ or even $O(N)$ [1, 4, 5]. The method of moments (MoM) has been successfully used in several cases [1, 2]. As expected, it is most accurate for smooth unimodal distributions, where the relatively low order moments reliably approximate the distribution [4]. The fast multipole method (FMM), recently developed by Greengard and Rokhlin in 1987 [5], shows remarkable accuracy with arbitrary distributions, overcoming some weaknesses of the MoM. We are mainly interested in efficiently and accurately modeling the nonlinear effects present in a space charge dominant beam. The purpose of this paper is to evaluate and compare the MoM and FMM performance for a test case involving a simplified model of UMER.

IDEALIZED UMER

The University of Maryland electron storage ring has been designed and built specifically for the study of space charge dominated, high intensity beams in a localized, inexpensive setting. Some of the design specifications are shown in Table 1, with our specific settings in the lower section [3]. The design is such that the electron bunches fill the ring, allowing a quasi-2D approximation. We included only the main recirculation (RC) sections, each consisting of two equivalent FODO sections with a guiding dipole in the middle of each FODO section.

Table 1: The UMER Design Specifications are Listed in the Top Half and Our Relevant Simulation Conditions are in the Bottom Half

Circumference	11.52 m
Electron energy	10 keV
$\beta(=\frac{v}{c})$	0.2
Current	1–100 mA
Aperture	2.95 cm
Pulse Length	40 ns
Lap time	197 ns
Pulse repetition rate	60 Hz
Turns	30
Simulated current	6 mA
FODO period	0.32 m
# of FODO sections	36
Dipole bend	10°
Dipole effective length	3.82 cm
Quadrupole current	1.826 A
Quadrupole effective length	5.164 cm
Initial emittance (X,Y)	(5.28×10^{-8},4.94×10^{-8})
Integration region	5.25σ

RESULTS

MoM

Reference [1] explains the details of our implementation of the MoM and FMM. For the MoM, there are three separate orders to which we will refer. The space charge order (SO) is the order of computation for the space charge map. The map order is the order of computation for the regular transfer map or equivalently the order of the

Copyright © 2013 CC-BY-3.0 and by the respective authors

differential algebra vectors (DAO).The moment order (MO) is the order of the sample moments used to model the particle distribution. The main purpose for the development of the MoM was the ability to extract self-consistent transfer maps that include space charge. However, the same method can be used for tracking space charge dominated beams. On the other hand, it is not clear how accurate is the MoM for tracking. Therefore, we focus on tracking capabilities in this paper. We started with a spatially uniform, angularly Gaussian beam that almost fills the ring acceptance.

In principle, the map order and space charge order do not have to be equal. We performed a study on the effects of mismatched DAO and SO, up to $DAO = SO + 3$, with overall maximum order at 18. We also constrained the SO and MO to be equal. We first examined the final emittances of our 6 mA electron beam. Figure 1 shows our final emittances. We calculated the emittances in X and Y using the standard deviations in position and angle of the beam and plot the total emittance. The results show that high order space charge effects are important, as expected, while no other high order effects are present in the ring.

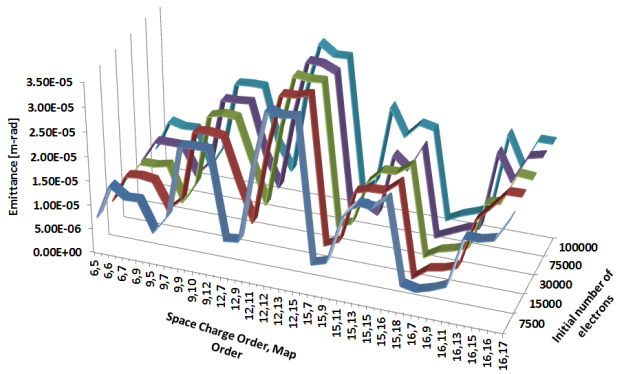

Figure 1: Comparison of Final Emittance [m-rad] vs. Space Charge Order, Map Order vs. N_p using the moment method for the UMER model.

In Figure 1, we compare the final total emittance with the space charge order, map order and number of particles, N_p. The emittance grows with map order and space charge order. The growth is mainly in the Y emittance. The variation in the plateau heights reflect the well-known fact about the optimal truncation order, i.e. best space charge order. As detailed in [1], there are two competing effects: increasing the space charge order improves the modeling of the distributions in the ideal case, but the finite number of particles introduce noise, which affect the sample moments that in turn decrease the accuracy due to the large condition number of the matrix that embodies the linear relationship between the moments and the coefficient set of the distribution function expansion. As shown in Table 2, the final emittances also reflect this slight instability of the moment method tracking, with optimal order seen around 12. The evolution of the particle distribution showed significant formation of halos and chaotic regions. The differences are minor between N_p. Our beam lifetimes showed similar behavior to the emittance, low survival at low map order, and approximately same survival once DAO equals SO. The timing results for the idealized UMER model are shown in Figure 2. We only show three representative order sets for each N_p.

Table 2: Averages and Standard Deviations of the Final Emittances at Plateau for SO 12, Sampling DAO 12,13,15 for $N_p = 7500, 15000, 30000, 75000, 100000$ After 30 Turns. Convergence is achieved in map order.

N_p	Average [m-rad]	σ
7500	3.399×10^{-5}	4.376×10^{-7}
15000	3.433×10^{-5}	5.79×10^{-7}
30000	3.420×10^{-5}	1.996×10^{-7}
75000	3.347×10^{-5}	7.651×10^{-7}
100000	3.308×10^{-5}	1.147×10^{-6}

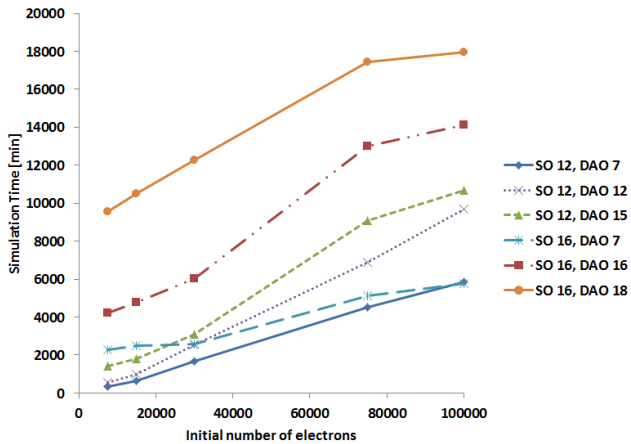

Figure 2: Comparison of Simulation time for 30 turns in mins using the moment method for the UMER model.

As shown in Figure 2, the simulation time exhibits roughly linear behavior. At low map, high space charge order, the number of particles decreases due to higher order space charge terms being truncated which would cancel strong lower order terms. This significantly decreases simulation time and leads to the kinks. Overall, we can achieve accurate results at high orders but expect unreliable predictions for low space charge order, showing the importance of higher order space charge terms.

FMM

Our implementation of the fast multipole method is one of the few using the differential algebraic framework. There are some key concepts to the FMM calculation worth noting here, but the full details may be found in a number of references [1, 5, 6]. We will refer to the number of boxes as N_{box}. The current box of interest, the nth box, will be designated our target box and all others will be designated sources. We use the single level FMM where we subdivide the space only once, into N_{box} equal size boxes. For the potential calculation, each nonempty source box is Taylor expanded with respect to the target box. Thus, the simulation time depends on N_{box}, N_p, SO, and the number of

Copyright © 2013 CC-BY-3.0 and by the respective authors

coefficients for the expansion in the FMM akin to the moment order, which we will call the FMM order (FO).

Due to time constraints, we decided to only run the FMM in tracking mode for 1 turn rather than 30 as for the MoM and at $N_p = 7500, 15000$ to compile the results in this paper. Preliminary tests showed the emittances from the FMM stabilize extremely quickly, usually within 1 turn, and the time per turn behaves consistently. Beam lifetime exhibits similar behavior, but we are hesitant to assume consistent lifetime for all FMM orders and N_p. For this study, our simulation has $N_{box} = 40^2$. A future study will test the dependence on N_{box}. Our results are shown in Figure 3 and Figure 4.

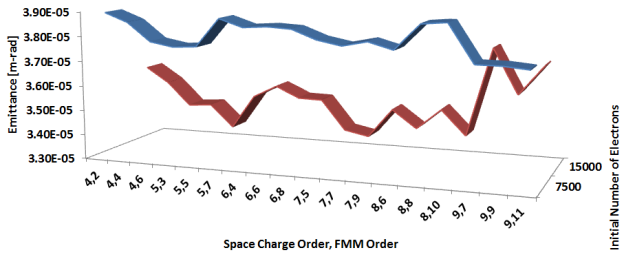

Figure 3: Final emittances [m-rad] after 1 turn vs. Space Charge Order, FMM Order using the fast multipole method.

Table 3: Averages and Standard Deviations of the Final Emit-tances at SO 9, Sampling FO 7,9,11, and $N_p = 7500$, 15000 After 1 Turn for the UMER Model Using the Fast Multipole Method

N_p	Average [m-rad]	σ
7500	3.746×10^{-5}	5.315×10^{-8}
15000	3.691×10^{-5}	9.185×10^{-7}

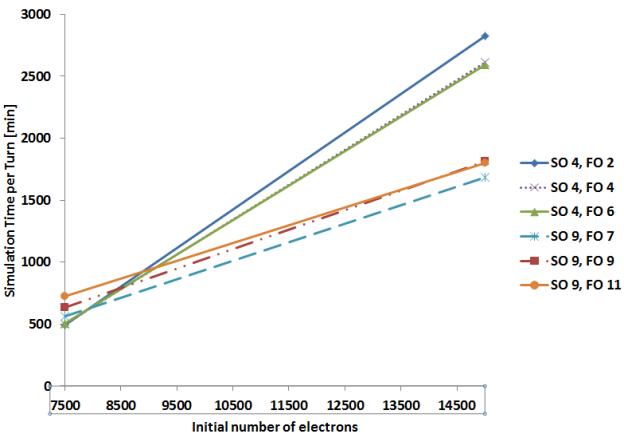

Figure 4: Simulation time per turn [mins] vs. initial number of electrons for select space charge orders, FMM orders using the fast multipole method.

In Figure 4, the simulation times per turn using the FMM tracking mode slightly depend on the orders. We reserve judgment on its N_p dependence at this time. In Figure 3, the final emittance after 1 turn for the idealized UMER model exhibits a small variation. Table 3 shows the averages and standard deviations for the final emittances at SO 9 as a function of FO for $N_p = 7500, 15000$. The relatively erratic emittance at SO 9, FO 7-11, $N_p = 15000$ is due to requiring more turns for the emittance to stabilize. The evolution of the distributions showed similar behavior to what was shown with the moment method, but the variation is no longer significant, thus it may be attributed to the chaotic nature of space charge.

CONCLUSIONS

Our study shows the various orders strongly affect our MoM results. Convergence in terms of moment and map order are achieved. There is no convergence in space charge order. Our optimum SO is 12 for SVD cutoff parameter of 1×10^{-12}. The MoM shows little dependence on N_p. From its emittances, The FMM shows slightly more dependence on N_p but stabilizes for large N_p.

Our FMM shows stable results. There is a hybrid mode implemented using FMM for tracking and MoM for map extraction but has not been studied thoroughly yet. More detailed comparisons will be forthcoming. We plan to optimize our FMM implementation for reduced runtime and further improve our MoM implementation.

A PICARD ITERATION BASED INTEGRATOR *

H. Schaumburg, NIU, DeKalb, IL 60119, USA
B. Erdelyi, NIU, DeKalb, IL 60119, USA

Abstract

Picard iteration is mainly used as a theoretical tool to establish the existence and uniqueness of a solution to an initial value problem. We have developed a method based on Picard iteration that computes the exact Taylor polynomial of the solution to arbitrary order. The method has been implemented in COSY INFINITY to numerically solve Coulomb interactions.

INTRODUCTION AND BACKGROUND

Picard iteration generates a sequence of functions $\phi_n(t)$ related to the solution of the initial value problem

$$\begin{cases} \mathbf{y}' = \mathbf{f}(t, \mathbf{y}) \\ \mathbf{y}(t_0) = \mathbf{y}_0 \end{cases}.$$

When $\mathbf{f}$ satisfies a local Lipschitz condition with respect to $\mathbf{y}$ on U, a connected open subset of $\mathbb{R}^{m+1}$ and $(t_0, \mathbf{y}_0) \in U$, the Picard iterates given by

$$\phi_0(t) = \mathbf{y}_0$$
$$\phi_n(t) = \mathbf{y}_0 + \int_{t_0}^{t} \mathbf{f}\left(s, \phi_{n-1}(s)\right) ds.$$

converge to a unique solution of the IVP up to the boundary of U [1]. In general, ϕ_n may converge slowly to the exact solution.

The Picard iteration based integrator described in this paper has three main advantages. The the integrator has arbitrary order, is time adaptive, and has dense output. Dense output refers to the integrator being able to take time steps of variable length without having to recompute previous steps. These advantages are intertwined to balance local truncation error with computational efficiency. When smaller time steps are required, the order can be reduced to maintain efficiency. When a larger time step is appropriate, the order can be increased to maintain lower local truncation error.

The advantages of the integrator make it well suited for modelling the motion of charged particles. The forces in Coulomb interactions are proportional to the inverse of the square of the distances between particles. There are situations such as when two particles with same signed charges are on a near collision course. If too large of a time step is taken, the large repulsive force between the particles as they move closer to one another may not be considered and the integrator will give physically unrealistic results. An integrator with dense output can avoid these errors.

* This work was supported in part by the U.S. Department of Energy, Office of Nuclear Physics, under Contract No. DE-SC0008588, and Office of High Energy Physics, under Contract No. DE-FG02-08ER41532, with Northern Illinois University.

THEORY BEHIND THE INTEGRATOR

First, we will introduce notation to write Taylor polynomials. When f has a Taylor series centered at a with nonzero radius of convergence, define the operator $\mathcal{T}_{t,a}^{n}$ acting on function f to be the degree n Taylor polynomial centered at a for f. That is

$$\mathcal{T}_{t,a}^{n}[f] = \sum_{k=0}^{n} f^{(k)}(a) \frac{(t-a)^k}{k!}.$$

Main Theorem Statement

The main theorem below supplies two Picard iteration based integrators with different compositions. From the initial Taylor polynomial $\mathcal{T}_{t,0}^{0}[\mathbf{z}(t)] = \mathbf{z}_0$, we can find the next Taylor polynomials using either recursive relationship below. After each iteration, the local truncation error drops by an order of magnitude. Algorithm 1 in the implementation and results section shows how to implement the first composition.

Theorem 1. *Let* $\mathbf{z}\,'(t) = \mathbf{f}(t)$ *and* $\mathbf{z}_0 = \mathbf{z}(0)$. *Suppose* $\mathbf{z}$ *has a Taylor series centered at* 0 *with nonzero radius of convergence* R *and* $t < R$, *then*

$$\mathcal{T}_{t,0}^{n}[\mathbf{z}(t)] = \mathbf{z}_0 + \int_0^t \mathcal{T}_{s,0}^{n-1}\left[\mathbf{f}\left(\mathcal{T}_{s,0}^{n-1}[\mathbf{z}(s)]\right)\right] ds$$
$$= \mathbf{z}_0 + \int_0^t \mathcal{T}_{s,0}^{n-1}\left[\mathcal{T}_{s,\mathbf{z}_0}^{n-1}[\mathbf{f}] \circ \mathcal{T}_{s,0}^{n-1}[\mathbf{z}(s)]\right] ds.$$

In order to prove theorem 1, we need two lemmas. In order to show the first lemma, we will need the Faà Di Bruno formula [2], which is a generalization of the chain rule.

Theorem 2 (Faà Di Bruno)**.** *If* g *and* f *are functions with a sufficient number of derivatives, then*

$$\frac{\mathrm{d}^m}{\mathrm{d}t^m} f(g(t)) = \sum \frac{m!}{\prod_{i=1}^{m} b_i!} f^{(k)}(g(t)) \prod_{i=1}^{m} \left(\frac{g^{(i)}(t)}{i!}\right)^{b_i}$$

where the sum is over all different solutions in nonnegative integers $b_1, \ldots, b_m$ *of* $b_1 + 2b_2 + \cdots + mb_m = m$ *and* $k \equiv b_1 + b_2 + \cdots + b_m$.

Let $S_{m,k}$ denote the nonnegative integer solutions of $b_1 + 2b_2 + \cdots + mb_m = m$ and $k \equiv b_1 + b_2 + \cdots + b_m$, and $T_{n,m,k}$ denote the nonnegative integer solutions of $b_1 + 2b_2 + \cdots + nb_n = m$ and $k \equiv b_1 + b_2 + \cdots + b_m$.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Lemma 1. *Suppose g has a Taylor series centered at a and f has a Taylor series centered at $g(a)$ with nonzero radii of convergence. Then,*

$$\mathcal{T}^n_{t,a}[f \circ g] = \mathcal{T}^n_{t,a}\left[\mathcal{T}^n_{t,g(a)}[f] \circ \mathcal{T}^n_{t,a}[g]\right].$$

Proof $\mathcal{T}^n_{t,a}\left[\mathcal{T}^n_{t,g(a)}[f] \circ \mathcal{T}^n_{t,a}[g]\right]$ will be directly evaluated. The two things needed to start are

$$\mathcal{T}^n_{t,a}[g] = \sum_{k=0}^{n} g^{(k)}(a)\frac{(t-a)^k}{k!}$$

and

$$\mathcal{T}^n_{t,g(a)}[f] = \sum_{k=0}^{n} f^{(k)}(g(a))\frac{(t-g(a))^k}{k!}.$$

Plugging the first one into the second one, the following can be done:

$$\begin{aligned}
&\mathcal{T}^n_{t,g(a)}[f] \circ \mathcal{T}^n_{t,a}[g] = \sum_{k=0}^{n} f^{(k)}(g(a))\frac{(\mathcal{T}^n_{t,a}[g]-g(a))^k}{k!}\\
&= \sum_{k=0}^{n}\frac{f^{(k)}(g(a))}{k!}\left(\sum_{i=0}^{n} g^{(i)}(a)\frac{(t-a)^i}{i!} - g(a)\right)^k\\
&= \sum_{k=0}^{n}\frac{f^{(k)}(g(a))}{k!}\left(\sum_{i=1}^{n}\frac{g^{(i)}(a)}{i!}(t-a)^i\right)^k\\
&= \sum_{k=0}^{n}\frac{f^{(k)}(g(a))}{k!}\sum_{T_{n,m,k}}\frac{k!}{\prod_{i=1}^n b_i!}\prod_{i=1}^{n}\left(\frac{g^{(i)}(a)}{i!}(t-a)^i\right)^{b_i}\\
&= \sum_{k=0}^{n}\sum_{T_{n,m,k}}\frac{f^{(k)}(g(a))}{k!}\frac{k!}{\prod_{i=1}^n b_i!}\prod_{i=1}^{n}\left(\frac{g^{(i)}(a)}{i!}(t-a)^i\right)^{b_i}.
\end{aligned}$$

The fourth step is done using a combinatorial argument. Think of each $\frac{g^{(i)}(a)}{i!}(t-a)^i$ as a letter α_i. What is being counted by $\frac{k!}{b_1!\,b_2!\,b_3!\ldots b_n!}$ is the number of words with k letters that have b_1 letter α_1's, b_2 letter α_2's, $\ldots$, and b_n letter α_n's.

In $T_{n,m,k}$, $m = b_1 + 2b_2 + \cdots + nb_n$. It must be that $b_i = 0$ when $i > m$ for $i = 1, 2, \cdots, n$. In $\mathcal{T}^n_{t,a}\left[\mathcal{T}^n_{t,g(a)}[f] \circ \mathcal{T}^n_{t,a}[g]\right]$ each term has degree n or less, so $m \le n$. In this case, $T_{n,m,k} = S_{m,k}$, and we have

$$\begin{aligned}
&\mathcal{T}^n_{t,a}\left[\mathcal{T}^n_{t,g(a)}[f] \circ \mathcal{T}^n_{t,a}[g]\right]\\
&= \sum_{k=0}^{n}\sum_{S_{m,k}}\frac{(t-a)^m}{m!}\frac{m!}{\prod_{i=1}^m b_i!}f^{(k)}(g(a))\prod_{i=1}^{m}\left(\frac{g^{(i)}(a)}{i!}\right)^{b_i}\\
&= \sum_{m=0}^{n}\frac{(t-a)^m}{m!}\sum_{S_{m,k}}\frac{m!}{\prod_{i=1}^m b_i!}f^{(k)}(g(a))\prod_{i=1}^{m}\left(\frac{g^{(i)}(a)}{i!}\right)^{b_i}\\
&= \sum_{m=0}^{n}\frac{(t-a)^m}{m!}\frac{\mathrm{d}^m}{\mathrm{d}t^m}f(g(t))\\
&= \mathcal{T}^n_{t,a}[f \circ g].
\end{aligned}$$

□

Lemma 2. *Suppose g has a Taylor series centered at a and f has a Taylor series centered at $g(a)$ with nonzero radii of convergence. Then,*

$$\mathcal{T}^n_{t,a}\left[f(\mathcal{T}^n_{t,a}[g])\right] = \mathcal{T}^n_{t,a}[f \circ g].$$

Proof

$$\begin{aligned}
\mathcal{T}^n_{t,a}\left[f(\mathcal{T}^n_{t,a}[g])\right] &= \mathcal{T}^n_{t,a}\left[f \circ (\mathcal{T}^n_{t,a}[g])\right]\\
&= \mathcal{T}^n_{t,a}\left[\mathcal{T}^n_{t,(\mathcal{T}^n_{t,a}[g])(a)}[f] \circ \mathcal{T}^n_{t,a}\left[\mathcal{T}^n_{t,a}[g]\right]\right]\\
&= \mathcal{T}^n_{t,a}\left[\mathcal{T}^n_{t,g(a)}[f] \circ \mathcal{T}^n_{t,a}[g]\right]\\
&= \mathcal{T}^n_{t,a}\left[f \circ g\right]
\end{aligned}$$

The second line is from applying lemma 1. The third line can be seen noting that $\left(\mathcal{T}^n_{t,a}[g]\right)(a) = g^{(0)}(a) = g(a)$ and $\mathcal{T}^n_{t,a} \circ \mathcal{T}^n_{t,a} = \mathcal{T}^n_{t,a}$. □

We are now ready to prove theorem 1.

Proof From lemma 2,

$$\mathcal{T}^{n-1}_{s,0}\left[\mathbf{f}\left(\mathcal{T}^{n-1}_{s,0}[\mathbf{z}(s)]\right)\right] = \mathcal{T}^{n-1}_{s,0}\left[\mathbf{f}\left(\mathbf{z}(s)\right)\right].$$

This implies

$$\begin{aligned}
&\mathbf{z}_0 + \int_0^t \mathcal{T}^{n-1}_{s,0}\left[\mathbf{f}\left(\mathcal{T}^{n-1}_{s,0}[\mathbf{z}(s)]\right)\right]ds\\
&= \mathbf{z}_0 + \int_0^t \mathcal{T}^{n-1}_{s,0}\left[\mathbf{f}\left(\mathbf{v}(s)\right)\right]ds\\
&= \mathbf{z}_0 + \int_0^t \sum_{k=0}^{n-1}\frac{\mathrm{d}^k}{\mathrm{d}s^k}\left[\mathbf{f}\left(\mathbf{z}(s)\right)\right](0)\frac{(s)^k}{k!}ds\\
&= \mathbf{z}_0 + \sum_{k=0}^{n-1}\int_0^t \frac{\mathrm{d}^k}{\mathrm{d}s^k}\left[\mathbf{f}\left(\mathbf{z}(s)\right)\right](0)\frac{(s)^k}{k!}ds\\
&= \mathbf{z}_0 + \sum_{k=0}^{n-1}\frac{\mathrm{d}^k}{\mathrm{d}s^k}\left[\mathbf{f}\left(\mathbf{z}(s)\right)\right](0)\int_0^t \frac{(s)^k}{k!}ds\\
&= \mathbf{z}_0 + \sum_{k=0}^{n-1}\frac{\mathrm{d}^k}{\mathrm{d}t^k}\left[\mathbf{f}\left(\mathbf{z}(t)\right)\right](0)\frac{t^{k+1}}{(k+1)!}\\
&= \mathbf{z}_0 + \sum_{k=0}^{n-1}\mathbf{z}^{(k+1)}(0)\frac{t^{k+1}}{(k+1)!}\\
&= \sum_{k=0}^{n}\mathbf{z}^{(k)}(0)\frac{t^k}{k!}ds = \mathcal{T}^n_{t,0}[\mathbf{z}(t)].
\end{aligned}$$

From lemma 1,

$$\mathcal{T}^{n-1}_{s,0}\left[\mathbf{f}\left(\mathbf{z}(s)\right)\right] = \mathcal{T}^{n-1}_{s,0}\left[\mathcal{T}^{n-1}_{s,\mathbf{z}(0)}[\mathbf{f}] \circ \mathcal{T}^{n-1}_{s,0}[\mathbf{z}(s)]\right].$$

It follows then that

$$\begin{aligned}
\mathcal{T}^n_{t,0}[\mathbf{z}(t)] &= \mathbf{z}_0 + \int_0^t \mathcal{T}^{n-1}_{s,0}\left[\mathbf{f}\left(\mathcal{T}^{n-1}_{s,0}[\mathbf{z}(s)]\right)\right]ds\\
&= \mathbf{z}_0 + \int_0^t \mathcal{T}^{n-1}_{s,0}\left[\mathcal{T}^{n-1}_{s,\mathbf{z}_0}[\mathbf{f}] \circ \mathcal{T}^{n-1}_{s,0}[\mathbf{z}(s)]\right]ds.
\end{aligned}$$

IMPLEMENTATION AND RESULTS

Implementation

The Picard iteration based integrator was implemented using COSY INFINITY. COSY has several unique data types including differential algebra (DA) vectors which were used to store the Taylor polynomials. Many operations on DA vectors are also efficiently coded into COSY such as polynomial multiplication and composition. Built in operations allow for computing the Taylor expansions of various functions to specified order [3].

Algorithm 1 below describes how to compute $\mathbf{z}(t)$ at the points $t = \frac{T}{N}, \frac{2T}{N}, \cdots, T$. Here, T is the total time interval under investigation with N time steps of length Δt. This algorithm uses the first composition in Theorem 1.

Algorithm 1 Picard Iteration Based Integrator

input $\mathbf{z}_0,\ \mathbf{f}(\mathbf{z},t)\ T,\ N,$ Tolerance
$\Delta t \leftarrow \frac{T}{N}$
$\hat{\mathbf{z}_0} \leftarrow \mathbf{z}_0$
for $i = 1 \rightarrow N$ **do**
  Compute the "best" smaller time step to use $\frac{\Delta t}{M}$, and an appropriate ORDER for the Taylor series that keeps the local truncation error $\mathcal{O}$(Tolerance).
  $\hat{t} \leftarrow \frac{\Delta t}{M}$
  for $j = 1 \rightarrow M$ **do**
    $\phi_0(t) \leftarrow \hat{\mathbf{z}}_0$
    for $k = 1 \rightarrow$ ORDER **do**
      $\phi_k(t) \leftarrow \hat{\mathbf{z}}_0 + \int_0^t \mathcal{T}_{s,0}^{k-1} \left[\mathbf{f}\left(\phi_{k-1}(s), s\right)\right] ds$
    end for
    $\hat{\mathbf{z}}_0 \leftarrow \phi_{\text{ORDER}}(\hat{t})$
      ▷ *The above is* $\mathbf{z}\left([i-1+j/M]\Delta t\right)$.
  end for
  Write $\hat{\mathbf{z}}_0$ ▷ *This is* $\mathbf{z}(i\Delta t)$.
end for

In the loop from $j = 1$ to $j = M$ the time scale for the initial value problem is shifted left when j increases so that the initial condition involves $t_0 = 0$.

$$\begin{cases} \mathbf{z}' = \mathbf{f}(t, \mathbf{z}) \\ \mathbf{z}(t_0) = \mathbf{z}_0 \end{cases} \rightarrow \begin{cases} \mathbf{z}' = \mathbf{f}(t - t_0, \mathbf{z}) \\ \mathbf{z}(0) = \mathbf{z}_0 \end{cases}$$

This matches the conditions for Theorem 1 and reduces the work of evaluating the definite integral by making the second indefinite integral evaluation 0.

Results

One test of the integrator was to consider a system with a proton following a circular orbit around another super massive particle with opposite charge. The momentum of the proton was set at $\frac{2\,m\,c}{3\times10^5}$ where m is the mass of a proton, and the mass of the massive particle was set at $10^{40}\ m$. Balancing the centrifugal and Coulomb forces, the radius of the orbit is approximately $0.512 \times 10^{-5} m$. For this test, the time step is fixed at around $\frac{0.24169}{c}$s. The theoretical trajectory and integrator computation for the four thousandth orbit are plotted in Fig. 1 as thick black semicircles and red circled points, respectively.

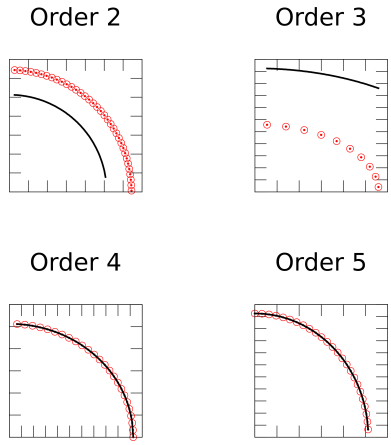

Figure 1: Orbiting Particle Trajectories at Different Orders

Additional details concerning the integrator's performance have been studied [4].

CONCLUSION

By utilizing the Picard iteration based integrator described, a wide class of functions can be integrated numerically. The integrator has the advantages of being variable order, being time adaptive, and having dense output. These advantages have been utilized in a successful implementation to solve Coulomb interactions using COSY INFINITY.

A USER FRIENDLY, MODULAR SIMULATION TOOL FOR LASER-ELECTRON INTERACTIONS*

S. Seung, G. Andonian, M. A. Harrison, S. Wu (RadiaBeam, Santa Monica), T. Shaftan (BNL, Upton, Long Island, New York), D. L. Bruhwiler (University of Colorado at Boulder, CIPS)

Abstract

The code RadTrack was developed to accurately model observable beam parameters in real laboratory environments RadTrack is a fast, reliable computational application that can calculate radiation observables in complex interactions between realistic laser and electron beam distributions. The interaction between laser and electron beams is important in processes such as inverse Compton scattering and inverse free electron laser schemes. Modeling these interactions, RadTrack incorporates functions from Synchrotron Radiation Workshop (SRW) with full parsing support to capitalize on well-established radiation generation and propagation code available for start-to-end simulations, while expanding simulated radiation to x-ray regimes [1]. RadTrack is based on the Python environment, which uses a hierarchal module system and possesses built-in data types that will allow further expansions of the code. The code provides an intuitive visualization work canvas that emphasizes the users overall objective.

INTRODUCTION

RadTrack is designed to addresses a number of issues in the accelerator community, with special attention to the radiation properties for direct comparison to available diagnostics. To achieve this, the code emphasizes modularity, breaking down these issues into digestible pieces. The graphical user interface is built on a visualization canvas that easily generates and displays important information. The interface is intuitive for seamless management of start-to-end simulations, which incorporate several codes. The interface allows for simple parallelization for complex, memory demanding calculations. RadTrack was developed as a code that can calculate beam dynamics as well as emitted radiation processes, in a transparent, intuitive manner,.

Complete modelling of a beam from its inception to detection, requires a complicated string of start-to-end studies, employing a concatenation of various function-specific simulations to achieve a high degree of confidence in the final outcome. RadTrack is specifically designed to address start-to-end simulations by seamlessly stitching I/O from various codes and file formats.

The code, RadTrack, was originally developed as an extension to the radiation code QUINDI [2] to calculate the radiative effects of bending beam trajectories. QUINDI was developed for a specific problem and its results benchmarked to experiments at Brookhaven National Laboratory Accelerator Test Facility [3]. RadTrack makes use of QUINDI's particle tracker and radiation field solver, which are based on the Lorentz for and Lienerd-Wiechert potentials, respectively [4]. RadTrack is able to generate laser and electron beam distributions and pass these distributions through an extensive library of optics, magnets and diagnostics, in particular, the use of undulators is important to many laser electron interaction schemes, such as laser heating, laser slicing and sub-femtosecond temporal diagnostics. Figure 1 displays the work flow and modular philosophy of the code; this is advantageous for implementation of the functions, where multiple outputs of codes are parsed as inputs into subsequent codes.

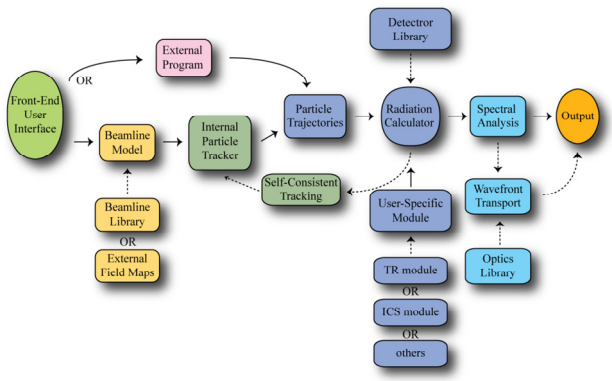

Figure 1: Work flow chart between physics modules, radiation modules, wave front propagator and various libraries.

LASER-ELECTRON INTERACTIONS

The motivation to develop a comprehensive software package that incorporates detailed beam dynamics calculations and radiation interactions has roots in many scientific cases prevalent throughout the advanced accelerator and light communities. Here are some laser electron interactions and their applications:

- The laser-heater is a laser-electron electron interaction in an undulator that increases the beam energy spread in a controllable way to reduce microbunching instability.
- The interaction between a relativistic electron beam and a high power laser induces an undulator-like radiation process that have the ability to produce short wavelength photons [5].
- The interaction between the laser and electron bunch is used to generate a beam energy modulation on the 100 femtosecond scale in storage rings.

* This work is supported by US DOE Grant No. DE-SC0006284.

Copyright © 2013 CC-BY-3.0 and by the respective authors

- Recent studies have explored the use of an advanced laser-electron interaction coupled inside an undulator, resonant at the laser wavelength, to achieve sub-femtosecond resolution on the electron beam longitudinal profile [6].
- The recent echo-enabled FEL projects reported from SLAC describe the energy modulation due to a laser in two undulators resonant at the laser frequency or harmonic [7]. The code Genesis can model this FEL experiment [8].

INPUT DATA VISUALIZATION

Laser and Particle Distribution

RadTrack incorporates an instinctive beam distribution panel. Initial beam parameters (used for the source particles) are defined and a 6-dimensional phase space distribution is generated. The user specified inputs include beam moments, correlations, various degrees of noise, and complex modulations or Courant-Snyder parameters. This panel also supports the importing of 6-dimensional particle distributions from external codes, such as ELEGANT [9]. Alteration of beam parameters is handled by textual input or sliders and buttons on the graphical displays, allowing for intuitive creation of particle distributions (such as rescaling of twiss parameters).

Generation of an initial laser distribution is handled in a similar manner, with interface analogues of the particle beam distribution panel. The inputs include wavelength, transverse profile, longitudinal profile, power, beam waist sizes and chirp factor.

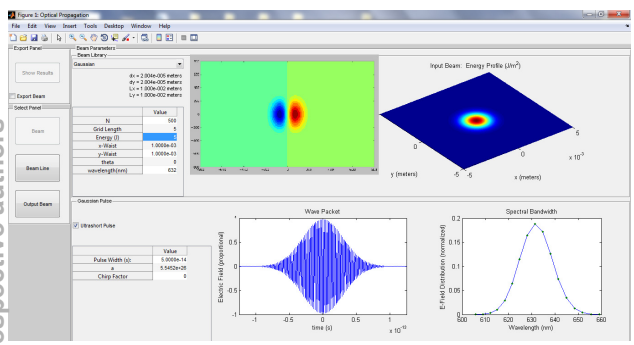

Figure 2: Laser beam generator I/O page from RadTrack, displaying a Gaussian profile, a simple MxN profile and temporal distribution

Beamline Constructor

The definition of the beamline lattice is addressed graphically in RadTrack. Beamline elements, such as drifts, bending magnets, quadrupoles, undulators, etc. are selectable and editable in a text dialog. The reference particle trajectory is calculated and plotted through the displayed beamline for immediate visualization (and error-checking). RadTrack allows for the placement of the detector for radiative processes at arbitrary locations, defined by beam offsets and rotations in the form of Euler angles. This allows for the modelling of bending radiation, such as synchrotron or edge radiation.

Generation of an optical beamline is also graphically generated in RadTrack, with panel analogues of the particle beamline lattice generator.

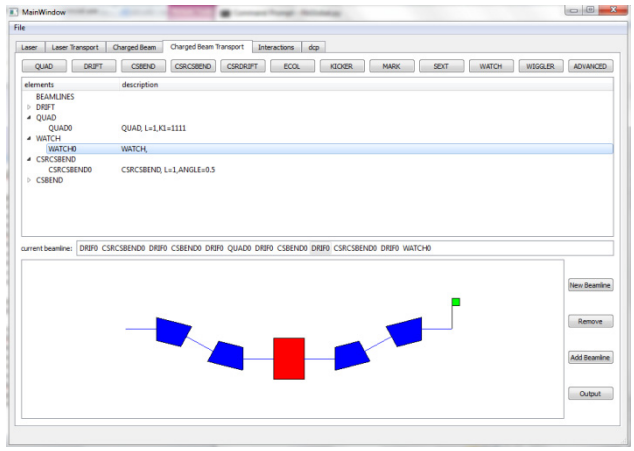

Figure 3: Beamline constructor written in Python with a streamlined interface and dynamic graphical previews.

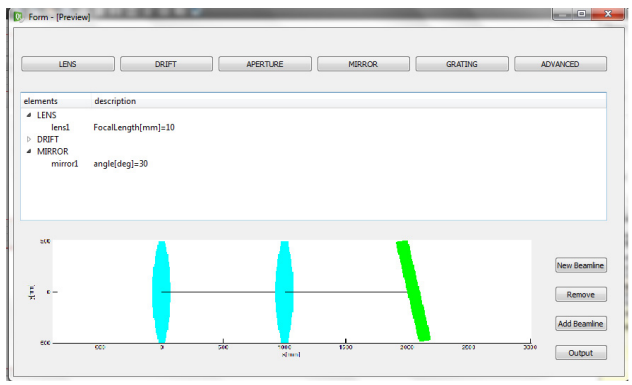

Figure 4: Optical beamline constructor

Originally written in MatLab, RadTrack has been slowly ported over to Python, offering more dynamic and streamlined controls. RadTrack is now equipped with very intuitive drag and drop abilities, where elements created by the user can be dragged from an organized list of available elements and dropped into a beamline. The graphics are also dynamic, as a graphical preview is generated when a user clicks on an element or beamline, and as a user creates a beamline. From there, a user can output a file that can be tuned as an ELEGANT input file or other external codes.

OUTPUT DATA VISUALIZATION

Added to RadTrack is the ability to view and explore data files generated from external code, such as ELEGANT, SRW, QUINDI, plain text files, etc... Parsers were written to identify simulation parameters, display

Copyright © 2013 CC-BY-3.0 and by the respective authors

the data in tables. Drop down menus allow the user to select which data sets to graph and RadTrack automatically labels the x and y axis. A toolbar is implemented to be able to zoom in, edit and save graphs. Very large files are broken down into pages and previewed in tables. Convenient functions allow RadTrack to identify filenames and current directories. Some mathematical functionality, such as Fourier transforms and running averages are able to be performed on desired data sets.

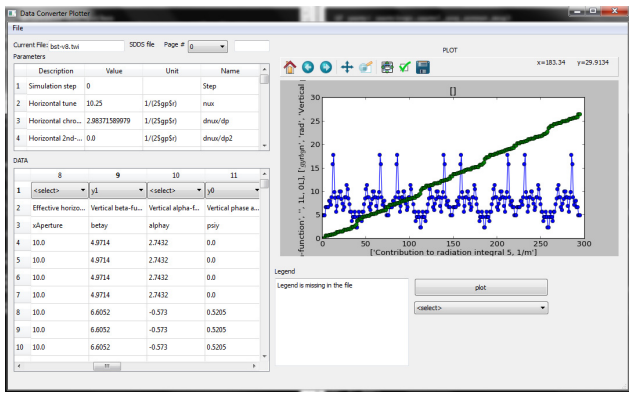

Figure 5: Viewing and plotting data from a self-describing data set (SDDS) [5] file, plotted is the horizontal beta function (blue) and the vertical phase advance (green).

CONCLUSION

RadTrack is a user-friendly tool used for the calculation of beam trajectories and emitted radiation of high brightness beams. The novel user-interface is accessible to a wide range of users and incorporates intuitive features such as the visualization of beam phase space densities and the graphical display of beamline lattice files in real time. It also incorporates a seamless method for start-to-end simulations and parallel extensions via the project management aide. Laser-electron interactions have myriad applications in Free Electron Lasers, ultrafast diagnostics, inverse Compton scattering, laser heating and slicing. One can easily see the convenience of being able to simulate all these processes and devices in a single easy to use interface.

MULTIPACTING SIMULATION OF ACCELERATOR CAVITIES USING ACE3P*

Lixin Ge, Kwok Ko, Zenghai Li, Cho-Kuen Ng and Liling Xiao
SLAC, Menlo Park, CA 94025, U.S.A

Abstract

ACE3P [1] is a 3D parallel finite element code suite for cavity design and optimization including electromagnetic, thermal and mechanical effects. Taking advantages of the power of computing on multi processors, ACE3P's particle tracking module Track3P allows efficient multipacting (MP) simulation by extensive scanning in field gradient and on cavity surface to identify the occurrences of MP activities. The output from Track3P simulation includes the determination of resonant trajectories and their locations, the calculation of electron impact energy on cavity surface, and the evaluation of the electron enhancement counter as a function of field gradient. The sensitivity of MP on secondary emission yield can be readily obtained through post processing. The basic capabilities of Track3P for MP simulation will be presented.

INTRODUCTION

Multipacting (MP) is an undesireable, resonant built-up of electrons inside RF structures. It can cause wall heating and high power breakdown of RF components, prolong processing time and limit the achievable design field gradient. While most of the soft MP barriers could be processed through RF, the presence of a hard MP barrier prevents a RF component from reaching its design power or field gradient level.

Much work has been done on MP studies to identify potential MP events and to mitigate MP activities. In recent years, with more computing power, full 3D simulation tools have been developed to investigate potential MP activities. High resolution EM field, correct representation of particle emission from curved surface, realistic SEY curve for surface material and comprehensive post-processing of particle data to identify MP events are the basic requirements for accurately simulation of MP. Furthermore, the use of high performance computing allows efficient MP simulation by making use of hundreds to thousands of CPU cores running in parallel, by which the speedup in computation time facilitates extensive parameter scans. Track3P, a 3D parallel particle tracking code, provides a MP simulation tool with these advanced modeling and computational features. It has been extensively benchmarked against experiments and applied to model and predict MP activities for the design of many accelerator cavities and RF components.

MULTIPACTING SIMULATION USING ACE3P

ACE3P

ACE3P (Advanced Computational Electromagnetics 3D Parallel) is a comprehensive set of conformal, higher-order, parallel finite-element electromagnetic codes with two unique features. First, it is based on higher-order curved finite element method for high-fidelity modeling and improved solution accuracy. Second, it is implemented on massively parallel computers for increased memory (problem size) and speed. The six modules of ACE3P cover a wide range of simulation capabilities for accelerators: Omega3P for calculating cavity modes and damping, and S3P for transmission in open structures in frequency domain; T3P for calculating wakefields and transients in time domain; Track3P for MP and dark current studies using particle tracking; Pic3P for RF gun design with particle-in-cell (PIC) method; and TEM3P for multi-physics analysis including EM, thermal and mechanical effects.

Track3P Characteristics

Track3P provides accurate and efficient simulation for MP by tracking particle trajectories under the influence of RF fields or external static fields. The RF field in an accelerator structure is first solved by Omega3P or S3P, which calculates the EM field to high accuracy using higher-order basis functions (up to 6^{th} order), and then loaded into Track3P for particle tracking. In a similar manner, external static electric and magnetic fields can be read into the code as input field data. The high-fidelity geometry representation built in the finite-element method allows realistic modeling of particle emission on cavity wall. Track3P constructs the MP map by identifying resonant particle trajectories. With a realistic secondary electron yield (SEY) curve provided by experiments, Track3P can calculate the particle enhancement counter and locate MP regions. This is achieved using the versatile postprocssing tools that have been developed to identify the onset of MP through various parameter scans.

MP Module in Track3P

The following describes the procedure for modeling MP in Track3P. Electrons with specified kinetic energy and emission direction are launched from specific surfaces at different phases over a full RF period. The initial launched electrons follow the electromagnetic fields in the structure and eventually hit the boundary,

Copyright © 2013 CC-BY-3.0 and by the respective authors

where secondary electrons are emitted. The tracing of electrons will continue for a specified number of RF cycles, after which MP trajectories are determined and the MP types (order: # of RF cycles to return to the original site; point: # of sites on the wall) are identified. The necessary condition for MP is when the trajectory traced out by consecutive emissions is in resonance with the RF cycle. These particles impact on the surface at the same locations with the same impact energy. When the impact energy falls in the range with SEY greater than unity, the resonant trajectory is considered as a MP event. One can also estimate the strength (soft or hard) of the MP event by the value of the SEY.

TRACK3P SIMULATION CAPABILITIES

Track3P has been extensively benchmarked against theories and measurements [2-7]. In a typical MP run, Track3P generates a large amount of particle and field information data such as the position and momentum as a function of time and the history of particles in a resonant trajectory. Various diagnostics and postprocessing tools have been developed to provide simulation capabilities for modeling MP in realistic cavities for accelerator projects. The basic capabilities are as follows.

Determination of Resonant Trajectories

MP activities are due to the resonant built-up of electrons inside an RF structure. The first step to identify the occurrences of MP is the formation of resonant particle trajectories. Based on the resonant particle information, one can identify potential MP locations, types (order and points), and determine impact energies. Fig. 1 shows the locations of resonant particles in the HOM coupler of the SNS SRF cavity at the field level of 4.22 MV/m. The resonant particles are located at the coupler gap region. By drawing out one typical resonant trajectory, the MP type is found to be first order and two point, with impact energies 490 eV and 650 eV on the inner and outer walls of the gap, respectively [8].

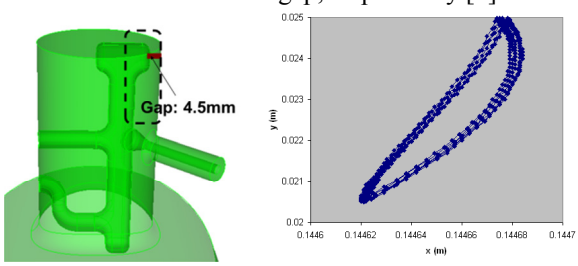

Figure 1: MP simulation of SNS HOM coupler. Left: Locations of particles with resonant trajectories; Right: A resonant trajectory at 4.22 MV/m field gradient.

Construction of MP Susceptible Zones

The main objective of MP simulation is to determine the field levels at which potential MP activities occur. In Track3P simulation, the tracking of particles will be carried out by scanning a range of field levels at a prescribed field step increment. Resonant particles are identified at each field level, and based on this information it is possible to construct potential MP zones. Fig. 2 shows the impact energy as a function of field level for the FRIB Quarter Wave Resonator (QWR) and the locations of the impact positions of resonant particles at all field levels [4]. A hard barrier MP band is found at low field levels from 800V to 7.5kV, with impact energies corresponding to SEY values near its peak. The simulation result agrees well with the high power test data which showed a processing barrier at 1.2kV ~ 7.2kV.

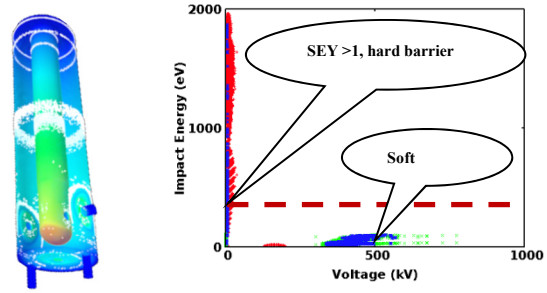

Figure 2: MP simulation for FRIB Quarter Wave Resonator. Left: Resonant particle impact positions at all field levels; Right: Impact energy vs. accelerating voltage for particles with resonant trajectories. Red color indicates resonant particles at the top region of cavity, and green at the middle and blue at the bottom.

Calculation of Enhancement Counter

One parameter to quantify MP is the enhancement counter, which is given by

$$\mathrm{ec} = \delta_1 * \delta_2 * \cdots \delta_m$$

where $\delta_1, \delta_2 \cdots \delta_m$ are the number of secondary electrons generated at the 1st, 2nd, … mth impacts determined by the SEY curve. Generally, when ec > 1, there will be potential MP activities. The larger the ec is, the harder the MP barrier. In Track3P simulation, the calculation of the enhancement counter is treated in postprocessing by applying the SEY on the impact energies of resonant particles, and thus one can use different SEY curves to estimate the effects of different surface material properties from a single computer run. Fig. 3 shows the MP simulation results for the MICE 201 MHz cavity [9]. Three enhancement counters are plotted using three different SEY curves [10]. Although the SEY curves have different magnitudes for the range of electron impact energies, the peak enhancement counter is found in the same region at the field levels of 2~4 MV/m. As a result, this MP event is believed to be a hard barrier.

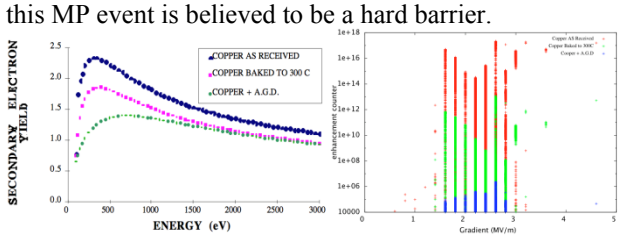

Figure 3: MP simulation for MICE 201 MHz cavity. Left: Three SEY curves; Right: Enhancement counters calculated using the three SEY curves.

Effects of External Magnetic Field

In addition to loading Omega3P or S3P field, Track3P can load external magnetic field as input. This feature has been applied to improve the designs of the 805 MHz and 201 MHz Muon cooling cavities by studying external magnetic field effects [6]. Fig. 4 shows the location of resonant particle activities around the coupler iris of the prototype 805 MHz Muon cooling cavity without external magnetic field and with 3T solenoid magnetic field. It can be seen that MP activities appear at different locations of the coupling iris.

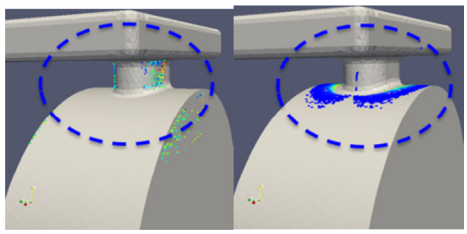

Figure 4: Resonant particle activities around coupler iris for the prototype 805 MHz Muon cooling cavity. Left is with 3T external magnetic field; Right is without external magnetic field.

Modeling of RF Window

The study of ceramic windows such as in couplers requires the implementation of emission on internal surface of the model [2]. Fig. 5 shows the simulation result for the TTFIII coupler with a ceramic window. A 2-point resonant trajectory occurs between the ceramic window and the inner conductor on the cold side of the coupler.

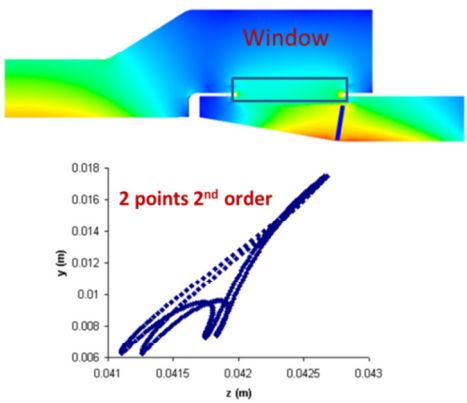

Figure 5: Resonant particle activities in the window region of the TTFIII coupler. Top: the electric field pattern; Bottom: a close-up of the resonant trajectory between the window and the metal wall.

Mitigation of Multipacting

Once MP activities are found in a cavity design, their effects can be mitigated by modifying the geometry where they occur [6]. In conjunction with Omega3P for calculating the RF fields, Track3P can evaluate MP effects at each iteration of the geometry change. For example, the original 805 MHz Muon cooling cavity suffered from severe gradient degradation and surface damage. Through simulation, a new design is achieved which significantly reduces the peak surface field by rounding the coupling slot and using an elliptical disk (see Fig. 6).

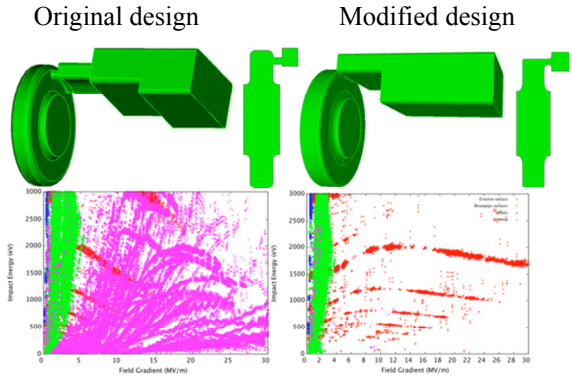

Figure 6: MP studies for 805 MHz Muon cooling cavity. MP locations: Windows (green); Disk rounding (blue); Coupling iris (magenta); Others (red).

SUMMARY

Track3P is the particle tracking module of the parallel finite-element code suite ACE3P and has been applied to study multipacting in accelerator cavities. Running on massively parallel computers, Track3P provides an efficient simulation tool in identifying multipacting barriers, locations and types of trajectories during the design or operation process of cavities. Track3P has been extensively used to study multipacting activities in many accelerator cavities and helps successfully mitigate multipacting effects and thus improve cavity designs.

INTER-BUNCH COMMUNICATION THROUGH CSR IN WHISPERING GALLERY MODES*

R. Warnock †, SLAC National Accelerator Laboratory, Menlo Park, CA, USA
J. Bergstrom, Canadian Light Source, Saskatoon, SK, Canada
M. Klein, Synchrotron SOLEIL, Gif-sur-Yvette, France

Abstract

Theory predicts that coherent synchrotron radiation (CSR) in electron storage rings should appear in whispering gallery modes, which are resonant modes of the vacuum chamber, characterized by their high frequencies and concentration near the outer wall of the chamber. Such modes produce an extended wake field behind a particle bunch, which can influence the CSR from a succeeding bunch in a train. We review experimental evidence for the resonances and for the inter-bunch communication. We then present a calculation based on coupled Vlasov-Fokker-Planck equations which confirms an effect seen experimentally, namely that increasing the charge in a leading bunch increases the radiation from a following bunch.

RESONANCES: THEORY AND EVIDENCE

Synchrotron radiation in electron accelerators is strongly affected by the metallic vacuum chamber surrounding the beam, as was already shown theoretically by Schwinger in 1945 [1]. In the parallel plate model of the chamber [1] there is an exponential suppression of radiation at wavelengths greater than $\lambda_0 \approx 2h(h/R)^{1/2}$, where h is the separation of infinite conducting plates, and R is the radius of the particle's circular trajectory lying in the midplane. The model is made more realistic by adding conducting side walls perpendicular to the plates, so that the beam moves in a circular torus of rectangular cross section, with width w and height h. For w of order h, the cutoff λ_0 is roughly the same as before, but a markedly different physical picture emerges.

Radiation to infinity is now forbidden, and radiation synchronous with the beam appears in resonant modes, sharply concentrated in frequency [2]. We call these *whispering gallery modes*, because of a close analog in acoustics [3]; similar phenomena are widely studied in RF engineering and optics. .

A theoretical spectrum of resonant modes is shown in Fig. 1, which is a plot of the real part of the radiation impedance $Z(k)$ for a beam centered in a circular torus with rectangular cross-section and resistive walls of conductivity σ [2]. The parameters correspond to those of the ANKA light source in Karlsruhe: $R = 5.559$m, $w = 6.8$cm, $h = 3.2$cm, $\sigma = 1.33 \cdot 10^6$ (SI units). The power spectrum of CSR is proportional to $ReZ(k)|\hat{\lambda}(k)|^2$, where $\hat{\lambda}(k)$ is the Fourier transform of the bunch profile.

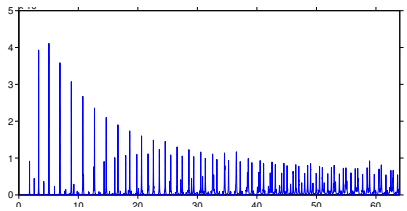

Figure 1: Re $Z(k)$ in ohms for ANKA parameters, vs. $k = 1/\lambda$ in cm^{-1}.

At ANKA and other light sources (CLS, BESSY, MLS, *et al.*) there are large flared vacuum chambers where the IR radiation is extracted, and these may alter the observed spectrum in comparison to that of the smooth toroidal model. The longitudinal electric field $E(s,t)$ may always be regarded as a function of the two independent variables $z = s - \beta ct$ and s. That leads to the concept of position dependent wake $\mathcal{W}(z,s)$. We define

$$\mathcal{W}(z,s) = E(s,t)\ ,\ \bar{\mathcal{W}}(z) = \frac{1}{C}\int_0^C \mathcal{W}(z,s)ds\ . \quad (1)$$

The average $\bar{\mathcal{W}}(z)$ over the circumference C is probably adequate to describe the bunch dynamics, since the synchrotron period is large compared to the revolution time. We suppose that $\bar{\mathcal{W}}$ can be approximated as the wake from the impedance of the smooth toroidal model, with central radius R equal to the bending radius of the dipoles.

Note that an interferometer at the position $s = s_{IR}$ of a flared IR chamber will see a field with time dependence given by $\mathcal{W}(z - \beta ct, s_{IR})$, in general different from the time dependence of $\bar{\mathcal{W}}(z - \beta ct)$. Specific theoretical modeling of fields in the flared chamber will be necessary to compare interferometer data with theory.

In an older ring, the NSLS-VUV at Brookhaven, the IR chamber is the same as in other dipoles, so the aforementioned difficulty is not so severe. Moreover, a power spectrum was measured at VUV in the bursting CSR mode, using a Michelson interferometer and also microwave techniques. In Ref.[4] a good fit of the model to experimental positions of spectral lines was shown. Zhou [5] did a similar fit including straight sections, but with less detailed discussion of low frequency lines. The straights induce a width of the lines, which could be part if not all of the explanation of experimental widths.

Spectra of CSR have been observed with high precision at the Canadian Light Source (CLS), by using an interferometer with resolution down to 0.001 cm^{-1}. The spectra show a remarkable stability with respect to changes in the machine setup and the structure of the IR beam line. Figure 2 compares a power spectrum (red) taken in the bursting mode of CSR with one bunch at 2.9 GeV, on 18/5/2010, with another (blue) taken in the continuous mode with 210 bunches at 1.5 GeV, on 30/1/2012. The latter was multiplied by a factor of 8 to aid comparison. Because of the large change in the beam one expects the positions of peaks to agree better than the relative heights, as is found, but even the relative heights show a lot of similarity between the two runs. We take this stability as a strong indication that the spectrum is determined primarily by the vacuum chamber and bends.

The form of the IR chamber at CLS is shown in Fig. 3. Equations to model fields in this structure are under study. As the crudest approximation we can try the simple toroidal model with an increased distance d from the beam to the outer wall. With $d = 33$cm the spacing of the dominant TE modes [2] is $\Delta k = \Delta(1/\lambda) = 0.073\mathrm{cm}^{-1}$, fitting the fine structure of the spectral data.

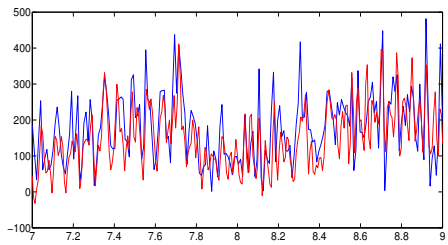

Figure 2: CLS spectra from two very different runs, power (a.u.) vs. k in cm^{-1}.

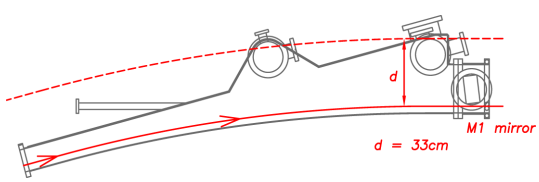

Figure 3: Vacuum chamber of CLS at dipole where IR is extracted

LONG RANGE WAKE FIELD: THEORY AND EVIDENCE

An impedance like that of Fig. 1 implies an appreciable wake field at long distances from the bunch, much greater than the bunch length. Fig. 4 shows the wake potential corresponding to Fig. 1, as a function of distance in centimeters, with the head of the bunch on the right. A feature of the model, if not of the real system, is that the wake wraps all the way around the ring, resulting in a precursor field in front of the bunch. If we try to model the wake field expected at the IR chamber of the CLS, using the effective beam-to-wall distance d as mentioned above, we get the rather different long-range wake pattern of Fig. 5.

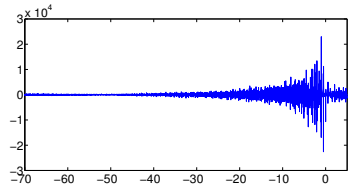

Figure 4: Wake potential $W(z)$ in V/pC from impedance of Fig. 1., vs. z in cm.

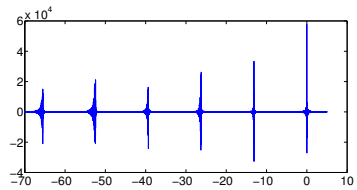

Figure 5: Wake potential for CLS model with $d = 33$cm.

Experiments which aspire to observe the wake field directly were carried out at the CLS, following an idea of S. Kramer to put a microwave horn and diode detector at a backward port (in the horizontal pipe seen in Fig. 3) in one of the two IR dipole chambers. The diode has a bandwidth of roughly 50-75 GHz, and receives signals traveling opposite to the direction of the beam, which might come from backward reflections off structures present in the chamber. Fig. 6 shows a typical oscilloscope trace of the diode signal. Labeling the prominent *downward* peaks from left to right as 1 to 4, we have a plausible explanation as follows: 1 and 2 are reflections from the first downstream obstacle in the flared chamber, a copper photon absorber (in second circle from right in Fig. 3), whereas 3 and 4 are from the next obstacle, a structure supporting the M1 pick-off mirror. The 1-3 separation corresponds closely to the separation of these obstacles. Peak 1 is seen as the prompt wake field from the bunch, while peak 2 is a delayed pulse in the wake field, about 13.5 cm behind the bunch; similarly for 3 and 4, coming from the later reflection. The point to emphasize is that the distance from bunch to delayed wake pulse is very close to the reciprocal of the average spacing of peaks in the power spectrum shown in Fig. 2, namely $\Delta k \approx 0.073\mathrm{cm}^{-1}$. Correspondingly, the distance between the center burst and the first side peak in the interferogram is 13.5cm, as is the spacing of peaks in the naive theory of Fig. 5.

The interpretation of the peaks in terms of reflections is given added weight by a second experiment in which the diode was moved to a "normal" dipole chamber. That resembles the special IR chamber, but lacks the pick-off mirror and has a slotted wall (centered slot of width 1 cm) between the beam and the large flared box. The analog of

Copyright © 2013 CC-BY-3.0 and by the respective authors

peaks 1-2 is seen, but that of 3-4 goes away, in accord with the absence of the mirror support structure.

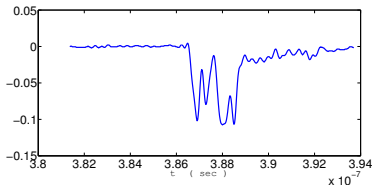

Figure 6: Signal (a.u.) from backward viewing diode at CLS vs. time in seconds.

Further evidence of a long range wake field comes from an experiment at ANKA by V. Judin [6] and collaborators. This observed THz radiation with a fast bolometer having sufficient time resolution to distinguish radiation from individual bunches. A large number of buckets were filled with known but varying amounts of charge. Bolometer signals from the various bunches were sorted into two groups: the blue group in which the preceding bunch in the fill has at least 10% less charge, and the red group in which the preceding bunch has at least 10% greater charge. The power signals were preponderantly greater for the red group, as is seen in the histogram of Fig. 7. The latter gives the distribution of red and blue signals relative to a curve which is a global fit to all the signals.

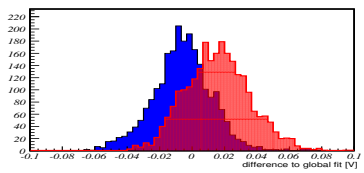

Figure 7: Radiation enhancement by higher charge in preceding bunch.

VLASOV-FOKKER-PLANCK (VFP) SIMULATION WITH TWO BUNCHES

We demonstrate the effect of the long range wake field from whispering gallery modes by solving a nonlinear VFP system for two bunches in two adjacent buckets, taking ANKA parameters for which the interbunch spacing is 60cm. The impedance is that of Fig. 1. We have two coupled VFP equations, each referring to the longitudinal phase space distribution for a bunch in its beam frame, but with a term in the wake field defined by the distribution of the other bunch. The equations are solved by the method of Ref.[7] , but with bi-cubic rather than bi-quadratic interpolation to update the distribution. The initial distributions are Haïssinski equilibria, which are highly unstable at the currents considered.

We plot the total coherent power (a.u.) radiated by each of the two bunches vs. time in synchrotron periods. There are $N_a = 1.14 \cdot 10^9$ particles (0.49mA)in bunch

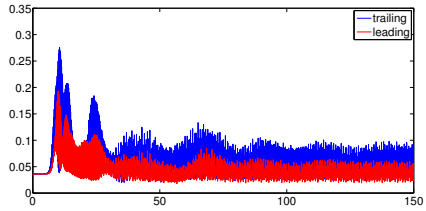

Figure 8: Power from two bunches with equal charges.

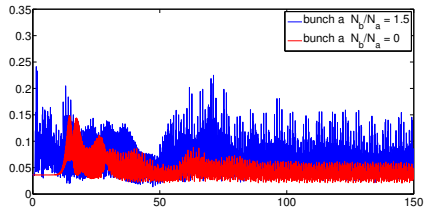

Figure 9: Power from trailing bunch (a), with and without leading bunch, which has 50% more charge.

(a), and an unperturbed bunch length for both bunches of $\sigma_z = 1.92$mm, typical for a low-α setup of ANKA used in CSR runs. For Fig. 8 we have $N_a = N_b$, but the power from the trailing bunch (blue) is consistently greater than that from the leading bunch (red). Fig. 9 shows the power from trailing bunch (a), without a leading bunch (red) and with a leading bunch having 50% more charge (blue). The strong enhancement due to the leading bunch is perhaps surprising in view of the seemingly small wake potential at 60cm shown in Fig. fig:wake, but is believed to be an authentic consequence of the model, evidently a feature of the unstable bunch dynamics at the large (but realistic) currents considered. Of course, the corresponding calculation with the parallel plate impedance shows no inter-bunch communication.

ACKNOWLEDGMENT

We thank S. Kramer, B. Billinghurst, V. Judin, and all the others who contributed to the experiments.

REVISED VIEW OF BASIC FEL EQUATIONS AND A NONLINEAR VLASOV DESCRIPTION*

R. Warnock †, SLAC National Accelerator Laboratory, Menlo Park, CA, USA

Abstract

The standard one-dimensional FEL equations are revised to incorporate a new approach to the wiggle average, in a context of continuous frequency. It has a firmer mathematical foundation, and leads to an interesting reformulation in the time domain. The equations are interpreted as a nonlinear Vlasov system for a continuous distribution function of ponderomotive angle and energy spread. Numerical solutions are illustrated.

VLASOV THEORY OF THE FEL

A linearized version of the Vlasov or Vlasov-Klimontovich equation is accepted as the natural mathematical framework for an analytic discussion of the basic mechanism of the FEL, at distances up to and including the exponential growth region. At greater distances along the undulator a nonlinear saturation comes into play, and to understand that regime one usually resorts to a simulation based on a limited number of representative particles. I explore an alternative approach, based on the full nonlinear Vlasov equation. The general advantage of nonlinear Vlasov over particle simulations is in reduction of modeling noise, but there may also be opportunities for analytic studies of the nonlinear equation. This approach requires a representation of the phase space distribution as a smooth function. To account for granularity from the finite particle number in the startup of the SASE process, I take the initial distribution to be noisy but smooth in the mathematical sense, namely a truncated formal Fourier series of a random discrete particle distribution.

REVISED TREATMENT OF BASIC FEL EQUATIONS

I first review a different treatment of basic FEL equations in one degree of freedom. I work with equations for general continuous frequency ν, and perform the wiggle average at general ν, not just at integers. Moreover, the averaging is now in a form that is justified by the mathematical theory of averaging of differential equations. The new equations suggest a more radical step, namely to reverse integration orders so as to pass from the frequency domain to the time domain (more exactly the domain of the ponderomotive angle). The kernel in the new scheme, analogous to a wake potential, has compact support and intriguing properties.

I consider planar electron motion in a planar undulator, with z and x being longitudinal and transverse position coordinates. A general representation of the transverse electric field is [1]

$$E_x(z,t) = \int_{-\infty}^{\infty} \hat{E}_x(\nu,z) e^{i\nu k_1(z-ct)} d\nu \ , \qquad (1)$$

assuming only that the field is smooth and decaying at infinity as a function of $\alpha = k_1(z-ct)$. Here $k_1 = 2\pi/\lambda_1$ is the wave number of the fundamental optical mode. A similar representation holds for the current density $J_x(z,t)$, in the sense of Fourier transforms of generalized functions if the source consists of point particles. A calculation invoking the wave equation and the slow variation approximation (dropping the second derivative), followed by the inverse FT with respect to α, yields the result

$$\frac{\partial \hat{E}_x(\nu,z)}{\partial z} = -\frac{Z_0}{2} \hat{J}_x(\nu,z) \ , \qquad (2)$$

with SI units, Z_0 being the impedance of free space.

To derive $\hat{J}_x$ assume a volume density of electrons

$$n_e(z,t) = -\frac{e}{\Sigma_\perp} \sum_{j=1}^{N} \delta(z - z_j(t)) \ , \qquad (3)$$

where $\Sigma_\perp$ is an average transverse area of the beam. Then by applying the formula for velocity v_x in the undulator one finds

$$J_x(z,t) \approx \frac{1}{\gamma_0} K \cos\zeta \ n_e(z,t) \ , \ \zeta = k_u z \ , \ \gamma = \gamma_0(1+\eta) \ , \qquad (4)$$

where $k_u = 2\pi/\lambda_u$ is the undulator wave number and the approximation is $|\eta| \ll 1$, used without comment henceforth. Now take the FT of J_x with respect to α, and for each j change the integration variable from α to u where $t = t_j(u)$, $z_j(t_j(u)) = u$. Next introduce the ponderomotive angle θ as a convenient phase space coordinate, namely

$$\theta = \alpha + \chi(\zeta) \ , \quad \chi(\zeta) = \zeta + \xi \sin 2\zeta \ , \quad \xi = \frac{1}{2 + 4/K^2} \ , \qquad (5)$$

and define

$$\theta_j(z) = \alpha_j(z) + \chi(\zeta) = k_1(z - ct_j(z)) + \chi(\zeta) \ . \qquad (6)$$

Then the FT of the current becomes

$$\hat{J}_x(\nu,z) = -\frac{ecNK}{\gamma_0 \Sigma_\perp \lambda_1} w(\zeta,\nu) < e^{-i\nu\theta(z)} > \ , \qquad (7)$$

$$w(\zeta,\nu) = \cos\zeta \ e^{i\nu\chi(\zeta)} \ , \qquad (8)$$

$$< e^{-i\nu\theta(z)} > = \frac{1}{N} \sum_{j=1}^{N} e^{-i\nu\theta_j(z)} \ . \qquad (9)$$

Now to make contact with Vlasov theory imagine a smooth phase space distribution function $f(\theta,\eta,z)$. It and its projection are normalized to 1:

$$\int d\theta \int f(\theta,\eta,z)d\eta = 1\ , \quad \rho(\theta,z) = \int f(\theta,\eta,z)d\eta\ . \tag{10}$$

The mean value of $\exp(-i\nu\theta(z))$ over the discrete distribution will be identified with the mean value at z over the continuous distribution, which is the Fourier transform of the bunch form:

$$\frac{1}{2\pi} < e^{-i\nu\theta(z)} >= \frac{1}{2\pi}\int e^{-i\nu\theta}\rho(\theta,z)d\theta = \hat{\rho}(\nu,z)\ . \tag{11}$$

Returning to Eq.(2) and using (7) and (11) the field is calculated merely by integrating with respect to z. Then the equations of motion for η and θ can be derived in a standard way, so that they take the form

$$\frac{d\eta}{dz} = -\kappa\int w^*(\zeta,\nu)e^{i\nu\theta}d\nu\int_0^z w(\zeta',\nu)\hat{\rho}(\nu,z')dz'\ , \tag{12}$$

$$\frac{d\theta}{dz} = 2k_u\eta\ , \tag{13}$$

where

$$\kappa = \frac{k_1 Z_0 (eK)^2 N}{2mc\gamma_0^3\Sigma_\perp}\ . \tag{14}$$

Eq.(12) is stated for the case of zero initial field in the integration of (2). Now the differential equations (12) and (13) are to be integrated, using the Vlasov equation to update the distribution function, hence updating $\hat{\rho}(\nu,z')$ through (10) and an FT , at each integration step dz. The Vlasov equation is

$$\frac{\partial f}{\partial z} + \frac{d\theta}{dz}\frac{\partial f}{\partial\theta} + \frac{d\eta}{dz}\frac{\partial f}{\partial\eta} = 0\ . \tag{15}$$

The update is done by the method of local characteristics, "local" referring to the procedure of holding the electric force constant over an integration step in z. Thus

$$f(\theta,\eta,z+dz) = f(\theta - d\theta_{E(z)}, \eta - d\eta_{E(z)}, z)\ , \tag{16}$$

the subscripts indicating an evaluation of coordinate increments with the field having its values at z.

It is usual to make use of the average of the "wiggle factor" w over one undulator period at integer ν, which is given by a Bessel function expression $[JJ]_q/2$ at odd $\nu = 2q+1$, and is zero at even ν [2] The average is used to replace w in ν-neighborhoods of integers which are, unfortunately, not well defined. One can avoid the ambiguity and proceed more naturally as follows, for arbitrary continuous ν. Change the independent variable from z to $\zeta = k_u z$ and integrate in steps $\Delta\zeta = 2\pi p$, that is in steps of p undulator periods with p an integer (in practice a small integer, say 1 to 5, proves to be satisfactory). During a step, $\hat{\rho}(\nu,\zeta')$ is regarded as constant, so comes out of the integral in (12).

Note that local integrals of w are a phase factor times a function $g_p(\nu)$:

$$\int_{\zeta_n}^{\zeta_{n+1}} w(\zeta,\nu)d\zeta = e^{in\nu\Delta\zeta}\ \Delta\zeta\ g_p(\nu)\ ,$$

$$g_p(\nu) = \int_0^{2\pi p}\cos u\ \exp\left[i\nu(u - 2\xi\sin 2u)\right]du\ . \tag{17}$$

Then putting $\zeta_n = n\Delta\zeta$, the differential equation for $\zeta\in[\zeta_n,\zeta_{n+1}]$ has the form

$$\frac{d\eta}{d\zeta} = -\frac{\kappa}{k_u^2}\int w^*(\zeta,\nu)e^{i\nu\theta}d\nu\Big[\hat{\rho}(\nu,\zeta_n)\int_{\zeta_n}^{\zeta} w(\zeta',\nu)d\zeta' + \Delta\zeta\ g_p(\nu)\sum_{m=0}^{n-1}\hat{\rho}(\nu,\zeta_m)e^{im\nu\Delta\zeta}\Big] \tag{18}$$

So far the integrals of w have arisen naturally, without invoking the concept of averaging. Finally, averaging is introduced by replacing the r.h.s. of the differential equation (18) by its average over the interval $[\zeta_n,\zeta_{n+1}]$. This local averaging of the vector field of an ODE gives an approximation with rigorous error bounds attributed to Eckhaus [3]. With the definition

$$h_p(\nu) = \frac{1}{(\Delta\zeta)^2}\int_0^{\Delta\zeta} w^*(v,\nu)\Big[\int_0^v w(u,\nu)du\Big]dv\ , \tag{19}$$

the averaged equation on the interval $[\zeta_n,\zeta_{n+1}]$ is

$$\frac{d\eta}{d\zeta} = -\frac{\Delta\zeta\ \kappa}{k_u^2}\int e^{i\nu\theta}d\nu\Big[h_p(\nu)\hat{\rho}(\nu,\zeta_n) + e^{-in\nu\Delta\zeta}|g_p(\nu)|^2\sum_{m=0}^{n-1}\hat{\rho}(\nu,\zeta_m)e^{im\nu\Delta\zeta}\Big] \tag{20}$$

I take (13) and (20) as the basis for the numerical work of the following. The functions $|g_p(\nu)|^2$ and $h_p(\nu)$ (divided by their values at $\nu = 1$) are plotted in Fig.1 for $p = 3$. The peaks get narrower with increasing p.

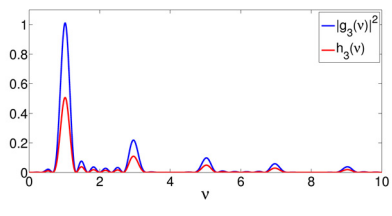

Figure 1: Functions appearing in Eq.20 (normalized)

A REFORMULATION IN THE θ DOMAIN

Introducing the definition (11) of $\hat{\rho}$ and reversing the order of integrations one can recast (20) in θ-space as

$$\frac{d\eta}{d\zeta} = -\frac{\kappa}{k_u^2}\int d\theta'\Big[T_p(\theta-\theta')\rho(\theta',\zeta_n) + \sum_{m=0}^{n-1}S_p(\theta-\theta'-\zeta_n+\zeta_m)\rho(\theta',\zeta_m)\Big]\ . \tag{21}$$

Copyright © 2013 CC-BY-3.0 and by the respective authors

The kernels S_p and T_p are

$$S_p(\theta) = p\int d\nu |g_p(\nu)|^2 e^{i\nu\theta}\ ,\ T_p(\theta) = p\int d\nu h_p(\nu) e^{i\nu\theta}\ . \tag{22}$$

These functions have compact support (vanish outside a finite interval) as can be seen from the Paley-Wiener theorem [4]. Also $T_p(\theta) = S_p(\theta)$ for $\theta > 0$ and is zero for $\theta < 0$. The graph of S_3 is shown in Fig.2.

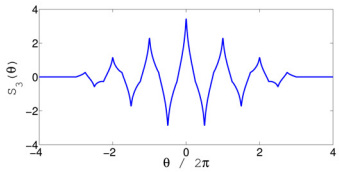

Figure 2: The kernel $S_p(\theta)$ for $p = 3$.

NUMERICAL VLASOV SOLUTIONS

To reduce the FEL equations to the simplest form, one assumes that the field and source are periodic in θ with period 2π, giving the so-called steady state case with identical motion in all buckets. More generally one can take a period $2\pi n_b$ of n_b buckets, and this can imitate the non-periodic case for large n_b. The following results are from a periodic code with arbitrary n_b, which represents f by its values on a grid, and implements the update (16) by bicubic interpolation to off-grid points. Parameters are for the LCLS: undulator parameter $K = 3.7$, Pierce parameter $\rho = 6 \cdot 10^{-4}$ (as defined in [1]). In terms of the normalized length $\bar{z} = 2\zeta\rho$ the gain length as given by linear theory is $1/\sqrt{3}$ ([1], §4.5.1).

I first take a single bucket, using a 400×400 grid in (θ, η)-space and $p = 1$ (integration step of one undulator period). The initial distribution is Gaussian in η with $\sigma = \rho$, times the truncated Fourier series of a random uniform distribution in θ of 50000 particles. There is no initial seed of the field. The calculation takes one minute on a single processor (2.3 GHz). Integration for 30 gain lengths gives the gain curve shown in Fig.3 (left). Fig.3 (right) shows the slope of the log of the power (blue) and the value $\sqrt{3}$ that this has in the linear theory (red). The linear prediction is good from about 5 to 12 gain lengths.

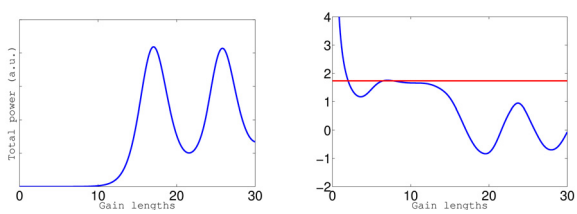

Figure 3: Left: power vs. number of gain lengths; Right: slope of log of power (blue) and its value in linear theory (red).

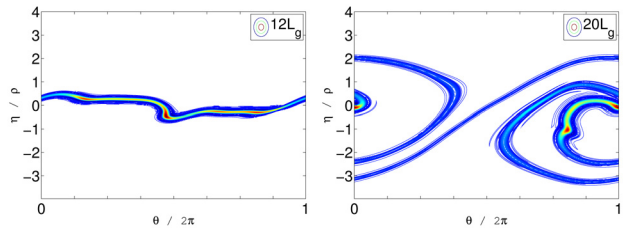

Figure 4: Phase space at 12 and 20 gain lengths.

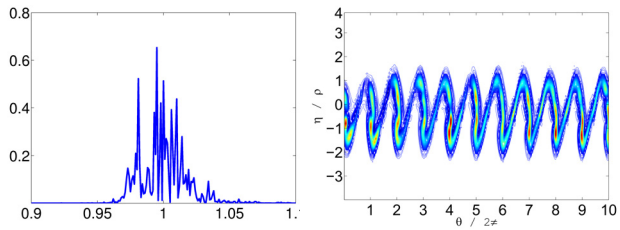

Figure 5: Field spectrum and phase space density, SASE model.

Fig.4 shows contour plots of phase space densities near the end of the exponential region and well into the saturation region.

To model the SASE mechanism one needs in principle a non-periodic θ dependence. To realize this numerically I take instead a long period of $n_b = 1000$ buckets, and also increase the Peirce parameter to $\rho = 0.01$, to decrease the computation time while still demonstrating the qualitative picture of SASE. I integrate to 8 gain lengths, at which point the coherence length $c\sigma_\tau$ is $4.8\lambda_1$ (by Eq.(4.155) in [1]), much less than the bunch length of $1000\lambda_1$; this should mean that the non-periodic case is well imitated. The frequency distribution in the field, $|\hat{E}_x(\nu)|^2$, appears near $\nu = 1$ as in Fig.5 (left). The expected number of spikes in a very crude estimate ([1], p.90) is $M \approx n_b\lambda_1/4c\sigma_\tau = 52$, not grossly different from what is seen. The phase space density in 10 adjacent buckets is shown in Fig.5 (right).

ACKNOWLEDGMENT

Conversations with G. Stupakov, Z. Huang, W. Fawley, R. Ruth, and J. Ellison were very helpful. The work was started at Gennady Stupakov's suggestion.

MODELING LOCALIZED STATES AND BAND BENDING EFFECTS ON ELECTRON EMISSION ION FROM GaAs*

Abstract

High acceptor doping of GaAs and (Cs, O) surface coating leads to downward band bending terminating with effective negative electron affinity surface. The periodicity breaking at the surface together with the formed potential leads to one or more localized states in the band bending region together with effective Fermi level pinning. We report results on how to calculate the band bending potential, the Fermi level pinning, and localized states as functions of GaAs p-doping density, surface density of states, and temperature. We also consider how these surface properties affect electron emission.

INTRODUCTION

High-average current and high-brightness electron beams are needed in advanced applications such as ultra-high Free-Electron Lasers, electron cooling of hadron accelerators, and Energy-Recovery Linac light sources. Semiconductor cathodes, such as negative electron affinity GaAs-based cathodes, are known [1] to have good quantum efficiency (QE) (10% achieved experimentally), low thermal emittance with prompt response time [2], and are candidates to achieve high average current up to 100 mA.

However, how to design, fabricate, and reliably operate semiconductor cathodes at high average current (reaching 100 mA) still represents a major problem. Some of the most important effects to understand are related to surface space charge region, controlling the electron affinity and band bending as a function of surface properties and charge propagation to the surface [3, 4].

In addition to experiments, simulations provide a complementary way to efficiently explore relevant parameter sets. Moreover, they allow us to obtain data on properties that are currently not accessible through experiments or very difficult to measure. For example, the energy distribution of electrons inside the cathode material in the region of the emission surface is directly accessible in the simulations but very difficult to measure in experiments. Producing high fidelity simulations data of semiconductor cathode properties depends on accurate modeling of the surface space-charge region. Specifically, the calculation of the band bending region (BBR) energy profile, determination of Fermi level pinning (e.g. for GaAs cathodes), development of localized electron levels with emission from them, and how the electron affinity depends on these properties significantly affect electron emission.

Emission from localized states has been shown to contribute to the observed energy distribution of electrons from GaAs and one approach was proposed to explain it [3] that depends on specific properties of the potential across the GaAs-vacuum interface. Similar effects were considered for emission from diamond but the model developed was based on a different surface potential [5].

We have already done simulations with a surface band bending profile that uses a quadratic approximation [6]. Here, we provide a general approach for calculation of the band bending profile and the Fermi level pinning for GaAs.

BAND BENDING AND LOCALIZED STATES

The surface band bending arises as a consequence of the space charge region that develops as a result of the symmetry breaking and appearance of surface states. The electrostatic potential in the band bending region (BBR) is determined from the solution of the Poisson equation:

$$\nabla \cdot (\varepsilon \nabla \phi) = q \left(n\left[\phi\right] - p\left[\phi\right] + N_A^-\left[\phi\right] - N_D^+\left[\phi\right] \right), \quad (1)$$

where $\varepsilon(\mathbf{r})$ is the dielectric constant, q is the fundamental charge, n and p are the electron and hole densities in the conduction and valence band, respectively, N_A^- and N_D^+ are the densities of ionized acceptor and donor impurities when present. Generally, all charge densities are non-linear functions of the potential. When periodicity is preserved in the emission surface, the resulting non-linear Poisson equation is effectively one-dimensional. For p-doped GaAs, when the donor density can be neglected and the acceptors are fully ionized, it has the form:

$$\frac{d^2U(x)}{dx^2} = \frac{q^2}{\varepsilon k_B T}\left(N_A - \frac{2N_V}{\sqrt{\pi}} F_{1/2}\left(\eta_V - U(x)\right)\right), \quad (2)$$

where $\eta_V = (E_V - E_F)/k_BT$ (with E_V the valence band maximum in bulk and E_F the Fermi level, k_B the Boltzmann constant and T the lattice temperature), $U(x) = q\phi(x)/k_BT$, $N_V = 2\left(\frac{m_{dh}k_BT}{2\pi\hbar^2}\right)^{3/2}$ with m_{dh} a hole-related effective mass, and $F_{1/2}(x) = \int_0^\infty \frac{\sqrt{u}}{1+e^{u-x}}du$. The boundary conditions imposed on the 1D non-linear Poisson equation are determined from the requirement of zero

applied field in bulk:

$$\frac{dU}{dx}\left(x \to \infty\right) = 0,$$

and a given value at the semiconductor surface

$$U\left(x = 0\right) \equiv U_S \equiv q\phi_S / k_B T.$$

This 1D non-linear Poisson equation can be solved by a finite difference discretization and then using a Newton-Ralphson algorithm to find the roots of the resulting matrix equation.

In the case of non-degenerate semiconductors, $E_V + 3k_BT \leq E_F \leq E_C - 3k_BT$ where E_C is the minimum of the conduction band in bulk, the solution for the band bending potential can be expressed in the integral form:

$$\mathrm{sgn}\left(U_S\right) \int_{U(x)}^{U_S} \frac{du}{F\left(u,\, U_F\right)} = \frac{x}{L_D}, \qquad (3)$$

where

$$F\left(x, y\right) = \sqrt{e^y\left(e^{-x} + x - 1\right) + e^{-y}\left(e^x - x - 1\right)},$$

$U_F = \left(E_i - E_F\right)/k_BT$ with E_i the Fermi level for the intrinsic semiconductor (no ionized impurities), and $L_D = \sqrt{\frac{\varepsilon k_B T}{2q^2 n_i}}$ with n_i the conduction band electron density in the intrinsic case.

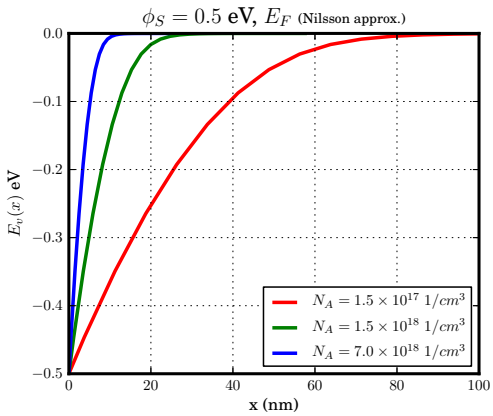

Figure 1: Calculated band bending energies as a function of acceptor doping for three different values. The band bending for $N_A = 7 \times 10^{18}$ cm^{-3} and $\phi_S = 0.5$ eV is in agreement with previously published data [3].

The value of the potential ϕ_S at the surface is determined from the requirement to satisfy charge neutrality. Since U_F is calculated from bulk properties as a function of temperature and bulk doping density, we can determine the band bending potential $U(x)$ by numerically solving Eq. (3). We have implemented a bisection algorithm to evaluate the integral in Eq. (3) and find its root for a given value of x. The value of $U(x)$ for the lower limit of the integral from the calculated root value represents the band bending potential at distance x from the GaAs surface. Results from the code are shown in Fig. 1 for three different acceptor doping densities and a pinned surface potential energy $q\phi_S = 0.5$ eV. The results demonstrate the importance to consider the nonlinear corrections since the band-bending profiles deviate from the initially assumed quadratic form. Moreover, we can now directly obtain the depth of the band bending potential in GaAs when varying the bulk acceptor density. Finally, the obtained band bending profile for $N_A = 7 \times 10^{18}\ cm^{-3}$ is in good agreement with previously published data [3].

For the results presented in Fig. 1, the Fermi level position was calculated from bulk properties using Nilsson's approximation (see [6] and references therein).

The value of the potential ϕ_S at the surface is determined from the requirement to satisfy charge neutrality. Moreover, at specific surface conditions for GaAs, the surface potential ϕ_S and the Fermi level are pinned. For

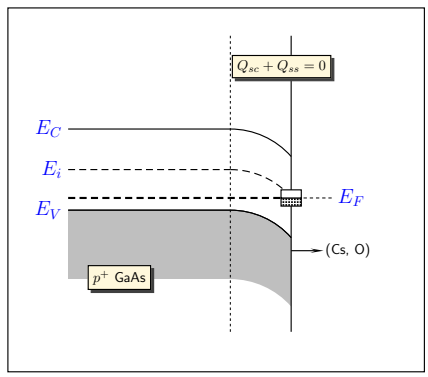

Figure 2: The Fermi pinning regime is reached when the band bending leads to overlap of the energy of the surface states (shown in the diagram with the partially filled rectangle) with the chemical potential E_F.

p-doped GaAs and downward band bending $\phi_S > 0$ at the surface and $\phi\left(x \to \infty\right) \to +0$ in bulk, the space-charge region is negatively charged since near the surface: $p\left(x\right) - N_A = p\left(x\right) - p_{bulk} < 0$. For this case, charge neutrality at the surface can be satisfied if there are surface donor states that are positively charged. The surface band bending ϕ_S is determined from the charge neutrality condition $Q_{ss}\left(\phi_S\right) + Q_{sc}\left(\phi_S\right) = 0$ where $Q_{ss}\left(\phi_S\right)$ is the total change density on surface states and $Q_{sc}\left(\phi_S\right)$ is the space-charge surface density $\left|Q_{sc}\left(\phi_S\right)\right| = \left|\varepsilon \frac{d\phi(x=0)}{dx}\right|$. For a given type of a surface donor state with density N_{sd}, Q_{ss} is determined from:

$$Q_{ss}\left(\phi_S\right) = qN_{sd}\left(1 - 1/\left(\exp\left(\beta\left(E_{sd} - E_F\right)\right) + 1\right)\right),$$

where E_{sd} is the energy of electrons on the surface state, determined by atomic properties and is at a given position (0.55 eV for GaAs) relative to the valence band maximum at the surface effectively making $E_{sd} - E_F$ a function of ϕ_S. The band bending potential determined from the charge neutrality condition is reached when $E_F \approx E_{sd}$

as shown in Fig. 2. The plots in Fig. 3 indicate the onset of the Fermi level pinning for different N_A values and approaches to calculate E_F (the bottom right plot uses an exact numerical calculation for the Fermi level rather than the Nilsson approximation). From the plots at low bulk doping in Fig. 3, the Fermi level and ϕ_S are pinned for for $N_{sd} \geq 10^{12}$ cm^{-2} while for high doping, the pinning regime is reached for $N_{sd} \geq 10^{13}$ cm^{-2}. The Fermi level

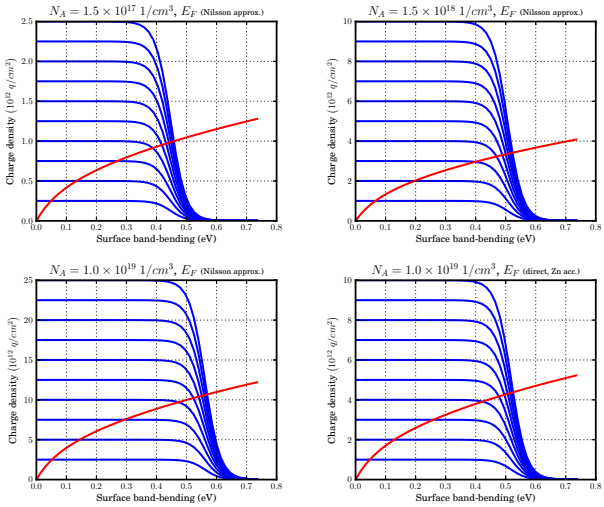

Figure 3: The intersection of each Q_{ss} curve (for a given surface state density N_{sd}) with the Q_{sc} curve for given doping concentration N_A determines the value of the surface band bending ϕ_S.

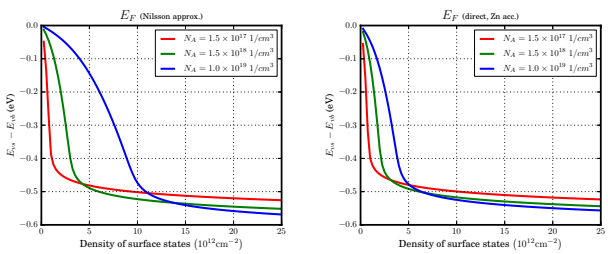

Figure 4: When the band bending leads to $E_F \approx E_{sd}$, the Fermi level at the surface changes only by $2.3k_BT$ per decade of surface state density. This is the regime of effective Fermi level pinning due to the small change of E_F with further increase of the surface density of states.

pinning regime is clearly revealed when we calculate ϕ_S as a function of the surface density of states for different bulk acceptor concentrations. Results from these calculations are shown in Fig. 4. In the pinning regime, the surface band bending ϕ_S changes little when further increasing the surface density of states N_{sd}. Note that the values for which the Fermi pinning regime starts, $N_{sd} \sim 10^{12}$ to 10^{13} cm^{-2} is still orders of magnitude smaller that the value 10^{15} cm^{-2} for the density of a complete monolayer of adatoms.

Finally, we briefly mention the importance of including emission from localized states that develop in the BBR. This effect was demonstrated in electron emission energy distribution data for GaAs [3]. The localized energy levels can be calculated by self-consistently solving the Schrödinger-Poisson equations in the BBR. We have prototyped an implementation to solve the Schrödinger-Poisson equations self-consistently and are currently investigating results from it with different emission surface potentials. Note, however, that depending on the boundary conditions imposed when solving the Schrödinger-Poisson equations, emission from quasi-stationary levels and electron lifetime on them has to be included in the calculations [3].

SUMMARY

We reported here results for calculation of the band bending region and pinning of the Fermi level in p-doped GaAs as a function of the acceptor doping concentration and the density of surface states. The results allow for accurate evaluation of the band bending in the surface space-charge region. The calculated band bending profiles can be used as input in codes to simulate charge transport and electron emission from semiconductor cathodes. Emission from localized states represents another important effect that is still to be properly integrated in photocathode simulations.

Abstract

Buildup of electron plasmas in accelerator cavities poses a serious threat to performance for current and future accelerators. Traveling-wave rf diagnostics are an effective, non-destructive way to measure electron clouds, although determining the true cloud density from spectra is difficult due to the effects of reflections, non-uniform cloud density, and magnetic field effects. We model traveling-wave rf diagnostics of electron clouds by simulating spectra using both harmonically modulated plasma dielectric models, and dielectric models based on simulated electron cloud densities. We compare here the differences in computed side band spectra due to different magnetic field configurations for Main Injector parameters, and report on computational challenges inherent to numerical modeling of systems with large variances of spatial and temporal scales.

RF DIAGNOSTICS PROVIDE DIAGNOSTIC MEASUREMENT OF ELECTRON CLOUDS

Electron clouds have been identified as a potential performance-limiting element in both hadron and lepton accelerators [1]. Recently, methods for measuring electron cloud densities in a non-destructive manner have been developed. These methods rely on measurement of rf signals injected into the beam pipe, either at a frequency just below the cutoff frequency (resonant rf method) or above the cutoff frequency (traveling wave method). For traveling wave rf diagnostics, the presence of an electron cloud plasma in the beam pipe induces a phase shift due to changes in the dielectric properties of the medium in which the rf is traveling. The plasma dielectric strength is modulated at the revolution frequency as the plasma builds up during bunch passages, and dissipates during gaps in the bunch train. This is typically observed in experiments as side bands at the revolution frequency, with a height that is proportional (in the linear approximation) to the average plasma density. Magnetic field effects also come into play with these diagnostics in two ways. First, magnetic fields may excite a cyclotron resonance [2, 3] that increases the phase delay per unit length, and second, magnetic fields will affect the electron trajectories that will in turn change the spatial distribution of electrons in the beam pipe and hence the dielectric properties of the plasma. It has been observed in both experiments and in simulations that dipole fields tend to align electrons in vertical stripes [4, 5]. Recent studies indicate that quadrupole fields may be able to trap electron clouds thereby leading to negative effects on the lead bunch in a train [6].

SIMULATION RESULTS

We are developing numerical models that are appropriate for simulating electron clouds and rf diagnostics in the Main Injector at Fermilab, using the plasma simulation framework VSim [7]. In all of the simulations reported here, we use a circular cross section beam pipe with radius 7.46125 cm, and 50 cm long. We use a mesh with 48 computational cells in the longitudinal direction, and 16 cells in each of the transverse directions. We simplify the bunch train structure from that in the actual Main Injector by modeling one full revolution as a single continuous bunch train of 18.8 ns bunches of roughly 8 GeV protons. We artificially set one revolution time to $2.0\mu s$, including an abort gap of 0.4μ s during which time there are no beam bunches. This sets the modulation frequency to 500 kHz. The cutoff frequency for this beam pipe is 1.1774 GHz, and we drive rf above this frequency to model traveling wave diagnostics.

Kinetic PIC Simulations

We first perform detailed electrostatic Particle-In-Cell (PIC) simulations of electron cloud buildup using VSim. We start with a low-density, uniformly distributed, cold electron plasma in a circular beam pipe with radius 7.46 cm. We solve for the electric fields electrostatically given the overall charge distribution and subject to the appropriate boundary conditions; metallic boundaries on the beam pipe walls, and port boundaries on the open ends of the simulation domain. Port boundaries are a numerical filter model that effectively absorbs wave energy at a given phase velocity, preventing reflections from the boundary. We do not inject rf power in the kinetic simulations because we are focused on modeling cloud buildup here.

In buildup simulations we inject beam bunches with a spacing of 18.8 ns by specifying a time-dependent charge density that simulates the passage of proton beam bunches. Bunches cross the simulation domain for 1.2μs, followed by a 0.8μs abort gap, representing a single revolution. These times are chosen to demonstrate the physics of electron cloud buildup while maintaining numerical efficiency. In future simulations the actual Main Injector revolution period will be approached. Electrons that make up the plasma (cloud) are modeled as variable-weight kinetic par-

Copyright © 2013 CC-BY-3.0 and by the respective authors

ticles, and are pushed by electrostatic forces from other charges (space charge effects) and current sources (beam potential). Electrons are attracted to the potential of the beam as it passes and are accelerated across the beam pipe into the opposing wall. Electrons that are absorbed by the beam pipe walls emit low-energy secondary electrons according to the Furman-Pivi model [8]. These electrons are accelerated by subsequent bunches giving rise to a buildup of electrons, that saturates at a density that is about 0.7 times the linear beam density [9], where the cloud shields electrons from the beam potential.

In our buildup simulations we set the time step to be 18.86 ps in order to match the plasma dielectric simulations whose time steps are limited for numerical stability reasons (CFL condition), although we could relax this by a factor of at least 20 and just resolve the Debye length because these simulations are electrostatic. We save the 6D phase space for each particle at each time step. We then compute the charge density for the electron cloud from the particle positions and can subsequently use that density in plasma dielectric simulations over many revolution periods (see below).

Figure 1 shows the total energy of the cloud electrons as they build up. On average the energy follows the total number of electrons in the buildup and dissipation of the cloud. The inset shows fine-scale structure indicating bunch crossings. Spikes in the electron energy are due to a single bunch crossing, where the electrons are accelerated by the positively-charged bunch. Nearly all of this energy is lost when the (fast) electrons are absorbed by the walls. There is a short period of drift, capped off with a period where some (slow) electrons are absorbed by the walls that creates a reduction in the total energy that corresponds to a reduction in the total number of electrons.

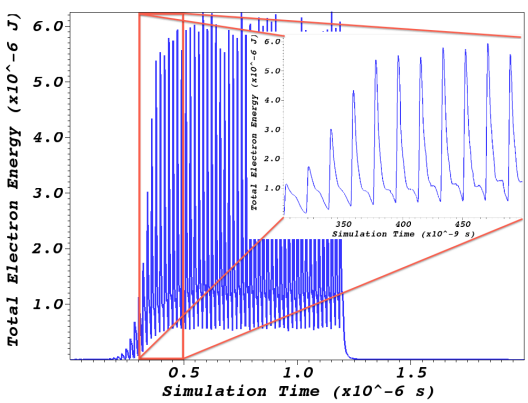

Figure 1: Total energy of the electron cloud as a function of simulation time. Bunch crossings punctuate the electron energy, which then relaxes as electrons are absorbed by the beam pipe walls.

Modulated Plasma Dielectric Simulations

We modulate the dielectric strength at a frequency of 500 kHz to match the kinetic buildup simulations, and simulate approximately 160 revolution periods with a time step of 18.86 ps, or approximately 16.78 million time steps. This corresponds to at least 550,000 rf periods, which is sufficient to resolve plasma-induced side bands. We use port boundaries to launch an rf wave into the simulation from the left boundary. This rf wave is then measured at the right end of the simulation after it has passed through the plasma dielectric.

In these simulations we model rf propagation through a plasma dielectric that is spatially uniform across the whole simulation domain, with an equivalent plasma density of 9.1×10^{12} electrons/m^3, corresponding to 8.0×10^{10} electrons at saturation during buildup in our kinetic PIC simulations. The dielectric tensor is modulated purely harmonically at 500 kHz, simulating the effects of dissipation of the cloud during gaps in the bunch train. Simulations such as these are much smoother than simulations where the plasma density at each time step is determined by particle positions from kinetic PIC simulations. They also serve to demonstrate the modeling capability of accurately generating synthetic spectra with side band structures, that can be directly compared to experimental results, and require numerical stability and accuracy over extremely long simulation times.

Figure 2 shows a portion of the synthetic spectrum for uniform, modulated plasma dielectric simulations. The left-hand plot shows the spectrum for a simulation run with rf at 50% above the cutoff frequency with no externally applied magnetic fields, and the right-hand plot is for a simulation driven at 5% above cutoff with a 0.06 T transverse dipole applied field, which is close to the cyclotron resonance. The spectrum is very smooth because the simulations plasma dielectric is spatially uniform, and the simulations are run for a long time which gives better frequency resolution. The first side band is readily seen at the modulation frequency and the height of the side band is dependent on the plasma dielectric constant, as expected.

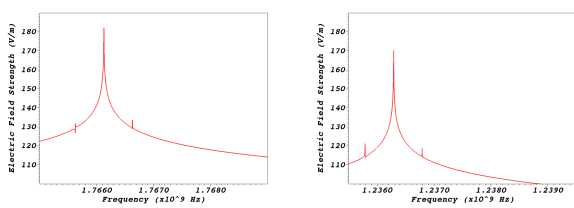

Figure 2: Synthetic spectra generated by harmonic modulation of plasma dielectric tensor. Left plot shows the spectrum with zero applied magnetic field, driven at 50% above the cutoff frequency. Right plot shows the spectrum with excitation of the extraordinary wave, near the cyclotron resonance with an applied dipole field of 0.06 T, and hence the upper hybrid resonance, driven at 5% above the cutoff frequency.

Copyright © 2013 CC-BY-3.0 and by the respective authors

The effect of externally applied magnetic fields on plasma-induced phase shifts in rf diagnostics has been documented [4, 5, 10]. Here we have performed simulations with different magnetic field orientations using the modulated plasma dielectric model. In Figure 2, the left-hand plot shows the spectrum for the case where there is zero magnetic field, as in a drift section. The right-hand plot shows the spectrum in the case where there is an applied dipole magnetic field with strength 0.06 T oriented in the transverse direction normal to the rf polarization. This orientation excites the upper hybrid resonance which modifies the side band strength. All other simulation parameters are the same between these simulations. Simulations in which an applied magnetic field is aligned parallel to the rf polarization do not show any enhancement in the side band strength.

Integrated Plasma Dielectric Simulations

For these simulations we implement a plasma dielectric model based on electron cloud densities derived from the kinetic simulations described above. For integrated plasma dielectric simulations we first convert particle positions from the buildup simulations into a 3-Dimensional density map that we use as input to our plasma dielectric model. We then perform plasma dielectric simulations for nearly 200 revolutions, changing the value of the dielectric tensor in each computational cell periodically according to the electron density in that cell. We repeat the electron densities determined in the corresponding kinetic buildup simulations every $2.0\mu s$, and sub-sample the electron positions, changing the corresponding plasma dielectric strength every 50 time steps for computational efficiency. We drive the rf at 2.2 times cutoff in these simulations.

Figure 3 shows a spectrum generated by converting electron cloud densities from the kinetic simulations into a 3-Dimensional field of dielectric strength over a single revolution period, and then repeating that pattern in a plasma dielectric simulation over 1,000,000 rf periods. The average density for these simulations is the same as the harmonically modulated plasma dielectric simulations discussed above. It may be expected that different fill patterns and modulation shape will affect the amplitudes of the side bands, as well as changing the power in higher-order side bands with respect to the first side band [11]. As can be seen in Figure (3), the first side band amplitude is somewhat larger in comparison to the harmonic modulation simulations. In addition, higher order side bands are observed, as is expected because the shape of the modulation of the electron density is more like a square wave than a purely harmonic signal. The spectrum overall is much coarser than the previous simulations, and there is more high-frequency noise. This is due to the discreteness of both the binning of electron positions to the computational grid, as well as undersampling effects.

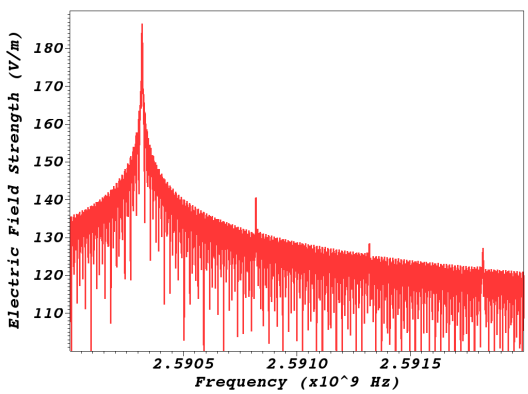

Figure 3: Simulated spectrum for integrated plasma dielectric model, where the 3-Dimensional electron densities from kinetic simulations determines the plasma dielectric strength.

CREATION OF GAMMA RADIATION USING ANNIHILATION OF CHANNELED POSITRONS IN CRYSTALS

Koryun B. Oganesyan*,
A.I.Alikhanyan National Science Lab, Yerevan, Armenia

Abstract

A possibility of channeling of low-energy ($5 \div 20\,Mev$) relativistic positrons with coaxial symmetry around separate crystal axes of negative ions in some types of crystals, is shown. The annihilation processes of positrons with medium electrons are investigated in details. The lifetime of a positron in the regime of channeling is estimated $10^{-6}\,sec$ which on a $10^9 \div 10^8$ is bigger than at usual cases.

INTRODUCTION

Studying of ways of generation of short-wave coherent radiation always was an essential problem of a science and was stimulated by its wide applied application. In work [1] one of the first the mechanism of radiation of relativistic electrons at their movement in periodic structures (see also [2]) was offered (later such types of structures have been named undulators). It at first sight imperceptible work later has essentially accelerated a process of creation of of modern devices the synchrophasotrons and the lasers on free electrons (see for example review [3]). In spite of the fact that the technology of generation of undulator radiation steadily is being developed and successes are obvious [4], however the problems also are obvious and they remain unresolved up to now. Let's note that the frequency of undulator radiation is being defined by length of its periodic element which in FELs and the undulators devices are macroscopic. Other defects of undulators their big sizes and used big energies of electrons. After opening of channeling of electrons (positrons) in crystals [5–7] and accompanying by its short-wave radiation [8] was appeared a hope to solve all the aforementioned problems. However these hopes up to now is justified only partially. In particular the problems of generation of short-wave radiation (x-ray) from less energetic electrons (of order a several Mev) on very small distances (of order a several micron) have been solved. Now a new problem arise. The point is that in the regime of channeling the particle (electrons and positrons) usually live very short time $\sim 10^{-14} \div 10^{-15}\,sec$. However this time is very short for conversion of a appreciable part of particle energy to energy of radiation. The short lifetime as well doesn't conduce to use of external factors for control by beam of channeling particles and to improving of spectral characteristics of radiation.

The quantum theory of channeling for electrons and positrons has been elaborated by many authors [8–10]. It is important to note that an electron in a crystal can commit both planar and axial channeling. At the same time only one type of real channeling for the positrons is known, the regime where a particle is localized between two adjacent planes. The possibility of axial channeling of positive particles has not been investigated, seriously up to now, because the crystallographic axes, irrespective of grade of crystal are been charged positively. However investigation of possibilities of axial channeling of positrons and, hence, the formation of metastable relativistic positron systems (PS) is a problem of utmost importance for a radiation physics.

In this work a role of different processes (scattering of positron on media electrons, the annihilation processes etc) in the expansion of energy levels of relativistic PS is analyzed and shown that PSs are metastable.

FORMATION OF RELATIVISTIC POSITRON SYSTEM (PS)

In previous work [11] we have shown, that if a low-energy relativistic positrons ($5 \div 20\,Mev$) are scattering under a small corners $\vartheta \le \vartheta_L$ (where ϑ_L is a Lindhard angle) on the axis $\langle 100 \rangle$ of chlorine ions Cl^- that they fall into regime of axial channeling. Moreover the motions of positrons concentrate between two cylinders that is very important from the point of view of movement stability. In particular, as was shown the effective $2D$ potential of channeling don't depend from temperature of media in a broad range of temperatures and has an order $-10\,eV$ depths of potential which is sufficient for formation a several quantum states of transverse motion. Recall that this type of effective potential can be in other crystals too. For example the effective potential of negatively charged ions O_2 axes often used in experiments of crystal SiO_2 is such.

In other words, the relativistic positrons in described regime of channeling don't interact with phonons subsystem. That means a main factor of de-channeling of particles in considered case is absent.

Taking into account the symmetry of effective potential for positrons around of the negative ions axis we can write the following analytical formula:

$$\begin{aligned} U_0(\rho) &= D_0(e^{-2\alpha\overline{\rho}} - 2e^{-\alpha\overline{\rho}}), \overline{\rho} = (\rho - \rho_0)/\rho_0, \\ \rho &= \sqrt{x^2 + y^2}, \end{aligned} \quad (1)$$

where the parameters for usual crystals are being found into intervals $D_0 = 5 \div 10eV$, $\alpha = 0.5 \div 0.8$ and $\rho_0 \sim 0.5d$, where d is a lattice constant.

The full wavefunction of positron in the potential (1) in atomic units $\hbar = c = 1$ is being solved exactly and represented in [11] and [12]

PROCESSES LEADING TO DECAY OF POSITRON-SYSTEMS

After exception of major factor of dechanneling the three different processes still remain which lead to decay of PS:

a) The annihilation of positron with electron of media on one γ photon;

b) The annihilation of positron with electron of media on two γ photons;

c) The scattering of positron on electrons of media.

The main problem now is investigation of processes investment in lifetime of PS.

Decay PA on One and Two γ Photon

It is obvious that PS may be illustrated as a system, with total zero spin (like of parapositronium), because the skeleton of negatively charged ions axis does not possess spin and accordingly there are not spin-spin interaction between it and the positron. In other words the interaction between positron and the axis only is an electromagnetic. Another distinction between positronium and PS is a possibility of decay of the last on one γ photon. Recall that in this case the conservation laws of energy and momentum takes place in view of presence of media.

This process is being defined by matrix element of first order [13]:

$$\langle f|S^{(1)}|i\rangle = \frac{2\pi i e}{\sqrt{2\omega}} \int \Psi^*(\mathbf{r}) \hat{e} e^{-i\mathbf{qr}} \psi(\mathbf{r}) d^3r \cdot \delta(\varepsilon_p + \varepsilon_e - \omega), \quad (2)$$

where Ψ and ε_p are the wavefunction and the total energy of positron, $\psi(\mathbf{r})$ and ε_e designed the wavefunction and the energy of media's electron, $\mathbf{q}$-is the momentum of γ photon, ω-its frequency. Taking into account that the distribution of electrons in positive as well in negative ions is given by spherical model JMGR, we can write the wavefunction of electrons system in factorized form:

$$\psi(\mathbf{r}) \equiv \psi(\rho, z, \varphi) = \frac{1}{\sqrt{d}} e^{i\eta(z)z} \chi(\rho), \quad (3)$$

where $\eta(z)$ is a momentum of media electron in the point z, it is supposed that the random function $\eta(z)$ has a zero average value. This means that the statistical averaging of random term in (3) is equal to unit $\langle e^{i\eta z/\hbar}\rangle = 1$. In addition $\chi(\rho)$ Gaussian function which is normalized to unit:

$$\chi(\rho) = \frac{1}{(\pi)^{3/4}\rho_0} e^{-\bar{\rho}^2/2}. \quad (4)$$

For the effective differential cross-section of annihilation we can write the following expression:

$$d\sigma = \frac{e^2}{2(2\pi)^2\omega} \sum_{\nu_e \nu_p} |Q|^2 \delta(\varepsilon_p + \varepsilon_e - \omega)\omega^2 \, do_\gamma, \quad (5)$$

where $do_\gamma = \sin\vartheta d\vartheta d\varphi$ the solid angle element in which is situated a photon momentum, ν_e and ν_e are a summation indices of electron and positron spins in the initial state. However for the considered problem the orientation of electrons spin does not play important role and correspondingly later we will ignore the summation. In (5) the term Q in weakly relativistic case is being written in the kind:

$$Q = \int \Psi^*(\mathbf{r}) \mathbf{e}\hat{\mathbf{v}} \, e^{-i\mathbf{qr}} \psi(\mathbf{r}) d^3r, \quad \hat{\mathbf{v}} = \frac{1}{i\mu}\nabla_{\mathbf{r}}, \quad (6)$$

where $\hat{\mathbf{v}}$ is the operator of positron velocity, correspondingly $\mathbf{e}$ - describes the unit vector of photon polarization. The expression (6) may be transformed to the form:

$$Q = \frac{(2\pi)^3}{\mu} \int (\mathbf{ep}') \widehat{\Psi}^*(\mathbf{p}') \widehat{\psi}(\mathbf{q} - \mathbf{p}') \, d^3p',$$

where $\widehat{\Psi}^*(\mathbf{p}')$ and $\widehat{\psi}(\mathbf{q} - \mathbf{p}')$ are Fourier transforms of corresponding wavefunctions:

$$\widehat{\Psi}(\mathbf{p}') = \frac{1}{(2\pi)^3} \int \exp(-i\mathbf{p}'\mathbf{r}) \Psi(\mathbf{r}) d^3r,$$
$$\widehat{\psi}(\mathbf{q} - \mathbf{p}') = \frac{1}{(2\pi)^3} \int \exp[-i(\mathbf{q} - \mathbf{p}')\mathbf{r}] \psi(\mathbf{r}) d^3r. \quad (7)$$

In (7) $\mathbf{p}'$-designates the momentum of positron which in considered case in toto coincides with its p_z projection. Analyzing of expression for $\widehat{\psi}(\mathbf{q} - \mathbf{p}')$ shows that the transition amplitude is more probably if positron and photon momentums coincides i.e. $\mathbf{q} = \mathbf{p}'$. Using the equality $(\mathbf{ep}') = p' \sin\vartheta'$ and above mentioned conclusion the expression (7) we can write in the following kind (see Fig 2):

$$Q = \frac{(2\pi)^3}{\mu} \widehat{\psi}(0) \int p' \, \widehat{\Psi}^*(\mathbf{p}') \, \sin\vartheta' d^3p', \quad (8)$$

where $d^3p' = p'_\perp d\theta dp'_\perp dp'_z$.

The function $\widehat{\Psi}(\mathbf{p}')$ is being calculated simply:

$$\widehat{\Psi}(\mathbf{p}') = \frac{(-1)^m}{(2\pi)^2} \frac{e^{im\theta}}{\sqrt{d}} \delta(p_z - p'_z) \Theta_m(p'_\perp),$$
$$\Theta_m(p'_\perp) = \int_0^\infty \Phi(\rho, 0) J_m(p'_\perp \rho) \sqrt{\rho} \, d\rho. \quad (9)$$

The calculation of cross-section we will begin with averaging of expression (8) by the photon polarization. It is obviously when we rotate the polarization vector $\mathbf{e}$ around photon's momentum $\mathbf{q}$ on the angle π at this time as may be shown, the angle ϑ' respectively is being changed in the limits $\pi/2 - (\beta_q - \beta_{p'}) \le \vartheta' \le \pi/2 + (\beta_q - \beta_{p'})$, where

Copyright © 2013 CC-BY-3.0 and by the respective authors

$\beta_q = \arccos(q_z/q)$ and $\beta_{p'} = \arccos(p'_z/p')$. After integration by angle ϑ' in Eq. (8) it is easy to find:

$$Q = -\frac{2(2\pi)^3}{\mu}\widehat{\psi}(0)\int p'\,\widehat{\Psi}^*(\mathbf{p}')\,\sin(\beta_q-\beta_{p'})d^3p'. \quad (10)$$

Now substituting (9) into (10) and making the elementary calculations we find:

$$\begin{aligned} Q &= -\frac{2(2\pi)^2}{\mu d}\,\delta(p_z-q_z)\widehat{\psi}(0) \\ &\times \int_0^\infty \bar{p}\,\Theta_0(p'_\perp)\,\sin(\beta_q-\beta_{\bar{p}})p'_\perp dp'_\perp, \end{aligned} \quad (11)$$

where $\bar{p} = \sqrt{{p_z}^2 + {p'_\perp}^2}$, the δ- function shows the momentums conservation law on z- axis.

Finally let's analyze the amplitude Q forward which is more probable direction of PS decay on one γ photon, when in the PS doesn't rotate. In this case with high accuracy take place the following equalities $\beta_q = 0$, $\beta_{\bar{p}} = \arccos(p_z/\bar{p})$ and $m = 0$.

Using these equalities we can substantially simplify expression (11):

$$Q = \frac{2(2\pi)^{5/2}}{\mu d}\,\delta(p_z-q_z)\widehat{\psi}(0)p_z^{1/2}\int_0^\infty \Theta_0(p'_\perp){p'_\perp}^{3/2}dp'_\perp. \quad (12)$$

Now using the expression (12) and standard connection between amplitude and transition probability [13] for the one-photon decay of PS we can write the following assessment:

$$P_\gamma \sim 10^6 sec^{-1}. \quad (13)$$

Recall that for finding assessment (13) we used the parameters of crystal $CsCl$.

The probability of PA decay on two γ photons [13] is

$$P_{2\gamma} \sim 10^6 sec^{-1} \quad (14)$$

At scattering of positron on a media's electrons the amplitude of transition is being described by S-matrix element of second order, similar to process of two photons' decay.

CONCLUSION

The problem of creation of sources for the generation of short waves radiation is a problem of utmost importance. The experimental discovery of the phenomenon of channeling of relativistic charged particles in crystals has given a good hope for creation of compact devices for generation of powerful radiation in X-rays region. Despite the made big efforts these hopes for a long time were not justified. The point is that at the channeling arises difficultly solvable problem connected with the short length of de-channeling. The characteristic times of channeling in axial or planar regimes accordingly of order $10^{-14}sec$ and $10^{-15}sec$, that does not allow to increase the share of radiated energy and a fortiori to control process. As have shown our recent investigations this problem is being solved if we consider the channeling of positrons of energy $5 \div 20\,Mev$ in particular, in ionic crystals of type $CsCl$ along the chlorine ions axis $< 100 >$. In this case in crystal forms $2D$ relativistic positron-systems which with phonons subsystem of lattice practically are not interacting. All other types of influence on PS, collisions with electrons of media, the scattering on lattice discreteness etc, are perturbations of essentially small or similar to PS annihilation processes order. In other words in mentioned way with high probability it is possible to create of $2D$ relativistic PSs in media with the lifetimes bigger than $t \sim 10^{-6} \div 10^{-7}\,sec.$ This means that we solved the main problem on way of creation of nano-undulators which have very large lifetimes and by which we can control.

HOW ACTS PLANE WIGGLER MAGNETIC FIELD INHOMOGENEITY ON THE SPONTANEOUS RADIATION AND THE GAIN

Koryun B. Oganesyan*, A.I. Alikhanyan National Science Lab, Yerevan, Armenia

Abstract

A relativistic electron motion in a transversally inhomogeneous magnetic field of a wiggler is shown to consist of fast (undulator) and slow (strophotron) components. By separating fast and slow motions and by averaging equations of motion over fast undulator oscillations, we find spectral intensity of strophotron spontaneous emission in such a system. By solving similarly equations of motion in the presence of an external light wave, we find the gain in a Free-Electron Laser based on the interaction of light with the strophotron mode of the electron motion. Both the strophotron gain and the corresponding intensity of spontaneous emission are shown to be well separated spectrally from the usual undulator parts.

INTRODUCTION

Usually FEL [1, 2] use the kinetic energy of relativistic electrons moving through a spatially modulated magnetic field(wiggler) to produce coherent radiation. The frequency of radiation is determined by the energy of electrons, the spatial period of magnetic field and the magnetic field strength of the wiggler. This permits tuning a FEL in a wide range unlike atomic or molecular lasers. In usual FEL magnetic field of wiggler is supposed to be uniform. But really the magnetic field is inhomogeneous in transverse direction(see for example [3]). It is important to take into account this inhomogeneity. This account leads to complex motion of electrons: fast undulator oscillations along the wiggler axis and slow strophotron motion [4] – [9] in transverse direction . In the next section we describe the equation of motion of electrons moving along the axis of the wiggler with transversal inhomogeneous magnetic field. In the Sec. III and IV we calculate the spectral distribution of spontaneous emission and the gain correspondingly.

EQUATIONS OF MOTION

The vector potential of undulator's magnetic field has a form [10]

$$\overrightarrow{A_W} = -\frac{H_0}{q_0}\cosh q_0 x \sin q_0 z \;\; \hat{j} \tag{1}$$

where H_0 is the strength of magnetic field and $q_0 = 2\pi/\lambda_0$, λ_0 - period of wiggler, $\hat{j}$ unit vector in y direction.

The change of energy is

$$\frac{d\varepsilon}{dt} = 0, \qquad \varepsilon = const \tag{2}$$

* bsk@yerphi.am

Further we consider paraxial approximation when

$$q_0 x < 1 \tag{3}$$

Taking into account (3) the magnetic field (1) becomes

$$H_x = H_0\left(1+\frac{q_0^2x^2}{2}\right)\cos q_0 z; H_y = 0;$$
$$H_z = -H_0 q_0 x \sin q_0 z \tag{4}$$

Then we can write equations of motion taking into account (2) ($p_{x,y,z} = v_{x,y,z}\varepsilon$)

$$\begin{aligned}
\ddot{x} &= -\left(\frac{eH_0}{\varepsilon}\right)^2 x\sin^2 q_0 z \\
\dot{y} &= \frac{eH_0}{\varepsilon q_0}\left(1+\frac{q_0^2x^2}{2}\right)\sin q_0 z \\
\ddot{z} &= -\frac{1}{2q_0}\left(\frac{eH_0}{\varepsilon}\right)^2 \sin 2q_0 z(1+q_0^2x^2)
\end{aligned} \tag{5}$$

After averaging first equation of Eq. (5) on period $2\pi/q_0$ and taking into account that $\overline{\sin^2 q_0 z} = 1/2$ we have

$$\ddot{x} + \Omega^2\, x = 0 \tag{6}$$

which has a solution

$$x = a_0\cos(\Omega t + \theta_0) \tag{7}$$

where

$$\begin{aligned}
\Omega &= \frac{eH_0}{\sqrt{2}\varepsilon}; \qquad a_0 = \sqrt{x_0^2+\frac{\alpha^2}{\Omega^2}}; \\
\cos\theta_0 &= \frac{x_0}{a_0}; \quad \sin\theta_0 = -\frac{\alpha/\Omega}{a_0}; \\
\theta_0 &= -\arctan\frac{\alpha}{x_0\Omega}
\end{aligned} \tag{8}$$

Averaging of the second equation of Eq. (5) gives

$$\ddot{z}^{(0)} = 0; \quad \dot{z}^{(0)} = v; \quad z^{(0)} = vt. \tag{9}$$

The solution of the second equation of Eq. (5) using Eq. (7) and Eq. (9) has a form

$$\begin{aligned}
\delta z &= -\frac{\Omega^2}{2q_0^2}t + \frac{\Omega^2}{4q_0^3}\sin 2q_0 t \\
&+ \frac{a_0^2\Omega^2}{16q_0}\sin\{2(q_0+\Omega)t + 2\theta_0\} \\
&+ \frac{a_0^2\Omega^2}{16q_0}\sin\{2(q_0-\Omega)t - 2\theta_0\}
\end{aligned} \tag{10}$$

Copyright © 2013 CC-BY-3.0 and by the respective authors

So, for z we have

$$\begin{aligned} z &= t\left(1-\frac{1}{2\gamma^2}-\frac{\Omega^2}{2q_0^2}\right)+\frac{\Omega^2}{4q_0^3}\sin 2q_0 t \\ &+ \frac{a_0^2\Omega^2}{16q_0}\sin\{2(q_0+\Omega)t+2\theta_0\} \\ &+ \frac{a_0^2\Omega^2}{16q_0}\sin\{2(q_0-\Omega)t-2\theta_0\} \end{aligned} \quad (11)$$

Here we take into account, that $1-v=\frac{1}{2\gamma^2}$, where $\gamma=\frac{E}{mc^2}$ is a relativistic factor, m- mass of electron, c- velocity of light and E- energy of electrons.

Limitations used in above consideration are

$$a_0 q_0 < 1; \quad \frac{\Omega}{q_0} < 1; \quad a_0\Omega_0 < 1 \quad (12)$$

In longitudinal direction(along axis z, wiggler's axis) electrons perform fast undulator oscillations, while in transverse direction they perform slow strophotron oscillations in one direction(x direction) and fast undulator oscillations in another direction(y direction).

SPONTANEOUS EMISSION

Now using the solutions for x Eq. (7), $\dot{y}$ Eq. (5) and z Eq. (11), we can find the spectral intensity of a spontaneous emission. The spectral intensity of emission in the z axis direction (wiggler's axis) is determined by the formula [11]

$$\frac{d\varepsilon}{d\omega do}=\frac{e^2\omega^2}{4\pi^2}\left|\int_0^T dt[\vec{n}\times\vec{v}]e^{i\omega(t-z)}\right|^2 \quad (13)$$

where do is an infinitely small solid angle in the z direction and T is electron traveling time through wiggler.

Using formulae [12]

$$e^{-iA\sin x}=\sum_{-\infty}^{\infty}J_n(A)e^{-inx} \quad (14)$$

with Bessel functions $J_n(A)$ we find

$$\begin{aligned} \frac{d\varepsilon}{d\omega do} &= \frac{e^2\omega^2\Omega^2T^2}{8\pi^2q_0^2} \\ &\times \sum_{n,m,k=-\infty}^{+\infty}\left[(I_{n+1,k,m}-I_{n,k,m})^2\frac{\sin^2 u_y}{u_y^2}\right. \\ &+ \left.\frac{a_0^2q_0^2}{2}(I_{n,k,m+1}-I_{n,k,m})^2\frac{\sin^2 u_x}{u_x^2}\right] \end{aligned} \quad (15)$$

where

$$\begin{aligned} u_y &= \frac{T}{2}\left[\omega\left(\frac{1}{2\gamma^2}+\frac{\Omega^2}{2q_0^2}\right)-(2n+1)q_0-2m\Omega\right] \\ u_x &= \frac{T}{2}\left[\omega\left(\frac{1}{2\gamma^2}+\frac{\Omega^2}{2q_0^2}\right)-2nq_0-(2m+1)\Omega\right] \\ I_{nkm} &= J_{n-k}(Z_1)J_{\frac{k+m}{2}}(Z_2)J_{\frac{k-m}{2}}(Z_2); \\ Z_1 &= \frac{\omega\Omega^2}{4q_0^3}; \quad Z_2=\frac{\omega a_0^2\Omega^2}{16q_0} \end{aligned} \quad (16)$$

Equation Eq. (15) describes the spectrum of emission consisting of a superposition of the spectral lines located at the combination frequencies of odd harmonics $(2n+1)\omega_{res,und}$ and even harmonics $2m\Omega_{res,st}$, and even harmonics $2n\omega_{res,und}$ and odd harmonics $(2m+1)\Omega_{res,st}$, $(m,n=0,1,2,...)$ where

$$\omega_{res,und}=\frac{2\gamma^2q_0}{1+\gamma^2\frac{\Omega^2}{q_0^2}}, \qquad \omega_{res,str}=\frac{2\gamma^2\Omega}{1+\gamma^2\frac{\Omega^2}{q_0^2}} \quad (17)$$

are resonance frequencies in undulator and strophotron correspondingly.

THE GAIN

The gain can be found from the above derived spectral intensity of a spontaneous emission (Eq. (15)) using Madey's theorem [13].

But in a derivation of these general relations between spontaneous and stimulated processes, some assumptions are used. They require a check in any new case. Therefore we prefer a direct derivation of the gain from equations of motion.

Now let electromagnetic wave propagates along z (wiggler axis) with vector potential

$$\overrightarrow{A_L}=-\frac{E_0}{\omega}\sin\omega(t-z)\left(\hat{i}\cos\alpha+\hat{j}\sin\alpha\right) \quad (18)$$

where ω is the frequency of electromagnetic wave and E_0 its electrical field strength, α is angle between x direction and vector of electric field strength of the propagating electromagnetic wave, $\hat{i}$ and $\hat{j}$ are the unit vectors in x and in y directions correspondingly.

The equations of electron motion in the wiggler (1) and electromagnetic (18) fields are

$$\begin{aligned} \frac{dp_x}{dt} &= -eH_0q_0xv_y\sin q_0z \\ &+ eE_0\cos\alpha(1-v_z)\cos\omega(t-z) \\ \frac{dp_y}{dt} &= eH_0\left[v_z\left(1+\frac{q_0^2x^2}{2}\right)\cos q_0z+q_0v_xx\sin q_0z\right] \\ &+ eE_0\sin\alpha(1+v_z)\cos\omega(t-z) \\ \frac{dp_z}{dt} &= -eH_0v_y\left(1+\frac{q_0^2x^2}{2}\right)\cos q_0z \\ &+ eE_0\cos\alpha\ v_x\cos\omega(t-z) \end{aligned} \quad (19)$$

and the rate of energy change is [11]

$$\frac{d\varepsilon}{dt}=e\overrightarrow{v}\overrightarrow{E}=eE_0(v_x\cos\alpha+v_y\sin\alpha)\cos\omega(t-z) \quad (20)$$

We are interesting in linear gain to find which is sufficient to obtain the first-order corrections $x^{(1)}(t)$, $y^{(1)}(t)$ and $z^{(1)}(t)$ to $x^{(0)}(t)$ Eq. (7), $y^{(0)}(t)$ Eq. (5) and $z^{(0)}(t)$ Eq. (11). These first-order corrections obey the equations(obtained from Eqs. (19))

Copyright © 2013 CC-BY-3.0 and by the respective authors

$$\begin{aligned}
\frac{dp_x^{(1)}}{dt} &= -\varepsilon_0\Omega^2 x^{(1)} \\
&+ eE_0\cos\alpha(1-v_z^{(0)})\cos\omega(t-z^{(0)}) \\
\frac{dp_y^{(1)}}{dt} &= eE_0\sin\alpha(1+v_z^{(0)})\cos\omega(t-z^{(0)}) \\
\frac{dp_z^{(1)}}{dt} &= eE_0\cos\alpha\ v_x^{(0)}\cos\omega(t-z^{(0)}) \qquad (21)
\end{aligned}$$

The linear (field-independent) gain is determined by the second order ($\propto E_0^2$),

$$\begin{aligned}
\frac{d\varepsilon}{dt} &= eE_0\left(v_x^{(1)}\cos\alpha + v_y^{(1)}\sin\alpha\right)\cos\omega(t-z^{(0)}) \\
&+ eE_0\omega\left(v_x^{(0)}\cos\alpha + v_y^{(0)}\sin\alpha\right)z^{(1)} \\
&\times \sin\omega(t-z^{(0)}) \qquad (22)
\end{aligned}$$

which is found from Eq. (20)

Now finding $x^{(1)}(t)$, $y^{(1)}(t)$ and $z^{(1)}(t)$ from Eqs. (21) and using $x^{(0)}(t)$ Eq. (7), $y^{(0)}(t)$ Eq. (5) and $z^{(0)}(t)$ Eq. (11) we obtain expression of electron emitted energy ($\Delta\varepsilon$) during time T and gain ($G = \frac{8\pi N_e}{E_0^2}\Delta\varepsilon$, N_e is electron beam concentration).

All these calculations are simple, although rather cumbersome. Here we present only the found result:

$$\begin{aligned}
G &= \frac{e^2\omega^2\Omega^2T^2}{8\pi^2q_0^2} \\
&\times \sum_{n,m,k=-\infty}^{+\infty}\Big[(I_{n+1,k,m}-I_{n,k,m})^2\sin^2\alpha \\
&\times \frac{d}{du_y}\frac{\sin^2 u_y}{u_y^2} + \frac{a_0^2q_0^2}{2}(I_{n,k,m+1}-I_{n,k,m})^2 \\
&\times \cos^2\alpha\ \frac{d}{du_x}\frac{\sin^2 u_x}{u_x^2}\Big] \qquad (23)
\end{aligned}$$

From Eq. (23) we conclude that maximum gain is achieved when vector of electromagnetic wave E_0 is directed in y direction ($\alpha = \pi/2$).

We calculate the spectral distribution of spontaneous emission and the gain of electrons moving in plane wiggler with inhomogeneous magnetic field. It is shown, that electrons do complex motion consisting of slow (strophotron) and fast (undulator) parts. We average the equations of motion over fast undulator part and obtain equations for connected motion. It is shown, that the account of inhomogeneity of the magnetic field leads to appearance of additional peaks in the spectral distribution of spontaneous radiation and the gain. Having much peaks and using the well-known mode-locking one can obtain ultrashort impulses.

GENERATION OF INTENSIVE TRANSITION RADIATION IN MODULATED MEDIUM

Koryun B. Oganesyan*, A.I.Alikhanyan National Science Lab, Yerevan, Armenia

Abstract

The 3D spin-glass system in the external standing electromagnetic field is considered. It is shown on an example of amorphous quartz, under the influence of a standing microwave field, at its certain parameters, superlattice is created in the medium where difference in values of dielectric constants of neighboring layers can be up to third order. This superlattice exists during the nanosecond, however it is sufficient for using it as a radiator for generation of transition radiation by relativistic electrons.

INTRODUCTION

The formation and governing of periodically modulated refractive index in media is a most important problem of solid state physics and material science. First of all it is related to the possibility of developing compact UV or X-ray Free-Electron Lasers (FEL) based on emission of transition radiation (TR) (see for example [1]). Currently the following two problems are discussed intensely:

1. A gas-plasma medium with periodically varied ionization density [2–9],

2. A special periodical solid-state superlattice-like (SSL) structures composed of layers with different refraction indexes [10–20].

TR is generated due to the difference in frequency-dependent dielectric constants (permittivity functions) of adjacent layers (remember that the radiation power is proportional to $[\epsilon_1^R(w) - \epsilon_2^R(w)]^2$, where $\epsilon_{1;2}^R(w) = Re[\epsilon_{1;2}(w)]$) [21]. Therefore, the possibility of controlling this difference by means of an external field is highly important. In other words, the problem here is to construct a superlattice with difference in dielectric constants of neighboring domains having the form $[\epsilon_1^R(w,\mathbf{g}) - \epsilon_2^R(w,\mathbf{g})]^2$, where $\mathbf{g}$ describes the controlling parameters, $\epsilon_1(w,\mathbf{g})$ and $\epsilon_2(w,\mathbf{g})$ are dielectric permittivity functions in neighboring regions. According to theoretical and experimental studies, the periodical structures may be formed in condensed matter by means of external electromagnetic or acoustic fields [22–25].

This idea was recently realized in TR generation experiments [26]. In particular, it was shown that at the passage of a beam of 20 Mev electrons through amorphous silicon dioxide $a - SiO_2$ with a standing electromagnetic wave (of 10 GHz frequency) inside, anomalous high short-wave radiation was produced. Preliminary studies explain this high intensity radiation as a result of multiple passage of the electron beam through interfaces between regions with different permittivity functions. Theoretically the appearance of $1D$ superlattice order in random media is explained by the polarization of media due to the orientational relaxation of elastic dipoles in the direction of external electromagnetic field propagation [27].

So, the main objective of this work is a systematic investigation of relaxation processes and critical effects in $a - SiO_2$ compound type disordered $3D$ systems under the action of external electromagnetic field that forms a standing wave in the medium, and in particular, to prove the possibility of formation of $1D$ periodic superlattice of permittivity function in the scales of space-time periods of standing wave.

FORMULATION OF THE PROBLEM

The starting point in our discussion will be the Clausius-Mossotti relation for dielectric constant. It is known that in isotropic media (as well as in crystals of cubic symmetry) the dielectric constant is well described by the Clausius-Mossotti equation [28–30]:

$$\frac{\epsilon_s - 1}{\epsilon_s + 2} = \frac{4\pi}{3}\sum_m N_m^0 \alpha_m^0, \qquad (1)$$

where N_m^0 is the concentration of particles (electrons, atoms, ions, molecules) with given m types of polarizability and α_m^0 correspondingly are polarizability coefficients. It follows from this formula that the static dielectric constant ϵ_s depends on the polarizability properties of particles as well as on their topological order. In the external field the homogeneity and isotropy of the medium is often lost. Then, it is expected that the formula (1) will be applicable after slight generalization.

The object of our investigation are solid state dielectrics of the amorphous silicon dioxide $a-SiO_2$ type. According to numerical $ab\ initio$ simulations [31], the structure of this type compound may be well described by the model of $3D$ disordered spin system.

In particular the $3D$ spin system we can represent as a $3D$ lattice with the lattice's constant $d_0(T) = \{m_0/\rho_0(T)\}^{1/3}$, where m_0 is the molecule mass, ρ_0 is the density and T is the temperature. We will assume also, that in each cell of this lattice there are only one randomly distributed spin (roughly polarized molecule).

We will suppose that the media under the influence of external standing electromagnetic field the electrical part

* bsk@yerphi.am

Copyright © 2013 CC-BY-3.0 and by the respective authors

of which has a kind:

$$E(x; E_0, \Omega, \lambda_s, \varphi_0) = E(x; \mathbf{g}) = 2E_0 \sin(\varphi_0)\cos(kx), \quad (2)$$

where $\varphi_0 = \Omega t_0$ and t_0 are respectively the initial phase and time, Ω is a wave frequency, $k = 2\pi/\lambda_s$ and λ_s is the wavelength, the symbol $\mathbf{g}$ shows the parameters of standing wave (controlling parameters) $(E_0, \Omega, \lambda_s, \varphi_0)$.

Here follows a natural question, how does the dielectric constant change on the scale of wavelength period and in time interval $\Delta t \ll \Omega^{-1} \sim 10^{-9} sec$, when the relaxation time of molecular dipoles is $\tau \sim 10^{-11} \div 10^{-12} sec \ll \Omega^{-1}$. This question is important since the processes associated with the Cerenkov and transition radiation produced in media are much faster than the above time scale. Note, that the time, during which a relativistic electron passes the wavelength ($\lambda_s \sim 10^{-4} cm$) of standing wave and the formation times of transition or Cherenkov photons in this layer is less than $10^{-15} sec$. This time interval is essentially less than the time, during which the standing wave is steady-state. Since the wavelength is supposed to be much larger than the inter-dipole distance $\lambda_s \gg d_0$, the Clausius-Mossotti relation is still true. In this case the main problem is to calculate the polarizability coefficient related to orientation effects.

Taking into account the external field, one can express the polarization of matter at an arbitrary point as the macroscopic self-consistent relation:

$$\mathbf{P}(\mathbf{r}) = \sum_{\boldsymbol{l}} \mathbf{p}\,(\boldsymbol{l} - \mathbf{r}) = \sum_m n_m \alpha_m (\boldsymbol{l} - \mathbf{r}) \mathbf{E}_{loc}(\boldsymbol{l} - \mathbf{r}), \quad (3)$$

where $\boldsymbol{l} \equiv \boldsymbol{l}(l_x, l_y, l_z)$ is $3D$ lattice vector, $\mathbf{p}$ is respectively the dipole moment of molecule. The second equation in (3) contributes to the value of dipole moment (spin). Note, that the number of the carriers of given polarization type in an elementary cell is $n_m \sim (d_0(T))^{-3}$, α_m being coefficients of the polarizability of corresponding types with due regard for external field and $\mathbf{E}_{loc}$ is the local field, i.e. the effective field that induces the polarization at the site of an individual molecule. The contribution of each effect to the net dipole moment per molecule is linear, that is actually verified by experiments. Under the action of external field the polarization of different types arise in media. However, simple analyzes shows that the values of polarizability coefficients due to orientation effects essentially exceed the others.

Note that the coefficient of elastic orientational polarizability in amorphous media $\alpha_{dip}(\boldsymbol{l}-\mathbf{r})$ is a random function of cell location. This fact is due to random orientation of local field strengths $\mathbf{E}_{loc}(\boldsymbol{l} - \mathbf{r})$ with respect to the external field $\mathbf{E}(x; \mathbf{g})$. Therefore, all terms in the right side of (1) are basically known and well studied in literature (see, e.g., [28–30]) except from those connected with the orientation effects.

The orientation effects have a collective nature and are characterized by average value of random sum $\sum_{\boldsymbol{l}} \alpha_{dip}(\boldsymbol{l}-\mathbf{r})$ (sum of random coefficients of orientational polarizability).

Multiplying both sides of equation (3) on the field (2), we find:

$$\mathbf{P}(\mathbf{r}, \mathbf{g})\mathbf{E}(x, \mathbf{g}) = -\delta U(\mathbf{r}, \mathbf{g}) = \sum_m n_m \Big[\sum_{\boldsymbol{l}} \alpha_m(\boldsymbol{l} - \mathbf{r}) \mathbf{E}_{loc}(\boldsymbol{l} - \mathbf{r})\Big] \mathbf{E}(x; \mathbf{g}), \quad (4)$$

where $-\delta U(\mathbf{r}, \mathbf{g})$ describes the potential energy of amorphous matter in the external field. The statistical properties of media in the direction of wave propagation will be considered later.

Taking into account (4), one can obtain the following expression for the part of potential energy of $3D$ spin system which is related with the orientational effects of spins in the external field:

$$-\delta U_{dip}(\mathbf{r}, \mathbf{g}) = \sum_{\boldsymbol{l}} \alpha_{dip}(\boldsymbol{l} - \mathbf{r}) \mathbf{E}_{loc}(\boldsymbol{l} - \mathbf{r}) \mathbf{E}(x; \mathbf{g}). \quad (5)$$

Let us separate a layer with volume $V = L_x \times L_y \times L_z$ in the infinite crystal lattice, where $L_x \sim (\lambda_s) \gg d_0(T)$ and $(L_y, L_z) \to (\infty, \infty)$. It is easy to see that this volume is filled with the infinite number of steric spin-chains with length L_x.

An important problem is now to calculate the mean value of the interaction potential between the spin layer and the external field.

Formally the following expression may be written for that:

$$-\delta U_V(\mathbf{r}, \mathbf{g}) = -\sum_{\boldsymbol{l}_\perp} \delta U_{L_x}(\boldsymbol{l}_\perp | \mathbf{r}, \mathbf{g}), \boldsymbol{l}_\perp \equiv \boldsymbol{l}_\perp(l_x, l_y),$$
$$-\delta U_{L_x}(\boldsymbol{l}_\perp | \mathbf{r}, \mathbf{g}) = \sum_{l_x} \alpha_{dip}(\boldsymbol{l} - \mathbf{r}) \mathbf{E}_{loc}(\boldsymbol{l} - \mathbf{r}) \mathbf{E}(x; \mathbf{g}) \quad (6)$$

where $-\delta U_{L_x}(\boldsymbol{l}_\perp | \mathbf{r}, \mathbf{g})$ is the interaction potential between the $1D$ steric spin-chain and external field. We will drop out calculating part and go to conclusion.

CONCLUDING REMARKS

In the present article a new microscopic approach has been developed for studying the properties of stationary dielectric constant and permittivity function in dielectric media under the influence of external standing electromagnetic field. The approach consists of the following two general steps:

1. Generalization of the Clausius-Mossotti equation for dielectric constant in the external standing electromagnetic wave;

2. Generalization of the equation for dielectric permittivity function taking into account the previous results.

Mathematically the problem is solved as follows. The dielectric medium in the external electromagnetic field is

Copyright © 2013 CC-BY-3.0 and by the respective authors

modelled as a $3D$ spin glass system under the influence of external field. Note that all general changes of properties of media take place in the wavelength scale of external field space-time period. We have investigated in detail the layer of medium that consisted of disordered $1D$ spin-chains with the length of the order of external field's wavelength. Taking into account the fact that on infinite (x, y) plane the distribution of spin-chains is isotropic we can use the Birgoff ergodic hypothesis (see 6) and to reduce the initial $3D$ spin-glass problem on a two conditionally separated $1D$ problems. It means that we can investigate each $1D$ problem separately. However we must remember, that at the solution of the second $1D$ problem the parameters of a first $1D$ problem ought to be taken into account.

In the work we have constructed all formulas which are necessary to allow for the contribution of orientational effects at calculation of stationary and frequency-depending dielectric constants.

As was shown in result of catastrophe in *C-M* equation, in the region of short wave-length, the difference between permittivities of neighboring layers may be essentially big.

Last circumstance allows us in homogenous and the isotropic dielectrics of spin-glasses type, artificially to create a superlattice from different permittivitys the parameters of which it is possible to control by external fields and use this structure for generation of extremely intensive transition radiation.

ULTRA-LOW EMITTANCE LIGHT SOURCE WITH A TORUS-KNOT TYPE ACCUMULATOR RING

A. Miyamoto and S. Sasaki
HSRC; Hiroshima Synchrotron Radiation Center, Hiroshima University
2-313 Kagamiyama, Higashi-Hiroshima, Japan

Abstract

We proposed a torus knot type synchrotron radiation ring in that the beam orbit does not close in one turn but closes after multiple turns around the ring. This ring is capable to have many straight sections and it is advantageous to installation of many insertion devices. Currently, we are designing a new ring based on the shape of a (11, 3) torus knot for our future plan 'HiSOR-II.' This ring is mid-low energy light source ring with a beam energy of 700 MeV. It has eleven 3.6-m-long straight sections though the ring diameter is as compact as 15 m.

In late years, some compact light source rings achieved very low emittance of several tens of nmrad. However for the ring we propose, the emittance can be reached less than 10 nmrad when the multi-bend scheme is adopted to the arc section. With this ultra-low emittance, the size and divergence of electron beam is smaller than the diffraction limited light in lower energy part of VUV region, and it will be very useful for many synchrotron radiation users' experiments. Therefore we are designing this ultra-low emittance light source ring having innovatively odd shape.

INTRODUCTION

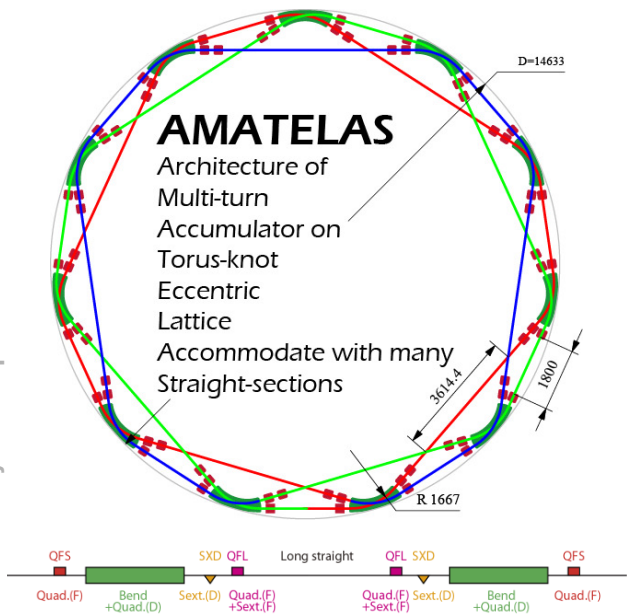

Figure 1: Schematic drawings of (11, 3) AMATELAS designed for HiSOR-II and the lattice of unit cell.

For small light source rings, it is very important to obtain a lot of straight sections in which we can install insertion devices, but it is difficult in reality because they are occupied by various magnets, RF systems or beam monitors. In this context we got a hint from the shape of the torus knot [1], and contrived the ring which had the orbit closed after multiple turns around the ring [2] and named it AMATELAS.

We are planning a new light source ring for our facility [3], therefore we are designing a new ring based on the shape of a (11, 3) torus knot for our future plan 'HiSOR-II' [4]. This ring has 11 long straight sections and we can place insertion devices efficiently by placing the elements such as quadrupole magnets near bending magnet, outside of the orbit crossing section. Furthermore, this ring has about 3 times longer closed orbit in comparison with the conventional ring, the diameter of this ring is as compact as 15 m, but its total orbit length is as long as 130 m. The AMATELAS ring designed for HiSOR-II and the lattice of unit cell are shown in Figure 1, and the main parameters of (11, 3) AMATELAS designed for HiSOR-II storage ring [5] is shown in Table 1, and beta or dispersion function of a unit cell is shown in Figure 2.

Table 1: The main parameters of (11, 3) AMATELAS for HiSOR-II storage ring

Perimeter	45.97 m
Orbit shape	(11,3) Torus knot
Perimeter	45.97 m
Orbit length	130.187 m
Beam energy	700 MeV
Straight sections	3.614 m ×11 1.728 m ×11
Betatron tune	(10.362, 7.807)
Natural emittance	17.9 nmrad
Chromaticity	(+1.0, +1.0)

ULTRA-LOW EMITTANCE WITH MULTI-BEND LATTICE

In late years, some compact light source ring achieved ultra-low emittance of several tens of nmrad. For VUV light sources, it means that it obtains the diffraction limited light to achieve such a low emittance beam. Generally, the beam emittance to obtain the diffraction limited light is given as the following.

$$\varepsilon \leq \frac{\lambda}{4\pi}$$

If energy of the light from undulator is 10 eV, this equation shows that emittance should be less than about 10 nmrad. We judged emittance of this size to be possible by adopting the multi-bend lattice, and we started the design ultra-low emittance light source ring for HiSOR-II.

Multi-bend lattice

In the original lattice shown in Figure 1, it has two bending magnets in one unit cell. It is advantageous to lower emittance that the bend is divided into more bends, however, we decided to adopt the multi-bend lattice having 4 bending magnets for reasons of the geometric size of this ring. There are many variations to length of magnets or drift spaces between the magnets in lattices having 4 bends in one cell, but we notice that placement is not so much easy from necessity to place on a torus-knot shape.

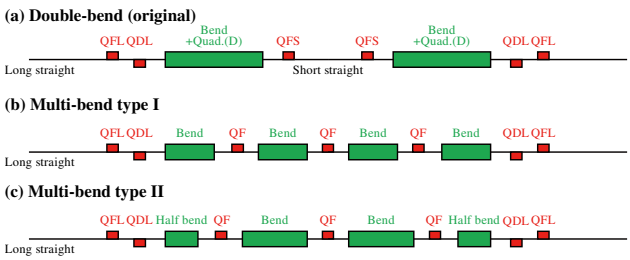

Figure 3: Multi-bend type cells compared with double-bend lattice. (a) is original double-bend lattice. (b) shows multi-bend lattice that all bends has equal length, and (c) is the other type that 2 bends at the end of arc have a half length.

The schematic draws of two types of the multi-bend lattices are shown in Figure 3. In this figure, (a) shows the original double-bend lattice, (b) and (c) are the multi-bend lattices. (b) shows the lattice that all bends has equal length. In another type (c), the length of two bends at the end of arc section is half of the ones in the central section.

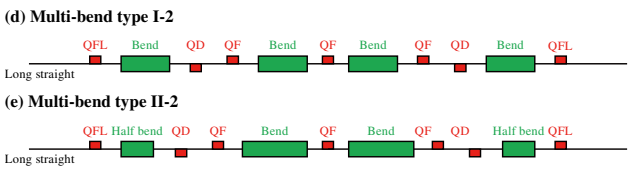

Figure 4: The modified lattices that the doublets are placed in the inside arc section.

In all lattices shown in Figure 3, quadrupole doublets are placed in the outside of arc section, but those doublets should be placed in the inside of arc to control the three parameters, β_x, β_y and η_x in a achromatic lattice better. These modified lattices from (b) and (c) in Figure 3 are shown in Figure 4.

Geometry

In original double-bend type lattice, beam orbit crosses in the bending magnets, but it is necessary to consider where it should cross in these multi-bend lattices. As for the simplest geometry, all magnets of arc section are placed in the outside of the crossing section, however actually it is impossible to have enough length. Therefore we consider some cases that the crossing section of the orbit is in the bending magnet of the edge of arc, in the specific quadrupole magnet and in the drift space.

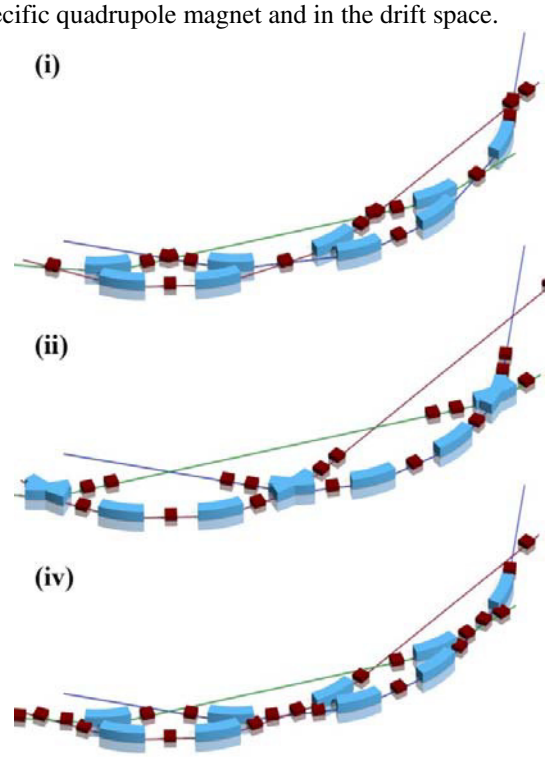

Figure 5: Geometries of multi-bend lattice type-I.

Figure 5 and Figure 6 show geometries in case of multi-bend lattice type-I and type-II. The crossing points of orbit are different in each geometries, it is placed in the singlet quadrupole in arc section in (i), in the bend of edge of arc in (ii), in the one of doublet quadrupole in (iii), in the drift space between the doublet in (iv). Because the crossing angle of the orbit is too small in Type-I (iii) and the magnets are not able to placed, it is not described in Figure 5

Copyright © 2013 CC-BY-3.0 and by the respective authors

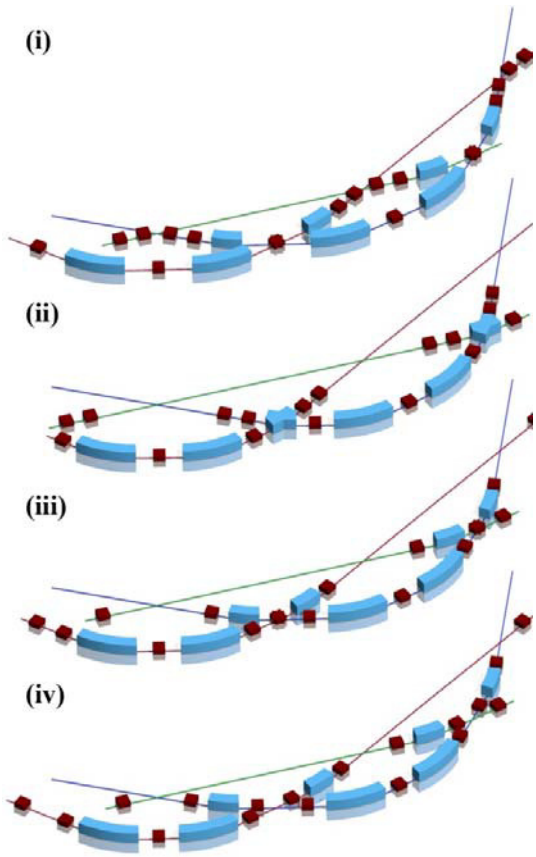

Figure 6: Geometries of multi-bend lattice type-II.

In these lattices, all bend has equal quadrupole force K=-1.8 [m^{-2}] except (iii) type that orbit crosses in bending magnet. Finally, the optical functions in the unit cell and natural emittance of each lattice are shown in Figure 7 and Figure 8.

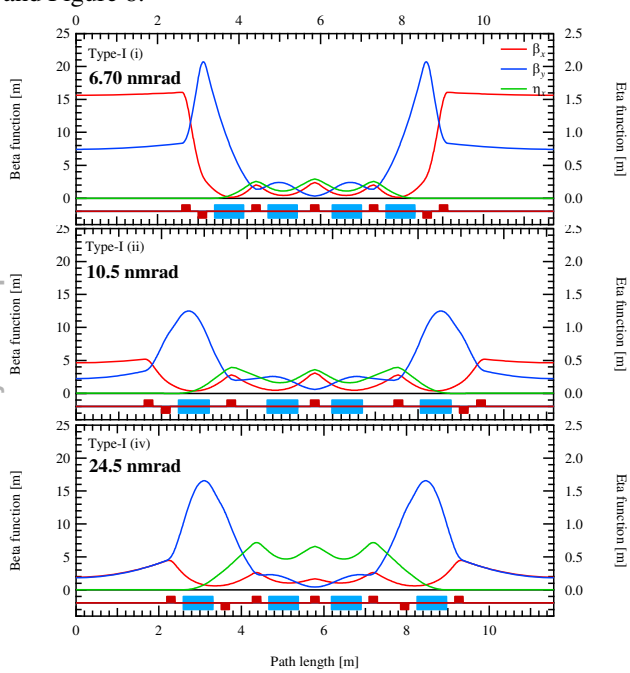

Figure 7: Optical functions of multi-bend lattice type-I.

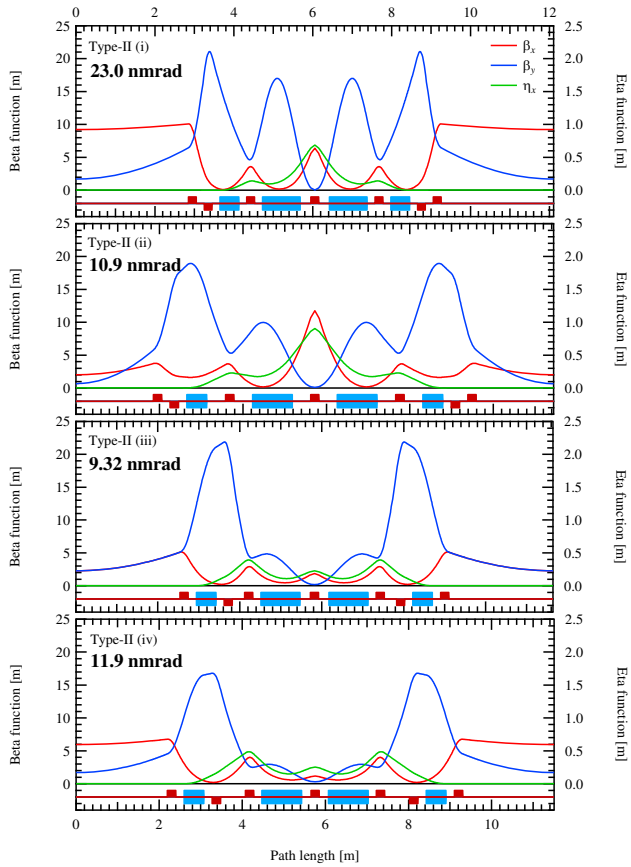

Figure 8: Optical functions of multi-bend lattice type-II.

SUMMERY

We are designing the light source ring based on the torus-knot shape as our future plan HiSOR-II. We can get smaller emittanc6e and may get diffraction limited light in the VUV region adopting a multi-bend lattice to this ring.

As a result of considering in various lattices in the linear dynamics, we were able to make the lattice that reached emittance less than 10 nmrad as our target. However, the geometric conditions by the torus-knot are severe, and it is necessary to consider about the effective chromaticity correction that does not reduce the dynamic aperture.

COUPLING AND BRIGHTNESS CONSIDERATIONS FOR THE MAX IV 3 GeV STORAGE RING

S.C. Leemann*, M. Eriksson, MAX IV Laboratory, Lund University, SE-22100 Lund, Sweden

Abstract

It is often suggested that the emittance coupling of a storage ring should be adjusted to the so-called diffraction limit corresponding to the shortest wavelength of interest. For 1 Å radiation this leads to a typical requirement of 8 pm rad vertical emittance. In ultralow-emittance storage rings like the MAX IV 3 GeV storage ring this corresponds to a comparably large setting of the emittance coupling (2.5%). This approach, however, does not produce the brightest radiation and needs to be revisited taking into account that overall photon brightness depends on the emittances of the electron beam and the intrinsic photon beam. This paper summarizes an analytic approach to maximizing brightness as a function of emittance coupling while retaining sufficient lifetime. Instead of "meeting the diffraction limit", we further reduce the coupling, thus increasing both the brightness and transverse coherence of the emitted radiation. We derive that reducing the MAX IV 3 GeV storage ring's vertical emittance to 2 pm rad (0.6% coupling) will increase brightness and transverse coherence by almost a factor two while 10 h overall lifetime can still be achieved.

INTRODUCTION

The MAX IV facility will use a 3 GeV linac and two storage rings to deliver synchrotron radiation to a broad and international user community across a wide spectral range and covering different temporal scales [1, 2]. The MAX IV 3 GeV storage ring has been optimized [3, 4] for insertion devices (ID's) producing high-brightness x-rays. A typical scenario is radiation at 1 Å produced in an in-vacuum undulator of roughly 4 m magnetic length. The intrinsic photon beam (i.e. the photon beam emitted by a single electron) emerging from such an ID [5] has a diffraction-limited RMS source size given by $\sigma_r = \sqrt{2L\lambda}/4\pi$ and its central cone has an RMS width $\sigma_{r'} = \sqrt{\lambda/2L}$ where L is the magnetic length of the ID and λ the (fundamental) emitted wavelength. This leads to the often quoted emittance criterion for diffraction limited radiation $\varepsilon_r = \sigma_r\sigma_{r'} = \lambda/4\pi$, which calls for 8 pm rad for 1 Å radiation.

In existing 3rd generation light sources, where the equilibrium emittance $\varepsilon_0 = \varepsilon_x + \varepsilon_y$ is several orders of magnitude larger than 8 pm rad, the conventional approach is to adjust the emittance coupling $\kappa = \varepsilon_y/\varepsilon_x$ by e.g. skew quadrupoles so that $\varepsilon_y \approx \varepsilon_r$. For small values of coupling $\varepsilon_x = \varepsilon_0/(1+\kappa) \approx$ const. The Touschek lifetime then scales like $\sqrt{\kappa}$ and the emittance coupling is therefore usually set "at the diffraction limit" and not much lower in order not to reduce overall beam lifetime.

This treatment, however, neglects the actual radiation process in the ID[1]. The brightness of the emitted radiation depends on the overlap of electron beam *and* intrinsic photon beam in phase space. This overlap, assuming a dispersion-free straight, is calculated as [5]

$$\Sigma_{x,y} = \sqrt{\sigma_r^2 + \sigma_{x,y}^2} = \sqrt{\frac{2L\lambda}{(4\pi)^2} + \varepsilon_{x,y}\beta_{x,y}}, \quad (1)$$

$$\Sigma_{x',y'} = \sqrt{\sigma_{r'}^2 + \sigma_{x',y'}^2} = \sqrt{\frac{\lambda}{2L} + \frac{\varepsilon_{x,y}}{\beta_{x,y}}}, \quad (2)$$

where $\beta_{x,y}$ is the beta function in the ID and we have assumed $\alpha_{x,y} = 0$ so that $\gamma_{x,y} = 1/\beta_{x,y}$. The spectral brightness of the emitted radiation is the flux at a specific wavelength[2] emitted from within a specific volume of transverse phase space volume, i.e.

$$\mathcal{B}(\lambda) = \frac{\mathcal{F}(\lambda)}{(2\pi)^2\mathcal{E}_x\mathcal{E}_y},$$

where $\mathcal{E}_{x,y} = \Sigma_{x,y}\Sigma_{x',y'}$ describes the effective emittance, i.e. the emittance of the overlap between electron beam and intrinsic photon beam[3]. In a nutshell, this motivates the push for low-emittance rings running with large amounts of stored current and long undulators with short period lengths.

Finally, since the transversely coherent flux emitted at a specific wavelength λ is given by

$$\mathcal{F}_c(\lambda) = \mathcal{B}(\lambda)\left(\frac{\lambda}{2}\right)^2,$$

the coherent fraction of the emitted radiation can be expressed as

$$\begin{aligned} f_c(\lambda) &= \frac{\mathcal{F}_c(\lambda)}{\mathcal{F}(\lambda)} = \frac{(\lambda/4\pi)^2}{\mathcal{E}_x\mathcal{E}_y} \\ &= \frac{1}{\sqrt{1+(\frac{\sigma_x}{\sigma_r})^2}\sqrt{1+(\frac{\sigma_{x'}}{\sigma_{r'}})^2}} \times \\ &\quad \frac{1}{\sqrt{1+(\frac{\sigma_y}{\sigma_r})^2}\sqrt{1+(\frac{\sigma_{y'}}{\sigma_{r'}})^2}}. \end{aligned} \quad (3)$$

[1] This approach also entirely neglects the horizontal plane and tacitly accepts that ID radiation will, at best, be diffraction-limited in the vertical plane only. Diffraction-limited light sources, i.e. storage rings where the equilibrium emittance is so low that both transverse planes can be operated at or below the diffraction limit, present a solution to this problem and have recently become a topic of great interest [6, 7].

[2] This spectral flux $\mathcal{F}(\lambda)$ is conventionally defined as the number of photons emitted per second and per 0.1% BW ($\Delta\lambda/\lambda$). It is proportional to the stored current and the number of undulator periods.

[3] A noteworthy consequence is that intrinsic photon and electron emittances are added linearly, not quadratically.

* simon.leemann@maxlab.lu.se

Copyright © 2013 CC-BY-3.0 and by the respective authors

It is interesting to note here, that even if the electron beam were perfectly matched to the intrinsic photon beam in transverse phase space, the coherent fraction achieved in this way would be only 25%. Increasing the coherent fraction beyond this level requires diminishing the electron beam's transverse phase space volume with respect that of the intrinsic photon beam.

MATCHING OPTICS TO ID RADIATION

Low-emittance storage rings need to be matched locally to strong ID's to prevent beta beating and tune shifts away from the working point [8]. In addition to such matching, the optics of the ring also need to be matched globally to a specific type of ID and a certain wavelength of interest in order to achieve highest brightness radiation. In 3rd generation light sources the source of radiation is a sheet beam where the horizontal emittance is much larger than that of the emitted radiation, while the vertical emittance and optics are usually the focus of matching efforts[4].

A first attempt at matching could be made by calling for perfect matching of the vertical beta function to a specific ID

$$\beta_y \stackrel{!}{=} \beta_r = \frac{\sigma_r}{\sigma_{r'}} = \frac{L}{2\pi}, \qquad (4)$$

which turns out to be independent of wavelength. This, however, leads to very small beta functions in the ID's which, in connection with the narrow gaps (4 mm are typically assumed), quickly leads to acceptance and hence lifetime issues[5]. On the other hand, one can easily show that $\beta_y = L/2$ ensures maximum acceptance for a given ID and gap setting. In the MAX IV 3 GeV storage ring, assuming a typical in-vacuum undulator of 4 m magnetic length, this has led to a choice of $\beta_y = 2\,\mathrm{m}$ at the center of the long straight sections.

In terms of optics matching to the ID, this choice of β_y is a factor π too large and hence the overlap needs to be improved by appropriate choice of emittance coupling. Assuming the MAX IV 3 GeV storage ring is operated "at the diffraction limit" $\varepsilon_y = 8\,\mathrm{pm\,rad}$[6], inspection of Eqs. 1 and 2 reveals that for the typical in-vacuum undulator, in the vertical plane the angular overlap is dominated by the intrinsic photon beam, while the spatial mismatch is caused by the height of the electron beam in the ID. Figure 1 illustrates this situation: the horizontal mismatch between intrinsic photon beam and electron beam is very large while the vertical overlap can be considerably improved by choosing a reduced coupling.

[4] In addition, horizontal optics in straight sections are often also constrained by other requirements, e.g. large β_x required for injection.

[5] Note also, even if the vertical emittance is set at the diffraction limit and the vertical beta function is adjusted according to Eq. 4, the effective vertical emittance will still be twice the vertical intrinsic photon emittance according to Eqs. 1 and 2. This already indicates that a further reduction of vertical emittance pays off.

[6] Note this corresponds to $\kappa = 2.5\%$, a very relaxed requirement for emittance coupling compared to existing 3rd generation light sources. This is a consequence of the ultra-low emittance lattice of the MAX IV 3 GeV storage ring.

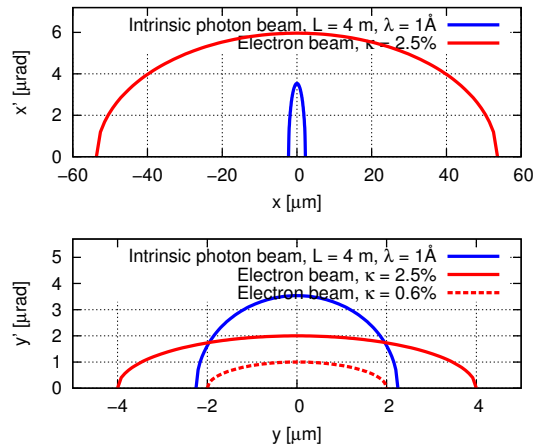

Figure 1: RMS beam size of the intrinsic photon and electron beam in phase space assuming 1 Å radiation emitted from a 4 m undulator installed in a long straight section of the MAX IV 3 GeV storage ring.

MAXIMIZING BRIGHTNESS AND COHERENCE

Since for very small values of coupling, $\mathcal{E}_x \approx \mathrm{const}$, as a consequence of $\varepsilon_x \approx \varepsilon_0 = \mathrm{const}$ (in the absence of IBS), the brightness scales as

$$\mathcal{B}(\lambda) \propto \frac{1}{\mathcal{E}_y} = \frac{1}{\Sigma_y \Sigma_{y'}},$$

and hence one can expect a substantial brightness increase by reducing the vertical electron emittance. The results of an exact calculation assuming two typical ID's are displayed in Fig. 2.

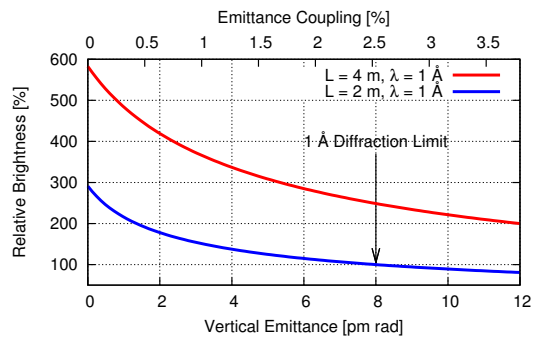

Figure 2: Brightness increase as emittance coupling is reduced for two ID's tuned to 1 Å. The brightness values have been normalized to that of the short ID operated at 8 pm rad. The effect of IBS has not been included.

Although 2 pm rad is a very low vertical emittance, it corresponds to 0.6% coupling which is comparable to presently operating light sources. Tracking studies for the MAX IV 3 GeV storage ring [4, 9] indicate roughly such a level of emittance coupling can be expected as a result of imperfections (magnet and alignment errors) as well as application of orbit correction and linear optics corrections.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Tracking studies have also quantified the decrease of Touschek lifetime and the emittance increase caused by IBS at 500 mA as a result of operating at reduced coupling. These studies have shown that the increase of IBS blow-up can be counteracted by bunch lengthening using Landau cavities. Furthermore, although Touschek lifetime reduces by roughly 50% as a consequence of the coupling reduction, with bunch lengthening from Landau cavities operated at the third harmonic (leading to stretching by roughly a factor five over the natural bunch length [10]) it should remain around 25 h, sufficient to ensure overall lifetime around 10 h.

Figure 3 shows the spectral brightness for a 3.3 m long in-vacuum undulator operated in the MAX IV 3 GeV storage ring at 500 mA. The roughly two-fold brightness increase at wavelengths around 10 keV as a result of coupling reduction from the diffraction limit to 2 pm rad can be clearly recognized.

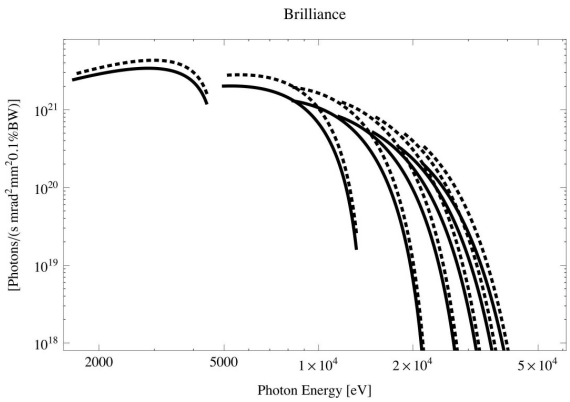

Figure 3: Spectral brightness at peak energy for a 3.3 m long in-vacuum undulator (18 mm period, 4 mm gap, 1.15 T effective field) installed in the MAX IV 3 GeV storage ring at 500 mA stored current for a vertical emittance of 8 pm rad (solid line) and 2 pm rad (dashed line) [7].

In addition to offering much higher brightness for x-rays, the reduced coupling also increases the transverse coherence of the emitted radiation. Figure 4 shows the degree of transverse coherence according to Eq. 3 for three undulators in the MAX IV 3 GeV storage ring tuned to three different wavelengths. Roughly a factor of two increase in coherence at 1 Å when going from the diffraction limit to 2 pm rad vertical emittance can be recognized. Note, however, that even for an ideal sheet beam no more than 2.1% transverse coherence can be achieved at 1 Å because of the mismatch in the horizontal plane (cf. Fig. 1, top). Higher levels of transverse coherence can be observed for softer radiation, albeit with a reduced dependence on emittance coupling since the overlap becomes dominated by the intrinsic photon beam's phase space volume.

CONCLUSIONS

We have demonstrated that setting the vertical emittance below the diffraction limit can lead to a substantial increase of brightness for x-rays. The emittance coupling in the MAX IV 3 GeV storage ring is expected to be close to the required 0.6% and can be adjusted using the skew quadrupoles in the lattice. Since the impact of this reduced coupling on lifetime and IBS emittance blow-up can be mitigated by the Landau cavities, we will be able to offer a vertical emittance of 2 pm rad to our hard x-ray users. Transverse coherence is also improved by this reduction in coupling. However, the horizontal mismatch persists and hence transverse coherence at 1 Å remains low. A fully diffraction-limited storage ring delivering round beams to ID's below the diffraction limit in both planes simultaneously presents a possible solution.

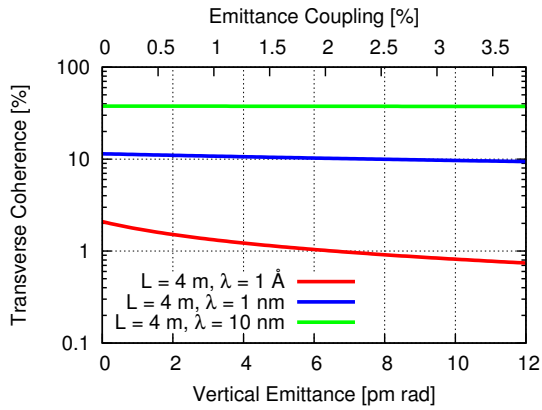

Figure 4: Degree of transverse coherence as a function of emittance coupling for radiation emitted at different wavelengths from ID's installed in a long straight section of the MAX IV 3 GeV storage ring.

SIMULATION OF USING ORBIT BUMPS TO TEST SEXTUPOLE COMPENSATION FOR THE SHORT PULSE X-RAY SYSTEM AT THE ADVANCED PHOTON SOURCE *

M. Borland†, V. Sajaev, ANL, Argonne, IL 60439, USA

Abstract

As part of an ongoing upgrade of the Advanced Photon Source (APS), a Short Pulse X-ray (SPX) system is being developed based on two sets of crab cavities separated by 180 degrees vertical phase advance. Emittance growth due to incomplete cancellation of the kicks from the sets of cavities is a concern. Simulations predict that it can be controlled by adjustment of the sextupoles between the cavities. To test these predictions, we can use orbit bumps that reproduce the trajectories of individual particles through the sectors in question. We present results of simulations of such tests, showing the degree to which the emittance growth and other properties of the machine will differ for optimized and unoptimized sextupoles. We also show results of recent experimental tests.

INTRODUCTION

One of the challenges of operating the Short Pulse X-ray (SPX) facility [1, 2] will be preserving the small vertical size of the APS beam. Vertical emittance increase was predicted in early simulations of SPX [3]. It results mainly from additional coupling occurring due to large vertical trajectories in sextupoles between the SPX cavities [4]. This emittance increase is undesirable because it decreases the x-ray brightness seen by all users. It also increases the minimum x-ray pulse duration that SPX can deliver.

We also found that lifetime and injection efficiency were negatively affected by this strong local coupling through stronger excitation of nearby nonlinear resonances. We resolved these problems in simulation by optimizing the sextupoles between the SPX cavities so as to minimize the vertical emittance growth, while at the same time preserving injection efficiency and lifetime [5].

Owing to the expense and complexity of SPX, it is desirable to test as many aspects of the beam dynamics ahead of time. With deflecting cavities, every longitudinal slice of the beam travels on its own vertical trajectory. The amplitudes of those trajectories depend on the longitudinal position of the slice. Without deflecting cavities, we cannot recreate this behavior completely, but we can generate a real orbit bump using orbit correctors where the entire beam would go on a trajectory corresponding to some beam slice. We could thus verify that the effect of the orbit bump on coupling and nonlinear dynamics is reduced when properly optimized sextupoles are used.

† borland@aps.anl.gov

Any two vertical correctors bracketing a straight section can be used to produce a trajectory that exactly corresponds to a trajectory originating from a single vertical kick somewhere in the straight section. Using existing correctors powered at modest levels, we can simulate deflections equivalent to a cavity deflecting voltage of about 4 MV without loss of stored beam. Note that this is a very stringent test, not only because it exceeds the intended maximum deflection by a factor of two, but because with actual deflecting cavities, very few electrons experience deflections that are close to the maximum possible deflection, owing to the small 33° rms phase spread of the bunch.

LATTICE OPTIMIZATION

The lattices used for the simulations and experiments are mock-ups of the planned operational lattices. The latter will differ from today's lattice by long straight sections (LSS) in straight sections 1, 5, and 7, as well as a special insertion with reduced horizontal beam size (RHB) in straight section 20. Two of the LSSs (in straights 5 and 7) are associated with SPX, being required in order to make room for the cryomodules. The vertical phase advance between these straights (i.e., through sectors 6 and 7) is ideally 2π. The LSSs are mocked up by setting to zero certain magnets that would be removed to make an actual long straight.

The tests require two lattices: one in which the sextupoles in sectors 6 and 7 are optimized to minimize SPX emittance growth, and a second with normal sextupoles in those sectors. The first lattice was optimized using a direct genetic algorithm [6] with fictitious zero-length crab cavities located located 1.2 m downstream of the center of straight sections 5 and 7. The cavities were powered at 2-MV deflection strength during the optimization of dynamic aperture, lifetime, and vertical emittance growth. The optimization was very effective, giving a nominal lifetime of over 11 hours for 24 bunches, 100 mA, 1% coupling, and $\xi_x = \xi_y = 5$; dynamic acceptance of -15 mm; and emittance growth of less than 1 pm on a base of 35 pm.

The second lattice started from the first, but the sextupoles in sectors 5 and 7 were identical to those in sector 1, while the sextupoles in sectors 6 and 8 were identical to those in sector 2. This condition results from the fact that straight sections 1, 5, and 7 are all long straights. This optimization also worked well, but not as well as the previous one, which is perhaps not surprising given that it had fewer knobs with which to work. The lifetime was just under 10 hours, with dynamic acceptance beyond -15 mm.

SIMULATION RESULTS

The purpose of the simulations is to determine whether we can realistically expect to measure differences between the two lattices. Lacking a calibrated model for these lattices, we used 500 random error ensembles, with realistic error levels, with the quadrupole tilt error level chosen to give a vertical emittance of about 10 pm. The vertical emittance was computed for each ensemble using the 6D equilibrium beam moments computation in `elegant` [7]. However, some ensembles gave much higher vertical emittance, so we selected those ensembles giving a vertical emittance of 10 to 15 pm for use in the remaining simulations. For the uncompensated lattice, we had 140 ensembles left, while for the compensated lattice we had 127.

For each ensemble, we performed simulations with bump amplitudes up to 4 MV equivalent. Figure 1 shows the Courant-Snyder invariant of the orbit outside the bump vs voltage for the two cases. Even for 4 MV equivalent, the error bars nearly overlap, indicating that bump leakage is not a reliable way to distinguish between the lattices.

The conclusion is more promising for the vertical emittance, as shown in Figure 2. Here we see that at the 2-MV level the two cases will be separated by a significant gap. Hence, we can expect to see a significant difference when we perform experiments.

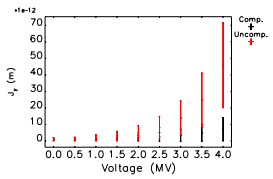

Figure 1: Courant-Snyder invariant vs equivalent deflecting voltage for lattices with and without compensated sextupoles, for many error ensembles.

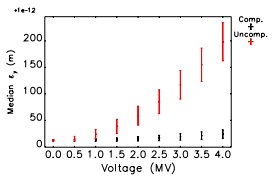

Figure 2: Median vertical emittance vs. equivalent deflecting voltage for lattices with and without compensated sextupoles, for many error ensembles.

We also simulated the dynamic acceptance (DA) and local momentum acceptance (LMA) [8], and computed the Touschek lifetime from the latter. These are to be seen from a different perspective, since we do not expect the configuration with compensated sextupoles to perform as well as the uncompensated case. The compensation is required to reduce the vertical emittance and is designed to have an acceptably small impact on nonlinear dynamics. In comparison to the last set of calculations, these are far more CPU intensive. Hence, we performed runs for only five values of voltage from 0 to 4 MV. In addition, for the LMA computations we used only 50 of the ensembles (subject to the same selection process described above).

For dynamic acceptance, we used all the available ensembles (subject to the vertical emittance limit described above). We tracked 400 turns using parallel `elegant` [9] with kick elements, rf, and lumped synchrotron radiation.

Figures 3 and 4 show the DA for the compensated and uncompensated cases. We see that up to 3 MV, the DA is maintained at nearly the level for the uncompensated case, dropping signicantly for both cases at 4 MV.

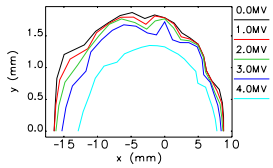

Figure 3: Median dynamic acceptance for case with compensated sextupoles as a function of equivalent deflecting voltage.

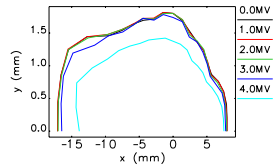

Figure 4: Median dynamic acceptance for case with uncompensated sextupoles as a function of equivalent deflecting voltage.

Simulations of the LMA show that the uncompensated case is significantly worse as the equivalent voltage is increased, which is not surprising [5]. However, when we compute the Touschek lifetime for each ensemble using `touschekLifetime` [10], including the inflated emittances computed above, we see that the lifetime is significantly longer for the uncompensated case, as seen in Figure 5. This is a result of the larger vertical emittance, and hence this measurement would add nothing new.

The momentum acceptance can be measured more directly by scanning the main rf voltage V_m. Figure 6 show the momentum acceptance as a function of equivalent deflecting voltage. The difference of more than 0.2% in momentum acceptance for an equivalent voltage of 3 MV corresponds to the difference between 8.2 and and 8.7 MV in V_m, which should be measurable.

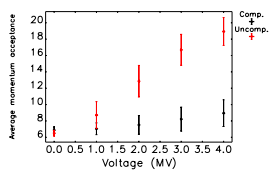

Figure 5: Touschek lifetime as a function of equivalent deflecting voltage for compensated and uncompensated sextupoles.

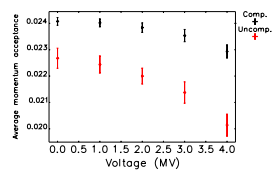

Figure 6: Average momentum acceptance as a function of equivalent deflecting voltage for compensated and uncompensated sextupoles.

EXPERIMENTAL RESULTS

The mock-up lattices desribed above were set up during storage ring studies, using the so-called "reference" orbit, which goes through the centers of magnets rather than accommodating user steering. Figure 7 shows the beta functions after the lattice setup was completed for the lattice with compensated sextupoles.

Copyright © 2013 CC-BY-3.0 and by the respective authors

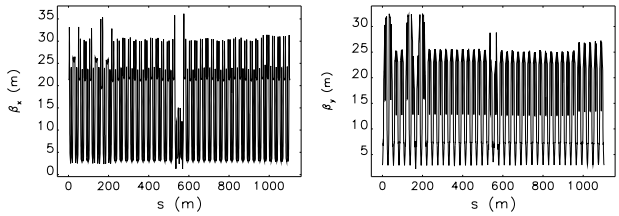

Figure 7: Beta functions of the lattice with compensated sextupoles as measured by the response matrix fit after optics correction.

We used pairs of A:V1 and B:V1 correctors bracketing straight sections 5 and 7 to generate the orbit bumps. The ideal corrector settings nearly closed orbit bumps, with maximum orbit distortion outside the bump of only 2% of the bump amplitude. To improve the bump closure further, we decided to change manually only the pair of correctors around straight section 5 while the other pair of correctors was controlled by orbit feedback.

According to the simulations presented above, the biggest distinction between the lattices shows up in the vertical emittance—and therefore beam size—dependence on the orbit bump amplitude. We performed scans of the bump amplitude for both sets of sextupoles and recorded the beam sizes. Figure 8 shows the dependence of the vertical beam size on the orbit bump amplitude, which is presented in the units of the equivalent deflecting voltage. This plot should be compared with Figure 2. As expected, the lattice with compensated sextupoles shows almost no beam size dependence on the deflecting voltage amplitude, while the lattice with uncompensated sextupoles shows strong dependence. This measurement has verified that the emittance growth can be controlled by optimizing sextupoles.

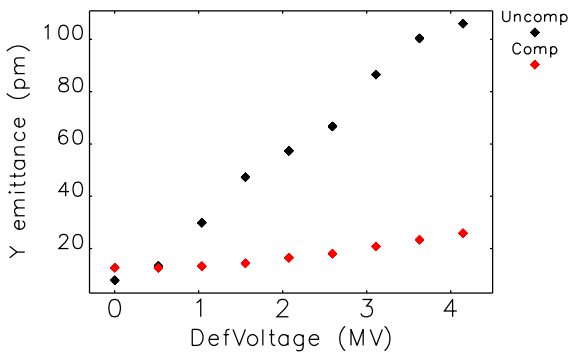

Figure 8: Measured vertical emittance dependence on the equivalent deflecting voltage for lattices with and without compensated sextupoles.

We also measured lifetime and injection efficiency as a function of the orbit bump amplitude. Figures 9 and 10 show the results. Simulations predict that for the lattice with compensated sextupoles the lifetime should not change significantly in the range of deflecting voltage up to 4 MV (see Figure 5). In our measurements, the lifetime stayed approximately constant for the orbit bumps corresponding to deflecting voltage in the range from -4 MV to +3 MV, which roughly corresponds to the predictions.

We have not directly measured the dynamic acceptance of the lattices. However, we have recorded injection efficiency, which can be used as a measure of the dynamic acceptance since our efficiency is defined mostly by the dynamic acceptance of the storage ring. The dynamic acceptance simulations show no big effect for voltages up to 3 MV and then a reduction for 4 MV (Figures 3 and 4). The measurements gave us good injection in the range of orbit bumps corresponding to voltages from -4 MV to +2.5 MV. This again roughly corresponds to simulations.

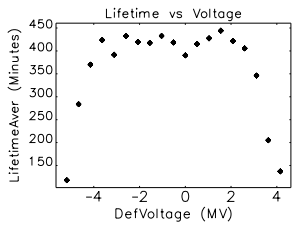

Figure 9: Lifetime as a function of the orbit bump amplitude presented in units of the deflecting voltage for compensated sextupoles.

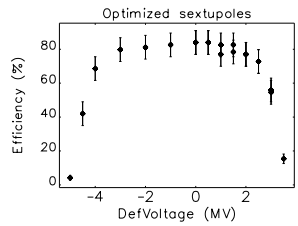

Figure 10: Injection efficiency as a function of the orbit bump amplitude for the compensated sextupoles.

CONCLUSIONS

We performed simulations and experiments to investigate whether use of closed orbit bumps is a valid way to simulate the sextupole compensation scheme for SPX. In simulation, we found that vertical emittance and, to a lesser extent, momenmtum aperture, should show a measurable difference between the two configurations. Experiments verified that the emittance growth is controlled by the compensating sextupoles.

A SEVEN-BEND-ACHROMAT LATTICE AS A POTENTIAL UPGRADE FOR THE ADVANCED PHOTON SOURCE*

M. Borland†, V. Sajaev, Y.-P. Sun, ANL, Argonne, IL 60439, USA

Abstract

The Advanced Photon Source (APS) is a 7-GeV storage ring light source that has been in operation since 1996. In that time, the emittance has dropped from 8 nm to 3 nm. The increasing feasibility of multi-bend-achromat lattices (e.g., the MAX-IV project) promises the possibility of a much greater reduction in emittance. In this paper, we show the design of a symmetric seven-bend-achromat lattice, including linear optics, nonlinear dynamics optimization, magnet requirements, and performance with errors.

INTRODUCTION

There is now wide-spread interest in multi-bend achromat lattices as a means of achieving significantly lower emittance in light source storage rings. Notable efforts include the MAX-IV [1] and SIRIUS projects [2], which are under construction, as well as proposed upgrades for ESRF and SPring-8. A recent report of the Basic Energy Sciences Advisory Committee recommended re-examination of existing upgrade plans for US storage rings to explore the potential of such a lattice. Such work was already on-going at the Advanced Photon Source (APS), but has now taken on renewed urgency.

We have explored a number of lattice concepts, including designs similar to the one being built at MAX-IV. In this paper, we present a design based on the hybrid-multi-bend achromat (HMBA) concept proposed by ESRF [3].

LATTICE OPTIMIZATION

The HMBA lattice is distinguished from the MAX-IV-style lattice by having a dispersion bump between the outer pairs of dipoles, which also feature a longitudinal gradient. Sextupoles are located only in the dispersion bump, by virtue of which their strengths are dramatically reduced. In addition, the phase advance between pairs of sextupole centers in the two dispersion bumps for any sector is 3π and π for the horizontal and vertical planes, respectively.

We started with a lattice file provided by N. Carmignani of ESRF. The first step was to modify the angles for a 40-sector ring (ESRF has only 32 sectors) and perform some basic matching to get a stable lattice. This gave acceptable dynamic acceptance (DA) and local momentum acceptance (LMA), albeit in the absence of errors, and an emittance of about 80 pm at 6 GeV.

For further development, our goal was to reduce the emittance as far as possible, consistent with workable lifetime and sufficient injection aperture for on-axis, swap-out injection [4]. Toward this end, we performed a wide-ranging scan of the integer and fractional tunes that covered over 4000 possible working points with $\nu_x : (99, 109)$ and $\nu_y : (32, 39)$. For each target working point, we used `elegant` [5] to perform linear optics optimization to minimize the emittance, obtain relatively small < 3 m beta functions at the insertion devices (IDs), restrain the maximum beta functions below 20 m, ensure the correct phase advance between sextupoles, ensure the correct overall geometry, etc. In this process, essentially every parameter of the lattice was allowed to vary, including strengths, lengths, and positions of all elements.

Once matching was completed, we corrected the chromaticity to $+2$ in both planes, using a reflection- and translationally-symmetric sextupole distribution. We then used `Pelegant` [6] to perform tracking without errors to determine the maximum stable amplitudes for momentum and amplitude deviations, which involved evaluation of particle survival, crossing of integer and half-integer resonances, and diffusion rates. Figures 1 and 2 show maps of natural emittance and minimum LMA. Note that the latter is often limited at the high-dispersion point and may be smaller than indicated by the tunes vs momentum offset. Figures 3 and 4 show maps of the beta functions at the IDs, which would ideally both be 1.5 m to maximize brightness.

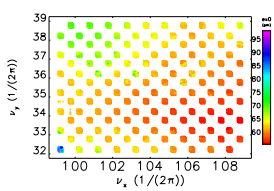

Figure 1: Map of natural emittance vs working point.

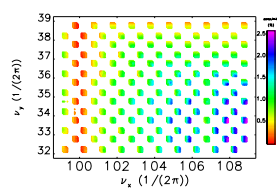

Figure 2: Map of minimum momentum acceptance vs working point.

Since not all parameters can be simultaneously optimized, we performed a non-dominated sort [7], which yielded a handful of superior solutions from which to choose. Dynamic acceptance (DA) and lifetime were optimized for several of these using a tracking-based multi-objective genetic algorithm (MOGA) [8]. This included fine adjustment of the working point and linear optics, as well as adjustment of individual sextupoles. Following ESRF, we organized the sextupoles into 12 families with

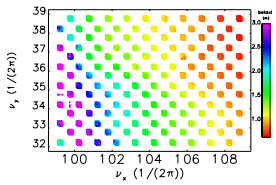

Figure 3: Map of $\beta_{x,ID}$ vs working point.

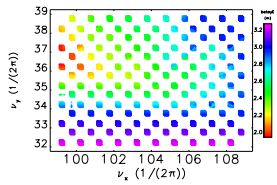

Figure 4: Map of $\beta_{y,ID}$ vs working point.

two-period translational symmetry. Figure 5 shows the lattice functions for the best configuration, while Table 1 lists lattice properties. Of particular note is the natural emittance, which is below 60 pm, and the rather small beta functions at the IDs in both planes. Quadrupole strengths are under 80 T/m, while sextupoles have $|B''| < 6.5kT/m^2$. In the remainder of this paper we present detailed results for this configuration.

Table 1: Parameters of the Optimized Lattice

$\nu_x = 105.45$	$\nu_y = 34.15$
$\epsilon_0 = 59$ pm	$\sigma_{\delta,0} = 0.094\%$
$U_0 = 2.1$ MeV/turn	$\alpha_c = 6 \times 10^{-5}$
Max. $\beta_x = 12.5$ m	Max. $\beta_y = 20$ m
Max. $\eta_x = 73$ mm	
$\beta_{x,ID} = 1.3$ m	$\beta_{y,ID} = 2.9$ m
$\tau_x = 13.5$ ms	$\tau_\delta = 15$ ms

NONLINEAR DYNAMICS

Figures 6 and 7 show the results of frequency map analysis (FMA). We see that the horizontal tune shift with amplitude is quite large. As we'll see below, the regions of the frequency map with no data (e.g., around x=0.5 mm) correspond not to particle loss, but to difficulty determining the tune of the particle when it starts near the $\nu_x = 0.5$ resonance. Detailed simulations with errors showed no particle loss resulting from this resonance. The momentum-dependent tunes and FMA are shown in Figures 8 and 9. Here again we see voids in the FMA resulting from particles with hard-to-determine tunes, not particle loss.

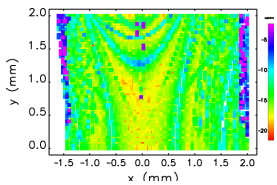

Figure 6: FMA in x-y space.

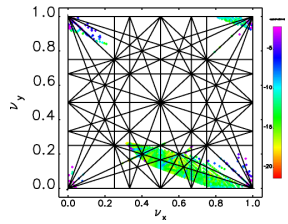

Figure 7: FMA in ν_x-ν_y space.

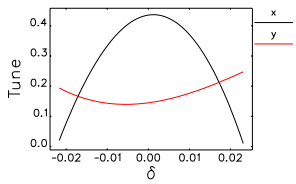

Figure 8: Tunes versus momentum offset.

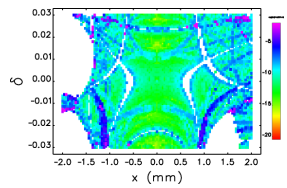

Figure 9: FMA in x-δ space.

For further evaluation, we need a set of error ensembles. We constructed these by first computing lattice functions and 6D equilibrium beam moments for 12,000 ensembles, then selecting those with beta beats between 7 and 10% and $\kappa = \epsilon_y/\epsilon_x : [0.1, 0.2]$. This resulted in 93 ensembles that represent possible machine instances with somewhat large uncorrected errors. We also added systematic multipoles to the quadrupoles and dipoles, at a level of 1% per multipole at a 10-mm radius. Performance with these large errors provides a stringent test of the robustness of the lattice.

DA simulations, shown in Figure 10, exhibit a dynamic aperture of $|x| > 1.3$ mm and $|y| > 1.7$ mm, more than adequate for on-axis injection given that the beam size from the booster will have $\sigma_x = 0.2$ mm and $\sigma_y = 0.3$ mm. The DA search algorithm included radiation damping and had a sufficiently small step size to ensure that the $\nu_x = 0.5$ resonance would not be stepped over. To further verify this, we tracked particles clustered around $x = 0.625$ mm, corresponding to a shift tune bracketing $\nu_x = 0.5$ for each of the 93 ensembles. In tracking for 1500 turns with damping and quantum excitation, no particles were lost, even though many were observed to move across the resonance. Evidently, the tune shift with amplitude is so large that this resonance is not harmful.

Local momentum aperture (LMA) was determined for the 93 ensembles, and is shown in Figure 11. The 10^{th} percentile aperture is over $\pm 2\%$, an acceptable result.

Again, owing to the voids in the FMA shown in Figure 9, we performed additional tracking to verify that the LMA search algorithm did not step over any aperture limits. This consisted of tracking 4100 turns (one longitudinal damping

Copyright © 2013 CC-BY-3.0 and by the respective authors

time) with an 91x91 grid of particles with $x : [-2, 2]$ mm and $\delta : [-4, 4]$ %. A 2-d histogram of the accepted particles for 16 error ensembles, shown in Figure 12, shows the expected region of stability for off-momentum particles.

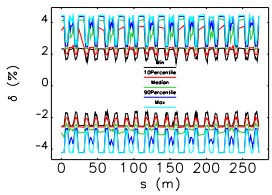

Figure 11: LMA for 93 ensembles, showing 25% of the ring.

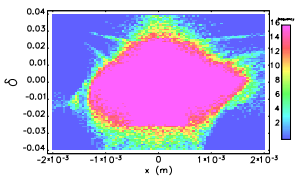

Figure 12: Grid of acceptance counts for 16 error ensembles.

INTRA-BEAM SCATTERING AND LIFETIME

We used `ibsEmittance` [9] to compute the effect of intrabeam scattering (IBS) for two bunch patterns at 200 mA, as a function of the emittance ratio, including a third-harmonic cavity that increases the rms bunch length to 20 mm. Figure 13 shows the effect on the horizontal emittance, which is fairly modest for $\kappa > 0.2$. The effects on energy spread are also modest.

Using the beam parameters from the IBS calculations, we computed the Touschek lifetime using `touscheckLifetime` [10] for the same two bunch patterns. This was done using the 93 LMA results described above, along with the ideal lattice functions. The results, shown in Figure 14, indicate that lifetime for $\kappa = 1$ is 40-60% longer than the lifetime for $\kappa = 0.2$. The gas-scattering lifetime was computed from the DA and the average beta functions listed above using the Toolkit for Accelerator Physics on Androids (TAPAs) [11]. The value is 32 hours, assuming a gas pressure of 2 nT and a gas mixture similar to that found in the APS today.

Since swap-out injection is envisioned, the required lifetime τ with N_b bunches is determined by the minimum possible bunch-swapping interval ΔT_s and the allowed droop $D = N_b \Delta T_s / \tau$ between swaps. With $N_b = 48$, $D = 0.1$, and $\Delta T_s \geq 5$ s, we need $\tau \geq 0.6$ h, which appears possible. For $N_b = 48$, the bunch charge is 15 nC, requiring a rather modest average current of 3.8 nA into the existing accumulator ring, assuming 80% overall efficiency. Accumulation of the required high-charge bunches is described in [12], while the swap-out injection scheme is described in [13].

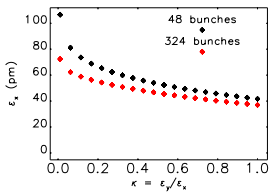

Figure 13: Effect of IBS on the horizontal emittance for 200 mA.

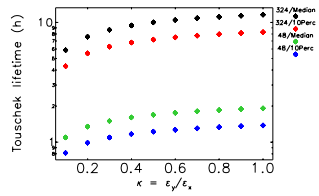

Figure 14: Median and 10^{th}-percentile Touschek lifetime for two bunch patterns.

CONCLUSIONS

A hybrid seven-bend achromat lattice has been developed that could replace the existing APS storage ring, providing a reduction in emittance from 3.1 nm to about 60 pm. Nonlinear dynamics was optimized using a tracking-based multi-objective algorithm, resulting in a design that appears workable for on-axis injection even in the presence of rather large errors. Intra-beam scattering does not have a dramatic effect for emittance ratios greater than about 0.2, even for 48 bunches in 200 mA. Lifetime appears to be workable with the existing APS injector.

ACKNOWLEDGMENTS

Parts of this work were performed using the Blues cluster at Argonne's Laboratory Computing Resource Center and the Mira cluster at Argonne's Advanced Leadership Computing Facility. Thanks to P. Raimondi, L. Farvacque, N. Carmignani, and others at ESRF for providing a copy of an earlier version of their lattice, which helped start this effort.

VARIOUS CANTING SCHEMES FOR UTILIZING MORE THAN ONE INSERTION DEVICE IN AN INSERTION DEVICE STRAIGHT SECTION *

V. Sajaev†, G. Decker, L. Emery, ANL, Argonne, IL 60439, USA

Abstract

Presently, the APS utilizes one simple canting scheme for separation of radiation generated by two insertion devices (IDs) located in the same ID straight section. This scheme is based on triangular horizontal orbit bump with one corrector located between the IDs and orbit distortion limited to the ID straight section only. However, this scheme does not allow for switching between the upstream and downstream devices, nor does it allow for one beamline to accept the combined radiation of both devices. These capabilities are being requested for future APS Upgrade. In this paper, we describe more advanced canting schemes that allow for these capabilities, and also present test results. The main complication here is that the orbit distortion is required to go through the storage ring magnets thus generating optics errors, which have to be corrected.

INTRODUCTION

The Advanced Photon Source (APS) is a 7-GeV third-generation synchrotron light source that has been serving a wide variety of users since operations began in 1996. 34 straight sections are used for installation of insertion devices, and each straight section allows space for up to two 2.4-meter-long devices. Because of ever-increasing demand for beam time from experimenters, over time several straight sections were modified to double the beamline capacity. This was done by introducing so called dual-canted undulators [1]. In this configuration, a chicane is created with a trio of dipole magnets with an undulator in each leg as shown in Figure 1 (1-mrad dipoles used to separate dipole radiation from the ID radiation [2] are omitted for simplicity). The result is an angular separation between the x-ray beams that can be exploited downstream to create two independent beamlines from a single straight section.

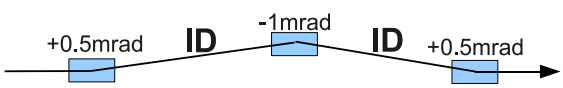

Figure 1: Canted ID straight section configuration presently used at the APS.

Since then, there have been a number of requests from user programs about the possibility of modifing this simple canting scheme to allow for better utilization of the insertion devices. The biggest problem with the present configuration is that the radiation from upstream and downstream devices cannot be switched between the two experimental stations. It is not a big issue presently because most of the insertion devices at the APS are similar to each other. But as more and more narrowly optimized devices are installed, the issue of switching the two photon beams can become more important. For example, the request to explore such a possibility already has come from the user group that plans to install one permanent magnet and one superconducting undulator in their straight section. In this paper, we will present several canting schemes and evaluate their performance from the accelerator physics point of view.

† sajaev@aps.anl.gov

SWITCHABLE CONFIGURATIONS

The most straightforward way to switch radiation of upstream and downstream undulators is just to flip the signs of the correctors that create the triangular orbit bump. The advantage of this approach is its simplicity and the fact that the orbit does not change outside of the ID straight section. This approach, however, has a major deficiency — the position of the radiation source will be shifted transversely by several mm after the switching, as shown in Figure 2. The shift will present challenges in both designing the beamline front end and the beamline optics. Therefore, it is desirable to create such an orbit bump that the source position does not change during the switch.

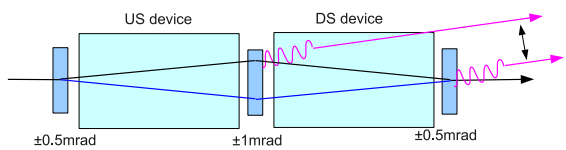

Figure 2: Diagram showing a position shift during ID switch in a triangular-bump configuration.

Symmetric Five-Corrector Bump (W-bump)

Using additional SR correctors outside of the ID straight section, we can make a bump such that source positions stay on the same line after the switch. Figure 3 illustrates the idea: when the beam travels along the trajectory shown in blue, the radiation of the upstream device goes into the inboard beamline; when the orbit is switched to the one shown in red, the downstream ID's radiation goes into the same inboard beamline. This configuration is strongly preferred by the users, but it presents difficulties for the storage ring operation – now the orbit will be changing outside of

the straight section. Non-zero orbit through sextupoles will result in optics distortion that needs to be corrected.

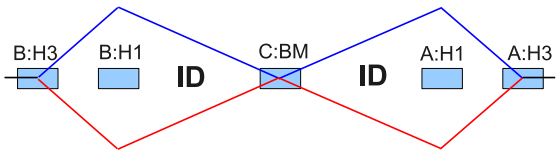

Figure 3: Five-kicker bump that allows photon beams to be sent from both undulators along the same line.

To generate this bump, we simultaneously matched orbit and beta functions using matching in `elegant` [3]. Two correctors on each side of the bump as shown on Figure 3 were used for orbit matching and eight quadrupoles around the straight section were used to match lattice functions. Figure 4 shows the resulting orbit and corresponding lattice functions for two sectors around the ID for no bump configuration and for positive and negative bumps. Lattice function changes are minimal and should not affect users.

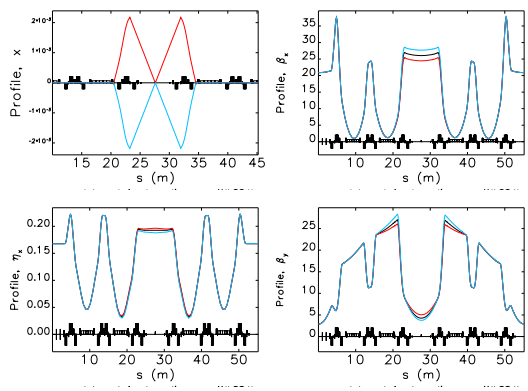

Figure 4: Lattice functions and orbit for two sectors around the ID straight section for W-bump. Starting from top left in clockwise order: orbit, horizontal beta function, vertical beta function, and horizontal dispersion. No bump, positive, and negative bumps are shown.

We also need to ensure that the nonlinear beam dynamics is not affected by this bump. Figures 5 and 6 show dynamic and local momentum apertures for no bump and for positive bump lattices. No effect on lifetime and injection efficiency is expected based on these simulations.

When combined with the 1-mrad bending angle required for the separation of the dipole and ID radiation, the strength of H1 correctors required to generate the orbit bump exceeds the limit. The easiest way to overcome this problem is to install additional correctors right next to the existing H1 correctors. However, this may shorten the length available for ID installation. Another approach is to involve more correctors in the creation of the orbit bump, but the upstream bending magnet radiation source can be slightly affected. From the storage ring operations point of view, however, all these configurations would work as good as the one presented here, and the choice is up to the user.

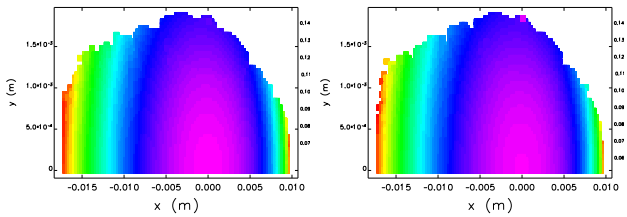

Figure 5: Dynamic aperture for the lattice without orbit bump (left) and with W-bump (right), color coding is horizontal tune.

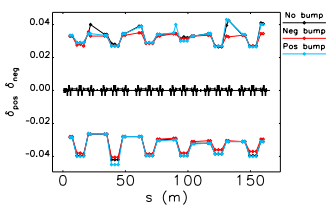

Figure 6: Local momentum aperture for lattice with W-bump.

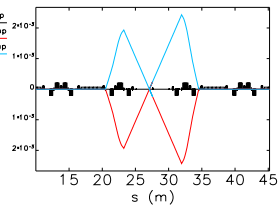

Figure 7: Orbit for W-bump with asymmetrically located central dipole.

One of the possible options for the APS Upgrade is introduction of several longer ID straight sections [4]. It is possible that insertion devices in a longer straight section would have different lengths. In that case, the central dipole does not have to be in the middle of the straight section. The same bump configuration would still work, as shown in Figure 7.

Antisymmetric Four-Corrector Bump

Another option possible in the W-bump configuration is sending the radiation of both devices down the same beamline. To do that, we just need to turn off the central dipole C:BM (Figure 3). Orbit and lattice functions for this bump are shown in Figure 8. Since beta function differences are almost invisible, we don't expect any effects on the nonlinear dynamics in this bump configuration.

Asymmetric Three-Corrector Bump

Recently, a user expressed interest in a configuration where most of the time the undulators will be used in an in-line configuration and only occasionally will the radiation be separated into two beamlines. The two configurations described above would completely satisfy this request. However, for simplicity of everyday operation it would be preferable to have the simplest possible in-line configuration — the straight non-canted configuration. This, however, would require the beamline front end to have an opening at 0 mrad angle relative to the line connecting closest to the ID dipoles. But the existing canted front-end design has only two openings at ± 0.5 mrad relative to that line. This design could still be used if the front end is moved by 0.5 mrad inboard. In the canted mode, this

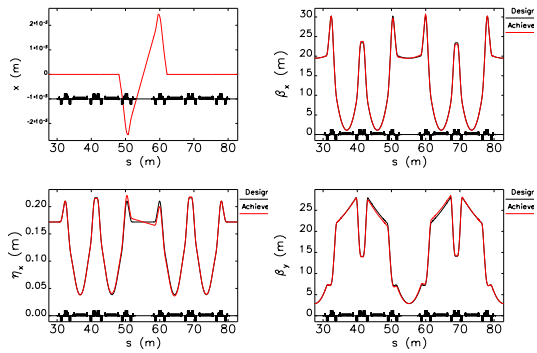

Figure 8: Lattice functions and orbit for two sectors around the ID straight section for an antisymmetric 4-corrector bump. No bump and negative bumps are shown. The order of the plot is the same as in Figure 4.

bump would start with C:BM magnet (see Figure 3). Orbit and lattice functions for this bump are shown in Figure 9.

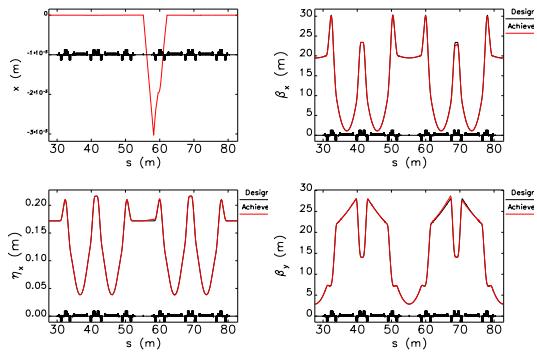

Figure 9: Lattice functions and orbit for two sectors around the ID straight section for an asymmetric 3-corrector bump. No bump and negative bumps are shown. The order of the plot is the same as in Figure 4.

LATTICE CORRECTION

For every case shown above, we first used matching in `elegant` to simultaneously create required orbit bump and adjust the quadrupoles to correct beta functions on the new orbit. For some cases, the matching turned out to be not an easy task and required clever choice and adjustment of varying parameters. This is a valid approach that we have used many times. However, in the real world we would probably just create a required orbit bump, then measure and correct beta functions. We might also change the quadrupoles to some pre-calculated values together with the orbit, but in the end we would still need to measure and correct beta functions.

We decided to test if we could skip beta function matching in the design of a canted lattice and just do optics correction on the new orbit. We wrote a script that performs two steps: runs `elegant` to match orbit bump and then runs our standard beta function correction program *calculateTwissCorrection* that uses SVD inversion of a beta function response matrix. Since the closed-orbit bump condition breaks after beta function correction, this two-step process is repeated for several iterations. The program is bump configuration-independent and can be used for different orbit bumps — it will only require a proper orbit-matching `elegant` file; the beta function correction part is universal. This process usually takes less time than direct matching, is easy to automate, and actually provides better corrected optics. Figures 8 and 9 actually show the results obtained this way.

OTHER ISSUES

To make it out of the vacuum chamber and into the beamline, the radiation would have to fit between the two absorbers that protect the vacuum chamber from dipole radiation and without touching them. Ray tracing shows that this condition is satisfied for all configurations discussed here. However, if the sign of the asymmetric 3-corrector bump is switched to the outboard, then the radiation of the downstream device will hit the wedge absorber W2. Therefore, this canting bump can only exist in the inboard configuration.

Another concern is the pollution of the x-ray BPM signal by the radiation from quadrupoles and sextupoles inside the orbit bump. We have calculated the magnetic fields that the electron beam will see along the canted orbit as a function of the orbit angle. We found that the strongest field encountered by the beam is in the central C:BM magnet, which is the same case as in the present triangular canting configuration.

There are some other issues that would need to be considered. For example, the good field region of the undulators would need to be about 5 mm wider to satisfy the field quality requirements on the switching orbit. Also, rf BPMs on the ID vacuum chamber would need to have an operational range of about ± 2 mm horizontally. This would require an increased distance between the BPM buttons.

CONCLUSIONS

We have simulated several orbit bump configurations that allow for dual-switchable undulator operation. For W-bump and for antisymmetric 4-corrector bump the required corrector strength exceeds the limit, but relatively easy solutions exist that slightly degrade the beamline performance. We have also shown that existing optics correction software can be used to recover lattice functions on the orbit bumps such that the nonlinear beam dynamics is only minimally affected.

NEW CONSIDERATION FOR INSERTION-DEVICE DIPOLE-ERROR PERTURBATION REQUIREMENTS WHEN INCLUDING THE EFFECTS OF ORBIT FEEDBACK*

L. Emery†, V. Sajaev‡ and A. Xiao§, ANL, Argonne, IL 60439, USA

Abstract

For various reasons insertion devices (IDs) in storage ring light sources generally produce small dipole perturbations on the stored beam, which is usually compensated by orbit correction. Tougher orbit stability requirements for the Advanced Photon Source Upgrade (APS-U) project have led us to revisit the requirements of these magnetic-field errors. When including the effect of orbit correction (slow orbit feedback plus fast orbit feedback), we realized that the field-error requirements change from a limit in absolute values of magnetic-field error integrals to that of *rates of change* in magnetic-field error integrals. Some modeling of the combined effect of ramping the strength of an ID with orbit correction will be presented. This new thinking has the potential of greatly alleviating the tuning requirements of insertion devices of all types.

INTRODUCTION

In the early stages of APS operation, perturbations from insertion device (ID) field errors was studied intensively, resulting in a set of ID field specifications [1]. Since then, many IDs have been built, measured, and placed into operation at APS. Their properties and the achievable manufacturing limits are by now well known.

The first- and second-field integrals of an ID are not zero, and also, very importantly, vary with gap. To maintain the source-point during user operations, these perturbations must be held within some limits relative to an appropriate short-term "average reference" condition, which is not necessarily the same as the open-gap condition or starting conditions.

The undulators are slow-moving devices; the induced perturbation on the stored beam has a time scale of 1 seconds to 2 to 3 minutes. When a device gap is scanned repeatedly near their closed position, the period could be a few seconds to a few minutes, depending on the experimenter's data collection requirements. At the smallest gap position a significant beam perturbation could take place within 1 second. Thus the frequency range of interest is, say, 0.01 to 1 Hz, the lower limit selected to be approximately the reciprocal of two minutes.

Given that the stored beam can be subjected to perturbations from general sources of all frequencies, a general beam stability requirement for APS-U was recently re-established (see Table 1). Just like the original APS beam stability requirement, this requirement is meant as a guide for setting limits on individual sources of perturbation. One of the specifications sets limits on all sources in the frequency range 0.01 to 200 Hz (middle column in Table 1).

As discussed previously, conventional undulators are expected to produce perturbations within a tiny fraction of that frequency range, while other sources produce perturbations over the whole frequency range. Thus some of the orbit motion spectrum integrals of Table 1 must be allocated to undulator perturbation limits. In other words, if 3 μm is the maximum allowable rms orbit motion in the x plane from all sources, then a smaller number, say, 1.0 μm, would have to be taken as the maximum allowable rms motion in the 0.01-1 Hz range for undulators.

NEW ALLEVIATING FACTORS

Restricting ID source perturbations to a small amount like 1 μm may seem impossible at first. However, there are many alleviating factors not considered until now and some complicating factors used for years that are no longer needed:

Previously it was assumed that ID gaps could be moving together. Actually, independently operated gaps rarely move together. This will remove a factor $\sqrt{N_{\mathrm{ID}}}$ due to the number of IDs.

If there are independent IDs whose gaps are scanned slowly for long periods, the perturbation frequency will be below the band (below 0.01 Hz), in which case orbit correction cancels the perturbation with very high (virtually "infinite") gain.

Two orbit correction systems are running full-time in different frequency bands and have particularly high gain (i.e., correction effectiveness) in the 0.01 - 1 Hz frequency range of interest. A high gain allows larger tolerances for ID perturbation. Figure 1 shows the gain of the orbit correction as presently configured.

ID gap feedforward on nearby storage ring dipole correctors can be used to reduce the effort from the feedback correctors by 90% in DC mode. However, we found that the EPICS network for communicating gap information is much slower than the dedicated reflective memory of the orbit feedback system. Thus a feedforward system for correcting the orbit perturbation would not be needed to improve stability.

The ID perturbation when the gap is moving is not really a sequence of steps but rather segments of ramp errors of

Table 1: Main Lattice Parameters and Beam Stability Requirements in rms and in Integrated Power Spectral Density in the 0.01 - 200 Hz Band

	Original specification	Achieved in APS Operation[1]	APS-U Require-ments [2]	Allocation for PM IDs[2]	Units
Goals or Performance in rms					
Δx	16	3.5	3	1.0	μm
$\Delta x'$	1.2		0.57	0.17	μrad
Δy	4.4	1.2	0.42	0.1	μm
$\Delta y'$	0.45		0.22	0.055	μrad
Goals in Integrated Power Spectral Density					
Δx			9.0	1.0	μm^2
$\Delta x'$			0.32	0.03	μrad^2
Δy			0.18	0.01	μm^2
$\Delta y'$			0.048	0.003	μrad^2

[1] 0.01 - 100 Hz band.
[2] All permanent magnet IDs, including APPLE, planar and revolver undulators.

various rates. An orbit correction will eventually compensate a step error, but will not be able to correct a perturbation that ramps in time. The resulting error, say, $e(t)$ is equal to the open-loop error orbit rate of change $r(t)$ times the DC correction time constant τ, i.e., $e(t) = r(t)\tau$. The time constant for DC orbit correction at APS is 0.25 seconds. (We might be able to reduce the time constant in the future.) If the ramp doesn't last too long, say, 10 seconds, then the AC-coupled fast orbit feedback (otherwise known as real-time feedback – RTFB) can further reduce the error because of the higher frequency components in the ramp perturbation.

Thus we conclude that the values of the field integrals as a function of gap are not the relevant quantity, rather the derivative is. This can loosen the requirements quite a lot.

The PSD integral from 0.01 to 200 Hz (and other ranges) of the BPM readbacks is continuously calculated by the APS control system with processing that exponentially averages the result with a 1-minute time constant, thus smoothing out spikes. The average over the BPMs at the ID sources will be compared to alarm limits and will be our criterion for stability during operations.

RAMP ERROR WITH FEEDBACK

The orbit perturbation produced by the first- and second-field integral errors of an ID is given by:

$$u(s) = \frac{e}{cp}\frac{\sqrt{\beta_s\beta_o}}{2\sin(\pi\nu)}\sqrt{I_1^2+\frac{I_2^2}{\beta_s^2}} \times \cos\left(|\phi(s)-\phi_s|-\pi\nu\right), \quad (1)$$

$$u_{\max} \approx \frac{e}{cp}\frac{\sqrt{\beta_s\beta_o}}{2\sin(\pi\nu)}\sqrt{I_1^2+\frac{I_2^2}{\beta_s^2}}, \quad (2)$$

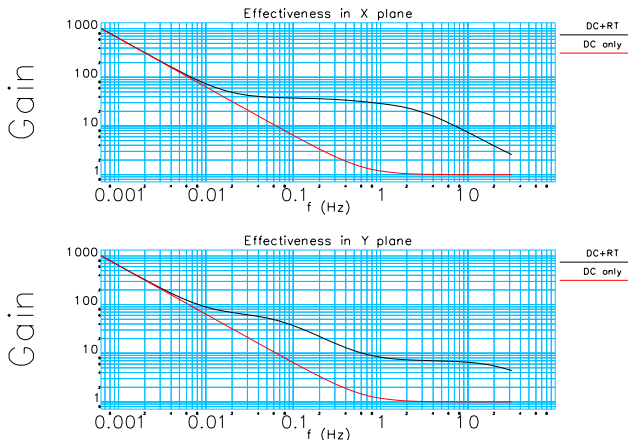

Figure 1: Correction effectiveness with slow correction only ("DC only") and with fast orbit feedback included ("DC+RT")

where u is either x or y; β_s and β_o are the beta functions at the source and the observation location respectively; $I_{1,2}$ are the normalized first- and second-field integrals (i.e., angle and position perturbation, respectively); ν is the betatron tune where we will assume values of $\nu_x = 0.18$ and $\nu_y = 0.22$; and $\phi(s)$ and ϕ_s are the phase advances at longitudinal coordinate s and at the source. The first- and second-field integrals have values roughly independent from each other and different limits will be imposed on each.

Equation (1) obviously indicates that the orbit error induced by a single perturbation is global around the ring, while Equation (2) gives the maximum expected orbit error at some other light source point around the ring. These equations remain valid with integrals and orbit varying slowly with time, of course.

Table 2: Requirements for First- and Second-Field Integral Rate of Change.

Field Integral	No orbit correction[1]	Orbit correction of ramp error, 5-second duration	Orbit correction of ramp error, indefinite duration
Rate of $\int B_y dz$	1.2 G·cm	21 G·cm/s	5.0 G·cm/s
Rate of $\int B_x dz$	1.0 G·cm	16 G·cm/s	4.0 G·cm/s
Rate of $\int dz \int B_y dz'$	2500 G·cm^2	43,000 G·cm^2/s	10,000 G·cm^2/s
Rate of $\int dz \int B_x dz'$	300 G·cm^2	4900 G·cm^2/s	1200 G·cm^2/s

[1] Values in this column are limits on actual field integrals, not their rate.

Most of what follows explains the reduction of the global orbit due to the global orbit correction system. However, even for perfect or infinite time response of orbit correction, there will be remnant local photon beam steering errors because we don't have correcting elements in the straight section. This spatial-domain limitation, though important, will be not be discussed here.

A simple frequency-domain model of the global orbit correction was created using Matlab (building upon scalar-orbit models written by [3, 4]). Since we are interested in the low-frequency part of the response, the effect of time delays and corrector response can be ignored. The results were shown in Figure 1. The gain is found to vary approximately as $1/f$, which is expected for a system under integral control, plus some additional help from the AC-coupled real-time feedback in the important range 0.1 Hz to 1 Hz. Figure 2 shows the time-domain scalar-model orbit response of a unit ramp perturbation (taking orbit and perturbation as unit-less quantities for simplicity). Without correction the orbit error would be equal to the perturbation. With integral correction only (slow orbit feedback),

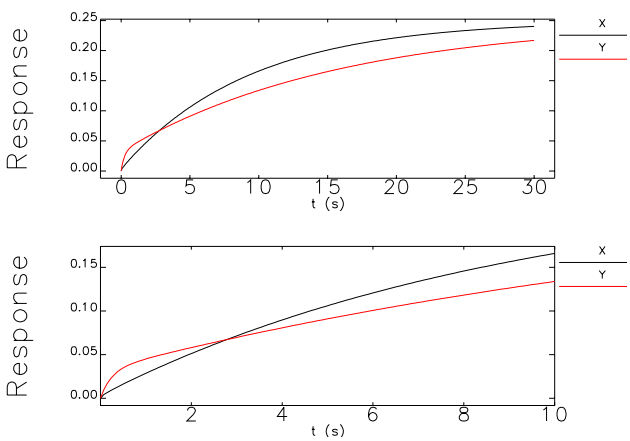

Figure 2: Response to unit-ramp orbit perturbation of our correction system. The average response within the first 5 seconds determines the ID perturbation specification.

the general error would be given by $e(t) = r(t)\tau$, where $r(t)$ = 1 s^{-1} (unit ramp) and τ = 0.25 s in our case. With the additional AC-coupled correction (fast orbit feedback), there is a short-term correction within the first 5 to 20 seconds. Taking the average orbit response over the first 5-second interval, we see that the net orbit response is 0.06 times the ramp rate in both planes. This small factor is reflected in the frequency domain plot of Figure 1, where the average effectiveness in the frequency range 0.1 to 1 Hz is about 20.

Because of the complex frequency dependence of the combined DC-AC system correction effectiveness, the actual orbit "ramp" error from IDs would have to be modeled on a case-by-case basis with orbit correction simulation for acceptance (using the present version of orbit correction).

ID INTEGRAL REQUIREMENTS

Finally we arrive at two sets of ID requirements: one for an arbitrarily long ramp and another (looser) set of stronger allowed perturbations assuming a 5-second ramp. The 5-second ramp-error duration was selected because it matches the worst-case behavior of most planar IDs perturbation.

Table 2 shows the specifications on the first- and second-field integral rates-of-change for these two ramp conditions assuming that each of these integrals will contribute to one half of the ID perturbation allocation of Table 1.

The requirement for the position stability is more severe than that of the angle coordinate, thus only the requirement based on position stability is given in the table.

According to this global orbit error analysis, an ID is allowed to have a somewhat large "peak" in the absolute value of field integrals as long as the peak is not come upon too quickly. One way to make a particularly difficult ID compliant to the rate limit is to make the gap move slowly in the gap-value range where the field integral changes quickly.

OPTICS DESIGN AND BEAM DYNAMICS OPTIMIZATION OF A FIVE-BEND ACHROMAT LATTICE FOR THE ADVANCED PHOTON SOURCE UPGRADE*

Yipeng Sun† and Michael Borland, ANL, Argonne, IL 60439, USA

Abstract

For the proposed future Advanced Photon Source (APS) upgrade, a multi-bend achromat design with very low emittance has been studied. Such a ring promises to enhance the photon brightness and transverse coherence by two orders of magnitude. In this paper, one possible lattice design is presented, which is composed of five-bend achromat arc cells. The linear optics design is done for an emittance of 150 pm at a beam energy of 6 GeV. The nonlinear optics are optimized using the Multi-objective Genetic Algorithm (MOGA) technique for good injection efficiency and beam lifetime. Beam dynamics performance is also preliminarily evaluated.

OVERVIEW

Storage rings based on alternate strong focusing have been widely used for many years in the design of colliders and synchrotron radiation light sources. Several focusing configurations have been invented and some of them applied in real ring construction and operation, including the separated-function FODO cell, combined function FD-cell, double-bend achromat (DBA), triple-bend achromat (TBA), and theoretical minimum emittance lattice (TME) [1].

In simplified form, the natural emittance in a storage ring scales as [2]

$$\epsilon_0 \sim \frac{F \cdot E^2}{(N_d N_s)^3 \cdot J_x}, \qquad (1)$$

where ϵ_0 is the equilibrium emittance in a storage ring, F is a dimensionless factor depending on the arc cell focusing, E is the electron energy, N_s is the number of sectors, N_d is the number of dipoles per sector, and J_x is the horizontal damping partition number.

To improve the photon brightness and coherence in a storage-ring-based light source, a low-emittance electron beam (matched to the photon beam) is needed. In general, the requirement to achieve very low emittance means employment of many weaker dipoles (smaller dispersion) and stronger quadrupoles (focusing). Stronger (or better) focusing approaches the ideal TME condition, while more dipole magnets direct us toward a multi-bend achromat (MBA) lattice where $M \geq 4$.

Such a lattice was first studied and proposed in the 1990s [3]. Similar ideas were also discussed for a future APS upgrade with MBA lattices [4] [5] [6], providing a lower natural emittance below 200 pm. The MAX-IV storage ring is the first MBA lattice being built and will be commissioned in 2015 [7]. It employs 20 seven-bend achromat (7BA) cells in a 528-m circumference, which provides an emittance of 330 pm at a beam energy of 3 GeV. ESRF is also proposing an upgrade using a hybrid multi-bend achromat lattice where larger dispersion is adopted to decrease sextupole strength [8].

Recently the APS has begun to explore replacing the current DBA lattice with a new MBA lattice as part of its ongoing upgrade project. A MAX-IV-like 7BA lattice [9], and an ESRF-like hybrid-7BA are being studied [5]. In this paper, another MBA design for the APS upgrade is presented, namely, a five-bend achromat lattice that provides an emittance of 150 pm at 6 GeV.

LINEAR OPTICS DESIGN

It is proposed to enhance the photon brightness and coherence by two orders of magnitude in the new APS MBA lattice. To achieve this goal, and to reuse as much existing hardware as possible, there are several optics design constraints:

- A natural emittance below 150 pm
- Match the existing ID beamline locations
- Maintain the bending-magnet beamlines
- 40 identical cells, each 27.6 m long
- Straight section length longer than 5 m
- Electron beam energy of 6 GeV
- Reuse the existing rf and injector system

Another important design constraint is from the available magnet technology. It is foreseen to use normal-conducting magnets with a bore radius around 12 mm. The drift length between magnets is limited to a minimum of 10 cm. The assumed maximum dipole, quadrupole, and sextupole strength are listed below.

- Combined dipole: dipole field $< 1\ T$; quadrupole gradient $< 50\ T/m$
- Quadrupole gradient $< 100\ T/m$
- Sextupole gradient $< 10000\ T/m^2$

Based on the above contraints, the linear optics matching is performed using ELEGANT [10]. The minimum magnet length is set to be 15 cm, with the magnet strength as low as possible. The linear optics in one sector is shown in Figure 1, where the starting and ending points are the insertion device (ID) center. One observes that the use of a triplet on either side of the ID straight has allowed tuning the beta

functions (β_x = 2 m, β_y = 1.9 m) at the ID to near the ideal value of L_u/π from the photon beam. In the central three TME-like cells, there are long dipoles combined with a quadrupole gradient. There are two quadrupoles in each dispersion-matching cell at the two ends. The maximum dipole field is 0.6 T, and the maximum quadrupole gradient is 65 T/m. The betatron phase advance is matched to be (2.206, 0.906), which generates a quasi-third-order achromat [11] in a storage ring consisting of 40 such identical 5BA cells.

There is limited space available for dedicated orbit/optics correction magnets and beam instrumentation. That means the correction magnets may need to be integrated into the main magnets. Alternatively, the main magnets could be made stronger and shorter, which would provide more free space. At a beam energy of 6 GeV, the main parameters of the storage ring are listed in Table 1.

Table 1: Parameters of the 5BA Storage Ring

Parameter	unit	value
Circumference	m	1104
Phase advance x/y per cell	2π	2.206/0.906
Tune x/y/s	2π	88.2/36.1/0.06
Natural chromaticity x/y		-166/-80

Energy spread	10^{-4}	9
RMS bunch length	mm	15

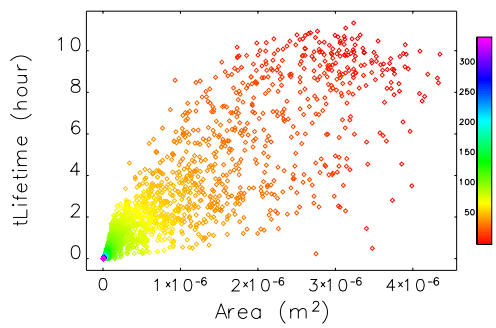

Figure 2: MOGA optimization plot. Horizontal axis is the dynamic acceptance area (β_x = 2 m, β_y = 1.9 m) and vertical axis is the Touschek lifetime.

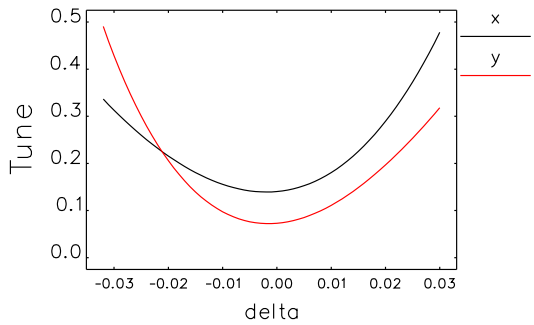

Figure 3: Horizontal (black curve) and vertical (red curve) betatron tune as a function of momentum offset $\Delta E/E$, dominated by second-order chromaticity.

NONLINEAR OPTICS OPTIMIZATION AND PERFORMANCE

In each 5BA cell, there are four families of focusing chromaticity sextupoles (SF) and another four families of defocusing chromaticity sextupoles (SD). The horizontal dispersion is zero in the straight section where there are six harmonic sextupoles. As with the linear optics, mirror symmetry is employed for the sextupole arrangement.

MOGA [12] is adopted to directly optimize both dynamic acceptance (DA) and Touschek ifetime from tracking simulations. The fractional tune is allowed to change in a range of (0.05, 0.45) while the linear optics is still matched. Six families of chromaticity sextupoles and three families of harmonic sextupoles are used as variables that may evolve "naturally" via the genetic algorithm. The two remaining chromaticity sextupoles (SF1 and SD1) are used to correct the first-order chromaticity to 1. A set of solutions with higher DA and lifetime are used as the parents for the next generation. The linear chromaticity penalty function also needs to be small. The MOGA optimization process is shown in Figure 2. It is observed that the DA area is increased from 2×10^{-7} mm^2 to 4×10^{-6} mm^2, and the Touschek lifetime is increased from 0.05 hours to

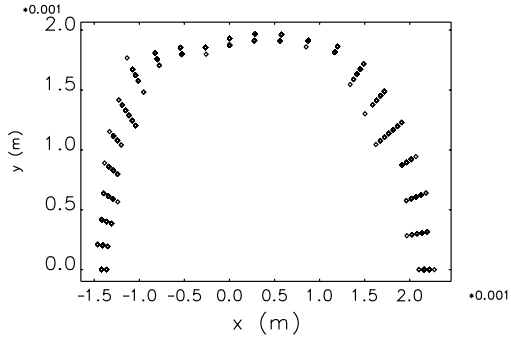

Figure 4: Dynamic acceptance with 50 ensembles of errors (random, systematic magnetic errors, and tilt errors on all the quadrupoles and sextupoles). Tracking is performed at the center of the ID where β_x = 2 m, β_y = 1.9 m.

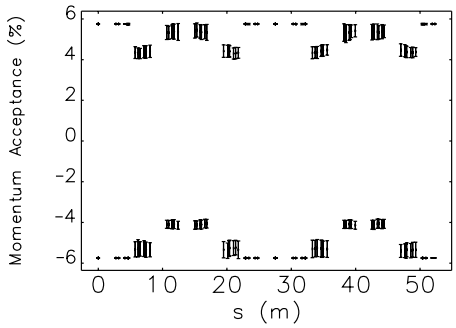

Figure 5: Local momentum acceptance with 50 ensembles of errors (random, systematic magnetic errors and tilt errors on quadrupoles and sextupoles). Tracking is performed at locations next to each magnet in two sectors (a total length of 55 m).

above 10 hours.

One of the best MOGA solutions was picked to be analyzed for its beam dynamics performance. The nominal dynamic acceptance area is 4.2×10^{-6} mm^2 and the Touschek lifetime is 10 hours. The sextupole gradient is less than 6000 T/m^2 with a sextupole length of 0.25 m. There is room to adopt longer sextupoles with lower strength. As mentioned above, the nonlinear optics aberrations are optimized using MOGA. The linear chromaticity is corrected to be 1, which counters the head-tail instability. Examining the solution found by MOGA, we find that the higher-order chromaticities are optimized such that the off-momentum tune spread is minimized. Given the fractional tune close to integer, the second order chromaticities are also optimized to be positive (less than 500), as shown in Figure 3. The global momentum acceptance is limited by the rf bucket, which is 3%.

Dynamic acceptance is the maximum stable transverse amplitude, which is determined by a single-particle numerical tracking simulation. It should ensure efficient acceptance of the injected beam with large emittance and energy spread. It may also impact on the circulating beam lifetime. As shown in Figure 4, the dynamic acceptance is 2 mm $\times$ 1.5 mm at the center of the ID where β_x = 2 m, β_y = 1.9 m. Fifty ensembles of magnetic errors and tilt errors are applied on the quadrupole and sextupole magnets. Note that errors are added to give optics beating of around 1%. No explicit misalignment errors are included, but the effect of such errors is nominally included by the choice of uncorrected optics beating. It is concluded that the DA is enough for on-axis swap-out injection. It is possible to increase the beta function in the injection area and reoptimize the DA for off-axis accumulation, which needs further investigation.

Scattering effects in the electron bunch change both transverse and longitudinal momentum of an electron. Local momentum acceptance is defined to be the maximum acceptable momentum change in a specified location. The mechanisms causing electrons to lose momentum may be physical aperture, DA, or rf bucket limitations. The LMA is determined by tracking and is shown in Figure 5. It is close to 4%, which ensures a good lifetime. (In this simulation we increased the rf voltage to reveal the limitation due solely to beam dynamics.) Collective effects are not studied yet, but expected to be on a smiliar level with the 7BA design [9].

CONCLUSION

A five-bend achromat lattice was developed for a possible future APS MBA upgrade. The linear and nonlinear optics are both optimized to improve the beam dynamic performance.

LINEAR SCALING ON CHOOSING A BUNCH COMPRESSION RATIO FOR AN FEL DRIVER*

Yipeng Sun†, ANL, Argonne, IL 60439, USA

Abstract

In this paper, a proper initial bunch length as a function of the main rf frequency and rf phase is estimated analytically by several approaches, assuming that no harmonic rf section is needed to linearize the energy modulation introduced during main rf acceleration. Next the upper limit of the bunch compression ratio in a single stage is evaluated analytically. The analytical relations derived on choosing a proper initial bunch length as a function of main rf frequency are confirmed by numerical simulation. These simple limits provide rough analytical estimations and may be beneficial for choosing bunch compression ratios in different stages of an FEL driver, especially in a first-stage bunch compression system where an harmonic rf linearization is usually applied.

OVERVIEW

A magnetic bunch compression system is normally adopted during the acceleration process of the electron beam, usually in several (two) stages. The basic idea is to first introduce an energy modulation (chirp) along the electron bunch in its longitudinal direction by an rf acceleration off-crest, then let the electron beam pass by a dispersive region where electrons in the head and tail of the bunch all move relatively towards the bunch center. Chicane- and wiggler-based bunch compressor designs were proposed and studied thoroughly in the 1990s, mainly for linear collider projects [1] [2] [3].

Due to the nonlinear nature of the rf sinusoidal wave and an initially long bunch length, higher-order energy chirps can not be neglected. Harmonic rf linearization of the longitudinal phase space of the electron bunch is normally employed to generate a more uniformly compressed bunch in a first-stage bunch compression. This paper discusses what is the limit on the bunch compression ratio in order to achieve a quasi-linear bunch compression without harmonic rf.

PROPER INITIAL BUNCH LENGTH WITHOUT HARMONIC RF

In this section, only the main rf acceleration section is considered, and a proper initial bunch length is derived as a function of rf frequency and rf phase, given that a quasi-linear compression is achieved with a reasonable bunch compression ratio adopted for each stage. There are two possible ways to quantify a quasi-linear compression. First, the contribution to final bunch length from nonlinearities (from rf acceleration and bunch compressors) could be evaluated and limited to a certain percentage. A second way is to compare the final bunch length calculated as the root mean square of the distribution with the one derived from a numerical fit of the final distribution (Gaussian fit if the initial distribution is Gaussian), and limit the difference between these two to a certain amount.

Energy Chirp Approach

First let us recall the energy modulation formula. For any one particle in a bunch, its relative energy offset after passing by an rf acceleration off-crest can be expressed as shown below:

$$\begin{aligned}\delta(z) &= \delta_i \frac{E_{i0}}{E_{f0}} + \frac{eV_0\cos(\phi + kz_i)}{E_{f0}} \\ &= a\cdot\delta_i + \frac{eV_0\cos(\phi+kz_i)}{E_{f0}}. \end{aligned} \quad (1)$$

where δ_i denotes the initial uncorrelated energy offset, E_{i0} is the central energy before rf acceleration, E_{f0} is the central energy after rf acceleration, e is the electron charge, V_0 is the rf voltage, ϕ is the rf phase, $k = \frac{2\pi}{\lambda}$ is the rf wave number, λ is the rf wavelength, z_i is the particle's longitudinal coordinate relative to the bunch center, and $a = E_{i0}/E_{f0}$ is the energy damping ratio.

The first- and second-order energy chirp from the main rf acceleration could be described by the rf wave number, rf voltage, and rf phase, solved from the same Taylor expansions discussed above, as shown below:

$$h_1 = -\frac{keV_0\sin\phi}{E_{f0}} \quad (2)$$

$$h_2 = -\frac{k^2eV_0\cos\phi}{2E_{f0}}. \quad (3)$$

Neglecting the energy chirp above the third order, the overall energy modulation from this main rf section can then be rewritten as

$$\delta(z) = a\cdot\delta_i + (h_1 + h_2\cdot z)z, \quad (4)$$

where $h_1 + h_2\cdot z$ denotes the effective first-order energy chirp.

One then observes that if z is small enough to make $h_1 + h_2\cdot z \approx h_1$, the overall energy modulation is almost linear; in that case harmonic rf linearization is no longer necessary. This condition could be interpreted as $|h_1| \gg |h_2\cdot\sigma_z|$ and further derived to be

$$\frac{c\cdot\tan\phi}{\pi\cdot f_{rf}\cdot\sigma_z} \gg 1. \quad (5)$$

† yisun@aps.anl.gov

Copyright © 2013 CC-BY-3.0 and by the respective authors

At this step, a proper initial bunch length can be expressed as a function of the main rf frequency and rf phase, as shown below. Here one assumes that a reasonable bunch compression ratio is adopted, with the detailed requirements discussed in the following section.

$$\sigma_{z,max} = D_0 \frac{2\tan\phi}{k_{rf}}, \tag{6}$$

where D_0 denotes an empirical constant whichthat is a small number much less than 1, which could be fitted from numerical simulation studies employing rf systems with different frequency (such as from L-band rf to X-band rf). As illustrated by the numerical simulation results below, in general D_0 should be less than 0.01 in order to maintain a relatively linear longitudinal phase space and a quasi-linear bunch compression without harmonic rf assistance. In general, the required value of D_0 depends on rf frequency, average rf phase adopted for introducing energy correlation, total compression ratio in all the stages, and the number of bunch compression stages. D_0 is inversely proportional to the rf phase and total compression ratio, while it is proportional to the number of bunch compression stages.

To generate a final hard X-ray FEL using normal photoinjector and undulator configurations, usually the electron bunch length needs to be compressed by 30-200 times of its initial value. If more stages of bunch compression are adopted, one only needs a smaller bunch compression ratio in each stage. This in turn requires only a small rf phase and small longitudinal dispersion (momentum compaction) of the bunch compressor systems. In this case, a larger constant D_0 and a longer initial bunch length can be tolerated.

Final Bunch Length Approach

A proper initial bunch length can also be evaluated by examing the expression of a final bunch length after bunch compression. Under a condition of linear optimal compression $1 + h_1 R_{56} = 0$, a similar required relationship is derived, $|h_1| \gg |h_2 \sigma_z|$. Assuming the electron bunch preserves a Gaussian distribution after passing by the dispersive region, the RMS bunch length can then be calculated as the integral shown below:

$$\sigma_z{}^2 = \int\int z_f{}^2(z,\delta) \cdot f(z,\delta) dz d\delta. \tag{7}$$

Then the expression $z_f(z,\delta)$ is derived with dispersion terms of the bunch compressor up to third order. After passing by the dispersive region, the longitudinal coordinate (relative to the bunch center) of any particle can be expressed as shown below:

$$z_f(\delta) = z_i + R_{56}\delta + T_{566}\delta^2 + U_{5666}\delta^3 + \ldots. \tag{8}$$

Take the correlated relative energy offset $\delta(z)$ in terms of energy chirp up to second order, keep the terms up to second order bunch compressor dispersion, and neglect the initial uncorrelated energy offset δ_i in higher-order terms above δ^2. The square of $z_f(\delta)$ is then calculated to be a polynomial of z.

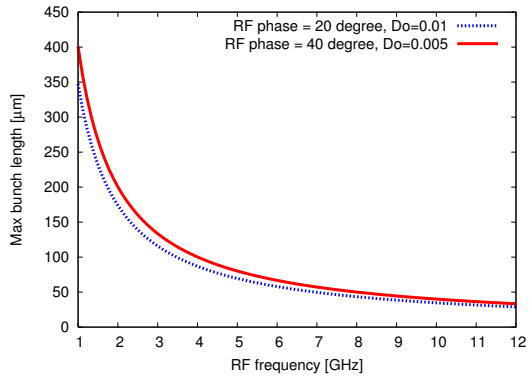

Figure 1: Proper initial bunch length as a funcion of rf frequency, for two given rf phases of 20 and 40 degrees. No harmonic rf linearization is included. A constant of $D_0 = 0.01$ is assumed for the 20-degree case, while $D_0 = 0.005$ is assumed for the 40-degree case.

One can then find the expression of the final bunch length by inserting $z_f^2(z,\delta_i)$ into the final bunch length formula andcalculate the integral. Here one needs to note that the integral of all the odd functions is zero, such as $\int\int z \cdot f(z,\delta) dz d\delta = 0$ and $\int\int z^3 \cdot f(z,\delta) dz d\delta = 0$. The expression of final bunch length only has entries from the integral of all the even functions. Under a condition of linear optimal compression, $1 + h_1 R_{56} = 0$, one finds that the final bunch length equals

$$\begin{aligned} \sigma_{z,f}^2 &= a^2 R_{56}^2 {\delta_i}^2 \\ &+ [2R_{56} a \delta_i (h_2 R_{56} + h_1^2 T_{566} + h_2^2 T_{566} \sigma_z^2) \\ &+ (h_1^2 \cdot T_{566} + h_2 \cdot R_{56})^2 \cdot \sigma_z^2] \cdot \sigma_z^2. \end{aligned} \tag{9}$$

Again, assuming a normal four-dipole chicane is employed as the bunch compressor, there is a fixed ratio between its first-order and second-order dispersion terms R_{56} and T_{566}, as $T_{566} = -1.5 R_{56}$. From the expression of final bunch length, one observes that the first term $a^2 R_{56}^2 {\delta_i}^2$ is from the initial uncorrelated energy spread, and the third term $(h_1^2 \cdot T_{566} + h_2 \cdot R_{56})^2 \cdot \sigma_z^2$ implies that the second-order chirp h_2 always adds on a first-order effect given as $T_{566} = -1.5 R_{56}$. However, a larger rf phase (close to on-crest point) can minimize the contribution from the third term. It is the second term that could be derived to give a similar final conclusion as discussed in the last section, with a required criteria of $|h_2 R_{56} + h_1^2 \cdot T_{566}| \gg |h_2^2 T_{566} \cdot \sigma_z^2|$. To repeat, the required relationship associated with the maximum tolerable bunch length is $|h_1| \gg |h_2 \sigma_z|$.

One could plot the proper initial bunch length as a function of rf frequency with different rf phase, as shown in Figure 1. One observes that for a lower rf frequency, the proper initial bunch length is longer, which is as expected. Another point is that if a higher rf phase can be employed, then the tolerable bunch length can be longer. In the next section, the analytical results derived above are checked

Copyright © 2013 CC-BY-3.0 and by the respective authors

and confirmed by numerical simulations with multi-stage bunch acceleration and compression based on rf systems with different frequencies.

Proper Compression Ratio in One Stage

In this subsection, a proper bunch compression ratio in one stage is discussed and an upper limit is drawn. Limited to first order, a compression ratio is approximated as shown below:

$$C = \frac{1}{1 + h_1 R_{56}}. \quad (10)$$

From the final bunch length expression one also observes that to keep an effectively linear bunch compression, there should be a limit applied on the bunch compression ratio. That means a bunch compression ratio can not be too large in one stage, otherwise the bunch compression is no longer linear.

Consider a first-order optimal bunch compression case. One has $1+h_1 R_{56} = 0$ and then could conclude that in this case, the final bunch distribution is only dependent on the nonlinear terms, which obviously breaks the linear compression requirement. So in general, there should be another criterion for a linear bunch compression that can be derived and shown in the following formula, up to second order. One needs to note that in the coefficient of term z^4, the relatively small uncorrelated initial energy offset δ_i and first-order associated term $4h_1 h_2 T_{566}(1 + h_1 R_{56})$ are neglected:

$$(1 + h_1 R_{56})^2 \gg (h_1^2 \cdot T_{566} + h_2 \cdot R_{56})^2 \cdot \sigma_z^2. \quad (11)$$

The above requirement in turn gives an upper limit on the bunch compression ratio in one stage. As there is a large acceleration in beam energy between subsequent stages, the nonlinear terms in the bunch energy chirp is also damped during acceleration. That damping effect helps to maintain a linear energy correlation. Also, as the bunch length becomes shorter from one stage to the next, the new contribution on the nonlinear energy chirp from the following linacs is smaller. Under this kind of configuration with more than two stages of bunch compression, a quasi-linear bunch profile should be easily achieved at the linac end. The requirement on bunch compression ratio in one stage (especially the first stage) is then approximated as shown below, which is a function of dispersion terms, energy chirp terms, and RMS bunch length:

$$C \ll \frac{1}{\sigma_z |h_1^2 \cdot T_{566} + h_2 \cdot R_{56}|}. \quad (12)$$

Combining all the above considerations, a bunch compression ratio between 5 and 10 may be adopted in one stage. The last point is that in general one should choose a weak chicane bunch compressor with small dispersion terms R_{56} and T_{566}, in order to minimize the contribution from higher-order terms.

Numerical simulation results [4] [5] are presented here, for two FEL driver designs based on different rf frequencies; these are the L-band rf (1.3 GHz) and the X-band rf (12 GHz) [6]. No harmonic rf correction is included here. The initial bunch length of $300\mu m$ and $40\mu m$ are adopted plus the rf frequency and phase. One could observe Figure 1 and find that $300\mu m$ and $40\mu m$ are the limited bunch lengths corresponding to the rf frequency of 1.3 GHz and 12 GHz, respectively. From the simulation results as shown below, one could conclude that the bunch compression process is quasi-linear, and a quasi-Gaussian bunch density profile is preserved. No spike in density profile is generated. These numerical simulation results confirm the validity of the above analytical derivations. It is noted that if one extends these two-stage bunch compression systems into three stages or more, the final bunch current profile could be more uniform, due to the reasons discussed above. In detail, the bunch compression ratio can be smaller in each single stage, and the dispersion terms R_{56} and T_{566} are also smaller in the bunch compressors. The relative energy-dependent-damping effect of the nonlinear energy chirp is also stronger given that more bunch compression stages are adopted.

CONCLUSION AND DISCUSSION

In this paper, analytical formulae are derived to estimate an initial proper bunch length as a function of rf frequency and rf phase in a linac-based FEL driver. These derivations may be benificial for an FEL driver design that has a mainly low bunch charge operation mode and that could achieve an initially short bunch length from the upstream photoinjector. It is also noted here that these limits only provide rough analytical estimations on the required bunch length and compression ratio, where assumptions have been made and no collective effects are included. A detailed bunch compression system design can start with these simple formulae and then be optimized by 3-D simulations with all effects included.

SIMULATION OF AN X-BAND HARD X-RAY FEL WITH LCLS INJECTOR*

Yipeng Sun†, ANL, Argonne, IL 60439, USA
Tor Raubenheimer, SLAC, Menlo Park, California 94025, USA
Paul Emma, LBNL, Berkeley, California 94720, USA

Abstract

In this paper, the accelerator design and start-to-end 3D macro particle simulation (using ELEGANT and GENESIS) of an X-band rf-driven hard x-ray FEL with LCLS injector is briefly discussed. A preliminary design and LiTrack 1D simulation studies were presented earlier [1]. In numerical simulations this X-band rf-driven hard x-ray FEL achieves/exceeds LCLS-like performance in a much shorter overall length of 350 m, compared with 1200 m in the LCLS. One key feature of this design is that it may achieve a higher final beam current of 5 kA plus a uniform energy profile, mainly due to the employment of stronger longitudinal wakefields in the last X-band rf linac [2].

OVERVIEW AND ACCELERATOR DESIGN

LCLS is the world's first hard x-ray FEL in routine operation, providing soft and hard x-rays to its users with good spatial coherence at wavelengths from 2.2 nm to 0.12 nm by varying the bunch energy from 3.5 GeV to 15 GeV [3]. Design and beam dynamic studies are performed for several X-band rf-driven hard x-ray FEL drivers [4]. A low-charge hard x-ray FEL design [5] employs the entire X-band photoinjector and rf linac, which are optimized for a very low bunch charge of 10 pC and an average SASE FEL power of over 10 GW in a pulse length of 5 fs (start-to-end simulation in a short undulator length of 20 m). Thanks to the small 3D emittance associated with the low bunch charge (short initial bunch length from photoinjector, etc.), a linear bunch compression is achieved in two stages of bunch compressors without the assistance of harmonic rf linearization.

A second hard x-ray FEL design also features the entire X-band photoinjector and rf linac, but is dedicated for a normal bunch charge of 250 pC [6]. The longitudinal phase space linearization is done in its first-stage bunch compression with a specially designed bunch compressor composed of dipole, quadrupole, and sextupole magnets. From the start-to-end simulation using computer codes ASTRA [7], ELEGANT [8], and GENESIS [9], it is shown that this FEL achieves an average SASE FEL power of over 30 GW in a pulse length of 50 fs.

Both of these two hard X-ray FEL designs described above achieve a shorter SASE FEL saturation length due to a shorter undulator period and a weaker undulator field. It is also noted that the low-charge hard x-ray FEL design [5] achieves a better final beam quality than the LCLS case.

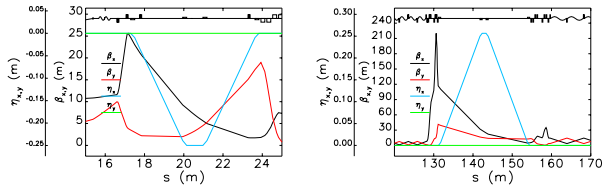

Figure 2: Beta functions and dispersion functions in the bunch compressors. Left: bunch compressor one, which is exactly the same as LCLS BC1; right: bunch compressor two, which is similar to LCLS BC2.

Analytical and numerical simulation studies show that the tolerance (charge and timing jitter, transverse misalignment) is acceptable for both of the above two hard X-ray FEL designs [5], [6].

A sketch of this compact (300 m) hard x-ray FEL driver using X-band accelerators plus an LCLS injector is shown in Figure 1. As previously mentioned, it employs an LCLS injector, which means that to the end of BC1 it is exactly the same as the LCLS. The only difference is that the S-band rf in Linac2 and Linac3 is replaced by an X-band rf. The BC2 design is similar to LCLS, at a beam energy of 4.3 GeV. For a bunch charge of 250 pC, the initial RMS bunch length is 690 μm from the S-band photoinjector. It is compressed to a final RMS length of either 6 μm (3-kA peak current) or 4 μm (5-kA peak current).

OPTICS DESIGN

The optics design of the linac, the bunch compressors, and the matching sections are done in MAD8 [10] and then converted to ELEGANT [8]. The TWISS parameters of bunch compressors one (BC1) and two (BC2), shown in Figure 2, are similar to the LCLS BC1 and BC2 (transverse phase-space matching to minimize CSR induced transverse emittance growth). The start-to-end TWISS parameters of the overall accelerator are shown in Figure 3. An average beta function of 10 meters and 20 meters are employed in Linac2X and Linac3X, respectively, to minimize both dispersive and wakefield-induced transverse emittance dilutions.

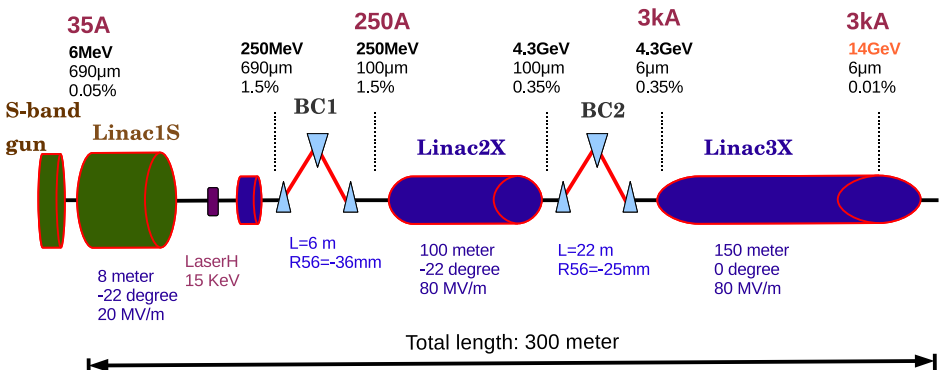

Figure 1: Sketch of a compact (300 m) hard x-ray FEL driver using X-band accelerators plus LCLS injector (up to the end of BC1). An average 'real estate' acceleration gradient of 60 MV/m is assumed in the X-band accelerator structures. The linac for the hard x-ray FEL achieves a final electron bunch energy of 14 GeV (same as the LCLS case) with a peak current between 3 kA and 5 kA (by tuning rf phase and then the bunch compression ratio). A final pulse duration length of 40-60 fs is achieved with a bunch charge of 250 pC. The sliced energy spread is between $0.01\% - 0.02\%$, and the sliced normalized transverse emittance is below 0.6 μm.

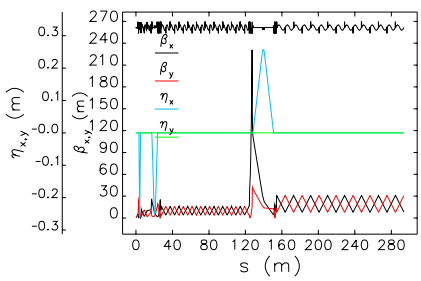

Figure 3: Beta functions and dispersion functions of the overall accelerator, from Linac1S (in Fig. 1) to the end of Linac3X (in Fig. 1) with a final beam energy of 14 GeV.

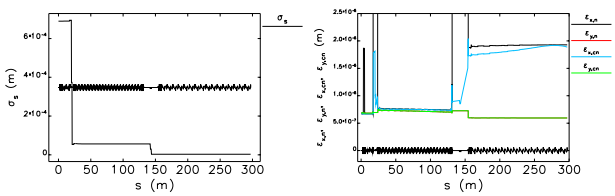

Figure 4: Left: RMS bunch length evolution along the linac, from ELEGANT simulation; right: projected and linear dispersion subtracted emittance evolution along the linac, from ELEGANT simulation.

ELEGANT SIMULATION

The beam dynamics simulation in the photoinjector is performed in ASTRA [7], and then a dumped beam is taken as the initial beam in the ELEGANT simulation. First-, second-, and third-order optics effects are included in the ELEGANT simulation, as well as all the collective effects, such as space-charge effect, incoherent and coherent synchrotron radiation, and transverse and longitudinal wakefields.

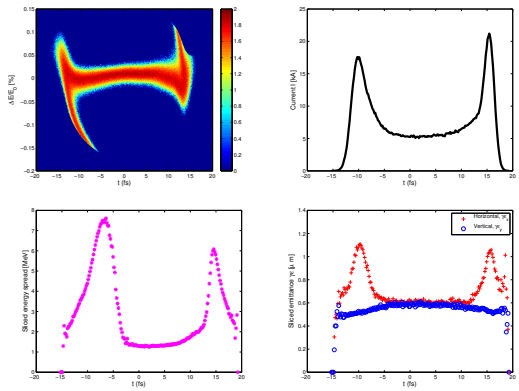

Figure 5: Electron beam properties at the end of Linac3X of this X-band-driven FEL driver, from ELEGANT simulation. Left top: longitudinal phase space; left bottom: longitudinally sliced energy spread; right top: current profile; right bottom: longitudinally sliced emittance.

The RMS bunch length and transverse emittance evolution along the accelerator are shown in Figure 4. Bunch compression ratios of 7 and 15 are achieved in a first- and second-stage bunch compressor. The final RMS bunch length is around 6-7 μm with a peak current over 3 kA. In the vertical plane the emittance is almost preserved. The horizontal emittance growth is mainly contributed from the coherent synchrotron radiation effects in the bunch compressors. Bunch compression ratios of 14 and 10 (for 5-kA final beam current case) could be achieved in a first- and second-stage bunch compression, respectively. The final beam current can be pushed to above 5 kA. The higher peak current at two ends (double horn) is due to compression with larger energy correlation (chirp) from longitudinal wakefields in Linac2X. There is a similar effect in the LCLS case.

Copyright © 2013 CC-BY-3.0 and by the respective authors

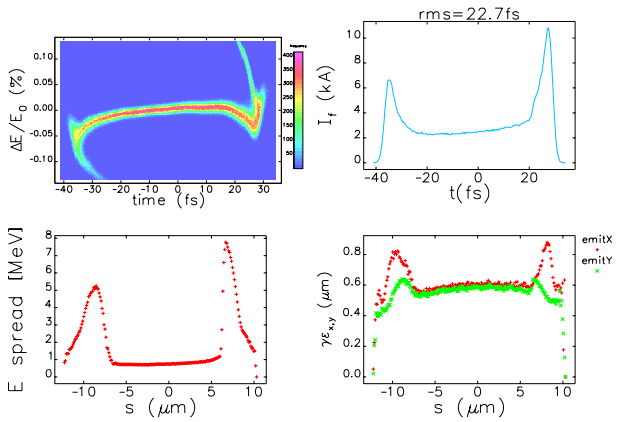

Figure 6: Electron beam properties at the end of LCLS Linac3, from ELEGANT simulation. Left top: longitudinal phase space; left bottom: longitudinally sliced energy spread; right top: current profile; right bottom: longitudinally sliced emittance.

Electron beam properties at the end of Linac3X of this X-band driven FEL driver are shown in Figure 5 from ELEGANT simulation, including longitudinal phase space, longitudinally sliced energy spread, current profile and longitudinally sliced emittance. A normalized transverse emittance of 0.6 μm is preserved at the core part of the electron bunch, with a pulse duration length of 40 fs. A peak current of 5 kA and a longitudinally sliced relative energy spread less than 2×10^{-4} is achieved. The residual correlated energy offset established in Linac1 and Linac2X is removed in Linac3X with the help of a strong X-band rf longitudinal wakefield, and a flat final energy profile is achieved at a final beam energy of 14 GeV.

A similar plot is shown in Figure 6 for the LCLS case. It is observed that the final beam current is over 5 kA in this X-band-driven FEL (3 kA for LCLS), and the sliced transverse emittance is similar for LCLS. A normalized transverse emittance of 0.5-0.6 μm is preserved at the core part of the electron bunch, with a pulse duration length of 70 fs. A peak current of 3 kA and a longitudinally sliced relative energy spread around 1×10^{-4} is achieved. The residual correlated energy offset established in Linac1 and Linac2 is removed in Linac3 with the help of an S-band rf longitudinal wakefield, and a flat final energy profile is achieved at a final beam energy of 14 GeV.

GENESIS SIMULATION

The electron bunch distribution generated from ELEGANT simulation is then fed into an undulator system, and the associated FEL performance is simulated and evaluated within the code GENESIS [9]. The same undulator setup is adopted for both this X-band-driven FEL and the LCLS, which is described below. An ideal undulator is designed to have a short period of $\lambda_w = 1.5$ cm, and the undulator strength K is chosen to tune the resonant FEL wavelength of $\lambda_r = 0.15$ nm, given the centroid energy of the electron bunch chosen at 14 GeV. No nonlinear magnetic field is included for the undulator model. No undulator tapering is adopted.

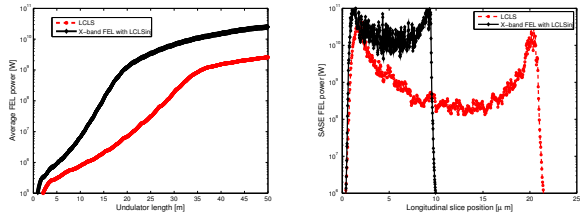

Figure 7: Left: FEL power evolution along the undulator; right: FEL power temporal profile at 50 m into the undulator. Red: LCLS case; black: the X-band-driven FEL.

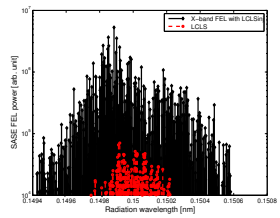

Figure 8: FEL power spectrum at 50 m into the undulator. Red: LCLS case; black: the X-band-driven FEL driver.

A comparison of the simulated FEL performance is shown in Figure 7 and Figure 8. As expected, this X-band-driven FEL achieves a shorter FEL gain length, a higher saturation power, and a higher FEL power at the same undulator length (benefiting from a higher peak current of 5 kA) as the LCLS case.

ACKNOWLEDGMENT

The author would like to thank C. Adolphsen, J. Wu, M. Woodley, A. Chao, Z. Huang, Y. Ding, and C. Limborg-Deprey for helpful discussions. The idea for this design is initially from C. Adolphsen et al. [1] and T. Raubenheimer. T. Raubenheimer proposed the push for higher peak current by employing stronger X-band wakefields [2]. Most of the work was done at SLAC. The paper was written at ANL.

ACHIEVING A QUASI-THIRD-ORDER ACHROMAT IN AN APS UPGRADE LATTICE*

Yipeng Sun† and Michael Borland, ANL, Argonne, IL 60439, USA

Abstract

The next-generation of storage rings will require stronger quadrupole focusing to achieve very low emittance. Stronger sextupoles (usually at smaller dispersion locations) are then necessary to correct the natural chromaticity and suppress the head-tail instability. The geometric and chromatic optics aberrations introduced by these sextupoles have a large impact on the beam dynamics performance. In this paper, it is discussed how to achieve a quasi-third-order achromat in a possible Advanced Photon Source (APS) multi-bend achromat (MBA) lattice. Repetitive identical MBA arc cells with specified phase advance and mirror symmetry are employed. The beam dynamics performance of such an achromat design is compared with a normal scheme.

OVERVIEW

The development of optical achromats started in the 1700s when achromatic doublets and triplets were invented to bring light of different frequencies to the same focal point. First-order achromats have been applied in particle accelerators for a long time. In the 1970s, K. Brown developed a systematic matrix-based approach to designing second-order achromats [1]. It adopts at least four identical cells with dipoles, quadrupoles, and sextupoles and can eliminate all geometric and chromatic aberrations up to second order. Two strong points being proposed are the integer phase advance in the entire beamline and the $-I$ phase separation between non-interleaved sextupoles to cancel even higher-order geometric aberrations. After that, similar third-order achromat design approaches were developed analytically and numerically [2] [3], where the concept of identical cells and integer phase advance is used again. Following these studies, W. Wan developed a general method with Lie algebra to design achromats to arbitrary order, taking advantage of mirror symmetry and using multipole magnets for each specified order (for example, octupoles for a third-order achromat) [4].

The latest PEPX design utilizes eight identical seven-bend achromat (7BA) cells in each arc section, where the total phase advance is an integer [5]. A third-order geometric achromat is achieved with the assistance of harmonic sextupoles [5]. In this paper, first a design similar to the APS storage ringe is presented. It employs more families of chromaticity sextupoles and may eliminate all geometric and chromatic aberrations up to third order. Then there is a discussion on how to achieve a quasi-third-order achromat in the APS upgrade lattices where 40 identical MBA cells have to be used and no dedicated straight sections are allowed.

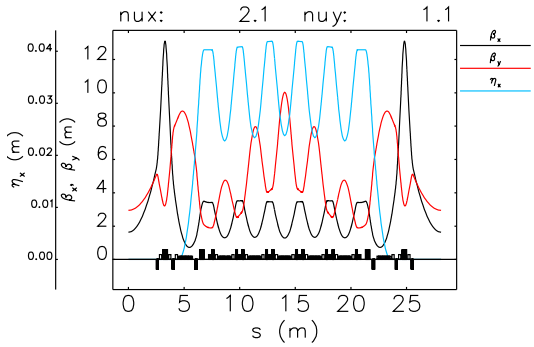

Figure 1: Twiss parameters in a 7BA arc cell with a length of 27.2 m. Natural emittance is 150 pm at a beam energy of 6 GeV. The black curve denotes horizontal beta function; red curve, vertical beta function; blue curve, horizontal dispersion function.

THIRD-ORDER ACHROMAT DESIGN

The current APS storage ring has a circumference of 1104 meters and is divided into 40 identical sectors. An APS-size ring is designed based on the third-order-achromat concept. Note that it may not fit in the current APS tunnel due to geometry, although the circumference is close to 1104 m. The ring consists of four arc sections plus short straight sections that are each 4 meters long. Each arc section has ten identical 7BA cells. The natural emittance is 150 pm at an electron beam energy of 6 GeV.

The linear and nonlinear optics optimization are performed with ELEGANT [6]. The Twiss parameters in a 7BA arc cell are shown in Figure 1. It is observed that in the central part there are five TME-like cells. Each cell consists of one combined function dipole (with defocusing quadrupole gradient), two focusing quadrupoles, and three sextupoles. The horizontal beta function and dispersion achieve a minimum in the center of the dipole magnet. The dispersion is matched to zero using two dedicated quadrupole magnets and an end dipole. A triplet is adopted outside of the end dipole to bring the beta functions down to β_x = 1.8 m and β_y = 3 m at the center of the insertion device (ID). The maximum dipole field is 0.45 Tesla and the maximum quadrupole gradient is 66 T/m.

The betatron phase advance of each 7BA cell is (2.1, 1.1) in units of 2π. The phase advance in each arc section is then (21, 11), i.e., multiples of 2π in both planes. In the 4-meter-

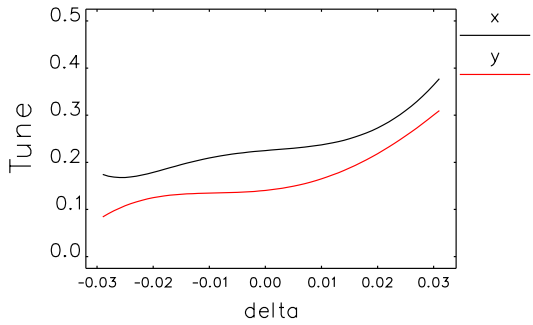

Figure 2: Horizontal (black curve) and vertical (red curve) betatron tune as a function of momentum offset $\Delta E/E$, dominated by third-order chromaticity.

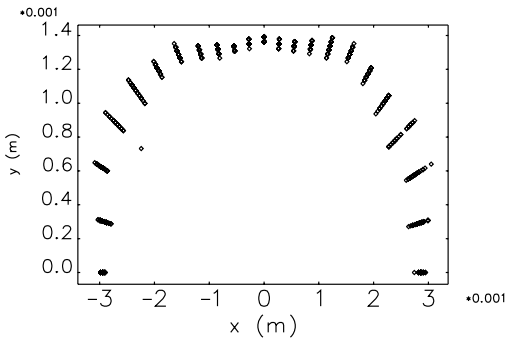

Figure 3: Dynamic acceptance with 50 ensembles of random, systematic, and tilt errors on quadrupoles and sextupoles. Tracking is performed at the center of the short straight section where β_x = 4 m, β_y = 1.2 m.

long straight section, which is between two arc sections, two triplets are placed with mirror symmetry. The linear optics is matched and the fractional tune of the storage ring is tunable in a range of (0.1, 0.4).

It is concluded that two families of sextupoles and five families of octupoles are enough to construct a third-order achromat [1] [2] [3]. In general, there are two independent linear chromaticity terms in the second-order matrix, and there are five independent terms in the third-order matrix (two second-order chromaticity terms, plus three transverse amplitude detuning terms). It is not realistic to use an octupoles plus sextupoles scheme due to limited space and maximum magnet strengths. Here only sextupoles are adopted to form a third-order achromat. Eight families of chromaticity sextupoles are placed in the dispersive region, while four families of harmonic sextupoles are placed between the end dipole and the ID.

Similar to the PEPX design [5], all third-order ($h10200$, $h10020$...) and most fourth-order ($h20200$, $h40000$...) betatron resonance driving terms are naturally cancelled between the ten identical cells [5]. These 12 families of sextupoles are tunable such that all the chromatic and geometric aberrations may be zero up to third order. In other words, the linear and second-order chromaticities ($d\nu/dp$ and $d\nu/dp^2$) can be tuned to zero, and the betatron resonance driving terms (up to fourth order) plus amplitude detuning terms ($d\nu_x/dJ_x$, $d\nu_x/dJ_y$ and $d\nu_y/dJ_y$) can be eliminated, too.

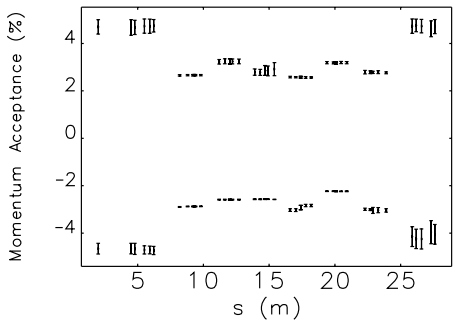

Figure 4: Local momentum acceptance with 50 ensembles of errors (random, systematic magnetic errors, and tilt errors on quadrupoles and sextupoles). Tracking is performed at locations next to each magnet in one 7BA arc cell (28 m).

As shown in Figure 2, the off-momentum tune variation is relatively small for a momentum offset up to 3%. The linear chromaticities are tuned to be 1 and the second-order chromaticities are close to zero. One observes that the off-momentum tunes are dominated by third-order chromaticities. We evaluated the lattice with 50 error ensembles, with 1% optics beating plus 1% coupling from strength and tilt errors in the quadrupoles and sextupoles. The dynamic acceptance (DA) was calculated by tracking for 400 turns, giving the results shown in Figure 3. We see that the DA is 3 mm (x) by 1.3 mm (y) at the straight section center where β_x = 4 m, β_y = 1.2 m. The shape of the DA curve is uniform and symmetric. The local momentum acceptance (LMA) was also evaluated at the exit of each magnet by tracking simulations. As observed in Figure 4, it is larger than 2%, which ensures a Touschek lifetime above four hours.

QUASI-THIRD-ORDER ACHROMAT AND BEAM DYNAMICS PERFORMANCE

"Quasi achromat" means that one wants to minimize/zero terms that are most relevant to the beam dynamics performance. For example, a chromatic achromat is essential in transporting a beam with large energy spread. As mentioned above, the lattice design described in the previous section may not fit the APS ring geometry. Alternatively, the following options are proposed and evaluated to achieve a quasi (or pure) third-order achromat in an APS MBA lattice. It is assumed to have 40 identical MBA cells.

- True third-order achromat with octupoles, excluded due to space constraints

Copyright © 2013 CC-BY-3.0 and by the respective authors

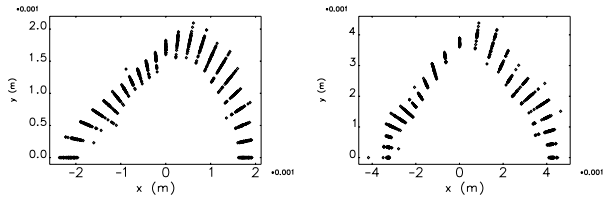

Figure 5: Comparison of dynamic acceptance shows that the quasi-third-order achromat scheme (right figure) has better performance.

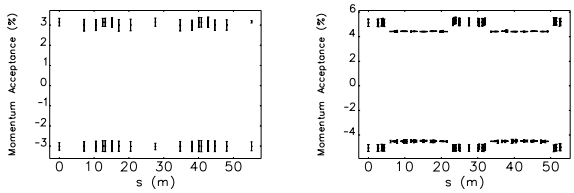

Figure 6: Comparison of local momentum acceptance shows that the quasi-third-order achromat scheme (right figure) has better performance.

- Add three additional quads at the two ends of every ten cells to change fractional tune, giving a superperiodicity of 4
- 40 identical cells, but each cell has phase advance like (2.104,1.103)

It is interesting to note that the third-order achromat condition is very sensitive to the phase advance. There will be large deviations of the resonance driving terms and detuning terms if the phase advance changes by 1×10^{-5} in each 7BA cell. Based on these considerations, option 3 is a good choice to achieve a quasi-third-order achromat in an APS MBA lattice. The 7BA cell phase advance is tuned to be something like (2.104,1.103), so that in ten repetitive cells the total phase advance is close to a multiple of 2π. The fractional tune is also naturally far away from integer resonance. Note that this scheme is also good for maintaining a large superperiodicity, which helps to suppress lower-order resonances.

A plain 7BA lattice was studied and optimized as one option for a future APS MBA upgrade [7]. It has a natural emittance of 150 pm at 6 GeV. The following two schemes are compared for their beam dynamics performance:

- Normal scheme with arbitrary phase advance in each 7BA cell
- Quasi-third-order achromat scheme, making a quasi-third-order achromat in ten 7BA cells

The lattice is almost the same for these two schemes. The arc sextupoles and harmonic sextupoles arrangements are exactly the same. The major difference is the phase advance. Both schemes are optimized for nonlinear beam dynamics performance, using a Multi-objective Genetic Algorithm [8]. As expected, the quasi-third-order achromat scheme has much smaller geometric and chromatic aberrations than the normal scheme. With the same error settings and tracking setup, the dynamic acceptance and local momentum acceptance are compared between these two schemes, as shown in Figure 5 and Figure 6, respectively. At a location with similar beta functions (roughly $\beta_x = \beta_y$ = 2 meters), the DA is 3.5×3.5 mm^2 for the achromat scheme, which is roughly a factor of two larger than the normal scheme. The LMA is also improved from 3% to 4%. As observed in Figure 7, there are fewer resonance lines showing up in the frequency map of the quasi- achromat scheme.

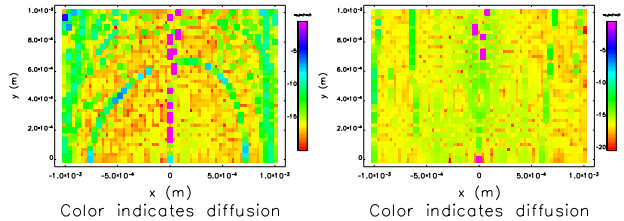

Figure 7: Comparison of frequency map analysis shows that the quasi-third-order achromat scheme (right figure) has better performance.

CONCLUSION

A true third-order achromat without octupoles was studied for an APS-size storage ring that has 150-pm emittance at 6 GeV. Quasi-third-order achromat schemes were also studied and implemented in APS MBA lattices. The effectiveness of the quasi-achromat scheme was confirmed for a plain 7BA lattice, as well as for a plain 5BA lattice [9] and a hybrid 7BA lattice.

ANALYTICAL EVALUATION OF CORRELATED TIMING JITTER CANCELLATION IN A STAGED BUNCH COMPRESSION SYSTEM*

Yipeng Sun†, ANL, Argonne, IL 60439, USA

Abstract

In this paper, the wakefield cancellation scheme on the timing jitter is revisited. The correlated timing jitter effects between the photoinjector laser and the linac rf phase are evaluated analytically. It is possible to minimize its impact on the final bunch length (peak current) variation by employing a longer linac with a lower acceleration gradient between bunch compressors one and two.

OVERVIEW

A staged magnetic bunch compression system is widely adopted in the acceleration process of the electron beam. It first introduces an energy modulation along the electron bunch in its longitudinal direction, then lets the electron beam pass by a dispersive region where electrons in the head and tail of the bunch all move relatively towards bunch center. Chicane- and wiggler-based bunch compressor designs were proposed and studied thoroughly in the 1990s, mainly for linear collider projects [1], [2], [3].

The stability of the final electron beam current depends on the timing and rf phase jitter, bunch compressor parameters, and electron beam charge variations. Gun laser to linac rf timing jitter (referred to as timing jitter)–the main timing error to be discussed in this paper–is considered to be correlated for all the linac sections as the sum of the uncorrelated (or random) rf phase jitter (different from rf source-to-source) tends to be small.

The bunch length variation due to jitter effects at the ends of the staged bunch compressors were studied in (and before) the LCLS initial design stage, and a longitudinal wakefield cancellation scheme was proposed with at least two stages of bunch compressions [4], [5], [6], [7], [8]. This scheme was also applied at the LCLS FEL [5], [7], [8]. A similar scheme is also proposed to reduce the energy chirp by employing the wake of coherent synchrotron radiation [9].

In this paper, this topic is revisited, while the associated formulae are rederived and extended analytically. The analytical result is verified by numerical simulations. It is possible to minimize the correlated timing jitter's impact on the final bunch length (peak current) variation by employing a longer linac with a lower acceleration gradient, between bunch compressors one and two.

† yisun@aps.anl.gov

ANALYTICAL DERIVATION

Neglecting the small initial un-correlated energy spread and considering only linear terms, the RMS bunch length after bunch compressor one can be expressed as

$$\sigma_{z1} = (1 + h_1 R_{56(1)}) \cdot \sigma_{z0}, \tag{1}$$

where σ_{z1} denotes the RMS bunch length after bunch compressor one, h_1 is the chirp of bunch compressor one, $R_{56(1)}$ is the first-order longitudinal dispersion in bunch compressor one, and σ_{z0} is the initial bunch length; and

$$h_1 = -\frac{k_1 e V_0 \sin\phi}{E_{f0}} \approx -k_1 \tan\phi \approx -k_1\phi_1, \tag{2}$$

where $k_1 = \frac{2\pi_1}{\lambda}$ denotes the rf wave number in the first rf section, E_{f0} is the central energy after rf acceleration, e is the electron charge, V_0 is the rf voltage, ϕ_1 is the rf phase, $k = \frac{2\pi}{\lambda}$ is the rf wave number, and λ is the rf wave length.

Given a timing jitter $\Delta\phi_1$, the change in the final bunch length is

$$\Delta\sigma_{z1} = -k_1 \Delta\phi_1 R_{56(1)} \cdot \sigma_{z0}. \tag{3}$$

Neglecting the residual damped energy chirp from the first rf linac $h_1 \cdot C_1 \cdot E_1/E_2$ ($C_1 = 1/(1 + h_1 R_{56(1)})$ denotes the compression ratio in BC1. Also the longitudinal wakefield effects in Linac2 only consider an energy chirp established in Linac2, which is h_2. The final RMS bunch length after the second bunch compressor can be calculated as

$$\sigma_{z2} = (1 + h_2 R_{56(2)}) \cdot \sigma_{z1}, \tag{4}$$

$$h_2 \approx -k_2\phi_2, \tag{5}$$

where σ_{z2} denotes the RMS bunch length after bunch compressor two, h_2 is the chirp of bunch compressor two, $R_{56(2)}$ is the first-order longitudinal dispersion in bunch compressor two, and $k_2 = \frac{2\pi_2}{\lambda}$ is the rf wave number in the second rf section.

After inserting the expression σ_{z1} into Eq. (4), one finds

$$\sigma_{z2} = (1 + h_2 R_{56(2)}) \cdot (1 + h_1 R_{56(1)}) \cdot \sigma_{z0}. \tag{6}$$

Given a linac rf timing jitter of $\Delta\phi_1$ and $\Delta\phi_2$ in the first and second rf linacs, the final bunch length is

$$\sigma_{z2} = \left[1 - k_2(\phi_2 + \Delta\phi_2) R_{56(2)}\right] \cdot \left[1 - k_1(\phi_1 + \Delta\phi_1) R_{56(1)}\right] \cdot \sigma_{z0}. \tag{7}$$

Copyright © 2013 CC-BY-3.0 and by the respective authors

The change of bunch length after the second bunch compressor is

$$\begin{aligned}\Delta\sigma_{z2} &= [-k_2\Delta\phi_2 R_{56(2)}(1-k_1\phi_1 R_{56(1)}) \\ &\quad -k_1\Delta\phi_1 R_{56(1)}(1-k_2\phi_2 R_{56(2)}) \\ &\quad +k_1k_2\Delta\phi_1\Delta\phi_2 R_{56(1)}R_{56(2)}]\cdot\sigma_{z0}. \quad (8)\end{aligned}$$

Inserting the bunch compression ratio in the first and second stage of bunch compressors, $C_1 = 1/(1+h_1R_{56(1)})$ and $C_2 = 1/(1+h_2R_{56(2)})$, into the above formulae, one finds

$$\begin{aligned}\Delta\sigma_{z2} &= [-k_2\Delta\phi_2 R_{56(2)}/C_1 \\ &\quad -k_1\Delta\phi_1 R_{56(1)}/C_2 \\ &\quad +k_1k_2\Delta\phi_1\Delta\phi_2 R_{56(1)}R_{56(2)}]\cdot\sigma_{z0}. \quad (9)\end{aligned}$$

Assuming the first and second rf linac have the same rf frequency $k_1 = k_2 = k$ (which also means that the same time jitter introduces the same change in the rf phase, $\Delta\phi_1 = \Delta\phi_2 = \Delta\phi$), one finds that the above formula can be simplified to

$$\begin{aligned}\Delta\sigma_{z2} &= k\Delta\phi[-R_{56(2)}/C_1 - R_{56(1)}/C_2 \\ &\quad +k\Delta\phi R_{56(1)}R_{56(2)}]\cdot\sigma_{z0}. \quad (10)\end{aligned}$$

From the above formula, one observes that in order to minimize the impact from timing jitter on the final bunch length, one needs to employ a linac with lower frequency rf (smaller k) and smaller longitudinal dispersion R_{56} in the bunch compressors. In order to keep similar compression ratios C_1 and C_2, a larger rf phase should be employed, given a required smaller longitudinal dispersion R_{56} in the bunch compressors. Further, assuming the same timing jitter for both the first and second rf linacs, the impact from both compression stages on the final bunch length always adds up.

Another effect that could be used to partially compensate the timing jitter is the longitudinal wakefield in the second rf linac [4], [5], [6], [7], [8]. The basic idea is that if a timing jitter in the first rf linac introduces a stronger compression in bunch compressor one, which in turn results in a shorter bunch length in the second rf linac, the energy chirp established by the longitudinal wakefield in the second rf linac is larger. For an under-compression scheme with normal four-dipole chicane compressor, the rising slope of the rf wave is employed (electron bunch is ahead of rf crest), which means that the bunch head has a lower energy than its tail. As the longitudinal wakefield always makes the bunch tail lose energy with respect to its head, the energy chirp from the wakefield has a sign opposite the rf chirp in the second rf linac. The timing jitter in the second rf linac is assumed to be the same as the one in the first rf linac, so this relative change in rf phase also introduces a stronger compression in bunch compressor two. However, the wakefield chirp fights the energy chirp established by the second rf linac and makes the bunch compression ratio smaller in this second stage, which partially compensates the timing jitter effects.

With the longitudinal wakefield effects in both the first and second rf linac included, the final bunch length is rewritten as

$$\begin{aligned}\sigma_{z2} &= \left[1+(h_2+h_{2w})R_{56(2)}\right] \\ &\quad \cdot\left[1+(h_1+h_{1w})R_{56(1)}\right]\cdot\sigma_{z0}, \quad (11)\end{aligned}$$

where h_{1w} denotes the linear energy chirp induced by longitudinal wakefield in the first rf linac, and h_{2w} is the linear wakefield energy chirp established in the second rf linac.

Given an electron beam energy of 250 MeV at bunch compressor one, a short first rf linac is employed, which means that the wakefield-induced chirp h_{1w} is relatively small and could be negligible. As discussed above, the wakefield chirp h_{2w} has a sign opposite the rf chirp h_2, which should be taken into account when the FEL bunch compression system is designed. Basically, it is the change in wakefield-generated energy chirp that could compensate a timing jitter between laser (electron bunch generation) and linac rf. Based on this point, a second rf linac with longer length should have a stronger relative change in wakefield-induced chirp when the electron bunch length is affected in a first-stage bunch compressor by timing jitter effect. A final electron bunch length at the end of bunch compressor two is then expressed as shown below, with timing jitter and wakefield effects considered up to first order. The rf phase ϕ_1 and ϕ_2 denote the ones that already have wakefield-induced energy chirp subtracted:

$$\begin{aligned}\sigma_{z2} &= [1-k_2(\phi_2+\Delta\phi_2 \\ &\quad -D(\sigma_{z1},k_2)\cdot L_{linac2})R_{56(2)}] \\ &\quad \cdot\left[1-k_1(\phi_1+\Delta\phi_1)R_{56(1)}\right]\cdot\sigma_{z0}, \quad (12)\end{aligned}$$

where $D(\sigma_{z1},k_2)$ denotes the unit-length change of wakefield-induced energy chirp in linac2, which is a function of rf structure (frequency) and electron bunch length in Linac2; and L_{linac2} is the length of Linac2.

In order to keep the same beam energy at BC2, the acceleration gradient in the second rf linac needs to be decreased. Another point is that, as the the second rf linac length is increased, the nominal wake-induced energy chirp is larger, which means that one has to adopt a larger rf phase in the second rf linac to cancel the wake effects and provide the necessary energy chirp. As discussed above, a larger rf phase also makes the timing jitter effect relatively smaller.

NUMERICAL SIMULATION

ELEGANT [10] simulations of a low-charge X-band hard x-ray FEL [11] are performed with timing jitter set on all linac rf phases up to 50 fs, which is successfully achieved in LCLS operation [12]. This timing jitter of 50 fs changes

Copyright © 2013 CC-BY-3.0 and by the respective authors

the Linac1 rf phase and in turn changes the electron bunch length at the end of bunch compressor one. The final relative RMS bunch length variation is around 20 % with the 35-meter-long Linac2, given a timing jitter of 50 fs between laser and linac rf.

One then can decrease the acceleration gradient in the second rf linac and increase the second rf linac length (employing more rf cavities), keep the same beam energy at bunch compressor two, and employ a stronger longitudinal wakefield in the second rf linac to cancel the timing jitter effect. However, a longer total accelerator length and a higher total cost are accompanied with increasing the second rf linac length and employing more rf cavities. A tradeoff needs to be made between the factors mentioned above and the tolerated timing jitter. Analytical and numerical studies show that decreasing the average acceleration gradient from 80 MV/m to 65 MV/m in the second rf linac could drop the final peak current variation to 12% [11]. The timing-jitter-induced peak current variation could be fully compensated if an average acceleration gradient of 50 MV/m is adopted in the second rf linac [11].

A second example is an X-band rf-driven hard x-ray FEL design with LCLS injector [13]. Similarly, the length of the second rf linac is tuned to compensate (or even overcompensate) the timing jitter impacts. As shown in Figure 1, the LCLS injector plus X-band linac case (blue curve) is much more sensitive to timing jitter than the normal LCLS case (red curve). This is due to the higher frequency of X-band rf. For these nominal cases, an acceleration gradient of 80 MV/m is adopted for X-band rf, while it is 20 MV/m for S-band rf in the LCLS. However, if one doubles the length of the second rf linac and adopts an acceleration gradient of 40 MV/m in the second X-band rf linac, the black curve shows that one could possibly cancel the timing jitter effect. In this specific example, the timing jitter effect on the final bunch length is over-compensated by the wakefields in the second X-band rf linac. One should also note that the rf phase in the second X-band rf linac is increased from 22 degrees to 33 degrees.

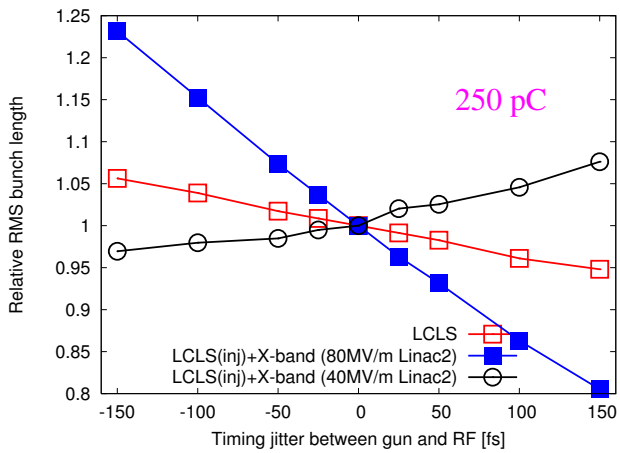

Figure 1: Relative bunch length after the final stage of bunch compression, as a function of timing jitter, for a bunch charge of 250 pC.

CONCLUSION

The longitudinal wakefield cancellation scheme is revisited in this paper. Analytical derivations are presented for bunch length and its variation in a staged bunch compression system. Under first-order approximation, the length of the second rf linac can be calculated analytically, which compensates the timing-jitter-induced bunch length variation. Simulation results of two X-band-rf-driven FEL drivers are presented where these cancellation schemes are applied.

X-BAND FEL DRIVER LINAC DESIGN WITH OPTICS LINEARIZATION*

Yipeng Sun†, ANL, Argonne, IL 60439, USA
Tor Raubenheimer, Juhao Wu, SLAC, Menlo Park, California 94025, USA
Paul Emma, LBNL, Berkeley, California 94720, USA

Abstract

In this paper, a compact hard x-ray FEL design is proposed with a single bunch charge of 250 pC, which is based on all X-band rf acceleration and two-stage bunch compression. It eliminates the need for a harmonic rf linearization section by employing optics linearization in its first-stage bunch compression. Emittance growth in the horizontal plane due to coherent synchrotron radiation (CSR) is investigated and minimized, to be on a similar level with the LCLS. An electron bunch distribution at the linac end is taken as the input for an FEL simulation in GENESIS, with a beam energy of 7 GeV. At an FEL radiation wavelength of 0.15 nm, a saturation length of roughly 40 meters can be achieved by employing an undulator with a period of 1.5 cm. Without tapering, an FEL radiation power above 10 GW is achieved with a photon pulse length of 50 fs, which is LCLS-like performance. The overall length of the accelerator plus undulator is around 250 meters, which is much shorter than the LCLS length of 1230 meters.

OVERVIEW AND ACCELERATOR DESIGN

In this paper, a very compact FEL driver is proposed with an accelerator length less than 200 m. An alternative way to do a linearized bunch compression in a first stage is proposed. The key point is to eliminate the harmonic rf section, and to apply an optics linearization instead, with a specially designed bunch compressor that includes quadrupole and sextupole magnets. Similar schemes have been proposed and studied preliminarily before, either in an analytical manner [1] [2] [3], by numerical simulations [1] [3] [4] [5], or in experimental measurements [3]. The second-order longitudinal dispersion T_{566} of this bunch compressor is precisely controlled and used to compensate the second-order curvature from the main rf acceleration. Third-order longitudinal dispersion U_{5666} can also be tuned to cancel the third-order rf curvature; however, in most cases this is not necessary as its impact is relatively small. Compared with a four-dipole chicane, this bunch compressor has the opposite sign of the linear longitudinal dispersion R_{56}. The main rf system in the first linac then has to work on the falling slope of the sinusoidal wave, which is the only way to shorten the bunch length; otherwise the bunch length is lengthened. In order to do a normal under-compression in the second stage, and still use longitudinal wakefields to remove the residual chirp in the last linac, one needs to do an over-compression in the first-stage bunch compressor. Over-compression may cause larger transverse emittance growth due to phase smear in the over-compression process, associated with energy change from coherent synchrotron radiation (CSR) in a dispersive region. The optics design of this bunch compressor needs to be investigated and optimized carefully to minimize these impacts.

The accelerator of this FEL driver is sketched in Figure 1. Compared with a similar hard x-ray FEL design based on S-band rf acceleration, this all X-band-based FEL has several potential advantages. One advantage is its compact size at the same final beam energy, due to the higher acceleration gradient provided by X-band rf cavities. In general the accelerator length is only one-fourth or one-third of the S-band-based accelerator. Besides, a shorter wavelength of X-band rf also makes the establishment of energy modulation easier, which then makes it possible to run on an rf phase closer to the crest and so save rf power. Another possible advantage is that it may be easier to manipulate the longitudinal phase space, especially in the second and last linac (for a two-stage bunch compression), mainly due to a much stronger longitudinal wake field of X-band rf. One may also benefit from a smaller CSR-induced emittance growth in bunch compressor two, as a larger energy correlation can be generated in Linac2 and then removed in Linac3, so the strength of the bunch compressor dipoles can be decreased.

NUMERICAL SIMULATION

In this section start-to-end ELEGANT [6] 6-D numerical simulation results are presented. The simulation starts at a beam energy of 50 MeV, where X-band photoinjector simulations show that an RMS bunch length of 160 μm could be achieved along with a normalized transverse emittance of 0.5 μm.rad at a bunch charge of 250 pC, by tuning the drive laser system, bunching system, and subsequent acceleration section [7]. Space-charge effect and velocity bunching are two dominant effects in this section from the production of the electron bunch and its acceleration to a beam energy of 50 MeV. The details on the simulation results of this part are not discussed here.

An electron bunch that consists of one million macro particles is then generated internally in ELEGANT, employing an RMS bunch length of 160 μm and a normalized transverse emittance of 0.5 μm.rad. The beam energy is 50 MeV and the single-bunch charge is 250 pC. The un-

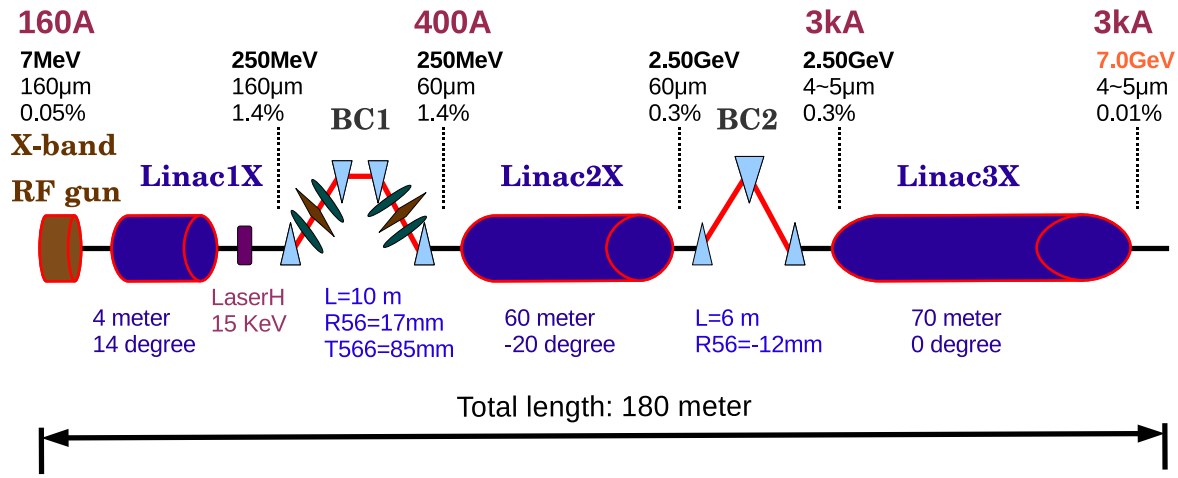

Figure 1: Sketch of an all X-band-based hard x-ray FEL accelerator design.

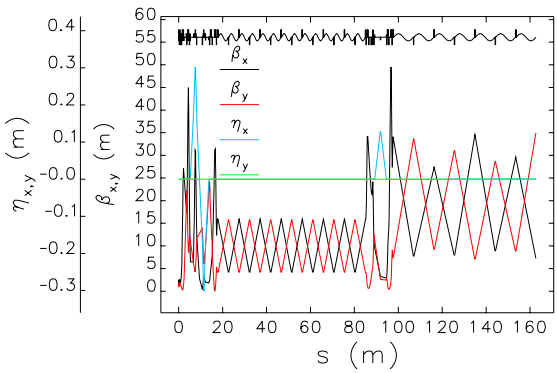

Figure 2: Start-to-end TWISS parameters, a beam energy from 50 MeV to 7 GeV. Black curve denotes horizontal beta function; red curve, vertical beta function; blue curve, horizontal dispersion function; and green curve, horizontal angular dispersion function.

correlated RMS energy spread is 12.5 keV. The distribution in both longitudinal and transverse planes is assumed to be a perfect Gaussian distribution. This electron bunch is transported through a first linac section (Linac1), bunch compressor one, a second linac section (Linac2), bunch compressor two, and a third linac section (Linac3). The start-to-end first order optics is illustrated in Figure 2, from entrance of Linac1 to the end of Linac3. The optics design is performed and optimized in an accelerator design code MAD8 [8] first, then translated into ELEGANT [6] format.

The CSR-induced transverse emittance growth is on a similar level between this X-band-driven FEL and the LCLS. In detail, while the vertical emittance is always preserved at 0.5 μm.rad during the acceleration and bunch compression, the horizontal emittance is increased to 0.55 μm.rad in the core part and 0.8-0.9 μm.rad in the bunch head and tail.

After the two-stage bunch compression, a peak current over 3 kA is achieved in a pulse length of roughly 50 fs. The vertical normalized emittance is preserved at 0.5 μm.rad, and the horizontal normalized emittance is increased by 20% on average. The residual correlated energy spread is removed in Linac3, mainly by the strong X-band rf longitudinal wakefield. The Linac3 runs on-crest with a total length of 70 meters. A final flat energy profile is achieved as shown in Figure 3, as well as the current profile, longitudinally sliced transverse emittance, and energy spread. This final electron beam is injected into the design undulator for a hard x-ray FEL with a radiation wavelength as short as 0.15 nm. The detailed FEL simulation and performance is presented below.

FEL SIMULATION

FEL performance is preliminarily studied, with the GENESIS simulation results presented in this section. In the following parts, we show a concrete example of FEL lasing at 0.15-nm wavelength, which is the same as achieved at LCLS. The undulator is designed to have a shorter period $\lambda_w = 1.5$ cm than the LCLS value of 3 cm, as the beam energy of 7 GeV is lower than the LCLS beam energy of 14 GeV. The undulator strength K is chosen so that the resonant FEL wavelength is $\lambda_r = 0.15$ nm according to Eq. 64 for $\theta = 0$ and $E = 7$ GeV. The electron bunch distribution generated from the ELEGANT simulation is then fed into an undulator system, and the associated FEL performance is simulated and evaluated within the code GENESIS [9]. The electron bunch transverse profile is matched into the undulator beamline where the average beta function is roughly 20 meters. No undulator tapering is adopted here to further

increase the FEL saturation power.

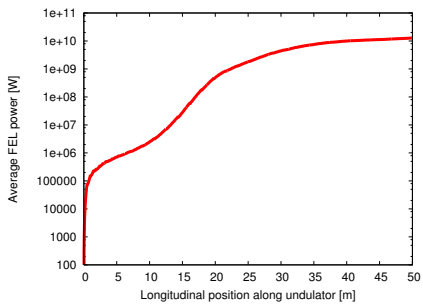

Figure 4: FEL power evolution along the undulator.

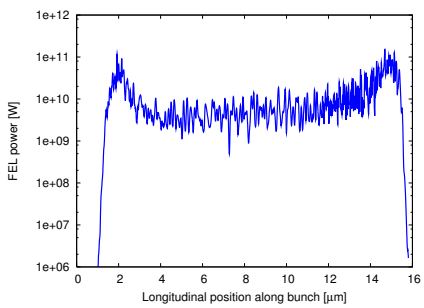

Figure 5: FEL power temporal profile at 40-m undulator.

Given a high peak current of 3 kA, plus a small sliced transverse emittance and energy spread, within a 40-m-long undulator the FEL radiation power can saturate at an average power of $P_{sat} \sim 10$ GW as shown in Figure 4. In comparison, LCLS achieves roughly 6 GW in 60 meters without tapering. An overall undulator length of 50 m is chosen to guarantee saturation. The temporal and spectrum profile of the FEL at 40 m of undulator is shown in Figure 5 and Figure 6, respectively.

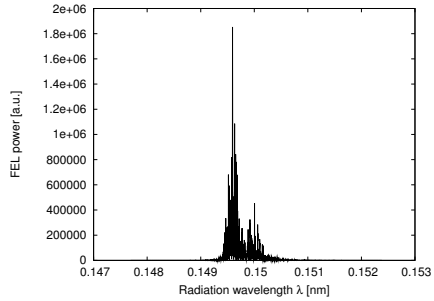

Figure 6: FEL power spectrum at 40-m undulator.

CONCLUSION

Start-to-end optics design and 6-D macro particle simulations are presented for an electron beam energy from 50 MeV to 7 GeV. The electron bunch is successfully compressed to a peak current above 3 kA, while its brightness is well preserved in both the transverse and longitudinal planes. The CSR-induced transverse emittance growth is at a similar level in both this X-band-driven FEL and the LCLS. This all X-band rf-based hard x-ray FEL could achieve LCLS-like performance in a shorter overall length of 250 meters.

Abstract

NSLS-II is a state-of-the-art third-generation light source under construction at BNL. As many facilities worldwide, NSLS II uses the EPICS control system to monitor and control all accelerator hardware. CSS is used for simple tasks such as monitoring, display, setting of PVs and browsing the historical data. For more complex accelerator physics applications, a collection of scripts are mainly written in Python. The controls group developed the services, such as channel finder, machine snapshot, data archiving, twiss server, unit conversion etc. This paper will present the tools that we have been using for commissioning.

INTRODUCTION

The NSLS-II [1] is a state of the art 3 GeV synchrotron light source under construction at Brookhaven National Laboratory. It consists of a 200 MeV linac, a booster ring accelerating beam from 200 MeV to 3 GeV, a 3 GeV Storage ring and transport lines in between them.

As many other facilities [2,3], NSLS II chose the Experimental Physics and Industrial Control System (EPICS) as its control system to monitor and control the accelerator hardware. It interfaces to the accelerator instruments and devices (such as Power supply, digitizer, and motor) with IOC (Input Output Controllers). Channel Access is used as the interface to the machine process variables (PVs).

The typical control applications include two types, simple monitor/control device and complex accelerator physics application for studies and machine optimization (measurements, data analyses and applying correction). Mainly, we use cothread to access the process variables (PVs) in Python script for complex accelerator physics applications and the CSS (BOY) [4] panel for simple tasks such as monitoring, displaying and setting of the machine Process Variables (PVs). Besides, MATLAB is also available for programming and EDM panels are used for Linac control system from the linac vendor Research Instruments, GmbH. All source codes including panel configurations are controlled and managed by mercurial version in the control system.

To keep the beam commissioning time efficient, various tools were developed for data displaying, collecting and processing. Besides machine status and physics applications, we also developed the daily used operation tools, such as save/compare/restore tool, data archive, alarm and warning monitor, elog, eticket, channel finder service and applications.

Prior the beam commissioning, we have two stages test with above tools, subsystem integration testing (IT: the hardware system level function verification) and machine extended integration test (EIT: mimic the beam commissioning and tune the machine). These verifications require time and look boring and redundant, but it is necessary as it may take weeks of commissioning time to fix different technical problem.

MACHINE STATUS APPLICATION

All of the monitor and control panels are created with software tools in Control System Studio (CSS), which is an Eclipse-based collection of tools to monitor and operate large scale control systems. The interface allows the operators to edit the desired ramp/soak profiles and provides the option to use predefined recipes.

The NSLS-II operation panels [5] include the user panels and the expert panels. They display the device status and parameters (setpoint and readback) and show the device performance. A user panel shows only information that user is required, such as the magnet current setpoint and readback. The expert panel shows all the information that expert can fully control the device or diagnose the device, such as power supply operation mode and magnet temperature.

HIGH LEVEL APPLICATION

Besides the devices status and control, we also develop high level applications to realize the accelerator physics application tools. It is to translate the raw/processed data from PV to the "physics" parameters, such as from the beam size reading from flags for beam emittance or beam energy measurement. The code was programmed with Python. Although we programmed the high level applications with Python, some of their GUIs (depending on operation needs) are implemented in the CSS, as part of operator panels, so that the operators have consistent live information and interface environment. The user can set parameters and monitor the progress in GUI as regular device PV set and monitor. This feature is realized through soft IOCs.

A screenshot of beam energy and energy spread measurement with flag VF2 is shown in Figure 1. It is in continuous mode, which means whenever the beam image updates, the beam energy and energy spread is updated correspondingly. It shows the beam image, horizontal beam profile, beam energy, beam energy spread, and the charge ratio in every 0.5% energy deviation.

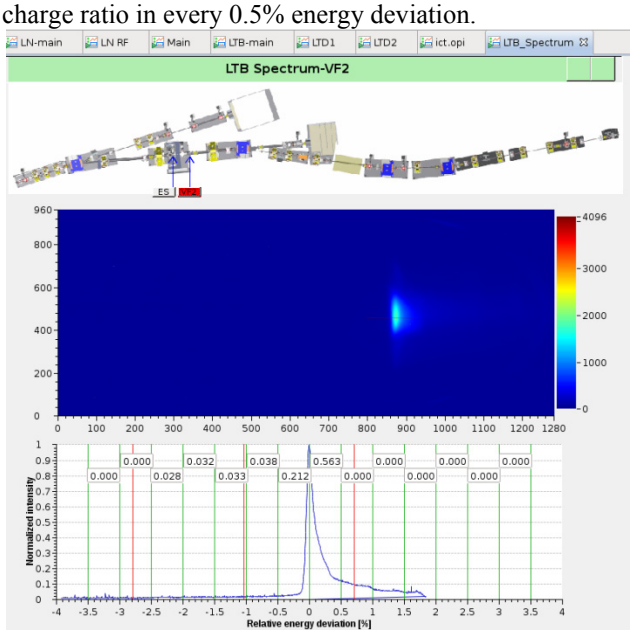

Figure 1: Screenshot of beam energy and energy spread measurement with flag VF2 in LTB transport line.

COMMISSIONING TOOLS

MASAR

The MASAR (MAchine Snapshot, Archiving, and Retrieve) [6] is an important tool used during the commissioning, which is developed by the NSLS-II Controls group for machine save/compare/restore function. MASAR is an EPICS V4 service, and it is a server-client based tool-set. The server and client are implemented in C++ and Python. The server takes machine snapshots, archives data in a relational database, and retrieves data from the database. The client provides a GUI that retrieves snapshot data, compares the data with the live machine, compare multiple snapshots, and restores the machine with given snapshot data.

The user creates a list of channels, which can be any record data type, such as scalar values, arrays or strings, that are important for the system in a configuration file and, then, MASAR saves the current configuration. To take a snapshot, the client specifies the name of the snapshot configuration and a name for this snapshot event. When the server receives a command to take a machine snapshot, the server retrieves the list of channel names in the configuration from the database. It then gets the current value of all the channels from IOC, and saves the data as a snapshot event into the database.

Channel Finder Service and Applications

The High level applications tend to prefer a hierarchical view of the control system where they can group channels by type (such as BPM, horizontal corrector) or location. These applications require retrieving a large set of channels' value or alarm state. Channel finder applications have simplified user interaction by requiring the user to providing only the channels' criteria that they are interested in, such as element type BPM or element Name ICT1, instead of the complete set of channels name.

User provides a list of channel names (PVs) with given properties and tags and channel finder service (CFS) [7] stores these information for different applications. The Properties are keyword-value pair data, where the keywords are predefined, such as element name with value P1, element type with value BPM, s Position with value P1 0.5 et. al, whereas the tags are plain strings, such as aphla.sys.LTB, aphla.sys.SR. The channel finder applications use CFS plugin, to query the service for a group of channels based on the set of criteria, which is based on one or any combination of channel name, properties and tags. The channel finder applications client are supported by CSS (such as channel viewer to show a group of PVs with their name, properties and tags, Channel line plot viewer to plot a group of PVs live data, waterfall plot to show time plot of all queried channels) or python (APHLA: accelerator physics high level application).

Channel Archiver

An EPICS Channel Archiver is installed to record the values of many interesting PVs over time (such as ICT charge, power supply readback, vacuum pressure, which are predefined by PVs' owner). This data is then available for online queries, for plotting with the CSS Data browser, and may be exported in several formats (such as spreadsheet, Matlab, h5) for analysis.

Figure 2 shows the historical view of the charge reading after linac from one ICT and two Faraday Cups with data browser.

SUB-SYSTEM INTEGRATION TEST

The purpose of the sub-system integration test [8] is to verify the device function along with utilities, timing system and control system in control room environment. Meanwhile, we do the diagnostics system calibration and develop more functions to improve the control system features for users. The subsystem testing include all diagnostics (such as ICT, FCT, FC, Flags, BPMs) devices, power supplies and RF system. We developed the test procedure, which includes the system interface block diagram, the system physics parameters and ranges, the control parameters and procedures on mechanical/controls testing, calibration and check points. During the process, we use external "known" signal to simulate the real beam in various situations, such as 1 Hz/2 Hz/ stacking mode with low/high bunch charge at single bunch mode/long pulse mode.

Most of the technical issues are solved during the integration test. But this test cannot fix some possible problems, such as magnet polarity error, which could only be revealed by beam.

For example, during the BPM system integration testing [9], a number of hardware issues has been found out and fixed (such as cable loose connection on a patch panel). Some BPMs four buttons' signal shows different behaviour and noisy frequency up to a few kHz were observed. This is solved by modifying the oscillator and installing a microwave absorber. The BPM position noise level is now improved down to 1μm. During the BR flags test, a parasitic background was observed on the screen images, which will also affect the beam image. To fix this problem, A set of the absorbers has been produced by BINP and installed into the flag tubes. During the ICT test, the beam signal source is 'replaced' by a pulse generator. We found LTB-ICT2 connection issues and four ICTs exhibit the readback difference, which is larger than 5% due to calibration. After repeating the calibration, the four ICTs readback difference came down to be less than 1% and the charge readback noise reduced below 10 pC.

EXTENDED INTEGRATION TEST

Prior to the Booster (BR) beam commissioning, we carried out the beam commissioning with simulated beam signals, called extended integrated testing (EIT) to prepare for the booster ring commissioning by operating the whole system as during the actual beam commissioning. The beam signals are simulated and generated by a computer program, ELEGANT. Then they are transported by the same data channel as the real beam signal would travel.

We developed shift schedule, daily shift plans and shift summaries, closely corresponding to the actual beam commissioning. The EIT activities consist of 4 hour shifts per day with shift team from BNL and BINP. The short and long term shift plans are based on real beam commissioning steps. The whole test lasts 10 weeks.

During this process, we tested and optimized all the operation screens, the high level applications and upgraded the operation tools. With readbacks from the power supply and RF systems, commissioning activities such as injection, first turn steering, achieving circulating beam, RF capture, closed orbit, acceleration ramp optimization and extraction can be set up and optimized. This proved itself to be an efficient way of debugging the controls- and the correction systems, as the applications bug can be quickly revealed with the known 'beam' signal. Many small issues and bugs, which would have us slowed down during the commissioning, have already been discovered and fixed during the test. For example, the large dipole BD1 IGBT fail caused the PS broken, which takes power supply group ~1 month to find and fix the problems. The feedforward function in quads is implemented as the error is larger than specification. The MASAR function is upgraded to accommodate the waveform channels. The ramp manager application is upgraded so that RF control with sequence and limitation is included and RF voltage waveform setting can be easily correlated with PS setpoint.

Moreover, the testing is carried out from the control room in a way which is almost identical to the commissioning with real beam. The operations procedures, the shift routines, the use of the logbook and much more were practiced and improved during EIT. For example, the online shift summary service was developed for easy search.

ACKNOWLEDGEMENTS

All of this work would not have been possible without constant support of all the NSLS II teams and the close collaboration with the BINP team.

Abstract

Short (subpicosecond) pulses are central to many of the next generation light source initiatives that are based on linear accelerators. Beam compression is performed by means of a chicane utilizing a correlated linear energy chirp. A small energy chirp is kept as the beam goes through the remaining accelerating stage to compensate for wakefield effects. It is necessary to compensate the residual energy spread before the beam enters the undulator stage. We present here a concept for a passive wakefield device - chirp corrector or dechirper, to perform this compensation. We have recently demonstrated a passive energy chirp correction by self-wakefield at the Brookhaven ATF facility. In this paper we present a progress report on development of these tunable chirp correction devices.

INTRODUCTION

Free Electron Laser (FEL) operation requires a high current beam. To reach high current, typically kA – level, the electron beam is compressed. Compression is performed by a chicane, a set of four dipole magnets arranged in a + - - + pattern. For the beam to be compressed by a chicane it has to have an energy chirp, a linear correlation between the energy and longitudinal coordinate. This correlation can be obtained by running beam off-crest in the accelerating section. A natural parameter to characterize the chirp is derived from the slope: the energy difference over the longitudinal coordinate difference in MeV/mm or equivalent. For compression in chicane a positive chirp required, i.e. the head of the beam has lower energy than the tail. In this case the lower energy particles (the head) have a longer path than the high energy particles in the tail. Hence the beam is compressed as the tail catches up with the head. After the compression the beam typically has a residual chirp on the order of 40 MeV/mm [1]. Prior to injection in the undulator this chirp has to be removed as it compromises the FEL lasing. In principle, this can be done by running the bunch off-crest in the accelerating section. Alternatively a passive wakefield device can be used by utilizing the self-acting wakefield induced by the electron bunch on itself [2]. In the original proposal such a device was called a "wakefield silencer". Similar proposals were also put forward in [3-5]. A new name "dechirper" or "chirp corrector" was used in [5] and adopted here as a generic name for the passive wake-inducing device whose sole purpose is to remove (or create) the energy chirp. Since the impact of the dechirper linearly scales with the length of the device and the charge of the electron bunch, it is convenient to characterize the dechirper strength in units of MeV/mm/m/nC. The experimental demonstration of the idea of the dechirper was first reported in [4] where a set of dielectric lined cylindrical waveguides with different apertures were used to produce wakefields with variable strengths. Although the use of different apertures in a cylindrical geometry gives a reasonable flexibility in adjusting the dechirper strength, a continuously tunable dechirper is nevertheless preferred. This device has been tested recently and in this paper we present some recent experimental results obtained using a tunable dechirper.

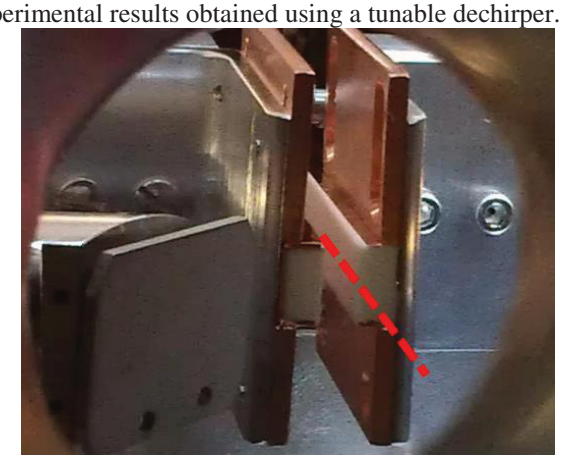

Figure 1: Tunable dechirper: two 10 cm long metallized alumina (ε=9.8) bars, 12 mm wide and 6.35 mm thick with 1 – 6 mm variable gap.

While propagating through the dechirper each electron emits Cherenkov radiation. For a particular structure this field can be simulated and in some cases calculated theoretically [6]. Integrating over the current distribution one can get the total wakefield inside the electron bunch. For dechirper operation we are interested in the self-wakefield, the fields inside the bunch. For a linear chirp correction the self-wakefield has to be quasi-linear. This can be obtained in a number of ways, using a single mode structure or a multimode structure. Naturally, a wake

generated by a beam can be represented by a set of modes excited in a structure. The dielectric-loaded waveguide can be made to support only one primary mode (with others having a weak coupling to the beam). This is typically done by using a thin layer of dielectric. If the wavelength of this mode is much larger than the length of the beam, then the self-wake is quasi-linear. This is obvious for a flattop beam as we convolve the constant current with the cosine wake to obtain a sine self-wake which is further approximated for short beams by a linear function of axial position. Similarly, a multimode structure would work in the case when most of the excited modes have wavelengths longer than the beam. We prefer working with a multimode structure as it is much simpler to handle in the experiment.

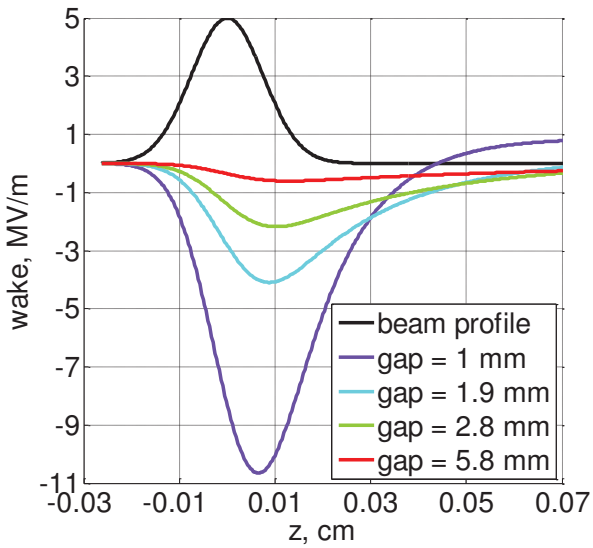

Figure 2: Principle of tunable dechirper: short range wakefields calculated for a Gaussian beam for four values of the dechirper gaps indicated on the plot. There is a linear part of the short range wake with amplitude changing as we change the dechirper gap.

The wake amplitude ~ $\eta \cdot q/a^2$, where η is the waveguide form factor, q is the charge and a is the characteristic size of the aperture. Hence tuning the transverse size of the aperture allows a corresponding adjustment of the strength of the chirp corrector (Fig. 2).

A chirp corrector also can be made using a corrugated structure [5]. Such structures typically operate as a single mode dechirpers. A multimode operation can be achieved by using deep corrugations, however, theoretical analysis in this case becomes complicated.

Defining the linear fit to the wakefield as illustrated in Fig. 3, we obtain for the dechirper strengths for a gaussian beam S_D = 45, 87, and 215 MeV/mm/m/nC using dechirper gaps = 2.8, 1.9 and 1 mm. It is important to point out that dechirper strength does depend on the beam distribution as illustrated in Figure 3. The self-wakefield slope differs slightly for gaussian and flattop beams.

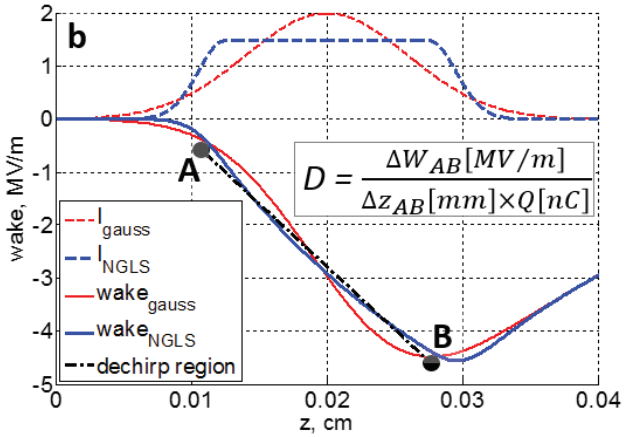

Figure 3: Illustration of the definition of the dechirper strength using the linear fit of the wakefield between points A and B (the case with a 1.9 mm dechirper gap is shown here). The red curve shows the profile of the electron charge distribution, NGLS-type 150 μm flattop beam (not to scale).

EXPERIMENTAL RESULTS

The experimental testing of a tunable dechirper was performed at the Accelerator Test Facility in the Brookhaven National Laboratory. We by accelerating electron bunch off-crest in the linac and obtaining an energy of 60 MeV and a positive 0.33 MeV/mm energy chirp. We had a longitudinal shaping setup for the beam that was part of another experiment and produced a quasi-triangular beam, 500 μm long with 54 pC charge. This was accomplished by a mask located at a point with a large energy dispersion between the two opposite sign dipole magnets [7]. The electron bunch length was measured with the interferometer using coherent transition radiation (CTR) from a foil located downstream of the second magnet.

The electron beam energy chirp was then manipulated by passing the electron bunch through a dechirper shown in Figure 1. After that, the electron bunch was sent into the spectrometer.

We measured the energy spread using a magnetic spectrometer. It was observed that the energy spread decreased as we closed the chirp corrector gap from 5.8 mm to 1 mm. Fig. 4 shows our experimental data: the beam is detected by a phosphor screen and imaged by a camera. On this image the horizontal dimension represents the particle energy, and the vertical dimension represents the vertical beam size. Due to the initial energy chirp one can see the correlation of the chirp value and the longitudinal projection of the beam on the spectrometer. Because the beam was quasi-triangular longitudinally and had an energy chirp, a linear correlation between the longitudinal coordinate and energy, the image on the spectrometer repeats the longitudinal beam profile, and we observe a triangular spot on the screen.

Copyright © 2013 CC-BY-3.0 and by the respective authors

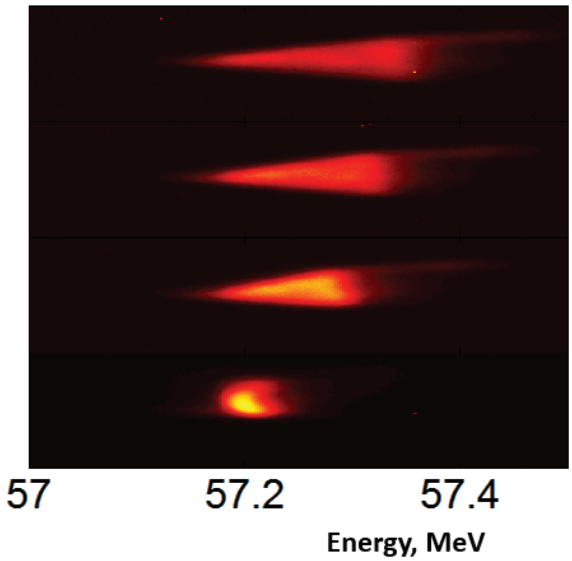

Figure 4: Experimental measurement: calibrated energy spectra of the beam passing through a chirp corrector with various gap sizes: 5.8, 2.8, 1.9 and 1 mm. The energy spread of the beam can be seen to decrease as the optimum gap size (1 mm) is approached.

When the dechirper gap was closed down to 1 mm we no longer observed any correlation and the energy spread was at a minimum. The energy chirp was calculated to be 0.33 MeV/mm (165 keV over a ~500 micron long triangular beam). This 0.33 MeV/mm was compensated in the 10 cm long dechirper. Since the total beam charge was 54 pC, the value of the dechirper strength in this case is 61±6 MeV/mm/m/nC.

In summary, our work has demonstrated a tunable dechirper, a passive wakefield device for reduction of the correlated energy spread. With this device, the 0.33 MeV/mm correlated energy spread of a 60 MeV, 54 pC electron bunch at the BNL Accelerator Test Facility (ATF) was completely removed by adjusting the gap between metallized alumina bars [8] (forming a planar dielectric structure) from 5.8 mm down to 1 mm.

Abstract

The Idaho Accelerator Center (IAC) has been operating nine low energy accelerators for THz and X-ray light sources, nuclear physics, and medical isotope productions. In November 2012, the IAC and RadiaBeam collaborated to upgrade an IAC 44 MeV L-band RF linac with a chicane bunch compressor and a THz radiator with numerous periodic gratings for the resonant Cherenkov radiation. By using the THz radiator and the re-optimized L-band linac with a new operational energy of 5 MeV, we could demonstrate a THz resonant Cherenkov radiation with a high average power of about 17 W in an RF macropulse without using any sub-ps laser or undulator. In this paper, we describe our upgrades and accelerator optimization experiences to perform the proof-of-principle experiments at the IAC.

INTRODUCTION

As various user applications such as diagnosis of early stage cancers, 3D imaging of teeth, security and weapon scanning, and quality control of commercial products have been developing, recently, THz users strongly request coherent THz light source which can supply a high average power ($\geq$ 1 mW). Jefferson Lab and several other laboratories have demonstrated accelerator-based high average power THz light sources by using the Continuous Wave (CW) or Energy Recovery Linac (ERL) technology. However, we need a big budget to construct such an ERL based THz light source facility. To realize a compact and cheap high average THz light source facility, we have developed a resonant Cherenkov radiation based THz radiator [1–3], and performed its proof-of-principle experiments at the Idaho Accelerator Center (IAC) by upgrading an IAC 44 MeV L-band RF linac [4–6]. The parameters of the 44 MeV linac and the THz radiator are summarized in Table 1, and the layout of the upgraded IAC 44 MeV L-band linac is shown in Fig. 1. The upgraded linac has a 85 kV DC gun instead of an RF photoinjector and a THz radiator instead of a undulator as shown in Fig. 1. To perform the proof-of-principle experiments of narrow-bandwidth resonant Cherenkov radiation with a specially designed THz radiator, RF phases and gradients of the 44 MeV linac structures were re-optimized to have a new operational beam energy of 5 MeV and to have the shortest bunch length of about 500 fs (rms). It is well confirmed that the multi-bunch beam loading effects or the long-range longitudinal wakefields can be used to generate coherent narrow-bandwidth resonant Cherenkov radiation [1, 2, 7, 8]. In our experiments, we used a 85 kV DC gun to generate a long bunch train with 2600 short single bunches in a 2 μs long RF macropulse. By sending the 2600 short bunches with a single bunch charge of about 30 pC into the THz radiator, we could get strong multi-bunch beam loading effects to generate a high average power THz radiation at 0.316 THz. In this paper, we describe upgrades of the IAC L-band linac, the THz radiator, and linac optimization experiences to generate a high average power THz radiation at 0.316 THz with the compact THz radiator.

Table 1: Parameters of Linac and THz Radiator

Parameter	Value	Unit
Maximum beam energy	44	MeV
Minimum beam energy	5	MeV
RF frequency	1300	MHz
Repetition rate of RF macropulse	30	Hz
Length of RF macropulse	2	μs
Bunches in a macropulse	2600	·
Single bunch charge	30	pC
R_{56} of bunch compressor	13.7	mm
Minimum rms bunch length	500	fs
Resonance frequency of radiator	0.316	THz
Grating period	234	μm
Grating groove depth	80.86	μm
Grating structure length	30.4	mm
Grating structure width	6.3	mm
Grating structure gap	1.256	mm
Phase advance per period	88	deg
Quality factor	2150	·
Gap-averaged shunt impedance	4.3	MΩ/m
Nomalized group velocity	0.8	·
Average THz power per macropulse	17	W
Bandwidth of THz radiation	10	%

UPGRADES FOR EXPERIMENTS

For the THz experiments, as shown in Fig. 1, we installed a THz radiator, which had been fabricated with the conventional CNC milling, a chicane bunch com-

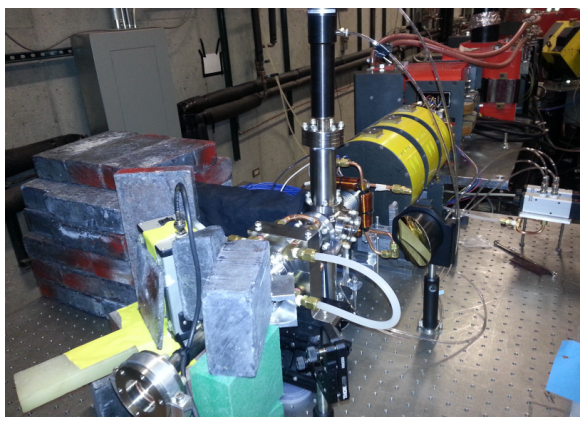

Figure 3: Upgraded beamline of the IAC 44 MeV linac for the IAC-RadiaBeam THz project.

pressor to compress electron bunch length, a quadrupole triplet (QMs) to change beam shape and to adjust focusing strength at the THz radiator, four horizontal and vertical steering magnets (STs) to adjust beam orbit along the beamline, a Coherent Transition Radiation (CTR) based interferometer to measure femtosecond long electron bunch length after the bunch compressor, an OTR screen to check the beam position and shape in front of the chicane bunch compressor, a YAG screen to check beam position and beam shape in front of the THz radiator, two Prosilica GigE CCD cameras to acquire beam shapes and positions at the OTR and YAG screens, a Faraday cup at the end of the beamline to measure electron beam charge going through the THz radiator [1, 5, 6]. In addition, as shown in Figs. 2 and 3, we had installed a homemade THz antenna in front of the left output-coupling Sapphire window of the THz radiator, and a GenTec QS-I-TEST SDX-1065 pyrodetector was installed in front of the right output-coupling Sapphire window of the THz radiator [1]. To acquire weak signals from the homemade antenna, we connected a Tektronix MSO72004 fast oscilloscope to the antenna with a 1.0 m long low loss copper coaxial cable. Since the cable length is only 1.0 m, we had to leave the oscilloscope in the linac tunnel with sufficient lead shielding. To control the oscilloscope from the linac control room, we used the remote desktop function of Windows XP. Since the cable is short and low loss one, it was very effective to find initial signals from the radiator [1]. The GenTec SDX-1065 pyrodetector was connected to a Tektronix TDS2014 slow oscilloscope with a 50 m long coaxial cable. Since the cable is long enough, the oscilloscope could be controlled at the control room directly.

To control newly installed magnets and Prosilica GigE CCD cameras remotely, we had installed EPICS accelerator control system. More details on the EPICS accelerator control system, the dipole magnets for the chicane and three quadrupoles for the triplet, and the Prosilica GigE CCD camera based beam imaging system can be found from references [4–6]. As shown in Fig. 1, the new 4.3 m long beamline for the THz experiments starts from the second 90 degree bending magnet (BM), which is located at right before the first 7 degree dipole magnet for the chicane bunch compressor. After installation of all components, the upgraded beamline is busy as shown in Fig 3. The 0.3 m long THz radiator consists of a molybdenum collimator set, cooling channels, two connecting flanges, and a pair of planar, side-open, copper gratings with symmetrical meander profile as shown in Fig. 2. Since the collimator has a 1.2 mm wide gap, good beam orbit steering is required to send electron beams through the THz radiator. Detailed design concepts of our THz radiator can be found from references [1, 2] and its parameters and performance are summarized in Table 1.

EXPERIMENTAL RESULTS

To detect THz signals from the THz radiator, first of all, we optimized the beam shape and orbit with steering magnets and the quadrupole triplet to get a weak transmission down to the Faraday cup. Then, we adjusted bunch length by optimizing RF phases of linac structures and chicane

Copyright © 2013 CC-BY-3.0 and by the respective authors

strength. After the bunch length optimization, we tried to improve beam transmission down to the Faraday cup with steering magnets and the quadrupole triplet. However, we could not get any THz signal from the GenTec SDX-1065 pyrodetector with 8 MeV electron beam, and the single bunch charge at the Faraday cup is much smaller than 1 pC. To overcome the high RF background noises, we installed a homemade THz antenna in front of the left output-coupling Sapphire window, and a Tektronix MSO72004 fast oscilloscope was connected to the antenna with a 1.0 m long low loss copper coaxial cable. Then, to improve the velocity bunching of the electron beam, we reduced beam energy from 8 MeV to 5 MeV. However, we could not get any signal from both the pyrodetector and the antenna either. In addition, the beam transmission to the Faraday cup was dramatically dropped at 5 MeV due to strong space charge forces at the THz radiator region when the beam was horizontally focused and longitudinally compressed at 5 MeV [1,6]. Therefore, we had to modify transverse beam shape from horizontally focused strip like one into uniformly distributed round one to reduce the beam spreading due to strong space charge forces in the THz radiator [1].

After the transverse beam shape modification, we could improve the beam transmission, and we could detect a weak cm-wavelength signal from the homemade THz antenna as shown in Fig. 4. The longer cm-wavelength radiation is generated by the wakefield induced at the 2 cm long horn antenna openings when the bunch length is longer than the grating period of 234 μm [1]. By adjusting RF phases for the velocity bunching, chicane strength for the magnetic compression, beam orbit, and beam uniformity against strong space charge forces, we could get good beam transmission down to the Faraday cup as well as the strong cm-wavelength signal from the homemade antenna as shown in Fig. 4. In that case, the single bunch charge at the Faraday cup was increased up to 30 pC. By compressing bunch length down to the grating period range, we could get a strong cm-wavelength signal from the homemade antenna and a strong THz signal from the pyrodetector as shown in Figs. 4 and 5. By analyzing signals from the pyrodetector, we found the fact that the average THz power of the RF macropulse with 2600 single bunches is about 17 W in the radiator [1]. We also got a similar power level by analyzing cm-wavelength signals from the homemade antenna. This is about two orders of magnitude higher average power than that was obtained with RF photoinjector based THz sources at low beam energies [8].

SUMMARY

Successfully, at 5 MeV, without any gun driving laser or undulator, we have demonstrated that a high average power THz radiation can be generated with a compact and cheap resonant Cherenkov radiation based THz radiator. The average THz power of an RF macropulse is about 17 W, which is is about two orders of magnitude higher average power than that was obtained with RF photoinjector based THz sources at low beam energies. We expect that

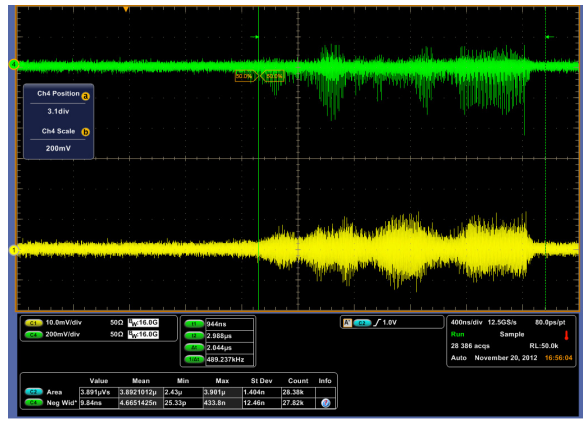

Figure 4: Tektronix MSO72004 oscilloscope signals at 5 MeV with a round beam shape: (top and green) signal from a Faraday cup, (bottom and yellow) signal from a THz antenna.

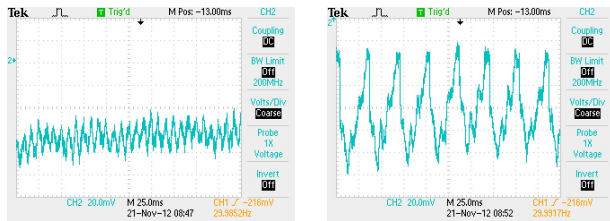

Figure 5: Tektronix TDS2014 oscilloscope signals from a GenTec pyrodetector at 5 MeV with a round beam shape: (left) when beam was off and (right) when the single bunch charge at the Faraday cup was about 30 pC, and the signal from THz antenna was strong as shown in Fig. 4.

the average power can be further increased by improving electron beam quality and by increasing RF macropulse length. By directly connecting the THz radiator to a multicell thermionic RF gun and an alpha magnet, we expect that the total length of the THz facility can be reduced down to several meters. By measuring average THz power from the THz radiator, hence the form factor of electron beam, we can also use the radiator to measure the femtosecond long bunch length of electron beams [1]. Abstract

We present the concept and results of pseudo-single bunch (PSB) operation - a new operational mode at the Advanced Light Source (ALS) - that can greatly expand the capabilities of synchrotron light sources to carry out dynamics and time-of-flight experiments. In PSB operation, a single electron bunch is displaced transversely from the other electron bunches using a short pulse, high repetition rate kicker magnet. Experiments that require light emitted only from a single bunch can stop the light emitted from the other bunches using a collimator. Other beamlines will only see a small reduction in flux due to the displaced bunch. As a result, PSB eliminates the need to schedule multi-bunch and timing experiments during different running periods. Furthermore, the time spacing of PSB pulses can be adjusted from milliseconds to microseconds with a novel "kick-and-cancel" scheme, which can significantly alleviate complications of using high power choppers and substantially reduce the rate of sample damage.

INTRODUCTION

A major limitation of synchrotron light sources is the ability to easily serve two classes of experiments simultaneously, namely, brightness or flux limited experiments and timing experiments. High brightness experiments require filling most of the rf buckets with electrons, thus maximizing the total current while minimizing the current per bunch. In such a multibunch filling pattern, the bunch spacing is typically only a few nanoseconds between electron bunches. On the other hand, timing experiments require longer times between x-ray pulses. For example, in the case of laser-pump x-ray-probe timing experiments, it is desirable to have only one x-ray pulse per laser pulse. Since such lasers operate between kHz and MHz rates, this implies a distance between pulses of ms to μs.

At the Advanced Light Source (ALS) facility, we have been exploring a new mode of operation that we call pseudo-single-bunch (PSB) operation, the goals of which are to allow multibunch and timing experiments to run simultaneously [1, 2, 3]. The idea behind PSB operation is to use a high-repetition (MHz)-rate, short-pulse (<100 ns) kicker [4] to vertically displace a single camshaft bunch relative to the bunch train. Experiments that require light emitted only from a single bunch can block the light emitted from the other bunches using a collimator with only light from the camshaft bunch reaching the experiment. The PSB timing could be at the orbital period (656 ns) or longer, depending upon how frequently the bunch is displaced.

Here we discuss the results of our studies on the PSB operational mode, especially the novel kick-and-cancel (KAC) scheme that can deliver a single pulse with adjustable frequency [3]. A similar idea was previously suggested [5], but to our knowledge this is the first time that it has been realized.

KICK-AND-CANCEL SCHEME

The idea of the KAC scheme is that by adjusting the ring tune and the PSB kick pattern, the camshaft bunch can first be displaced to a different orbit and then kicked back to its original one within a few turns. This KAC process can be repeated at will to create a PSB pulse with an adjustable repetition rate. Mathematically, the KAC scheme can be shown as follows. Assuming that a camshaft bunch is kicked at the i^{th} turn with a kick angle of θ_y, the orbit offset and angle at the n^{th} turn due to this kick are given by

$$\begin{aligned} y_n^i &= \theta_y \beta_y \sin[2\pi(n-i)\nu_y], \\ y_n'^i &= \theta_y \{\cos[2\pi(n-i)\nu_y] - \alpha_y \sin[2\pi(n-i)\nu_y]\}. \end{aligned} \quad (1)$$

To restore the orbit after the n^{th} turn, the superpositions of orbit offsets and angles from each kick need to be zero, i.e.,

$$\sum_{i=0}^{n} y_n^i = 0, \qquad \sum_{i=0}^{n} y_n'^i = 0. \quad (2)$$

Using the two equations above, we can solve the required vertical tune for given number of kicks and orbit turns. There are many possible solutions to Eq. (2). Just one example is presented here. In this example we wish to restore the orbit after two turns within two kicks. The orbit offsets and angles are created by these two kicks at the 2^{th} turn are

$$\begin{aligned} y_2^0 = \theta_y^0 \beta_y \sin 4\pi\nu_y, y_2'^0 &= \theta_y(\cos 4\pi\nu_y - \alpha_y \sin 4\pi\nu_y) \\ y_2^2 = 0, y_2'^2 &= \theta_y^0. \end{aligned} \quad (3)$$

Applying Eq. (2), we can solve the vertical tune $\nu_y = 0.25$.

To test this scheme at the ALS, the vertical tune of the storage ring needs to be adjusted to 9.25 from the nominal tune of 9.20. Figure 1 shows simulated beam orbits for this KAC scheme with the kick angle of 73 μrad. We can see that the beam orbit is displaced for two turns and then kicked back to the nominal one. For example, at the undulator beam line 6.0.1 as indicated in Fig. 1(c), the two orbits are displaced on both sides of the unkicked one, and

At the source point of beam line 3.1, the beam is displaced by -560 μm on the 1st turn and 395 μm on the 2nd turn; (c) close-up of straight 6. In the center of the insertion device the beam is displaced by -113 μm on the 1st turn and 188 μm on the 2nd turn; (d) close-up of beam line 10.3 source point. The beam is displaced by 10 μm on the 1st turn and -154 μm on the 2nd turn.

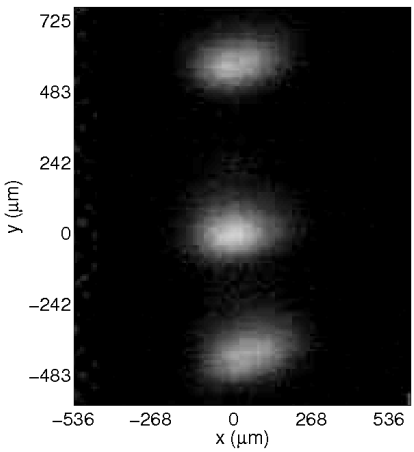

Figure 2: Beam image measurement at synchrotron diagnostic beam line 3.1. For this measurement, the storage ring was filled with a 5 mA single camshaft bunch, and the beam was kicked at the maximum kick-and-cancel frequency.

the maximum separation between them is about 250 μm at the center of the 6.0.1 insertion device.

It should be pointed out that the KAC may affect beam orbit stability through fluctuations of the kick amplitude, and affect the beam size by chromaticity and tune shift with amplitude. The reproducibility of the kick amplitude depends on the stability of the power supply. Measurements using an analog oscilloscope show that the relative fluctuations are approximately 2x10^{-3}, which gives rise to about 0.5 μm orbit motion (about 4% of the beam size). We have also carried out simulations using our accelerator modeling code to estimate the effects of chromaticity and tune shift with amplitude. The results show that beam size growth due to these effects is about 0.5 μm (rms) which is the same as the one caused by the fluctuations of the kick amplitude. These estimates indicate that for the ALS parameters beam orbit motion and beam size increase due to the KAC scheme should be acceptably small.

EXPERIMENTAL TESTS

We first tested this novel operation mode at our synchrotron diagnostic beam line 3.1. At this beam line, the x-ray pulse emitted from the bend magnet is first converted to visible light by a BGO crystal, and then imaged on a CCD camera. Figure 2 shows the measured beam image when the kicker is turned on. Clearly, there are three beam spots, the central one corresponding the un-kicked orbit and the other two the kicked orbits. The separation between the two kicked orbits is about 950 μm, which is consistent with the simulation. For this measurement, the storage ring was filled with a 5 mA single camshaft bunch, and the beam was kicked at the maximum kick-and-cancel frequency, i.e., there is no waiting period between each KAC process. Therefore, the three orbits have the same repetition rate of 500 kHz and the same current of 5/3 mA.

We tested this KAC operation mode at the bend magnet beam line 10.3.2. For this beam line, a side-deflecting toroid mirror forms a 1:1 image of the x-ray beam on a slit. The time-averaged x-ray intensity is measured using a YAG scintillator after the slit, the light from which is detected by a PIN diode. Figure 3 shows the x-ray signals by vertically scanning the slit when the kicker is turned on and off. For these measurements, the storage ring was filled with a 350 mA multibunch train and a 4 mA camshaft bunch. In the figure, the signal from the kicked camshaft is clearly seen on the shoulder of the main bunch background when the kicker is turned on. The signal to background ratio is about 10:1. Compared to the normal operation mode, the background from the main bunch train is suppressed by a factor of about 2500. The separation between the kicked camshaft signal and the main bunch peak is about 150 μm, which is consistent with the simulation.

We tested the KAC scheme at beam line 6.0.1 using a gated detector. The setup of the experiment is shown in Fig. 4(Top). For this test, the storage ring was filled with a 276 mA multibunch train and a 5 mA camshaft bunch. The x-ray pulse emitted from the undulator was measured using a gated avalanche photodiode at an end station of the beam line. Two measurements were carried out, one with a 50 μm slit centered on axis, and the other with the slit centered 190 μm off axis. For the on-axis measurement, the x-ray signals from the bunch train and unkicked camshaft bunches are clearly seen in Fig. 4(Middle); however, the pulses from the kicked camshaft bunch are missing for two turns since the camshaft bunch is displaced to different orbits during these two turns and the radiation from them is blocked by the slit. When the slit is moved off axis (up),

Copyright © 2013 CC-BY-3.0 and by the respective authors

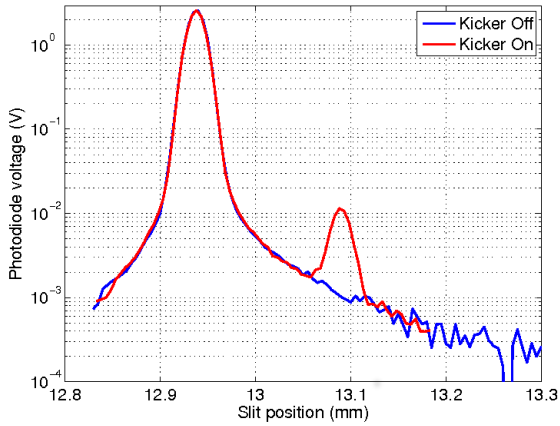

Figure 3: X-ray pulse measurements at a bend magnet beam line 10.3.2 with the kicker on and off. For these measurements, the storage ring was filled with a 350 mA multibunch train and a 4 mA camshaft bunch.

only the radiation from the displaced bunch at the second turn can pass through the slit. Therefore, we only see one pulse in Fig. 4(Bottom).

Finally, we tested this KAC scheme using an integrating (nongated) photodiode at beam line 6.0.1. For this test, the storage ring was filled with the same fill pattern as for the previous test, and the slit was moved off axis to a position where it would optimally transmit the light of the kicked bunch. At this slit position the background signal due to the unkicked bunches was suppressed by 3 orders of magnitude. This large suppression in the signal from the unkicked bunches directly translates to a substantial reduction in the sample damage rate.

CONCLUSIONS AND OUTLOOK

Our results show that with a relatively simple, inexpensive pulsed kicker magnet, it is possible to achieve both single-bunch and multibunch operations at the same time. With the proposed kick-and-cancel scheme, the pulse repetition rate of the PSB photon beam can be adjusted from Hz to MHz, which can significantly alleviate complications of using high-power choppers, substantially reduce the rate of sample damage, and greatly increase the variety and quality of experiments that can be done without using gated detectors.

Recently, ALS has successfully finished brightness upgrade [6]. The nominal working point of the storage ring lattice has been adjusted from the past (14.25, 9.20) to the current (16.25, 9.20). To make this KAC scheme available for beam users, we are planning to increase the vertical tune to 9.25. Horizontal tune scan has been carried out. The lattice with the tune of (16.18, 9.25) seems to be a very good candidate in terms of lifetime, injection efficiency and nonlinear beam dynamics. Further studies are undergoing to test this lattice and results look very promising. At this new working point, we could operate this KAC scheme during the normal operation, which would eventually allow to run

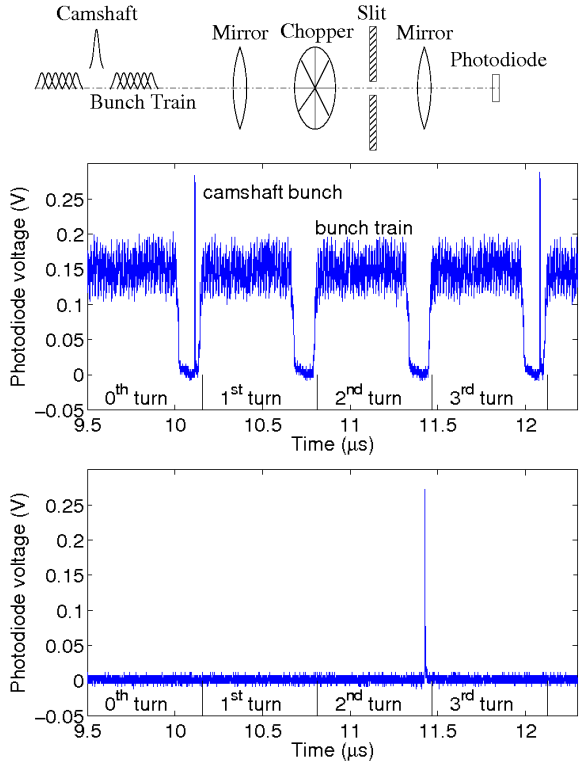

Figure 4: X-ray pulse measurements at an undulator beam line 6.0.1. (Top) Experiment setup; (Middle) On-axis measurement. The 50 μm slit is centered on axis. (Bottom) Off-axis measurement. The slit is off axis by 190 μm.

brightness and timing experiments simultaneously.

ACKNOWLEDGMENT

Authors would like to thank Tom Scarvie at LBNL for his help on the KAC lattice setup, and Slawomir Kwiatkowski, James Julian, David Plate, Ray Low and Ken Baptiste who constructed the PSB kicker and pulser. We also wish to thank the ALS management for their support and encouragement of these studies and LBNL's Engineering Division Director Kem Robinson for financial support for building the PSB kicker.

INITIAL LATTICE DESIGN STUDIES FOR A DIFFRACTION LIMITED UPGRADE OF THE ADVANCED LIGHT SOURCE

H. Tarawneh#, C. Steier, D. Robin, H. Nishimura, C. Sun, W. Wan
Lawrence Berkeley National Laboratory, 1 Cyclotron Rd., Berkeley, CA 94720 USA

Abstract

The Advanced Light Source (ALS) at Berkeley Lab has seen many upgrades over the years, keeping it one of the brightest sources for soft x-rays worldwide. Recent developments in magnet technology and lattice design appear to open the door for very large further increases in brightness [1], particularly by reducing the horizontal emittance, even within the space constraints of the existing tunnel. We are investigating the possibility of a new storage ring lattice that could approach the soft x-ray diffraction limit around 2 keV in both planes within the ALS footprint.

This note presents an overview of a candidate lattice for diffraction limited ALS and describes the optimization of the dynamical performance of the lattice. In addition on-axis injection scheme is foreseen for this ring and a candidate lattice for an accumulator ring, which will be built and housed either in the ALS storage ring tunnel or the booster tunnel, is also presented.

INTRODUCTION

A new compact lattice based on Multiple Bend Achromat [2] that is going to replace the existing ALS Triple Bend Achromat is being investigated. This design study of diffraction limited ALS (ALS-II) lattice has a goal of achieving a natural emittance of about 100 pm.rad and beam energy around 2 GeV.

This candidate lattice takes advantage of the fact that the ring admittance is defined by the small gap insertion devices and hence the use of small aperture magnets. This leads to the introduction of high magnetic strength where very low emittance with short circumference can be achieved.

The small emittance achieved by the candidate ALS-II lattice requires the usage of double RF system to lengthen the bunch and to operate with round beam to mitigate the effect of Intra Beam Scattering (IBS) and for lifetime considerations [3]. Bunch lengthening will also have large impact on mitigating the effect of beam interaction with the resistive metallic chamber and the chamber geometric discontinuities due small momentum compaction factor.

The ALS-II lattice strong focusing limits the dynamic aperture to few millimetres which requires an on-axis injection scheme based on swap-out [4]. A relatively small emittance ring, Accumulator ring, is proposed to inject into the ALS-II ring as the current ALS booster has a large emittance and will not deliver full charge in a single bunch needed by the swap-out injection scheme.

In the following sections, the choice of the ALS-II lattice and characterization of its dynamical properties and performance are discussed. The bunch lengthening with double RF system and the implications on emittance, lifetime will be discussed.

Also a candidate lattice for the accumulator ring and achieved dynamic performance will be presented.

CANDIDATE ALS-II LATTICE

A study has been performed for a lattice that could approach the soft x-ray diffraction limit around 2 keV in both planes within the ALS footprint. This lattice, while not fully optimized, demonstrates the feasibility of the ALS-II concept. The new lattice is based on a Nine Bend Achromat replacing the existing ALS Triple Bend Achromat, see Figure 1. The lattice preserves the 12-fold symmetry and the circumference of the present ALS while ultimately achieving a natural emittance of about 100 pm.rad at 2 GeV beam energy. The proposed lattice follows the hybrid configuration of the ESRF upgrade design that takes advantage of a large number of combined function bending magnets to reduce the horizontal emittance [5]. The matched cell structure serves two goals, matching the dispersion to zero in the straight section since the lattice is optimized for high brightness production and to create a large horizontal dispersion bump and large beta function for efficient natural chromaticity correction. Figure 2 shows the layout of one arc of the candidate lattice.

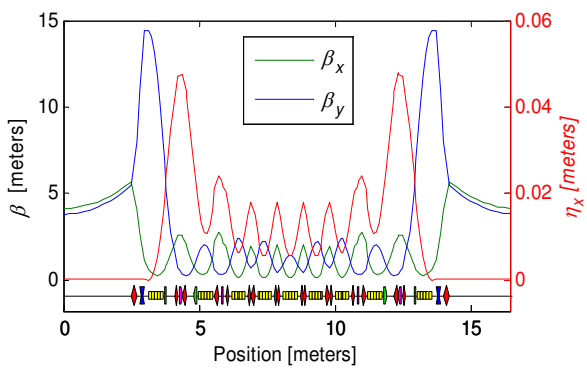

Figure 1: ALS-II candidate lattice Twiss functions.

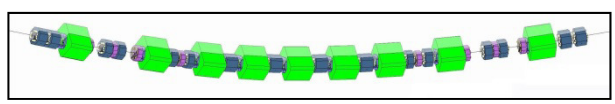

Figure 2: Layout of one arc of ALS-II lattice.

Multi-Objective Genetic Algorithm (MOGA) has been used to give an optimal solution based on the lattice elements [6]. The selected lattice provide identical optical functions in all straight sections with natural emittance of 100 pm.rad and horizontal and vertical beta functions of

Copyright © 2013 CC-BY-3.0 and by the respective authors

about 4 meters and zero dispersion. The choice is a compromise between matching the electron-photon phase spaces to maximize brightness at high photon energies and low natural chromaticities and hence adequate dynamic aperture needed for injection process. Table 1 summarizes the main parameters of the ALS-II lattice.

Table 1: Parameters of Candidate ALS-II Lattice

Parameter	Value
Beam energy [GeV]	2
Natural emittance [pm.rad]	100
Tune ν_x/ν_y	41.13/26.21
Natural $\xi_{x,y}$	-68/-64
Energy spread	8.13×10^{-4}
α_c	2.54×10^{-4}

NONLINEAR DYNAMICS

The proposed scheme for the chromaticity correction in the ALS-II lattice is based on compactness and flexibility. The small apertures in the sextupole magnets are used to introduce very strong sextupole fields. We avoided the introduction of these fields in the pole shape of the bending and quadrupole magnets where the flexibility of the lattice would have been compromised. The configuration of the matching cell which has relatively higher values of β_x, β_y and η_x functions is used to house four sextupole magnets families, two focusing and two defocusing ones, to correct the chromaticity.

The nonlinear effects driven by the strong sextupoles result in reduced dynamic aperture which hampers injection and reduces the Touschek lifetime. To overcome this, the ALS-II lattice will be operated at full coupling, i.e. with a round beam and an on-axis injection scheme. The dynamic aperture and momentum aperture of the candidate lattice is sufficient even when introducing errors ($> 200\sigma_{x,y}$) to allow high efficiency on-axis injection and provide decent beam lifetime (see Fig. 3). The off-momentum frequency map for the ALS-II lattice is shown in Fig. 4.

Mitigation of the impact of the IBS effect on the equilibrium emittance of the ALS-II lattice will be achieved by operating the lattice with full coupling where the vertical emittance is given entirely by betatron coupling and by bunch lengthening using a 3rd harmonic RF system. This leads to smaller electron density and hence less IBS growth rates in emittance. A factor of 4 lengthening, as shown in Fig. 5, gives an emittance growth of less than 20% using passive 3rd harmonic cavity at 500 MHz fundamental RF system and 500 mA beam current [7].

The momentum acceptance of the ALS-II lattice is dominated by dynamic aperture which will result in small Touschek lifetime. On the other hand, bunch lengthening is powerful mean to combat this effect where the particles loss due to Touschek scattering events is less with less dense bunches. Touschek lifetime for the ALS-II ring of 1.2 hour has been achieved with 100% coupling, i.e round beam and long bunches at 500 mA beam current [8].

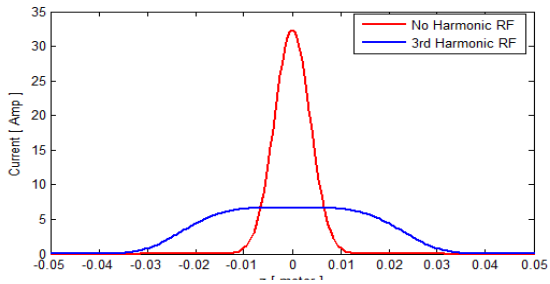

Figure 5: The bunch length of the standard and double RF system.

ON-AXIS INJECTION

The on-axis injection scheme is currently under study and it will be based on the swap-out scheme. A new accumulator ring will be built and housed either in the ALS storage ring tunnel or the booster tunnel. The

accumulator ring will act as a damping ring where its lattice will allow for off-axis injection from the current ALS booster and the extracted low emittance beam is injected on-axis into the small dynamic aperture of the ALS-II ring. Figure 6 shows a candidate lattice for the accumulator ring that fits into the current booster tunnel with 78 m circumference and provides an emittance of 2 nm.rad at 2 GeV with sufficient dynamic aperture to allow for off-axis injection from the ALS booster, see Fig. 7. A partial swap-out injection into ALS-II ring is foreseen as a compromise between how fast the pulsed magnets systems for injection and extraction from the ALS-II ring and the accumulator ring vacuum and RF systems to accumulate the full current of the main ring in case of full swap-out option.

The partial swap-out option relaxes these requirements on the accumulator ring in terms of collective effects, RF power need and safety envelope of the current ALS shielding wall. Also partial swap-out helps to minimize the impact of injection transients. This is because only the fraction (say 10-20% of the full current) being swapped will have a larger emittance and thus a smaller brightness. Thus the brightness will decrease by the same factor and then recover in a few damping times (~20 ms). This small drop in brightness for a relatively short time compared with the time between swap-outs (~1 minute) makes swap-out virtually transparent to most of the users.

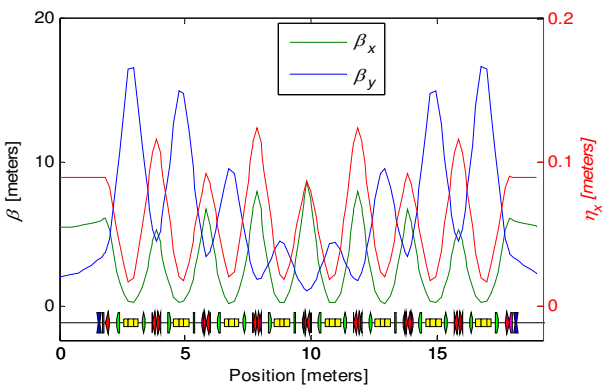

Figure 6: ALS Booster-size Accumulator ring lattice functions.

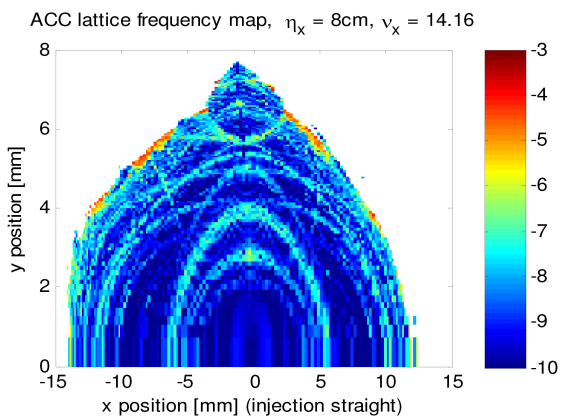

Figure 7: Accumulator ring dynamic aperture.

SUMMARY

The proposed baseline lattice for the ALS upgrade provides diffraction limited photon source up to 2 keV and fulfills the main constraints imposed by the fact that this upgrade is a replacement of the existing ALS storage ring. The lattice nonlinear effects are minimized by the proper configuration of the sextupole magnet families which results in a dynamic aperture sufficient for on-axis injection and lifetime with such strong focusing arrangement in one arc.

The use of double RF system to lengthen the bunches is powerful mean to mitigate IBS as a result strong focusing lattice and raise beam current threshold with decent Touschek lifetime.

Future work on achieving full coupling operation of the lattice and further optimization of the lattice momentum acceptance will be investigated. In addition studies of the injection process, fill pattern and accumulator ring choice need to be investigated to solidify the concept.

REMOVAL OF RESIDUAL CHIRP IN COMPRESSED BEAMS USING A PASSIVE WAKEFIELD TECHNIQUE

Abstract

The removal of residual chirp in XFELs is of paramount importance for efficient lasing. Although current S-band XFELs remove the unwanted residual chirp using off-crest acceleration after the final bunch compressor, this technique is not possible for XFELs with soft X-ray lines as there are no further accelerating structures. The off-crest dechirping technique is also expensive for future superconducting XFELs. In response, RadiaBeam Systems presents its work, building upon the theoretical work of Bane and Stupakov [1], in RF-free residual chirp mitigation using only passive techniques. Beam-induced longitudinal wakefields are produced with opposing corrugated plates which allow for an entirely RF-free chirp removal. Theory, engineering, and experimental results are presented.

INTRODUCTION

Beam dechirping is crucial for current and future XFELs. Accelerating and compressing sections of beamlines leave beam bunches with a residual chirp that must be removed for lasing. In the SLAC LCLS, dechirping requires hundreds of meters of off-crest accelerating structures. This is costly both in terms of accelerating cavity efficiency and beamline space [2].

RadiaBeam Systems has designed and manufactured a compact, low-cost corrugated plate system with an adjustable gap for tunable beam dechirping. Its dechirping characteristics were measured at the Brookhaven National Laboratory (BNL) Accelerator Test Facility (ATF).

THEORY

The driving theory for designing the passive dechirper system has been presented in papers by Bane, Stupakov, and Emma [2] [3]. The longitudinal wakefield generated by a single electron passing between the corrugated plates is given by

$$w(z) = \left(\frac{\pi^2}{16}\right)\frac{Z_0 c}{\pi a^2} H(z) cos\left(\frac{2\pi z}{\lambda}\right), \qquad (1)$$

where $Z_0 = \sqrt{\mu_0/\epsilon_0}$ is the impedance of free space, $H(z)$ is the unit step function, c is the speed of light, z is the coordinate along the beam path, and λ is the wavelength of the dominant mode of the wakefield given by

$$\lambda = 2\pi\sqrt{\frac{a\delta g}{2p}}. \qquad (2)$$

The remaining variables describe the dimensions of the corrugated plates. a is the distance of the plates from the beamline (half the plate separation); δ is the depth of the corrugations; g is the gap between corrugations; p is the period of the corrugations. These dimensions are listed in Table 1 and pictured in Figure 2. For compliance with the derivation assumptions, $p, d \ll a$ and $\delta \gtrsim p$ [2]. The transverse dimension of the plates is taken to be infinite.

The $\pi^2/16$ factor comes from the differing geometry between parallel plates and the circular pipe that was used in Stupakov and Bane's original derivation [4]. The wakefield produced by the bunch is found by convolving the single particle wakefield (Equation 1) with the longitudinal beam bunch charge density profile. For rectangular longitudinal profiles, the wakefield is linear in the region of the beam bunch as shown in Figure 1. For plates that satisfy the constraints above, the dechirping strength, h, is given by the slope of the linear region and can be calculated by

$$h = \left(\frac{\pi^2}{16}\right)\frac{Z_0 c Q L}{\pi a^2 l}, \qquad (3)$$

where Q is the bunch charge, L is the length of the dechirper, and l is the bunch length.

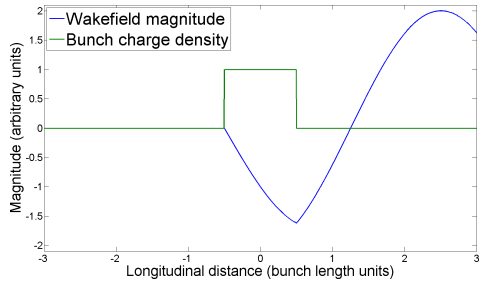

Figure 1: Bunch current profile and generated longitudinal wakefield.

CORRUGATED PLATE DIMENSIONS AND MANUFACTURE

The dimensions of the corrugated plates used in this experiment are listed in Table 1. The plates were fabricated

Material		Aluminum	

from aluminum for its light weight and ease of machining. Note that the conductivity of the plates does not affect the function of the dechirper as long as the fundamental mode of the wakefield is dominant [5].

The plates were actuated by stepper motor-driven linear motion feedthroughs–one at each end of each plate. This allows for control of the plates' vertical position, separation, longitudinal angle, and alignment with the beam. Figure 3 shows the corrugated plates and the attachments to the linear actuators above. Figure 4 shows a close-up of the plates after alignment.

PROCEDURE

The plates were installed in a box chamber on Beamline 2 at the BNL ATF and were aligned to the beam using an alignment laser. The beam parameters for the experiment are given in Table 2.

The measured dechirping strength (h in Equation 3) of a configuration is defined as the change in energy spread divided by the bunch length. A beam with a known bunch length and energy spread was passed between the plates. As the plate separation was varied, the change in energy spread was measured by a downstream energy spectrometer. Photographs of the plates (e.g., Figure 4) taken with a calibrated camera are used to measure the separation.

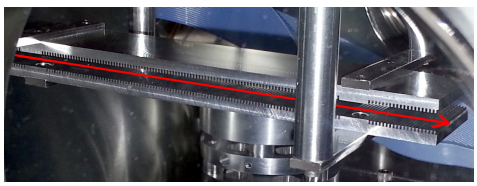

Figure 3: Full view of dechirper as installed. The red arrow indicates the electron beam path.

Longitudinal profile		Rectangular	

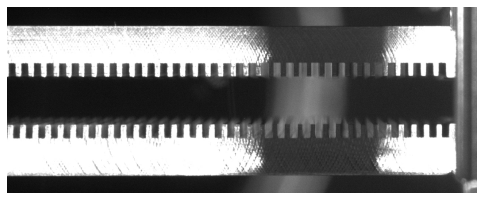

Figure 4: Side view of corrugated plates. Beam travels left to right. Note the corrugations are longitudinally misaligned by about a quarter of a period.

Bunch charge is measured by a downstream Faraday cup.

In a second round of measurements, the bunch charge was scanned at a fixed plate separation of 3.90 mm.

RESULTS

A selection of energy spectrum measurements at various plate separations can be seen in Figure 5. Figure 6 shows the dechirping strength of the corrugated plates as a function of plate separation. The blue line showing the dechirping strength was calculated by adding the wakefield-induced energy change (Equation 1 convolved with the bunch charge distribution and multiplied by the length of the dechirper) to the initial chirped beam. As the plate separation closes past a certain point, the theoretical dechirping strength peaks before reversing sign. This happens for two reasons. First, the beam gets over-dechirped and gains an increasing and oppositely-signed chirp. Second, the wavelength of the wakefield (Equation 1) shrinks to the extent that the wakefield is no longer linear. If the wakefield wavelength is sufficiently short, the bunch sees alternating positive and negative kicks along its length.

It can also be seen in Figure 6 that the measured dechirping power has the same behavior as the theoretical, but is weaker by about half. There are several possibilities for this that warrant further investigation:

- To what extent does the misalignment of the corrugations of the two plates reduce the strength of the dechirping wakefield? It was observed that the plates oscillated longitudinally by as much as half a corrugation period as they were actuated vertically (offset observable in Figure 4).

- Is the $\pi^2/16$ factor in Equations 1 and 3 sufficient to account for the different geometries (pipe vs. plates)?

Copyright © 2013 CC-BY-3.0 and by the respective authors

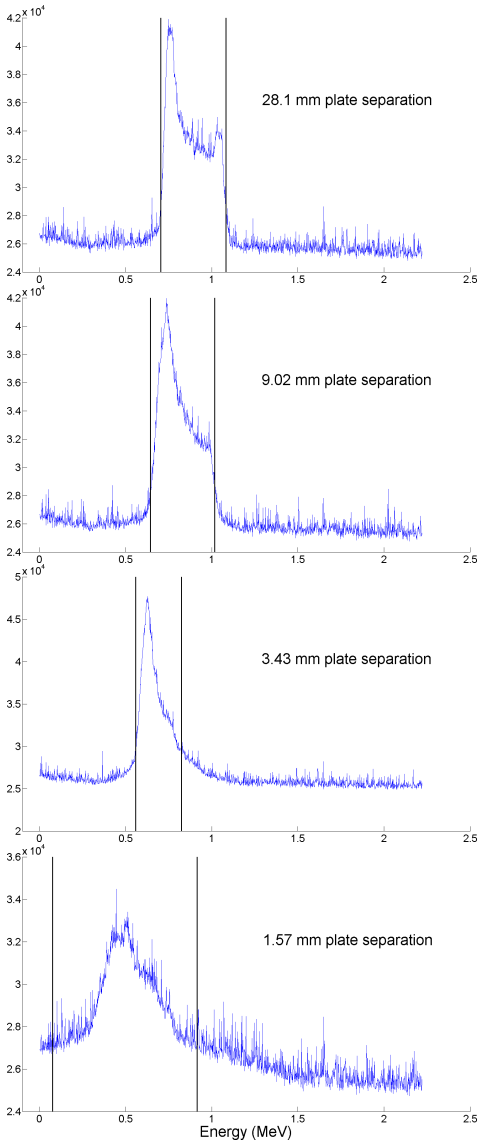

Figure 5: Energy spectrum plots at various plate separations. Note that closing the gap too much (smaller than ∼3.4 mm) results in a larger energy spread. The vertical lines designate the width where the intensity falls to 20% of the maximum height over the background.

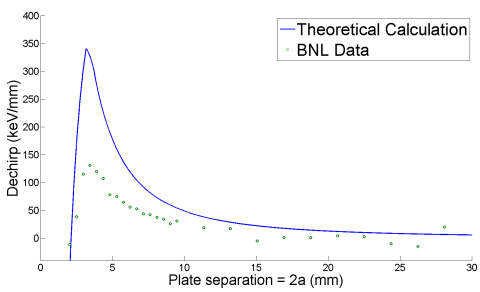

Figure 6: Dechirping Strength of parallel plates vs. Plate Separation, showing the measured dechirping strength at about half of theoretical predictions.

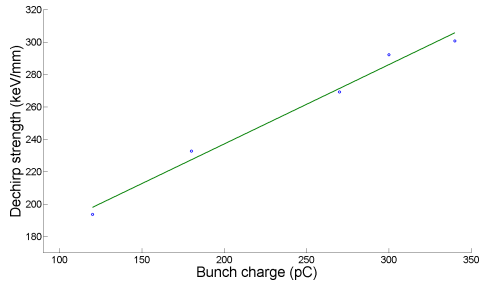

Figure 7: Dechirping Strength vs. bunch charge.

- How much of the measured energy spread is due to chirp, and how much is uncorrelated energy spread? The uncorrelated energy spread would result in an overestimation of the beam's initial chirp.

The result of the bunch charge variation experiment is shown in Figure 7. As expected, the relationship is linear.

FUTURE WORK

A second passive dechirping system is being planned that will involve a much longer corrugated plate section (>1 m) and an actuation system less prone to alignment errors. A longer dechirper is desirable because larger plate separations can be used, leading to longer wakefield wavelengths and a wider range of accepted bunch lengths. These are also more easily tuned by varying the plate separation for producing beams with near-zero chirp.

Furthermore, future experiments will make measurements with a deflecting cavity in addition to a dipole spectrometer to directly measure the beam's chirp. Transverse effects, especially any emittance blowup, will also be characterized.

ACKNOWLEDGMENTS

RadiaBeam Systems wishes to thank the staff at BNL ATF for their valuable assistance in this experiment. Special thanks to Karl Kusche and Christina Swinson for their personal involvement.

This is experiment is supported by an ongoing DOE Phase I Small Business Initiative for Research (SBIR) Grant, number DE–SC0009550.

Abstract

A free-electron laser (FEL) may be obtained by interaction of an electron bunch and a nearly copropagating laser pulse, where the laser pulse is sheared to extend the interaction length. When the angle between the electron beam axis and the propagation direction of the laser pulse greatly exceeds the reciprocal of the relativistic factor, the output radiation is nearly on the axis, and the FEL may be approximated by an axially aligned magnetostatic undulator. For a feasible laser-undulator FEL, we calculate gain using a one-dimensional model, as well as a three-dimensional model that includes degradation from diffraction and electron velocity spread.

INTRODUCTION

An electromagnetic plane wave that collides head-on with an ultrarelativistic electron bunch may create an FEL [1] that amplifies xrays whose frequency is ~$4\gamma^2$ times that of the incident "pump" wave [2], where γ is the electron bunch's relativistic factor. To obtain softer xrays, one can propagate a pump wave in nearly the same direction as the electron beam. By using a sheared laser pulse [3, 4], the electromagnetic field affecting the bunch is similar to a plane wave over an extended interaction length [5–8].

For the case where the propagation directions of the electron beam and the pump wave differ by an angle >> $1/\gamma$, a one-dimensional (1D) FEL model predicts maximum gain for xrays whose propagation direction differs from that of the electron beam by an angle << $1/\gamma$, and nearly identical gain for xrays that propagate on the electron beam axis. For this practical case, a magnetostatic undulator that is aligned with the electron beam approximates the laser undulator.

For a circularly polarized laser-undulator FEL with output wavelength of 2.5 nm described in Ref. [8], we use this magnetostatic undulator to calculate gain using the 1D model as well as a three-dimensional (3D) model [9].

ONE-DIMENSIONAL MODEL

The 1D model describes a uniform density of cold electrons interacting with a plane electromagnetic pump wave. In this model, maximum gain occurs for the electromagnetic wave that is a 180º reflection of the pump wave, when viewed in the beam frame of reference where the average electron velocity is zero [10].

*Work supported by the University of Wisconsin-Madison
bosch@src.wisc.edu

In the laboratory frame, consider a uniform density of cold electrons drifting with average velocity $\beta^* c$, where c is the speed of light, interacting with a pump wave. Let the z-axis describe the direction of the average electron motion while interacting with the pump laser, which propagates at an angle of θ_{pump} w.r.t the z-axis. A head-on collision is described by $\theta_{pump} = 180º$.

For small laser intensity, the forced electron oscillations in the beam frame are nonrelativistic, and the average axial velocity of the electrons in the lab frame is given by $\beta^* \approx \beta = (1-1/\gamma^2)^{1/2}$. In this case, the Lorentz-invariant undulator parameter K is << 1, where [2, 5, 8]

$$K^2 = 2 r_e I \lambda_{pump}^2 / (\pi m c^3) , \quad (1a)$$

$$K^2 = r_e I \lambda_{pump}^2 / (\pi m c^3) . \quad (1b)$$

Equation (1a) describes a planar undulator created by a linearly polarized pump wave, while eq. (1b) describes a helical undulator created by circular polarization. Here, r_e is the classical radius of the electron, I is the pump laser intensity, λ_{pump} is the pump wavelength and m is the electron mass. For larger values of K, the forced electron oscillations are relativistic in the beam frame. In the lab frame, $(K/\gamma)c$ is the maximum transverse electron velocity driven by the pump wave.

In the laboratory frame, the angular 4-frequency (c times the 4-vector) of the pump wave is

$$\overline{\omega}_{pump} = (\omega_{pump}, \omega_{pump} \sin\theta_{pump}, 0, \omega_{pump} \cos\theta_{pump}) . \quad (2)$$

A Lorentz transform gives the angular 4-frequency in the beam frame, which is moving at the velocity $\beta^* c$ [11]

$$\overline{\omega}'_{pump} = (\gamma^* \omega_{pump}(1-\beta^* \cos\theta_{pump}), \omega_{pump} \sin\theta_{pump}, 0, \gamma^* \omega_{pump}(\cos\theta_{pump} - \beta^*)) , \quad (3)$$

where the axial relativistic factor is defined by $\gamma^* = (1-\beta^{*2})^{-1/2}$. In the beam frame, the pump wave has angular frequency

$$\omega'_{pump} = \gamma^* \omega_{pump}(1-\beta^* \cos\theta_{pump}) , \quad (4)$$

and direction of propagation obeying

$$\cos\theta'_{pump} = \frac{\cos\theta_{pump} - \beta^*}{1-\beta^* \cos\theta_{pump}} . \quad (5)$$

For many cycles of interaction, the maximum FEL gain occurs for the wave given in the beam frame by a 180º reflection of the pump wave [10]. This wave is given in the beam frame by the same frequency as the pump

Copyright © 2013 CC-BY-3.0 and by the respective authors

$$\omega'_{xray} = \omega'_{pump} = \gamma^* \omega_{pump}(1-\beta^* \cos\theta_{pump}), \quad (6)$$

and opposite direction of propagation as the pump

$$\cos\theta'_{xray} = -\cos\theta'_{pump} = -\frac{\cos\theta_{pump} - \beta^*}{1-\beta^* \cos\theta_{pump}}. \quad (7)$$

The 4-frequency of this wave, in the beam frame, is given by multiplying the spatial components of $\overline{\omega}'_{pump}$ by –1:

$$\overline{\omega}'_{xray} = (\gamma^* \omega_{pump}(1-\beta^* \cos\theta_{pump}), -\omega_{pump} \sin\theta_{pump}, 0, -\gamma^* \omega_{pump}(\cos\theta_{pump} - \beta^*)). \quad (8)$$

A Lorentz transformation gives the 4-frequency for maximum FEL gain in the laboratory frame

$$\overline{\omega}_{xray} = (\gamma^{*2} \omega_{pump}[1+\beta^{*2} - 2\beta^* \cos\theta_{pump}], -\omega_{pump} \sin\theta_{pump}, 0, \gamma^{*2} \omega_{pump}[2\beta^* - (1+\beta^{*2})\cos\theta_{pump}]). \quad (9)$$

In the laboratory frame, the wave with maximum FEL gain has angular frequency

$$\omega_{xray} = \gamma^{*2} \omega_{pump}(1+\beta^{*2} - 2\beta^* \cos\theta_{pump}), \quad (10)$$

and propagation angle w.r.t. the z-axis of θ_{xray}, where

$$\cos\theta_{xray} = \frac{2\beta^* - (1+\beta^{*2})\cos\theta_{pump}}{1+\beta^{*2} - 2\beta^* \cos\theta_{pump}}. \quad (11)$$

MODELING BY AN AXIALLY ALIGNED MAGNETOSTATIC UNDULATOR

Consider the practical case where the pump propagation direction differs sufficiently from that of the bunch so that $\theta_{pump} >> 1/\gamma$. In this case $\theta'_{pump} >> \pi/2$ and $\theta'_{xray} << \pi/2$, while the output angle obeys $\theta_{xray} << 1/\gamma$. Provided that the undulator strength K does not greatly exceed one, $K\theta_{xray} << 1/\gamma$ is obeyed, so that the FEL gain for a wave propagating in the z-direction nearly equals the maximum gain occurring in the direction θ_{xray} [12]. We approximate the FEL with a magnetostatic undulator aligned to the z-axis, whose xray wavelength and K equal those of the laser undulator. For magnetostatic undulator period λ_u and electron oscillation frequency $\omega_u = 2\pi\beta^* c/\lambda_u$, the xray wavelength and frequency obey [1]

$$\lambda_{xray} = \lambda_u/(2\gamma^{*2}) \quad , \quad \omega_{xray} = 2\gamma^{*2} \omega_u/\beta^* \quad , \quad (12)$$

Thus, the axially aligned magnetostatic undulator has period

$$\lambda_u = \frac{2}{1+\beta^{*2} - 2\beta^* \cos\theta_{pump}} \lambda_{pump} \approx \frac{\lambda_{pump}}{1-\beta^* \cos\theta_{pump}}, \quad (13)$$

and electron oscillation angular frequency

$$\omega_u = (\beta^*/2)(1+\beta^{*2} - 2\beta^* \cos\theta_{pump})\omega_{pump} \approx (1-\beta^* \cos\theta_{pump})\omega_{pump}. \quad (14)$$

For head-on laser interaction, $\omega_u \approx 2\omega_{pump}$ [2].

For a general value of K, the average axial electron velocity in the undulator is $\beta^* c$, where [1]

$$\beta^* = \sqrt{1-(1+K^2/2)/\gamma^2}, \quad (15a)$$

$$\beta^* = \sqrt{1-(1+K^2)/\gamma^2}. \quad (15b)$$

Equation (15a) describes a planar undulator, while eq. (15b) describes a helical undulator.

In the 1D model, the FEL gain is parameterized by the Pierce parameter ρ which obeys [1]

$$\rho^3 = (n_e e^2 K^2 [JJ]^2)/(32\omega_u^2 m\varepsilon_0 \gamma^3), \quad (16a)$$

$$\rho^3 = (n_e e^2 K^2)/(16\omega_u^2 m\varepsilon_0 \gamma^3), \quad (16b)$$

where eq. (16a) describes a planar undulator while eq. (16b) describes a helical undulator. Here, e is the electron charge, n_e is the electron density, and ε_0 is the permittivity of free space. The term $[JJ]$ is a Bessel function factor

$$[JJ] \equiv J_0(K^2/[4+2K^2]) - J_1(K^2/[4+2K^2]), \quad (17)$$

which is nearly equal to 1 for $K << 1$.

For low gain G << 1, the energy gain for a laser undulator with N cycles is [1]

$$G = 2(4\pi)^3 \rho^3 N^3 [(2-2\cos\phi - \phi\sin\phi)/\phi^3], \quad (18)$$

where $\phi \equiv 2\pi N - 2\pi N_{rad}$ is the phase slippage through the undulator, in which N_{rad} is the number of cycles of amplified radiation which overtake an average electron while passing through the undulator. For this low-gain case, an evaluation of the laser-undulator gain in the electron beam frame [10] confirms that it equals that of the axially aligned magnetostatic undulator. The largest gain occurs for a slippage of 2.61 radians [10]

$$G_{max} = 0.27(4\pi)^3 \rho^3 N^3. \quad (19)$$

In the high gain limit, the xray radiation power grows exponentially in a gain length [1, 2]

$$L_G = \lambda_u/(4\pi\sqrt{3}\rho). \quad (20)$$

In principle, a crab cavity can be used to tilt the bunch so that the gain medium provided by the electrons is aligned in the direction of maximum gain.

Without a crab cavity, the gain medium extends farthest in the axial direction, and the gain in the axial direction nearly equals the maximum in the direction θ_{xray} [12]. The self-amplified stimulated emission (SASE) is expected to propagate at a small angle equal to or smaller than that given by eq. (11), with gain nearly equal to that of the axially aligned magnetostatic undulator. For a seeded FEL, amplification of an axially propagating xray is nearly the same as in the axially aligned magnetostatic undulator.

THREE-DIMENSIONAL MODELING

In Ref. [8], a 300-period circularly polarized laser undulator with K = 0.4336, produced by a 750-nm pump

Copyright © 2013 CC-BY-3.0 and by the respective authors

laser propagating at an angle of θ_{pump} = 0.0572 radian w.r.t. a 168.65-MeV electron beam, produces output at λ_{xray} = 2.5 nm. Equation (11) predicts maximum gain for θ_{xray} = 0.19 mrad << 1/γ, in agreement with eqs. (5.42) and (5.43) of Ref. [6]. We approximate the laser undulator with an axially aligned helical magnetostatic undulator with period of 0.458 mm and length of 0.137 m.

In Ref. [9], M. Xie uses numerical fits to simulations to provide a 3D model for the degradation of high-gain FEL performance from diffraction and the electron axial velocity spread due to slice emittance and slice energy spread. Using 1D and 3D models, we evaluated gain for the ideal case where a cylindrically symmetric electron beam is focused in the center of a magnetostatic undulator where the horizontal and vertical beta functions equal one-half of the undulator length. The average beam size in the undulator is given by horizontal and vertical beta functions equal to 66% of the undulator length. Table 1 lists the parameters that were modeled.

Table 2 shows calculated FEL properties—the Pierce parameter, exponential gain length, gain saturation length, and saturation power—for the 1D and 3D models. Comparing the models shows that the gain length is increased 50% by diffraction and the bunch's axial velocity spread. According to the 3D model, the FEL gain is $e^{9.2}$ =10,000 within the 0.137-m interaction length. SASE saturation, which requires interaction over 19 gain lengths, is not achieved. Effects from nonuniformity of the laser undulator are not included in these models.

The FEL properties depend smoothly upon the beam parameters and *K*-value, indicating that a small deficiency in one parameter can be compensated by improving a different parameter. The 1D Pierce parameter of 0.00215 is comparable to the relative slice energy spread of 0.001, so that the 3D gain length increases substantially if the energy spread is increased, as shown in Fig. 1(a). Figure 1(b) shows that increasing the normalized emittance to 0.2 mm-mrad doubles the 3D gain length.

SUMMARY

For a 300-period laser-undulator FEL created by interaction of an electron bunch with a nearly copropagating laser pulse, the FEL gain and saturation have been calculated by approximating the laser undulator with an axially aligned magnetostatic undulator. Xrays with a wavelength of 2.5 nm are predicted to by amplified by $e^{9.2}$ = 10,000 within the 0.137-m interaction length.

Table 1: Electron Beam and Undulator Properties

Beam energy	168.65 MeV
Slice energy spread	168.65 keV
Slice emittance (normalized)	0.06 mm-mrad
Peak current	800 A
β-function ($\beta_x = \beta_y$)	0.09 m
Undulator *K* value	0.4336
Output xray wavelength	2.5 nm

Table 2: Calculated FEL Properties

Calculated parameter	**1D model**	**3D model**
Pierce parameter (ρ)	0.00215	0.00143
Gain length [mm]	9.78	14.8
Gain saturation length [m]	0.186	0.275
Saturation power [GW]	0.29	0.204

STUDIES ON SHORT-BUNCH EXTRACTION AT CSNS RCS

Ye Zou, Jingyu Tang, Jinfang Chen
Institute of High Energy Physics, Chinese Academy of Sciences, Beijing 100049

Abstract

White neutron application requires short proton pulse length to obtain high time resolution for nuclear data measurements. Back-streaming neutron beam at the CSNS spallation target is to be exploited as a white neutron source. The available high RF voltage in the high intensity rapid cycling synchrotron (RCS) of the CSNS makes it possible to extract very short bunches by using the bunch rotation method. Special attentions have been paid to the bunch rotation during the slow acceleration, space charge effect and beam loading effect in the high-intensity RCS. Different extraction scenarios together with the changes in the injection have been studied. Together with the calculations, multi-particle simulations have been carried out to show the effectiveness of the method. With a sacrifice of about two-third beam power, the rms bunch length of the extracted beam can be reduced to about one eighth of the one in the nominal operation mode. Other scenarios also show the improvement in the bunch length.

INTRODUCTION

Back-streaming neutrons from the spallation target of CSNS (China Spallation Neutron Source) are very strong and harmful to the proton beam transport line if they are not well treated [1]. The studies found that the neutron beam has excellent properties of wide energy spectrum and time structure, and has been proposed to build a white neutron source for nuclear data measurement [2, 3]. The neutron pulse length is critical in defining the neutrons' energy by the time-of-flight method, and should be reduced as short as possible. The time structure of the back-streaming neutrons is jointly determined by the pulse length of the impinging proton beam and the thickness of the spallation target. Simulations show that the target thickness dominates the time resolution for the lower energy part of the wide-range energy neutrons, while the proton pulse length dominates the higher energy part. As the target length cannot be changed for this parasitic application, it would be interesting to shorten the proton pulse length by designing a special dedicated working mode for the CSNS accelerators. This paper presents the study about using the bunch rotation method in the RCS (Rapid Cycling Synchrotron of CSNS) to obtain very short proton beam bunches.

CSNS is a multi-disciplinary research facility under construction [4], which is to be built in two or three phases. In the first phase, the RCS is to accelerate beam from 80 MeV to 1.6 GeV in a repetition rate of 25 Hz, and the extracted beam power is 100 kW. Figure 1 and Table 1 show the layout and some parameters of the RCS.

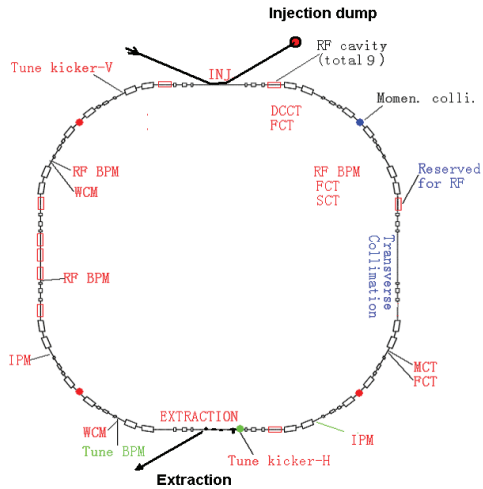

Figure 1: Layout of the CSNS RCS.

Table 1: Some Parameters of the CSNS RCS

Circumference (m)	227.92
Injection energy (GeV)	0.08
Extraction energy (GeV)	1.6
Maximum RF voltage (kV)	165
Betatron tunes (h/v)	4.82/4.80
RF harmonics	2
Transverse acceptance (πmm.mrad)	540
Collimation acceptance (πmm.mrad)	~350

SHORT-BUNCH EXTRACTION METHODS

There are two bunches per pulse in the extracted proton beam in the normal operation mode. The bunch length is determined by the RF voltage pattern and the longitudinal painting. The longitudinal painting is optimized to alleviate the space charge effects in such a high-intensity synchrotron. Compared with the simple method by designing a high RF voltage at the extraction, the bunch rotation method is more effective in shortening the bunch length for the extracted beam [5, 6]. The principle of the bunch rotation method is as follows: the RF voltage is adiabatically decreased from the normal extraction voltage to a low one, during which the bunch becomes gradually flat to follow the change of the RF bucket as long as the bucket still contain the beam with some margin. Then the RF voltage is quickly or non-

* zouye@ihep.ac.cn

Copyright © 2013 CC-BY-3.0 and by the respective authors

adiabatically increased to a high value. The mis-matched bunch will rotate in the enlarged RF bucket. After a quarter of synchrotron period, the bunch will reach the minimum length and then the single-turn extraction can be applied.

In small-amplitude or linear synchrotron motion approximation, the rms bunch length and height σ_τ and σ_δ in a matched RF bucket are expressed by

$$\sigma_\tau = \sqrt{\frac{A_{rms}}{\omega_0}}\left(\frac{2|\eta|}{\pi h e V \beta^2 E|\cos\varphi_s|}\right)^{\frac{1}{4}}, \quad (1)$$

$$\sigma_\delta = \sqrt{\frac{\omega_0 A_{rms}}{\pi\beta^2 E}}\left(\frac{heV|\cos\varphi_s|}{2\pi\beta^2 E|\eta|}\right)^{\frac{1}{4}}, \quad (2)$$

where $A_{\rm rms}$, ω_0, η, h and φ_s denote the invariant rms phase space area in eV-s, revolution frequency of the reference particles, phase-slip factor, harmonic number and synchronous phase, respectively. Suppose the RF voltage changes from the nominal setting V_i to V_1 adiabatically, and then to the maximum available value V_2 non-adiabatically. According to Eq. (1), the bunch extension ratio of the rms bunch length is equal to

$$r_{c\,max,V_i\to V_1} = \frac{\sigma_{\tau,i}}{\sigma_{\tau,m}} = \left(\frac{V_1}{V_i}\right)^{\frac{1}{4}} \quad (3)$$

where $\sigma_{\tau,i}$ and $\sigma_{\tau,m}$ denote the initial bunch length and the medium-stage bunch length, respectively.

After the non-adiabatic RF voltage change from V_1 to V_2, the bunch performs rigid quadrupole mode oscillations. After 1/4 of synchrotron period, the rms bunch length reaches the minimum, and can be expressed by

$$\sigma_{\tau,f} = \sqrt{\frac{A_{rms}}{\omega_0}}\left(\frac{2|\eta|}{\pi h\beta^2 E|\cos\varphi_s|}\right)^{\frac{1}{4}}\frac{(eV_1)^{1/4}}{(eV_2)^{1/2}}, \quad (4)$$

where $\sigma_{\tau,f}$ denotes the final bunch length. The compression ratio of the rms bunch length from V_1 to V_2 can be expressed by

$$r_{c\,max,V_1\to V_2} = \frac{\sigma_{\tau,m}}{\sigma_{\tau,f}} = \left(\frac{V_2}{V_1}\right)^{\frac{1}{2}}, \quad (5)$$

The total compression ratio of the rms bunch length from the initial voltage (V_i) to the low voltage (V_1) then to the final voltage (V_2) can be expressed as

$$R_{c\,max,V_i\to V_1\to V_2} = \frac{\sigma_{\tau,i}}{\sigma_{\tau,f}} = \left(\frac{V_1}{V_i}\right)^{\frac{1}{4}}\left(\frac{V_2}{V_1}\right)^{\frac{1}{2}}, \quad (6)$$

The bunch compression ratio depends only on the RF voltage ratio according to Eq. (6).

However, in practice, there are limitations to apply the bunch rotation method. In a high-intensity RCS, one has to consider the space charge effects during the bunch rotation process and the beam loading effect. The space charge effect may become strong when the bunch shortens during the bunch rotation. The initial beam emittance is also determined by the beam dynamics at the lower energy of the acceleration cycle, due to the space charge effects and the longitudinal microwave instability. The beam loading effect means that the circulating beam current detunes the RF cavities and becomes very important when the RF voltage is very low. To avoid the instability in the low-level RF control system, the ratio of the circulating beam current and the driving current from the RF amplifier should be controlled below a certain value, e.g. 6. This also limits the lowest RF voltage for V_1. The accumulated particles should be decreased to ease the above problems, and this leads to the reduction of the extracted beam power.

Different from its usual applications in compressor rings [7, 8] or slow cycling synchrotrons [9], in a high-intensity RCS, another important issue which should be considered seriously is the slow acceleration during the bunch rotation when the magnetic field is still ramping. The asymmetric RF bucket will deform the bunch shape and increase the final bunch length. The bunch rotation process should be started close to the maximum magnetic field, and this will delay the extraction moment slightly.

SIMULATION RESULTS

Multi-particle simulations with space charge with the ORBIT code [10] have been carried to show how effective the method in realistic cases is. Different injection scenarios and beam powers are studied in the simulations. The simulations are performed only in 1D longitudinal, while the transverse motion is kept in mind only by maintaining reasonable tune shifts with bunching factor because the transverse motion has no influence on the longitudinal one. In most cases, the chopping factor of 50% (defined as beam duty in the ring RF frequency) which is the one in the nominal working mode is used. With a reduced beam power or less accumulated particles, the RF voltage during the injection is reduced to obtain a small longitudinal emittance. In the nominal operation mode with full beam power, the RF voltage at injection is 29 kV. In a dedicated mode with 30% beam power, the RF voltage is decreased to 8.7 kV to keep the similar beam loading effect. Both chopping factors 50% and 30% are studied with the second giving smaller longitudinal emittance. The minimum and maximum RF voltage (V_1, V_2) before the bunch rotation are taken as 8.7 kV and 160 kV, respectively. During the last few turns of the bunch rotation which lasts about 0.2 ms or 200 turns, the Laslett tune shift reaches about -0.066, which is considered quite safe in a high-intensity RCS.

Figs. 2 and 3 show the longitudinal beam distributions just before the extraction in the nominal operation mode and in the dedicated operation mode, respectively. From the figures, one can see that a much shorter bunch length can be obtained in the dedicated operation mode. Fig. 4 shows the phase distribution of the extracted beam. For

Copyright © 2013 CC-BY-3.0 and by the respective authors

comparison, the rms bunch lengths for the extracted beam with different scenarios on injection and beam power reduction are shown in Table 2. With 30% chopping factor and 30% beam power together with the bunch rotation method, the rms bunch length of the extracted beam can be reduced to about one eighth of the one in the nominal operation mode. This can improve the time resolution of back-streaming neutrons almost by an order of magnitude at higher energy.

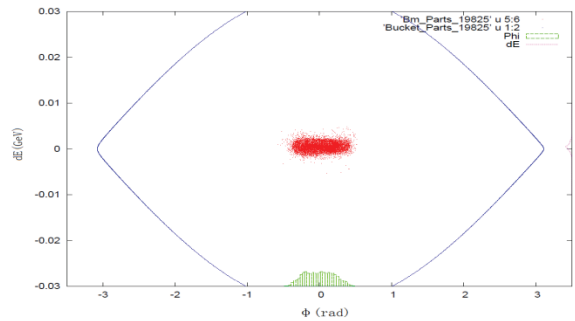

Figure 2: Longitudinal beam distribution just before the extraction in the nominal operation mode.

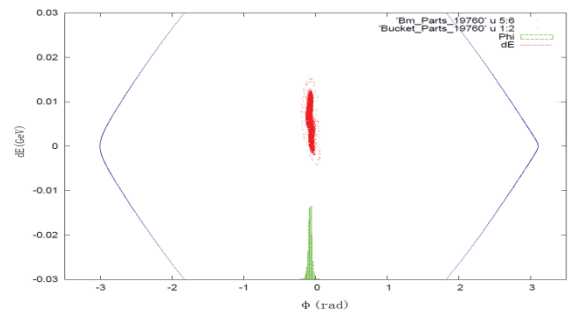

Figure 3: Longitudinal beam distribution just before the extraction in the dedicated operation mode with 30% chopping and 30% beam power.

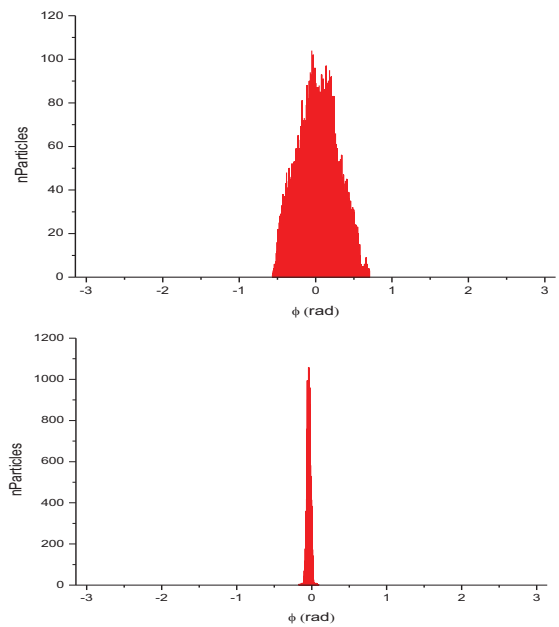

Figure 4: Phase distribution of the extracted beam. (Left: in the nominal operation mode; right: 30% beam chopping factor and 30% beam power).

Table 2: Rms Bunch Length with Different Chopping Factors and Beam Powers

Chopping factor (%)	Beam power remained (%)	rms length without rotation (ns)	rms length with rotation (ns)
50	100	13.0	7.5
50	50	11.0	3.5
50	30	9.3	3.3
30	30	7.2	1.7

CONCLUSIONS

The simulation studies show that the bunch rotation method by RF voltage manipulations is an effective one in short-bunch extraction in CSNS/RCS. In dedicated cases when the white neutron applications with high resolution are stressed, one can obtain a very short bunch length of about one eighth of the one in the nominal operation mode with a sacrifice of about two third beam power. Although the studies have been carried out with the CSNS parameters, the method should be applicable to other high-intensity proton synchrotrons with high available RF voltage.

DESIGN CONSIDERATIONS FOR THE ESS ACCELERATOR-TO-TARGET REGION

Thomas J. Shea, Eric J. Pitcher, Ken Andersen, Phillip Bentley, Paul Henry,
Pascal Sabbagh, Alan Takibayev, ESS, Lund, Sweden
Heine Dølrath Thomsen, Søren Pape Møller, ISA, Aarhus, Denmark

Abstract

When the European Spallation Source (ESS) is completed in Lund, Sweden, a superconducting linac will deliver a 5 MW proton beam to a rotating tungsten target. Moderated neutrons from this target will be delivered to a suite of 22 neutron instruments. In the accelerator-to-target region, design choices must balance the demands of the accelerator, the target, and the neutron instruments. For example, the transport line upstream of the target station expands and shapes the small, low emittance linac beam into a large beam that is safe for the target components. It must do this with low loss in order to reduce activation of the beam line and minimize a potential source of background in the neutron instruments. To meet availability goals, beam-induced damage to critical components must be avoided by instrumenting beamline components, deploying a suite of beam instrumentation within the target monolith, and interfacing some of these devices to the machine protection system. This paper will describe recent design changes in this region, highlighting considerations that are applicable to most high power facilities and also those that are unique to a long-pulse source like the ESS.

GOALS

The accelerator-to-target region serves three primary stakeholders: Neutron Science, Target, and Accelerator. Because the long pulse concept couples these stakeholders, the design must balance the needs of all three.

Neutron Science

Neutron instrumentation at a long-pulse source requires a reproducible pulse, both in terms of the time structure and the brightness. Most long pulse instruments under development for ESS use a combination of choppers and the instrument's total flight path length to tailor the neutron pulse and the available wavelength band to the desired characteristics. For example, a truncated pulse will lead to a hole in the wavelength band at the sample position during the time-frame. Therefore, during neutron production, the facility should provide full length pulses with reproducible structure.

The long pulse places additional unique requirements on the neutron instrumentation in terms of dimensions and background. The optimal arrangement of the instrument geometry to exploit the long pulse requires measurement across a frame boundary. In other words, the instruments will perform measurements with slow-moving, meV-energy neutrons at the same time that the proton pulse hits the target for the next pulse. Any contamination from MeV particles emitted by the accelerator and target that can be picked up by the instrument appear as a time-dependent background superimposed on the weak meV signals of interest. This background manifests itself as a systematic error that is correlated with the measurement time (e.g. [5]), and is most efficiently mitigated at its source.

Target

To survive between reasonably long replacement intervals, target components that intercept the proton beam core impose restrictions on the beam's density. These components include the rotating tungsten target, and the proton beam window that separates this target's atmosphere from the accelerator's vacuum. In addition, surrounding components can only receive a limited volumetric power density, and this imposes a limit on beam outside of the core footprint.

Neutron moderator and reflector assemblies also reside within the target system. Because neutron intensity can depend on proton beam position and current, the time to moderate neutrons from the spallation spectrum down to desired energies will determine that timescale for allowable fluctuations in proton beam position and current.

Accelerator

To meet the target requirements above, the transport line leading to the target must expand the bright beam from the linac into an acceptable footprint. To meet the requirements for the neutron pulse, fluctuations in beam position and current must be repeatable and also limited in magnitude and/or characteristic timescale. The transport line should also allow hands-on maintenance by limiting beam loss to well under 1 W/m and by enabling isolation of the components from target back shine.

PROTON BEAM TRANSPORT

Table 1 summarizes the proton beam parameters at the output of the ESS linac. The accelerator-to-target line receives the beam with these parameters and transform it into a beam with the parameters at the proton beam window (PBW) and target (Tgt) listed in Table 2. It accomplishes this by scanning or rastering an expanded beamlet across the target surface.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Table 1: Proton Beam Parameters at the End of the Linac

Parameter	Value
Nominal Power	5 MW
Energy	0.5 to 2 GeV
Pulse current	6.2 to 62.5 mA
Pulse Length	5 to 2860 μs
Repetition rate	14 Hz
Bunching frequency	352 MHz
RMS width in linac	2 mm

Table 2: Beam Parameters at the Target Station, Horizontal (H) and Vertical (V)

Parameter	Location	H	V
RMS size	CO	0.2 mm	0.4 mm
	PBW	10.0 mm	5.00 mm
	Tgt	12.6 mm	6.32 mm
Max. deflection	PBW	55.4 mm	12.7 mm
	Tgt	70.0 mm	16.0 mm
Avg. current density	PBW	88 μA/cm^2	
	Tgt	56 μA/cm^2	

Transport line optics are shown in Figure 1. The design proposal for the LANL MTS line [1] inspired this concept. The upstream matching quads, Q1–Q4, set the beamlet size on the target and provide a beam waist at the crossover (CO), where the beam deflections are minimized by design. Eight raster magnet dipoles (RMs) scan the beamlet, and they are centered on the action point (AP) with 4 acting in each plane. Downstream of the raster magnets, a quadrupole doublet, Q5+Q6, not only ensures the final beam size expansion, but imposes a transverse phase advance of π between the AP and the CO which becomes a pivot point for the deflections. In the presented optics, the peak integrated field per raster magnet is $\int B_y dL = 2.2\,\mathrm{mT.m}$ or $\int B_x dL = 3.8\,\mathrm{mT.m}$. To reduce modulation of the neutron intensity, the a rather high raster frequency of up to 40 kHz is specified.

As the location of the beamlet waist and also the pivot point for deflections, the CO becomes a suitable location for a small-aperture shield that absorbs most of the backstreaming neutrons. TraceWin [2] simulations including 3D space charge, demonstrate transport of 5×10^6 multiparticles through a $\lesssim 0.4$ mm RMS waist with no loss in the line or the aperture. This is an improvement over the previous design that was based upon nonlinear magnets [3]. Due to the limited magnification of the linac beamlet and the raster pattern's smearing of the beamlet, any transverse halo generated by the linac has a limited effect on the accumulated beam footprint at the target.

A suite of beam instrumentation supports tuning of the beam line [4]. During high power operations, a subset of this instrumentation also provides inputs to an interlock system that can suppress beam production upon detection of potentially damaging conditions.

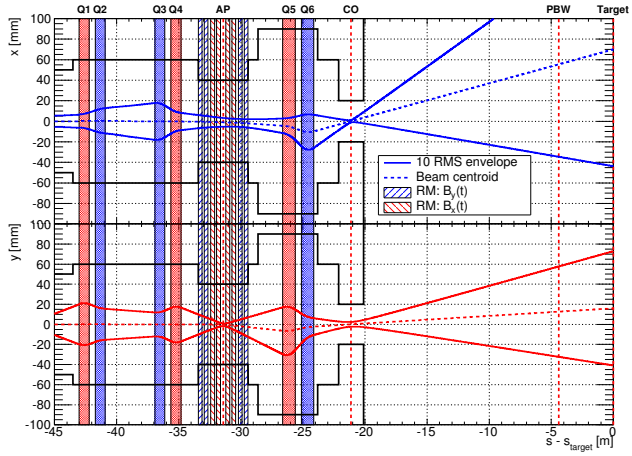

Figure 1: The final 45 m of the HEBT before the target surface. The optics are shown at maximum deflection.

TARGET

Rastering the beam the provides benefits described above, and with normal beam conditions, calculations show that the proton beam window, most delicate interceptive component, should provide the desired lifetime of about one year. However, off-normal situations must be considered and one of the most dramatic would be the simultaneous, undetected failure of all 8 raster magnet systems. In this case, a stationary beamlet with the parameters listed in Table 2 remains on the window. Beam instrumentation detects this condition and suppresses beam production before the arrival of the next pulse, but the window must survive the original errant pulse.

Finite element analysis has been used to analyse this situation. The calculations were performed using ANSYS and results were then post-processed using the RCC-MRx design standard, considering a dose up to 10 DPA. The calculation has been performed for a PBW made either from Al6061T6 or Ti6Al4V. The goal is indeed to fulfill RCC-MRx criteria from level A, meaning that the PBW can be used without inspection or replacement. The start values for this transient thermal analysis are those of a window subjected to nominal beam. A full unrastered pulse then induces a new temperature profile that is coupled one way to a transient structural analysis used for the RCC-MRx post-processing. The results summarized in Table 3 show that an aluminum window would require a replacement whereas a titanium window would not.

NEUTRONICS

As discussed above, the beam transport line employs a dynamic rastering system that scans a beamlet across the target surface. The impact on neutron beam characteristics has been assessed by incorporating time-dependent raster beams into a full MCNPX model of the target sta-

tion monolith. Each moderator-reflector assembly in the ESS target station contains 3 moderators: a cold para-hydrogen moderator, an upstream thermal water moderator, and a downstream thermal water moderator. Time-dependent brightness was tallied for all 3 moderators. With a horizontal rastering frequency of about 40 kHz and a vertical rastering frequency of 29 kHz, fluctuations for cold neutrons (i.e. 2.5 Å) are very small - less than a few percent. Maximum fluctuations were observed out of the downstream thermal moderator, about 6% RMS at 0.8 Å.

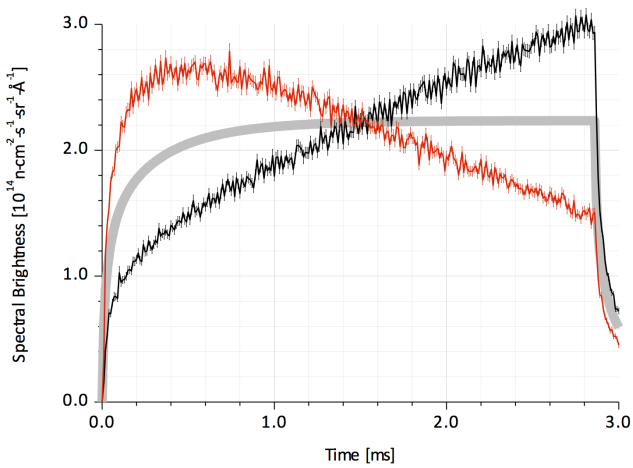

Figure 2: One example of an alternative scanning scenario. The beam is rastered vertically at 29 kHz and swept once horizontally during the 2.86 ms pulse. Thermal neutron pulses (0.8 Å) from upstream (red) and downstream (black) moderators are shown with the reference output from a square proton pulse shown in grey.

This effect on downstream thermal moderators can be exploited by using raster patterns like, for example, slow painting of the proton beam over the target in a horizontal direction while maintaining the rapid scanning in the vertical direction. In this case, high frequency deviations due to horizontal rastering are eliminated, while neutron pulse shapes exhibit rather interesting temporal features as depicted in Figure 2. Additionally, the study of the impact of beam rastering on updated conceptual designs of ESS moderators is underway.

NEUTRON INSTRUMENTS

The variations in the pulse structure as a result of the rastering of the proton beam onto the target offers several opportunities, particularly for thermal instruments, as the effect is most pronounced for short wavelength neutrons. By siting thermal instruments in the correct sector, the enhanced brightness of short wavelength neutrons at the end of the pulse can be harnessed by, for example, high-resolution diffraction instruments or a thermal chopper spectrometer. For example, through the use of a pulse-shaping chopper at 6-7m from the moderator surface, a wavelength band and wavelength uncertainty ($\Delta\lambda/\lambda$) is selected by a diffraction instrument. At the sample position, within the time-frame given by the 14 Hz repetition rate, the short wavelength neutrons (with a higher velocity) are selected from the end of the initial pulse, with enhanced intensity as shown in Figure 2. These neutrons give access to high Q at close to backscattering from the sample, which reveal the subtle structural details. As a general remark, boosting the neutron brightness for the short wavelengths will be very useful for all thermal instruments that employ pulse-shaping.

Delivery of the proton beam to the target with lower loss could also benefit neutron instruments. Reducing the potential for beam losses in this region by orders of magnitude could bring a proportional reduction in that contribution to the background. Other sources are now being investigated, with a focus on emission of particles from the accelerator berm that are transported as sky shine, and mechanisms of illumination of the instruments directly from the target, both external and internal to the neutron beamlines. Particular attention is being paid to the types of materials that can be used and the energies of the particles that illuminate them, and the physics processes that convert these transport mechanisms into measurable signals for detectors that are typically only sensitive up to 100s keV.

CONCLUSION

Particularly in a long pulse neutron source such as the ESS, the optimisation of the accelerator to target region can significantly enhance neutron source performance. Recent updates to the design, including the addition of raster scanning appear to provide performance benefits. This work is ongoing. In the near future, we plan to model updated moderator designs, and improve our understanding of neutron background with additional beam loss simulations.

Abstract

The Front End Test Stand Project (FETS) at RAL is being built to demonstrate fast beam chopping. This is required to create precisely defined gaps in the bunched H- beam which is essential in order to minimise beam losses in a synchrotron during injection. The gaps are created in the Medium Energy Beam Transport (MEBT) section of the FETS beam-line using a 'fast-slow' chopping scheme. This scheme uses two choppers, one fast and one slow, each kicks a portion of beam into its corresponding downstream beam dump. The challenge for the beam dump design is that it must occupy a limited longitudinal space to ensure that the beam transport is preserved and must absorb a beam power that is close to the sustainable stress limit of common engineering materials. This paper will describe the simulations made to study the cooling scheme required to absorb the power deposited in the dump plates for the fast and slow choppers.

INTRODUCTION

The FETS project requires two chopper beam dumps to withstand and safely dissipate power from the incident beam. The beam parameters, listed in Table 1, thus form the design criteria for these dumps [1].

Table 1: Parameters for the FETS Beam

Parameter	Value
Particle	H-
Beam Energy	3 MeV
Beam Current	60 mA
Pulse Length	20 ms
Duty Cycle	0.1
Maximum Power	180 kW
Average Power	18 kW

The beam is on for a 2 ms pulse in each 20 ms period. During this time, it is broken by choppers into a repeated cycle of ON/OFF states. The two choppers in the FETS project are denoted 'fast' and 'slow', based on their respective response times. During each ON stage of a chopper, it deflects beam particles to its corresponding downstream dump. The chopper timings have been designed in accordance with the ISIS synchrotron frequency of 1.5 MHz. The FETS beam has a frequency of 324 MHz, resulting in 216 periods of ON/OFF cycles, or beam bunches for each ISIS period [2]. Table 2 describes how these 216 beam bunches are broken by the fast and slow choppers.

*Supported by STFC
§ p.savage@imperial.ac.uk

Table 2: Sequenced Timing for the Fast / Slow Choppers

Number of bunches	Fast Chopper State	Slow Chopper State
4	ON	OFF
57	OFF	ON
4	ON	OFF
151	OFF	OFF

During an ON period of a chopper, its corresponding dump sees the full 180 kW of incident power. However, each chopper deflects only a certain proportion of the total 216 bunches, and the dump is required to dissipate power according to this proportion, as presented in Table 2. The sequence of states can be expressed in terms of the average power seen by the two dumps, shown in Table 3.

Table 3: Summary of Power Incident on Chopper Dumps

Number of bunches	Fast Chopper Dump	Slow Chopper Dump	Main FETS Dump
Percentage of total power dissipated	3.70%	26.39%	69.91%
Average power over 2 ms beam pulse	6.67 kW	47.50 kW	125.83 kW
Average power over 20 ms period	0.667 kW	4.750 kW	12.583 kW

PRELIMINARY DESIGN

This section describes the initial design decisions that have been taken for the chopper dumps. A rectangular plate-geometry was selected, with dimensions incorporating space constraints imposed by the FETS set-up. In this configuration, the deflected beam hits the plates at a shallow incident angle, with the power effectively distributed over a larger area, minimising the surface heat flux. Heat dissipates through the plate material, and is absorbed in water-cooled channels along the length of the plates.

The beam power must be safely dissipated by the plate and water cooling, and the material selection must be carried out accordingly. In order to select the material, existing beam dumps of similar specifications were first identified, and the materials used for these beam dumps were considered. Copper was then selected for the initial thermal analysis, with the possibility of using Nickel-coated copper in future simulations, should the radiation study deem this necessary. The subsequent analyses have all been carried out on a copper plate.

THERMAL ANALYSIS

Thermal analysis has been performed using General Particle Tracer (GPT), MATLAB and ANSYS software to support the design for the chopper dump plates, and identify points for refinement of the preliminary design [3-5].

Particle Distribution

The beam is characterised by a Gaussian-like energy spread. In order to determine the power distribution on the chopper dump plates, GPT simulations were carried out to determine the distribution of particles hitting the plates. Each simulation was conducted using 95,200 macro-particles, with each particle carrying an equal proportion of the total beam power. For each dump plate, the output of the simulation was the co-ordinate location of the beam particles, in the plane of the plate. The particle distribution is shown in Figure 1.

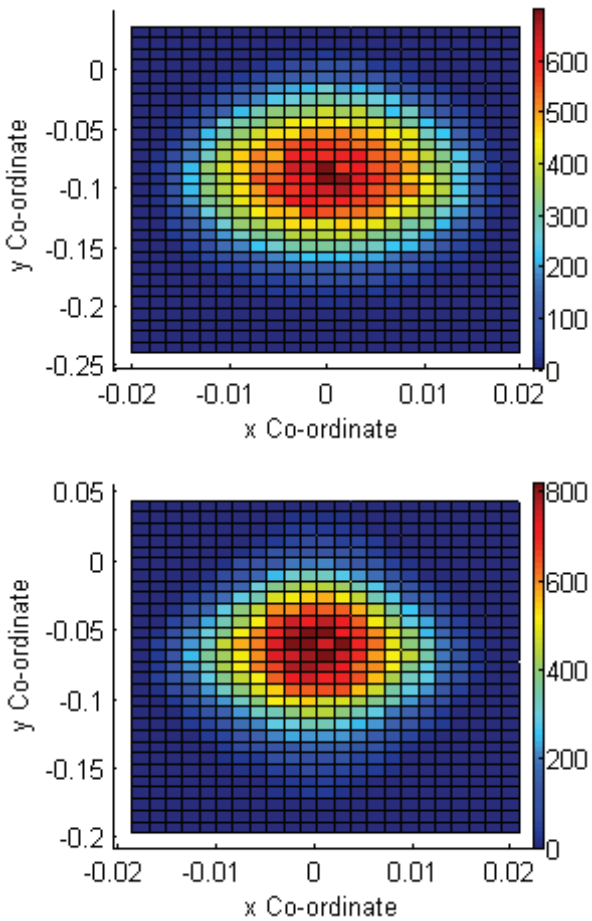

Figure 1: Particle distribution on the fast (top) and slow (bottom) chopper dump plates.

Finite Element Analysis Set Up

Finite element analysis (FEA) was conducted on the beam dump plate using the geometry described in the previous section. The boundary condition was a heat transfer from the beam on one surface, as obtained from the GPT simulations. For the transient and steady state analyses, the total power was distributed in proportion to the particle distribution described in Figure 1 for the fast and slow chopper dumps. The water-cooled channels were modelled using a convective heat transfer coefficient, with scope to extend to a full CFD analysis in future studies. The remaining plate surfaces were represented by a conservative zero heat flux model.

Steady State Analysis

The steady state temperature distribution for the two water-cooled plates under the influence of the time-averaged beam power of 0.666 kW and 4.75 kW to the fast and slow chopper dump plates respectively is presented in Figure 2.

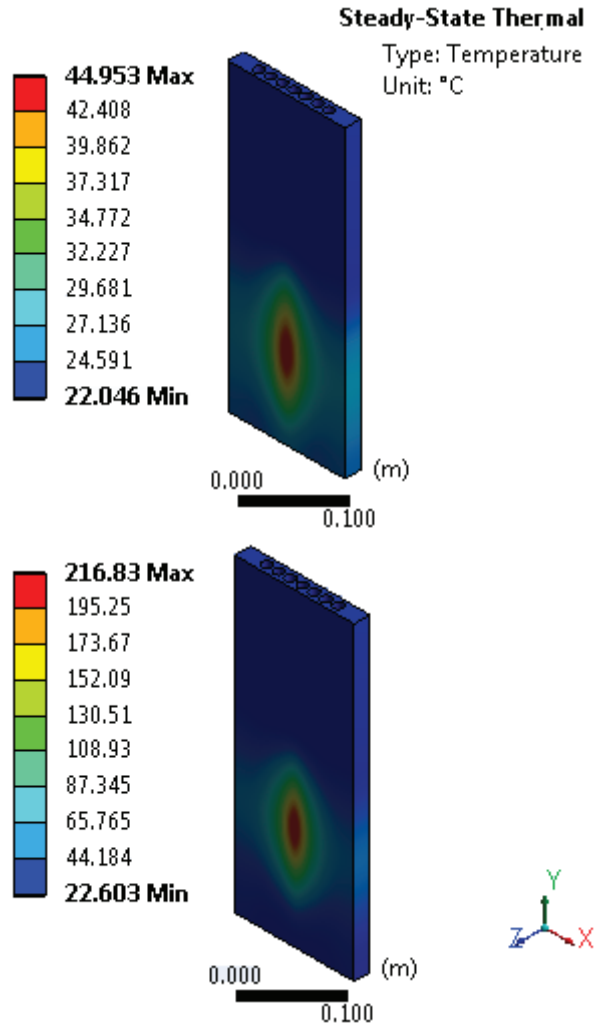

Figure 2: Steady state temperature distributions for the fast (top) and slow (bottom) chopper dump plates.

The maximum temperature obtained for the fast chopper dump, 45.0 °C is well below the creep temperature of copper, and the option of radiative cooling will be explored in future designs. The slow chopper dump has a maximum steady state temperature of 217 °C under active cooling by water. It is unlikely that radiative cooling alone will keep the maximum temperature below the creep temperature of copper.

Copyright © 2013 CC-BY-3.0 and by the respective authors

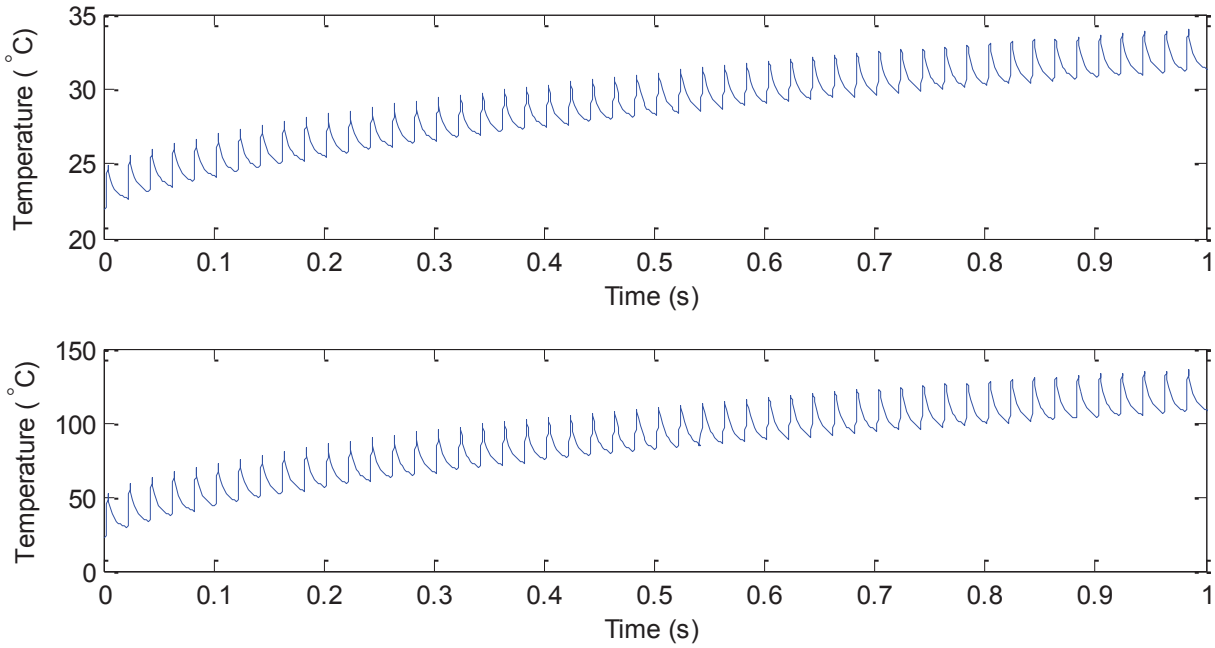

Figure 3: Graph of the maximum temperature as a function of time for the fast (top) and slow (bottom) chopper dump plates.

Transient Analysis

In the transient analysis, the beam power was applied for a period of 2 ms and then turned off for the next 18 ms, over consecutive cycles, in accordance with the data presented in Table 3. Time-averaged power over the 2 ms ON period of 6.67 kW and 47.5 kW were used for the fast and slow chopper dumps respectively, using the power distribution indicated in Figure 1.

Figure 3 illustrates the time history of maximum global temperatures of the two chopper dumps for the first 500 periods of these ON-OFF cycles. The difference in the vertical scale between the fast and slow chopper dumps should be noted; the slow chopper dump has a much larger ripple within each cycle. This represents the difference in heat flux applied to these dumps. Between subsequent cycles, it is seen that the temperature approaches the maximum steady state temperature for each dump, closely approximating an exponentially decaying trend. Within each cycle, the increase in temperature during the 2 ms period, followed by the decrease during the next 18 ms also follows similar kinetics.

CONCLUSION

The transient and steady state thermal effects of the incident beam on the two chopper dumps proposed for the FETS project have been investigated. The fast chopper dump has a maximum steady state temperature of 44.9 °C, and the slow chopper dump has a maximum steady state temperature of 217 °C. These results show that for the two chopper dumps, the material selected and geometry proposed are both thermally feasible.

The simulations done so far thus provide necessary groundwork for future analyses required in refining the design for the chopper dumps. Where approximations have been made to simplify the simulations, they have been conservative. There remains scope to incorporate a full computational fluid dynamics analysis to determine the variations in convective heat transfer coefficient along the water channels.

Additionally, it is necessary to translate the thermal analysis to determine the stress distribution, based on the plate mounting method. During the transient phase, temperatures vary by up to 30 °C in each pulse. This could lead to fatigue life problems if the stress levels are high. Subsequent work should also incorporate the effect of radiation on the material, to determine whether copper is feasible, or the copper bulk requires coating to enable the dumps to withstand the full beam power.

PROPOSAL FOR SIMULTANEOUS ACCELERATION OF STABLE AND UNSTABLE IONS IN ATLAS†

A. Perry, ANL, Argonne, IL, 60439, USA; IIT, Chicago, IL, 60616, USA
B. Mustapha, P.N. Ostroumov, ANL, Argonne, IL, 60439, USA

Abstract

The Argonne Tandem Linac Accelerator System (ATLAS) is the only national user facility for low-energy stable heavy ion beams. With the recent commissioning of the Californium Rare Isotope Breeder Upgrade (CARIBU), ATLAS will also be used to accelerate radioactive beams. We here propose to convert ATLAS into a multi-user facility by simultaneously accelerating stable beams from the ECR ion source and radioactive beams from an Electron Beam Ion Source (EBIS) charge breeder under development for CARIBU. Radioactive beams produced from EBIS will contain several charge states of the same isotope, and could be injected into ATLAS in short (~10μs) pulses. We propose modifications of the existing ATLAS low energy beam transport line that will allow the simultaneous injection and acceleration of one or more charge states from EBIS and a stable ion beam from the ECR. Beam dynamics simulations using the code TRACK confirmed the feasibility of these modifications. The realization of this concept will increase the available beam time, the intensity of radioactive beams and improve the quality of the delivered beams as well.

INTRODUCTION

The Argonne Tandem Linac Accelerator System (ATLAS) is the only national user facility for low-energy stable heavy ion beams. On a yearly basis ATLAS provides beam time in excess of 5000 hours to domestic and international users.

Recently, the californium rare isotope breeder upgrade (CARIBU) had been successfully commissioned at ATLAS [1]. CARIBU will produce, at full capacity, beams of ~80-160 amu fission fragments from a 1 Curie ^{252}Cf source. After thermal stabilization and mass separation, the fragments will be charge bred in a charge breeder based on an electron beam ion source (EBIS) [2]. This type of charge breeders yield higher breeding efficiencies with fewer contaminations and shorter breeding times compared to electron cyclotron resonance (ECR) based charge breeders. After charge breeding in EBIS, the radioactive beams will be injected into ATLAS, used as a post accelerator.

When radioactive beams from CARIBU become available, the already high demand for ATLAS beam time is expected to further increase. It may therefore be necessary to upgrade ATLAS into a multi-user facility - capable of simultaneously accelerating multiple beams and delivering them to different experiments. The feasibility of the proposed upgrade project relies heavily on two features:

a. The accelerator structure of ATLAS, consisting of individually-phased superconducting cavities, is extremely versatile, as was best demonstrated in the simultaneous acceleration of 8 charge states of Uranium through the booster linac section [3]. This enables the acceleration of stable and radioactive beams with charge to mass ratios differing by as much as 5%. Amongst the beams available for injection into ATLAS are numerous examples that meet this criterion, as shown in Table 1 below.
b. The radioactive beam from CARIBU EBIS will be pulsed with a pulse repetition rate of ~30Hz and a pulse length of ~10μs for a duty cycle of 0.03%. During the remaining time it will be possible to feed the accelerator with the appropriate stable beam.

Table 1: Some Beams with Similar Charge-to-Mass Ratios which can be Accelerated Simultaneously in ATLAS

Nominal Charge/mass	Stable Beams from ECR2	Radioactive beams from EBIS
0.15	$^{20}Ne^{3+}$, $^{86}Kr^{13+}$ $^{238}U^{36+}$, $^{133}Cs^{20+}$	$^{86}As^{13+}$, $^{106}Nb^{16+}$ $^{93}Kr^{14+}$, $^{93}Rb^{14+}$
0.16	$^{208}Pb^{33+}$, $^{56}Fe^{9+}$	$^{100}Y^{16+}$, $^{87}Br^{14+}$
0.18	$^{128}Xe^{23+}$, $^{84}Kr^{15+}$	$^{111}Tc^{20+}$, $^{138}Te^{25+}$
0.20	$^{20}Ne^{4+}$, $^{90}Zr^{18+}$	$^{131}Sn^{26+}$, $^{124}Cd^{25+}$
0.23	$^{56}Fe^{13+}$	$^{105}Ru^{24+}$, $^{101}Mo^{23+}$ $^{91}Sr^{21+}$, $^{83}Se^{19+}$

In order to achieve multi-user capability, 3 main points were identified:

- Injection of beams from two sources into the ATLAS Low Energy Beam Transport (LEBT).
- Modification of the ATLAS LEBT, which contains a 180 degrees bend, to accommodate for the transport of two beams with slightly different charge-to-mass ratios while introducing minimal emittance growth.

† This work was supported by the U.S. Department of Energy, Office of Nuclear Physics, under Contract No. DE-AC02-06CH11357.

Copyright © 2013 CC-BY-3.0 and by the respective authors

- Extraction of the beams after acceleration in ATLAS and their delivery to the designated experimental areas.

The primary challenge presented would be addressing the above points in a cost effective way and within the constraints of the available infrastructure.

LEBT MODIFICATION

A general layout of the proposed ATLAS LEBT is depicted in Figure 1. The orientation of the EBIS charge breeder platform with respect to the ATLAS accelerator beam line dictates a total 180° bend of the radioactive beam. In order to accommodate the transport of multiple beams with different charge-to-mass ratios simultaneously, it is necessary to make the transport line achromat. This may be accomplished by using the Double Bend Achromat (DBA, also known as the Chasman Green lattice) [4]. In the DBA, each 90° bend is composed of two 45° bending magnets and an intermediate quadrupole lens. Using the mirror symmetry with respect to a plane through the middle of the quadrupole, it can be shown that the lattice is doubly achromatic in first order if the quadrupole strength k_0 satisfies the equation:

$$k_0 tan\left(\frac{k_0 Q}{2}\right) = \frac{(1-cos\theta)tan(u)+sin(\theta)}{\rho\left\{1-cos(\theta)+\frac{S_1}{\rho}\left[(1-cos(\theta))tan(u)+sin(\theta)\right]\right\}}$$

where Q is the quadrupole length and S_1 the distance from the bending magnet to the quadrupole. ρ, θ and u are the bending magnet's radius, bend angle and exit edge angle respectively.

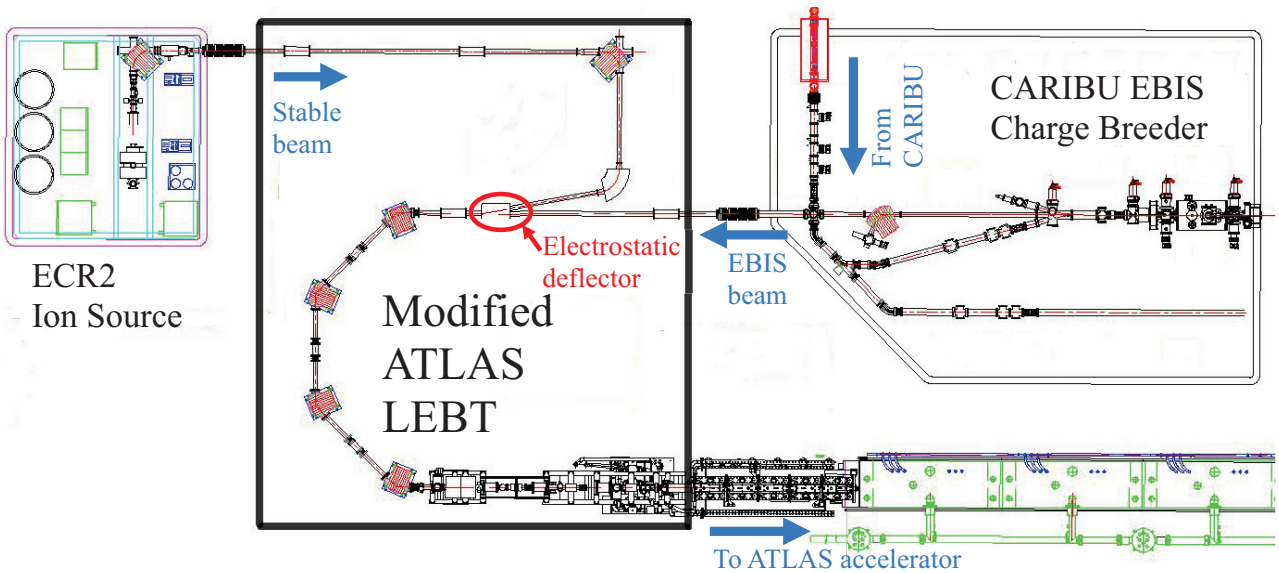

Figure 1: General layout of the proposed ATLAS low energy beam transport (LEBT) beam line. Arrows indicate the beam directions of the stable beam produced by ECR2, and the radioactive beam from EBIS.

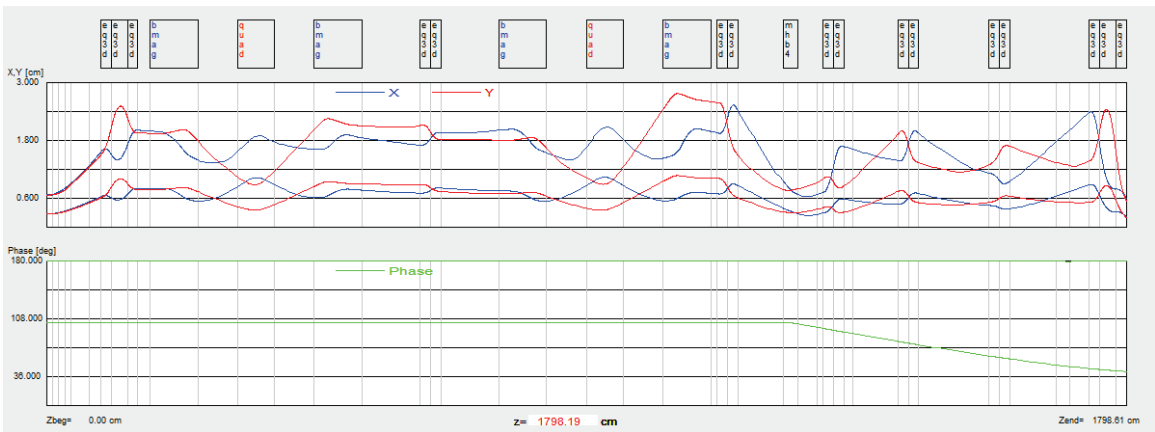

Figure 2: TRACK simulation results for the simultaneous transport of $^{132}Sn^{27+}$ from EBIS and $^{48}Ca^{10+}$ from ECR2. The RMS emittance growth in the 180° achromat bend is 1%.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Furthermore, double focusing can be achieved by the appropriate choice of S_1 and u.

In addition to creating the achromat lattice, we also propose to replace all the magnetic focusing elements in the LEBT with electrostatic lenses. The latter are more compact and hence preferable to magnetic lenses in the low energy regime. The maximum of the dispersion function is obtained inside the intermediate quadrupole lens and is given by:

$$D_{max} = -\frac{1}{2k_0}\frac{sin(\theta)}{sin\left(\frac{k_0 Q}{2}\right)}$$

Hence these quadrupoles will have a 5 cm aperture radius which is larger than the standard used until now.

The code COSY Infinity [5] was used to evaluate the transfer matrix of the lattice and confirm its achromaticity in linear order, as well as the effects due to nonlinear terms. The beam dynamics code TRACK [6] was then used to simulate the simultaneous acceleration of $^{132}Sn^{27+}$ ions available from EBIS charge breeder and $^{48}Ca^{10+}$ ions available from ECR-2. The beams were first transported in the modified LEBT (Figure 2) and then injected into the ATLAS Radio Frequency Quadrupole (RFQ) accelerator and subsequent superconducting accelerator.

INJECTION AND EXTRACTION

The EBIS charge breeder will output approximately 30 batches of particles every second, each approximately 10μs long. In order to inject these batches and the batches produced from the ECR ion source into the same beam line, an electrostatic deflector (switch) will be used (as shown in Figure 1. The electrostatic deflector is to deflect the stable beam into the downstream beam line, but it will be synchronized to switch off with the arrival of the EBIS beam batches, so they continue downstream without deflection.

The design of the deflector will rely on the CARIBU EBIS electrostatic deflector and its 'diagonal cut' design. As shown in [2] this deflector design produces minimal emittance growth. However, due to the higher energy of the particles a higher deflecting voltage (evaluated at ~50kV) will be used for our purpose. If a total switching time (rise and fall) of 2ms is allowed then the requirements from the power supply are relatively relaxed, and a 94% duty cycle of the stable beam is still possible.

The Extraction of one of the beams and its subsequent delivery to the designated experimental hall is more complex due to the higher energy after acceleration and limited space available. The extraction will take place after acceleration in the Positive Ion Injector (PII) and the Booster, where the particles reach energies greater than 5.5MeV/u. A combination of a kicker magnet and a septum magnet will be used for the extraction.

SUMMARY

We propose a cost effective redesign of the ATLAS LEBT to accommodate the transport of multiple beams simultaneously. TRACK simulations show that with a modified LEBT, based on the Double Bend Achromat lattice, multiple beams with a charge-to-mass ratios differing by up to ~3% can be transported from two sources and accelerated in ATLAS. This will make ATLAS capable of multi-user operation, a capability which is important in light of the high demand for beam time, which is expected to further increase once radioactive beams from the EBIS CARIBU become available.

In addition to that, the radioactive beams from CARIBU EBIS will contain a range of charge states. If the LEBT is modified in accordance to our proposal, two of these charge states can be transported simultaneously and injected into different RF buckets in the RFQ. This will increase the intensity of the radioactive beams delivered to users.

Lastly, TRACK simulations indicate that transporting the CARIBU EBIS beam in the present LEBT may result in significant beam quality degradation. This is due to the high dispersion in the current layout and the energy spread of the beams produced by EBIS.

Further work on the injection, extraction and acceleration of multiple beams is still required.

THE D-LINE PROJECT AT MICHIGAN STATE UNIVERSITY *

J.A. Rodriguez#, S. Chouhan, A. Lapierre, D. Leitner, G. Perdikakis, M. Portillo, S. Schwarz, M. Steiner, C. Sumithrarachchi, S.J. Williams, W. Wittmer, X. Wu, NSCL, East Lansing, MI, USA

Abstract

The Coupled Cyclotron Facility (CCF) at Michigan State University (MSU) has been used to produce rare isotope beams for more than a decade. Ions produced by an ECR source are accelerated using two superconducting cyclotrons in tandem with a stripper foil in between to boost their charge state. After the second cyclotron, a target and a fragment separator produce and select the rare isotope beam that is sent to the different experimental vaults. A gas stopper can be used to thermalize the beam before sending it to a low energy experimental area or to a charge breeder before the ReA re-accelerator. The D-line project includes a mass separator after the gas stopper and several beam transfer lines that connect it to the low energy experimental stations and to the charge breeder. In this paper, we will describe the project and give an update of its status including the results of the commissioning.

INTRODUCTION

One of the most important developments at the National Superconducting Cyclotron Laboratory (NSCL) during this past year has been the successful delivery of the first radioactive reaccelerated beam to users [1]. Together with the commissioning of the gas cell in the ion beam thermalization area [2], the charge breeder [3] and the reaccelerator [4], the completion of the D-line was one of the steps necessary to make this possible.

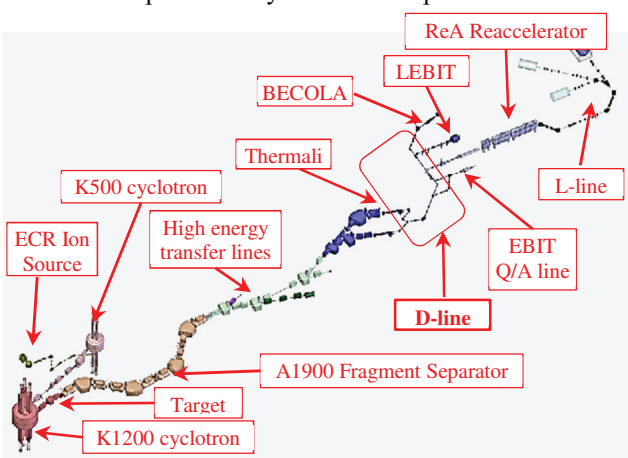

Figure 1: Layout of the CCF and ReA3 facilities (several high energy beam lines and experimental areas are not shown). The D-line connects the thermalization area with the low energy experimental hall and the charge breeder.

DESCRIPTION OF THE LINE

The main purpose of the D-line is to connect the beam thermalization area of the NSCL with the experimental devices in the low-energy experimental hall (LEBIT [5] and BECOLA [6]) or alternatively with the Q/A line before the charge breeder (EBIT) and the ReA3 reaccelerator. In addition, the line includes a mass separator that is used to select the Radioactive Isotope Beam (RIB) that is going to be studied and to clean the unwanted contaminants with a different momentum after extraction from the gas cell.

The line is designed to be able to transport efficiently beams with emittances of ~ 10 π·mm·mrad and energy lower than 60 keV. In its current configuration (Figure 3), the south line is used to transport stable beams from an off-line ion source. This beam has been used for commissioning of the D-line and downstream experimental devices. The north line is used to transport the RIBs previously thermalized in the gas cell.

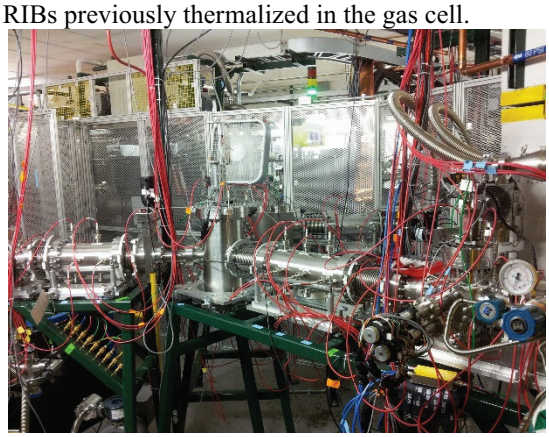

Figure 2: Merging point of the north and south lines. Starting from the left, the picture shows an electrostatic doublet, a bender and a triplet followed by the vacuum and diagnostic station before the mass separator.

With the exception of the dipole magnet used as a mass separator, all the other elements in the D-line are electrostatic. The beam is focused using electrostatic quads (10 cm long, 6 cm aperture, up to ±6 kV bias) normally grouped into doublets. In most cases, opposite electrodes are shorted inside the vacuum chamber and driven by a single power supply. However, some of them can be used as beam steerers since they can be biased independently. In addition, there are horizontal and vertical steering plates in all the diagnostic boxes. Spherical benders (up to ±10 kV bias) are used to deflect the beam 45 degrees at a time. Several of them have also been combined for deflection angles of 90 and 135 degrees. Some of them are mounted in movable drives in order to allow an inserted or retracted state to switch the desired beam and its destination.

A dipole magnet and two electrostatic doublets function

as a mass separator with a resolving power M/ΔM higher than 100. Horizontal movable slits in the object and image planes can be used to collimate the incoming beam and to discard the unwanted masses.

The 61-degree magnet was designed using TOSCA to produce a 0.79 T field for a current of 217 A (with uniformity better than 10^{-3} in its ±5 cm central region). It has a bending radius of 68 cm, a 6 cm vertical aperture and a 22 cm pole width.

The lattice was designed using COSY INFINITY (Figure 4) to accept beam from both the north and south line and transport it to the object point of the separator, where both beams are matched to. The beam is then transported using point-to-point focus to one of the low-energy experimental stations or to the Q/A line for injection into the charge breeder. The optics of each segment of the line is independent of the destination of the beam and, only the matching triplet before the object point of the mass separator needs to be adjusted when the origin of the beam is changed.

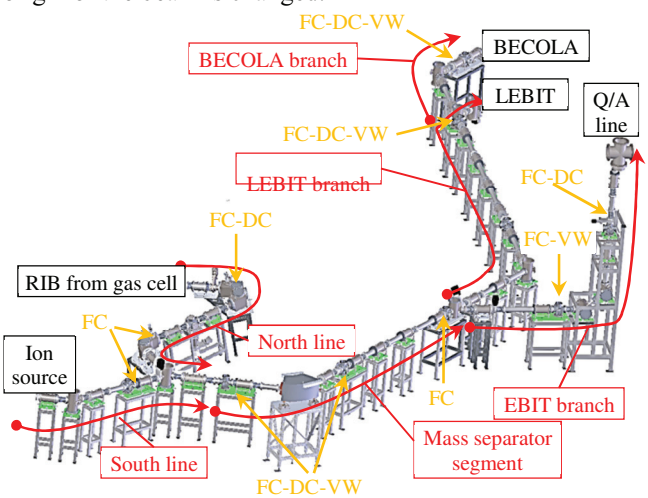

Figure 3: Layout of the D-line broken into different sections (in red), the beam origin/destination (in black) and a list of the diagnostics available at each location (in orange). FC stands for Faraday Cup, VW for MCP viewer and DC for decay counter.

There are ten diagnostic stations in the line and most of them are located at (or near) waists of the beam envelope (Figure 3). All the stations include Faraday cups and 5 mm diameter movable apertures (except for the ones in the object and image points of the separator which have movable horizontal slits). Six of the Faraday cups are equipped with silicon detectors to detect β-decays of the RIBs implanted in the Faraday cup current collector. Details of their design and associated DAQ can be found in [7]. In addition, there are five Multi Channel Plate (MCP) viewers and one more will be added in the future.

There are seven vacuum stations distributed throughout the beam lines. Each vacuum station includes a turbo pump with a gate valve, a cold-cathode gauge, two Pirani gauges and a venting valve. Each turbo pump is backed by a scroll pump (three of them directly, four of them through a common vacuum manifold). The beam line is split into six vacuum sections separated by gate valves to facilitate maintenance. The pressure in the lines typically reaches the 10^{-8} Torr range after two days of pumping.

The relative alignment of consecutive components in the line is better than 250 microns with the exception of some of the benders.

The high level controls have been built using Control System Studio (CSS). Using CSS to scale the energy of the line, to change the beam origin or destination or to complete mass scans is quick and convenient. However, at this time, different software is used to tune the lines and some additional work remains to integrate this capability in CSS.

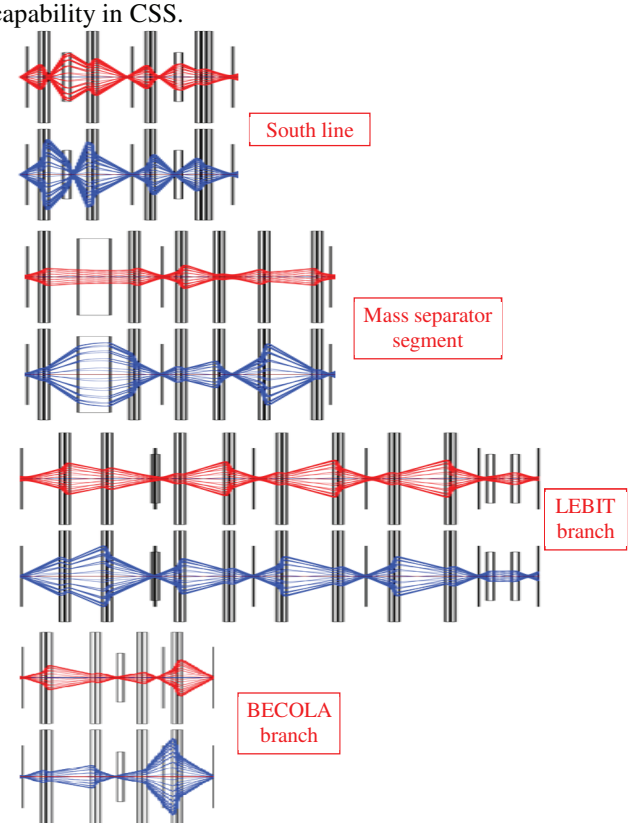

Figure 4: Ray calculations of beam transport in several segments of the line from South line to BECOLA (horizontal in blue, vertical in red)

COMMISSIONING OF THE LINE

Equipment Commissioning

The several hundred HV power supplies used in the line, their cables and connectors were tested during installation to confirm that none of them were damaged and that their polarity was correct. Several problems were identified and corrected during those tests.

The low-level controls and the interlock logic of the diagnostic drives were tested. The cables and electronics of the Faraday cups were checked using a calibrated current source and their electron suppressor biases were measured. Most of the decay counters and their data acquisition hardware and software were also tested using a Sr-90 radioactive source before installation. The low-

Copyright © 2013 CC-BY-3.0 and by the respective authors

level controls of the vacuum stations and the interlock logic of the gate valves were also checked.

Stable Beam Commissioning

Most of the segments of the D-line were commissioned using the off-line stable ion source upstream of the beam line. A ~2 mm misalignment in one of the doublets in the line was identified and tracked down to a faulty alignment monument. At the beginning of the commissioning with stable beam, 20-30 % of the beam was lost along the line and very strong non-linearities were observed in the MCP viewers. The problem was solved when the gas pressure in the ion extraction guide upstream of the D-line was increased. Originally, the beam was not cooled enough transversely and its emittance was larger than the acceptance of the line. Using the higher pressure now allows for only a few percent beam loss.

We have empirically found that the optimal settings of the last optical elements for injection into the experimental stations differ to a limited extent from those in the COSY model prediction. Also, slow beam jitter (with a period of several minutes) has been observed when the beam was injected into LEBIT. The sources of these problems have not been identified yet.

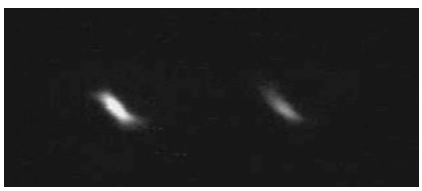

Figure 5: Image of two beams (corresponding to masses 76 and 77) as seen in the MCP viewer after the mass separator during one of the commissioning runs.

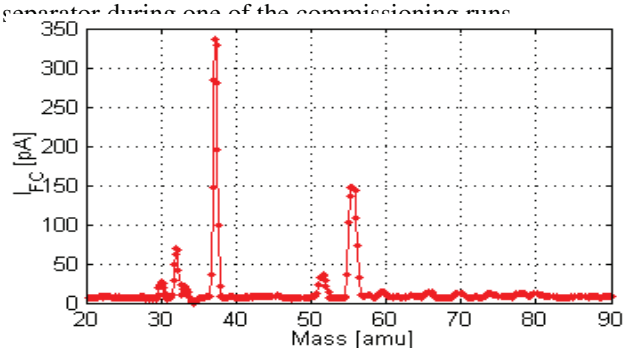

Figure 6: Mass scan during one of the Ga-76 commissioning runs. The different peaks correspond to different contaminant molecular beams produced in the gas cell as the high energy beam is slowed down and interacts with the residual gas. The two highest peaks correspond to mass 37 $[H_5O_2]^+$ and mass 55 $[H_7O_3]^+$.

Radioactive Beam Commissioning

Several commissioning runs with radioactive beams have been conducted during the last year. During these runs, the resolving power of the separator has been found sufficient (Figure 5) and the CSS-based mass scanning software developed for the separator has been tested (Figure 6).

In addition, the decay counters and their DAQ have been tested (Figure 7). The diagnostic team is working to improve their performance by reducing some of the EM

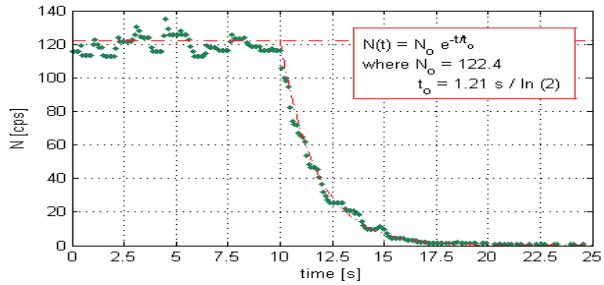

Figure 7: Decay curve for K-37 measured in the decay counter of the diagnostics station after the mass separator. The measured half-life is 1.21 s which is compatible with the expected value of 1.23 s.

CONCLUSION

The D-line project has been completed. All the segments of the line have been commissioned and the transport efficiency in all of them approaches 100 %. The line has been reliable at delivering hundreds of hours of stable and radioactive beams to both the low-energy experimental hall and to the charge breeder before the ReA3 reaccelerator.

ACKNOWLEDGMENT

Many people at the NSCL have worked together to complete this project. In particular, the authors would like to thank the machine shop, the controls, electrical engineering and mechanical design departments as well as the assembly, vacuum and alignment groups for their invaluable contribution to the project.

SYSTEMS ENGINEERING AND INTEGRATION ON THE FRIB PROJECT*

D. Stout#, T. Borden, N. Bultman, R. Frazee, M. Leitner, P. Nguyen, T. Russo, E. Tanke, C. Thronson, Facility for Rare Isotope Beams, Michigan State University, East Lansing MI, 48824 USA

Abstract

The Facility for Rare Isotope Beams (FRIB) will be a world-leading, DOE Office of Science national user facility for the study of nuclear structure, reactions, and astrophysics on the campus of Michigan State University (MSU).

Systems Engineering and Integration has been implemented at the outset to ensure that a requirements-driven design process is followed, and to ensure intra and inter-system compatibility. Top-level requirements have been allocated and subsequently elaborated between the Accelerator Systems, Experimental Systems, and Conventional Facilities. FRIB has developed a number of methods and tools to track requirements, establish interfaces, monitor design progress, and ensure overall system integration. These will be described in the paper.

FRIB PROJECT INTEGRATION

A superconducting, heavy-ion, driver linac will be used to provide stable beams of >200 MeV/u at beam powers up to 400 kW (~650 electrical micro-amps for uranium). The stable beams will be used to produce rare isotopes by in flight fragment separation. After fragment selection, the rare isotopes will be used at velocity (~0.5c), stopped, or reaccelerated. The MSU-led design and construction effort is supported by collaborations with many National Laboratories and other scientific institutions [1].

FRIB is integrated both vertically and horizontally. The vertical integration is achieved by the Systems Engineering methods discussed in the next section. Horizontal integration is achieved by the project organizational structure and by adherence to a consistent design process.

Project Engineers are identified within the three main FRIB Divisions, Accelerator, Conventional Facilities, and Experimental, and are responsible for integration within their Division.

The overall project design process is shown in Figure 1. At each significant project design phase, the key design products and expectations are defined with respect to the major design aspects: requirements, interfaces, drawings and specifications, manufacturing, and project management. At the beginning of each major design phase (i.e. preliminary or final design) deliverables for each sub-system are identified. These include specific analyses, tests, and prototypes that must be completed to demonstrate readiness for the next design phase, or for construction.

Defining the deliverables for each sub-system ensures coherence between the sub-systems, either by keeping their efforts on a similar schedule, or by clearly defining the interface points between sub-systems on different development schedules. This latter point is important since most projects usually cannot complete all design work simultaneously due to cost and design resource limitations. The other main advantage of clearly defining the deliverables and design expectations is that each sub-system manager then has a clear work plan for design. On FRIB these deliverables are used as part of the Earned Value Management System to measure and quantify design progress.

SYSTEMS ENGINEERING AND INTEGRATION OVERVIEW

Systems Engineering, as defined by the International Council on Systems Engineering [2], is an inter-disciplinary approach and means to enable the realization of successful systems. It focuses on defining customer needs and required functionality early in the development cycle, documenting requirements, then proceeding with design synthesis and system validation while considering the complete problem: Performance; Operations; Cost & Schedule; Training & Support; Test; Manufacturing and Disposal. Systems Engineering integrates all the disciplines and specialty groups into a team effort forming a structured development process that proceeds from concept to production to operation. Systems Engineering considers both the business and the technical needs of all customers with the goal of providing a quality product that meets the user needs.

Implementation of Systems Engineering can be tailored for a specific industry or laboratory. Many industries can amortize software, staffing, training, and set-up expenses over multiple platforms or projects. For one-off projects like FRIB, the same methods can be used, but off the shelf software and a leaner System Engineering staff are more appropriate.

Irrespective of the scale of the implementation, the "V" model is at the core of the Systems Engineering approach, and has been fully implemented for FRIB. This model breaks a system into sub-systems, equipment, and components, with specific requirements and interfaces at each level of decomposition. The right hand side of the "V" model is the subsequent aggregation of components, equipment, and sub-systems into a fully functioning system. This aggregation is accomplished by increasingly sophisticated levels of testing and integration. A requirements-based design is fundamental to the use of this model. By starting from a limited number of top-level system requirements, one can define the overall architecture and decompose the project into essential sub-

systems. Most sub-systems for FRIB are based on well-known accelerator technology.

REQUIREMENTS AND INTERFACE DEFINITION

Overall FRIB requirements were finalized during the conceptual design phase of the project. These requirements were captured in a draft Project Execution Plan, Project Requirements Document, and a Parameter list. The first two documents capture all requirements, and the Parameters list identifies the relevant sub-systems and some of their features. During preliminary design, these requirements were further divided into several "System Requirements Documents" for the accelerator, conventional facilities, experimental systems, personnel protection system, cryogenic plant and others. Because these are high level requirements, they were assigned to the specific sub-systems responsible for achieving them. The project captured these in a "Requirements Tracker", a spreadsheet capable of ensuring all requirements were assigned to a responsible system/sub-system. The tool also allows for selecting the requirements specific to a certain sub-system for verification at design reviews or during testing. Another important feature is that the tracker captures emerging safety requirements, assigns these requirements to a specific work element, and verifies their accomplishment. For example, radiation shielding and oxygen-deficiency hazard requirements are developed through calculations and analyses as the design progresses. The tracker facilitates capturing such evolving requirements.

Another essential area that requires definition and monitoring are interfaces, such as physical locations / connections, utility requirements, beam-handoff parameters, instrumentation and data interchanges, etc. FRIB developed an "Interface Tracker", an excerpt of which is shown in Figure 2, to identify interfaces and to retrieve the relevant information for a specific interface. Initial interface assignments, between magnets and power supplies for example, were identified. The appropriate interface documents were prepared, approved, and submitted to the FRIB document control center. The interface tracker visually identifies the interface and provides a hyperlink to the associated documents. It also quantifies the progress made in defining interfaces, so the project can ensure that interfaces are frozen before detailed design is started.

DESIGN VALIDATION

Initial design validation is the responsibility of the cognizant team. FRIB also conducts project-level reviews of all major sub-systems at the 30%, 60%, and 90%

completion points. The 30% review corresponds to the completion of the Preliminary Design Phase in Figure 1, and the 60% and 90% reviews are conducted during the Final Design Phase.

Currently the project is conducting 60% and 90% reviews. The purpose of the 60% review is to ensure all requirements and interfaces are finalized, all engineering analyses have been completed and support final detailed design, and the design addresses quality, manufacturing, and environmental, safety and health requirements. The 90% review is conducted to confirm the design is complete and ready for procurement.

External expert reviewers are essential for effective reviews, and FRIB policy requires independent review of high level of care systems, such as personnel protection systems.

DESIGN MANAGEMENT

FRIB uses key performance indicators to summarize the engineering progress over time. Progress is based on completion of interfaces, completion of 60% and 90% reviews, and final drawing/specification completion. A excerpt of a Design Progress Dashboard is shown in Figure 3.

Experimental Systems Division

31-Aug-13		Interfaces (%) From Tracker	60% Design Review (%)	Drawing (BTP) or Specification (BTS) % Complete	90% Design Review (%)	Overall Design Progress (%)

Figure 3: "FRIB Design Dashboard" showing progress.

Progress is plotted monthly to make sure FRIB is on track for major milestones. A sample graph is shown in Figure 4.

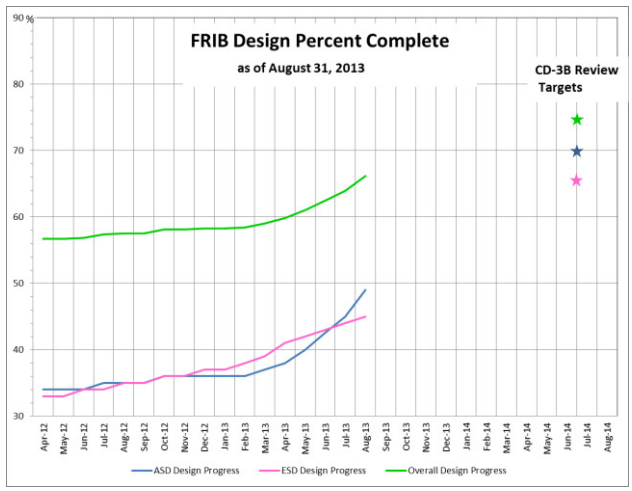

Figure 4: Sample Monthly Design Progress Report indicating progress and targets.

COMPONENT AND SUB-SYSTEM VALIDATION

The Project uses formal Acceptance Criteria checklists to identify the criteria that must be satisfied and to document the actual verification that the criteria is met. These lists are used for fabrication, testing, and will be used for installation and integrated testing. The Requirements Tracker previously mentioned supports criteria development, and it also captures the actual verification.

SUMMARY

FRIB has implemented an effective Systems Engineering and Integration Process:

- Tools are in place and used to manage requirements and interfaces; metrics provide managers current status of the design effort
- Review and validation processes will ensure designs meet requirements, including fabrication, installation and testing requirements.

STATUS AND OPPORTUNITIES AT PROJECT X: A MULTI-MW FACILITY FOR INTENSITY FRONTIER RESEARCH*

S. D. Holmes, M. Kaducak, R. Kephart, I.Kourbanis, V. Lebedev, S. Mishra, S. Nagaitsev, N. Solyak, R. Tschirhart, Fermilab, Batavia, IL 60510, USA

Abstract

Project X is a multi-megawatt proton facility being developed to support a world-leading program in Intensity Frontier physics at Fermilab. The facility will support programs in elementary particle and nuclear physics, with the potential for broader applications in materials and energy research. Project X is in the development stage with an R&D program focused on front end and superconducting rf acceleration technologies, and with design concepts for a staged implementation. This paper will review the status of the Project X conceptual development and the associated R&D programs.

PROJECT X MISSION AND GOALS

Project X is a high intensity proton facility that will support a world-leading U.S. program in Intensity Frontier physics over the next several decades. Project X is currently under development by Fermilab in collaboration with national and international partners. Project X will be unique in its ability to deliver, simultaneously, up to 6 MW of site-wide beam power to multiple experiments, at energies ranging from 235 MeV to 120 GeV, and with flexible and independently controlled beam time patterns. Project X will support a wide range of experiments utilizing neutrino, muon, kaon, nucleon, and atomic probes [1,2]. In addition, Project X will lay the foundation for the long-term development of a Neutrino Factory and/or Muon Collider.

PROJECT X REFERENCE DESIGN

A complete design concept, designated the Project X Reference Design [3], has been established supporting the above-described mission in an innovative and flexible manner. The Reference Design is based on a 3-GeV superconducting (SC) continuous wave (CW) linac, followed by an 8-GeV superconducting pulsed linac, and improvements to the Main Injector complex at Fermilab. The primary elements of the Reference Design are:

- An H^- front end based on a 162.5 MHz RFQ delivering 5 mA of beam current at 2.1 MeV into a medium energy beam transport (MEBT) line containing a wideband, bunch-by-bunch, chopper capable of accepting or rejecting bunches in arbitrary patterns and leaving 1 mA average (averaged over ~1 μsec) current for further acceleration;
- A 3-GeV SC linac operating in CW mode and capable of accelerating an average beam current of 1mA;
- A 3 to 8-GeV pulsed SC linac capable of accelerating a peak current of 1 mA with a duty factor of 4.3%;
- Rf splitters that can deliver beams at 1 and 3 GeV to at least three experimental areas;
- Experimental facilities to support experiments at 1 and 3 GeV;
- Modifications to the Main Injector (MI) and Recycler complex required to support 2-MW operations in the energy range of 60-to-120 GeV;
- All interconnecting beam lines.

STAGING STRATEGY

Fiscal considerations have motivated development of a staging plan for Project X, consistent with the following principles:

- The plan should provide compelling physics opportunities at each stage;
- Each stage should cost substantially less than $1B;
- Each stage should utilize existing infrastructure to the extent possible;
- The construction of each stage should minimize interruptions to the on-going research program;
- The full Reference Design capabilities should be achieved at end of the final stage.

The Reference Design has been developed consistent with these principles – the associated layout on the Fermilab site is shown in Fig. 1.

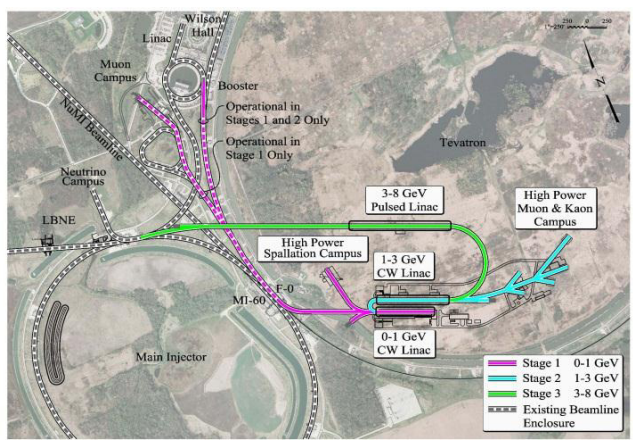

Figure 1: Project X Reference Design Stages.

Stage 1 is based on the 1-GeV CW linac. The 1-mA beam can be directed either to the existing 8-GeV Booster, the Muon Campus (currently under construction), or to a newly constructed High Power Spallation Campus. Stage 1 retires the existing 400-MeV linac and raises the Booster injection energy to 1 GeV,

* Work supported by the Fermi Research Alliance under U.S. Department of Energy contract number DE-AC02-07CH11359

Copyright © 2013 CC-BY-3.0 and by the respective authors

allowing a 50% increase in beam intensity. Stage 1 can simultaneously provide 1.2 MW to the long baseline neutrino target at 120 GeV, 80 kW to the Mu2e experiment [4], and 900 kW of beam power to the new Spallation Campus.

In Stage 2 the CW linac is extended to 3 GeV. The average beam current in the 1-GeV linac is increased to 2 mA with 1 mA available for the Booster and the Spallation Campus, and 1 mA passed into the 3-GeV linac for delivery to a newly constructed High Power Muon and Kaon Campus.

Stage 3 completes the Reference Design with the 8-GeV pulsed linac replacing the Booster as the injector into the Main Injector complex. The pulsed linac delivers a 1-mA peak beam current with a 4.3% duty factor (4.3 ms × 10 Hz). At Stage 3 the Main Injector can deliver 2.3 MW of beam power at any energy between 60-120 GeV. In addition, beam power is available for an 8 GeV program ranging from 0-170 kW, depending on the operating energy of the Main Injector.

The capabilities of Project X at each stage are given in Table 1.

Table 1: Project X Performance by Stage

	Stage 1	Stage 2	Stage 3
1 GeV Beam Power	0.9 MW	1 MW	1 MW
3 GeV Beam Power	---	3 MW	3 MW
8 GeV Beam Power	110 kW	110 kW	350 kW
120 GeV Beam Power	1.2 MW	1.2 MW	2.3 MW

R&D PROGRAM

The Reference Design provides the context for the Project X R&D program. The purpose of the R&D program is to mitigate technical and cost risks. The primary risks associated with Project X are identified as:

- Front End: The front end must provide an average beam current of 1-2 mA, with a peak current of 5-10 mA, with the beam assigned in a programmable manner into the linac rf buckets.
- H^- injection: All stages of Project X require injection via stripping over hundreds of turns. Space-charge mitigation requires foil painting. Other considerations include foil heating, and losses generated by partial stripping and/or or multiple scattering.
- High Intensity Main Injector and Recycler operations: Operations at intensities a factor of three beyond current experience require upgrades to the rf systems and control of a variety of beam instabilities.
- High Power Target Facilities: Target facilities for producing both secondary particle beams and spallation neutrons must accommodate >1 MW of incident beam power.
- Superconducting rf: A variety of cavities operating at different frequencies and with different geometric betas are required.

The R&D program as structured could support a Project X construction start in 2018.

Project X Injector Experiment (PXIE)

PXIE is an integrated front-end systems test, and is the centerpiece of the Project X R&D program [5]. PXIE will validate the concept for the Project X front end, thereby minimizing the primary technical risk element within the Reference Design. The PXIE layout is shown in Fig. 2.

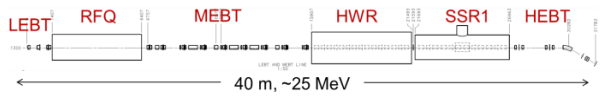

Figure 2: PXIE Layout.

PXIE will operate with the full Project X design parameters. These include delivering 5 mA average current from the RFQ, followed by 80% chopping within the MEBT for an average current delivered to the SC accelerating section of 1 mA. Two SC acceleration modules (HWR and SSR1) are expected to provide efficient acceleration with minimal emittance dilution to ~25 MeV. PXIE will utilize components constructed to Project X specifications wherever possible. This will provide an opportunity to re-utilize selected PXIE components within Project X.

PXIE is being undertaken by a collaboration of Fermilab with ANL, LBNL, ORNL/SNS, and four Indian institutions (BARC, IUAC, RRCAT, VECC).

Superconducting RF

The Project X linacs utilize modern SC radiofrequency (srf) technology as it has been developed over the last few decades. This technology is considered mature, and does not represent a significant technical risk within Project X; it is, however, a primary cost driver.

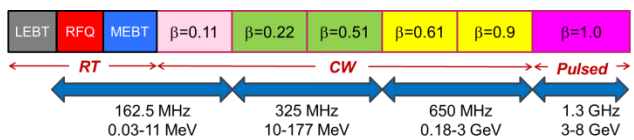

Figure 3: Project X Linac Technology Map.

Figure 3 displays the technology layout of the Project X linacs. A room temperature (RT) front end is followed immediately by superconducting accelerating modules extending from 2.1 MeV to 8 GeV. The linac operates in CW mode up to 3 GeV and in pulsed mode thereafter. Operation of a CW linac places a strong premium on achieving high Q_0 in order to reduce both operating costs and the capital investment in the cryogenic support systems [6]. A robust srf R&D program has been underway for several years at Fermilab in collaboration with national and international partners. This program

Copyright © 2013 CC-BY-3.0 and by the respective authors

originated as an initiative to develop 1300 MHz accelerating structures for the International Linear Collider [7] in the mid-2000s. The significant investment in ILC technologies made it natural to base the Project X design on sub-harmonics of 1300 MHz.

The status of srf development for Project X is summarized in Table 2. HWR and SSR signify half-wave and single-spoke resonators; LE650 and HE650 are both 5-cell elliptical cavities; while ILC is a 9-cell elliptical cavity (operating at lower gradient, but higher Q_0 than ILC) Substantial progress has been made on all cavity types. As an example Fig. 4 shows test results from six SSR1 cavities fabricated in industry, all of which meet the Project X performance specification and are planned to be used in PXIE and later in the Project X front end.

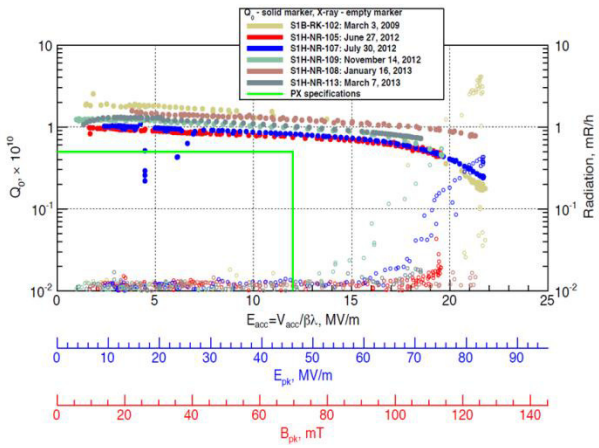

Figure 4: Dependence of Q_0 on accelerating gradient for SSR1 bare cavities at 2K. The green lines indicate the Project X specification.

SUMMARY

Project X is central to the strategy for future development of the Fermilab accelerator complex. A Reference Design has been developed that will support a world-leading program in neutrinos and other rare processes over the coming decades, and will provide a platform for future muon-based facilities. A staging strategy has been developed that provides compelling physics opportunities at each stage. An R&D program is underway with particular emphasis on front end and srf development. Project X could be ready to initiate construction in the second half of the current decade.

STUDIES OF FAULT SCENARIOS IN SC CW PROJECT-X LINAC*

A. Saini†, J.-F. Ostiguy, N. Solyak, V. P. Yakovlev
Fermilab, Batavia, IL 60510 USA.

Abstract

The success of the Project-X accelerator facility crucially depends on reliable operation of the 1 GeV superconducting (SC) continuous wave (CW) linac at stage-I. Operation at high intensity in CW mode puts stringent tolerances on beamline elements. Any fault affecting nominal operation of an accelerating or transverse focusing element will result in beam mismatch in the downstream sections. This in turn leads to emittance growth, and ultimately triggers beam losses. A robust lattice design allowing local retuning can make the machine operable even in the event of a fault, limiting the need for long unscheduled downtime. This paper presents studies performed to understand the consequences of failure of various elements. The outcomes of local retuning for different fault scenarios at critical locations in the linac are discussed.

INTRODUCTION

Project-X is a proposed multi-megawatt (MW) accelerator facility to be built at Fermilab[1]. It is envisioned as a multiuser facility that would support a diversified experimental program at the intensity frontier. In the current economic environment, funding profile limitations led to development of a staging strategy. The facility would be built in three stages. The first stage involves construction of 1 mA (average current), 1 GeV SC CW linac. The second stage would double the average current through stage I. Half of the beam would then be further accelerated in a 1-3 GeV SC CW linac. The final and third stage involves construction of 3-8 GeV SC pulsed linac. A detailed description of staging approach is presented elsewhere[2]. A schematic of the CW linac baseline configuration is shown in Fig. 1. It comprises a room temperature front end and a SC linac. The front-end includes an ion source, a low energy beam transport (LEBT) section, an RFQ and a medium energy beam transport (MEBT) section. The DC ion source delivers a nominal current of 5 mA at 30 keV. The beam is transported through the LEBT and matched to the RFQ. The RFQ operates at room temperature at a frequency of 162.5 MHz and accelerates the beam up to 2.1 MeV. The beam then enters the MEBT where it gets chopped to acquire the time structure required to drive different simultaneous experiments. Following the MEBT is a SC CW linac segmented into five sections. The first section is based on 162.5 MHz Half Wave Resonators (HWR) and accelerate the beam to $\sim$ 9 MeV. The next two sections use two types of 325 MHz Single Spoke Resonators (SSR) i.e. SSR1 and SSR2, to reach a kinetic energy of 156 MeV. The two final sections dubbed low beta (LB) and high beta are based on 5-cell, 650 MHz elliptical shaped cavities respectively designed for β_G = 0.61 and β_G = 0.90 .

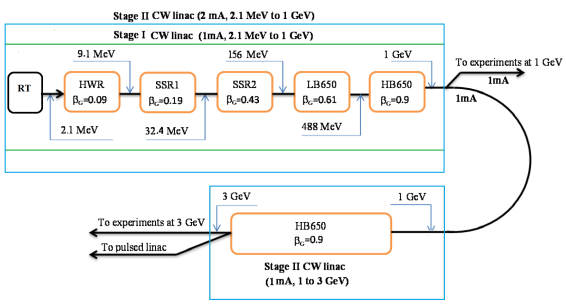

Figure 1: Acceleration scheme in Project-X CW linac.

GENERAL

Most of the complexity associated with a high intensity ion linac lays at low energy where dynamics is nonrelativistic and space charge effects are significant. The success of Project-X accelerator complex is therefore decisively dependent on reliable operation of the 1 GeV CW linac at stage-I. Failure of any element such as cavity, solenoid or quadrupole alters the focusing period of the beam, resulting in mismatch in the downstream sections. This, in turn, causes emittance growth and drives halo formation and beam losses. In some cases, the losses may be prevent safe operation. Unscheduled downtime is necessary to replace a faulty element and return to nominal operating conditions. Minimizing such unscheduled downtime is especially important in a multi-user facility where several experiments are running simultaneously. With that in mind, fault scenarios need to be accounted for in the optics design. The design should robust enough to allow localized compensation of the perturbation caused by an RF cavity or magnet failure. This paper presents studies performed to analyze various fault scenarios at critical locations in 1 GeV SC CW linac at stage-I of Project-X. Failure mitigation using localized compensation is demonstrated.

LOCAL COMPENSATION METHOD

The local compensation method involves re-tuning of elements in the vicinity of a failed element to restore a smooth beam envelope along the linac. Specifically, the RF phase and field amplitude of cavities are varied to recover the nominal beam energy and the longitudinal profile while

* Work supported by US DOE under contract DE- AC02-76CH03000.
† asaini@fnal.gov

solenoids and quadrupoles are varied to restore the transverse dynamics. The constraints and assumptions applied during local compensation for Project-X SC CW linac are summarized below:

- Cavity accelerating fields: Fields are varied to recover nominal beam energy subject to the constraint that surface peak magnetic field in cavity should not exceed 70 mT.
- Cavity synchronous phases are varied in such a way that ratio of synchronous phase to longitudinal beam size is greater than 4. This assumption is made to achieve sufficient longitudinal acceptance.
- Field gradient in quadrupoles and axial magnetic field in solenoids are varied subject to the constraint that they cannot exceed design limits. These are 10 T/m and 6 T for quadrupoles and solenoids respectively.
- Minimum user disruption: The number of re-tuned elements is minimized in order to expedite the process of compensation.
- Local compensation cannot result in any losses (100% transmission).

FAULT SCENARIOS IN CW SC LINAC

Sensitivity of the linac performance to element failure is location dependent. Studies have been performed for different fault scenarios to understand their impact. The fault scenarios at the most critical locations are discussed in this section.

Failure of First SC Cavity in HWR Section

The HWR is the first SC section in the linac. It accelerates and focuses the beam coming out of the MEBT. One focusing period in the HWR section is composed of a solenoid and a HWR cavity. Failure of the first cavity in the HWR section is considered the most critical due to the large transverse and longitudinal beam size at this location. Since the beam is non-relativistic (2.1 MeV) failure of the first HWR cavity results in significant phase slippage that tends to grows in amplitude and ultimately causes beam losses in high energy section.

The local compensation method is applied to re-tune the beam optics. A bunching cavity and a triplet in the upstream MEBT, one solenoid in the same period of failed cavity and one solenoid and one HWR cavity in each of the three downstream HWR periods are used to recover a smooth beam profile. In addition, two HWR cavities (one in each of the two following periods) is used to recover the design energy at the end of the HWR section. Figure 2 and figure 3 show $1\sigma_{RMS}$ longitudinal beam size and normalized rms longitudinal emittance respectively. Abrupt changes in beam size and emittance characterize the beam losses which occur at the beginning of 650 MHz, LB section. It can be observed that there is no beam loss after

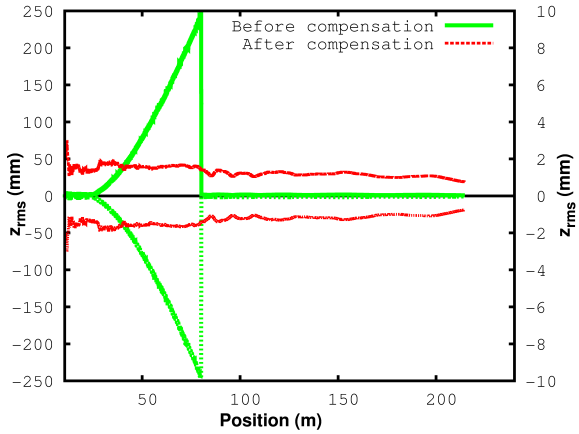

Figure 2: $1\sigma_{RMS}$ longitudinal beam size before (green) and after (red on secondary y-axis) local compensation of failure of first SC cavity in HWR section.

application of the local compensation method; the longitudinal emittance is also restored. Figure 4 shows the synchronous phase in the cavities and beam size for the re-tuned linac. Even with new setting of synchronous phases, the longitudinal acceptance is sufficient to accommodate a $6\sigma_{RMS}$ beam.

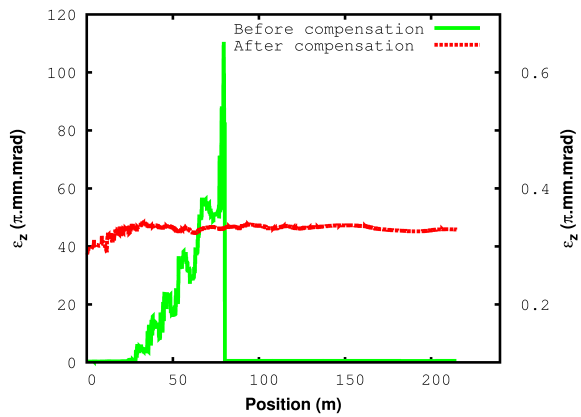

Figure 3: Normalized RMS longitudinal beam emittance before (green) and after (red on secondary y-axis) local compensation of failure of first SC cavity in HWR section.

Failure of First SC Quadrupole Doublet in LB Section

Solenoids are used to provide transverse focusing at low energy i.e. within the HWR, SSR1 and SSR2 sections. They are replaced with quadrupole doublets in the low beta (LB) and high beta (HB) sections. The nominal match between the SSR2 and LB section is very sensitive and involves outermost elements on both sides. Failure of the first SC quadrupole doublet is considered a critical event: it causes significant mismatch and envelope modulation in the downstream sections. Figure 5 shows $1\sigma_{RMS}$ transverse beam envelope before and after local compensation. It can be observed that failure of first SC quadrupole doublet in LB section results in significant distortion of trans-

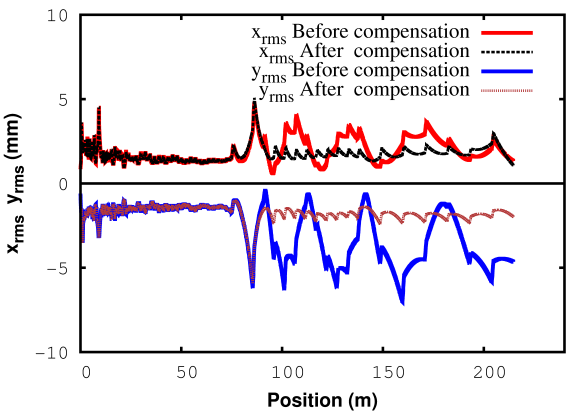

Figure 5: $1\sigma_{RMS}$ transverse beam envelopes before and after local compensation of failure of first SC quadrupole doublet in LB section.

verse beam profile, causing emittance growth in the downstream sections as shown in Figure 6. Again, application of the local compensation method results in a restored transverse beam profile and controlled emittance growth.

Failure of First Cavity in LB Section

Studies were performed to analyze the impact of a cavity failure at the frequency transition from 325 MHz to 650 MHz. It is found that failure of the first SC cavity in the LB section results in a 9 MeV beam energy reduction at 1 GeV linac output. However, no beam losses are observed. Fig. 7 shows that there are no abrupt changes in emittances. Emittance growth relative to baseline lattice [2] is less than 3% in longitudinal and horizontal plane and less than 7 % in vertical plane at the end of linac. We conclude that failure of cavity in the higher energy sections of the linac has minimal impact on performance.

CONCLUSION

Various fault scenarios were studied for the current Project-X baseline SC CW linac. Failures at critical locations, especially at low energy result in significant emittance growth and beam losses. Using local compensation, the optics design is flexible enough to allow recovery from failure of a RF single cavity or transverse focusing element. The output beam parameters and smooth beam profile in all planes are restored and 100% beam transmission is achieved.

DESIGN ISSUES OF HIGH INTENSITY SC CW ION LINAC FOR PROJECT-X FACILITY*

A. Saini†, N. Solyak, V. P. Yakovlev, Fermilab, Batavia, IL 60510 U.S.A.

Abstract

Project-X is a high intensity proton facility which is primarily based on superconducting (SC) continuous wave (CW) linac. One of the most challenging tasks of Project-X facility is to have robust design of SC CW linac which can provide high quality beam to several experiments and subsequent pulsed linac simultaneously. Among the various technical problems associated with the SC CW linac, halo formation, beam mismatch, uncontrolled emittance growth and beam losses are the most crucial as they can limit overall performance and reliability. Scope of this paper is to address these issues for reference design of Project-X SC CW linac.

INTRODUCTION

The application horizon of particle accelerators has been widening significantly in recent decades. Where large accelerators have traditionally been the tools of the trade for high-energy nuclear and particle physics, applications in the last decade have grown to include large-scale accelerators like synchrotron light sources and spallation neutron sources. Applications like generation of rare isotopes, transmutation of nuclear reactor waste, sub-critical nuclear power, tritium production, radiation damage studies, studies of rare processes and generation of neutrino beams etc. are the next area of investigation for accelerator scientific community all over the world. Such applications require high beam power in the range of few mega-watts (MW). One such high intensity proton beam facility is proposed at Fermilab, named as Project-X [1]. The success of Project-X facility is primarily dependent on reliable operation of 1 GeV CW linac at first stage which is capable of delivering 2 MW beam power. A detailed description of baseline design of the CW linac is presented elsewhere [2].

Design of the high beam power accelerators are based on stringent beam losses limit. High beam losses can result in severe problem in terms of radio-activations. The cumulative experience of high intensity operation with existing facilities such as LANSCE [3] is utilized to set threshold limit of beam losses. In order to ensure hand-on-maintenance in safe environment, beam losses must be limited to 1 W/m for beam energy at 1 GeV. This paper addresses main characteristics and crucial beam dynamics design issues for the high intensity ion linac in framework of 1 GeV SC CW linac for the Project-X facility.

EMITTANCE GROWTH

A low beam emittance ensures good output beam quality. Thus, minimal emittance growth along the linac is one of the primary objectives of optics design. The ion source determines initial transverse emittance of the beam which is transported to the RFQ through the low energy beam transport (LEBT) section. The magnets aberrations and non-linear space charge forces can result in a increase of transverse emittance in LEBT. It can be controlled, keeping beam size small and applying space charge neutralization. The longitudinal emittance is formed in the RFQ. A good beam matching at the upstream end of the RFQ minimizes transverse and longitudinal emittance growth along the RFQ. It is followed by the medium energy beam transport (MEBT) section which is comprised of bunching cavities and focusing magnets. Following is a SC CW linac. A robust design is capable to conserve emittance along the linac. It can be achieved using short regular focusing periods especially at low energy part of the linac. It results in smooth and linear changes in phase advance per meter (k). However, zero current phase advance in a focusing period should be kept below 90^0 to avoid envelope instability [4]. In order to avoid parametric resonance, focusing in linac is chosen such that $k_l \neq 2k_t$. Where k_l, k_t are wave numbers of the longitudinal and transverse oscillations respectively. Furthermore, non-linear space charge forces can result in excitation of coupling resonances which causes coupling between longitudinal and transverse motion. It results in abrupt emittance transfer between the planes. Figure 1 shows emittance coupling between longitudinal and transverse plane in first few sections of one of the variants of Project-X CW linac. It can be noticed that longitudinal emittance ϵ_l reduces at the expense of transverse emittance ϵ_t. In order to mitigate free energy transfer from one

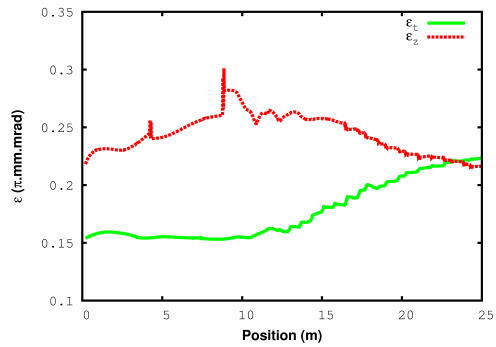

Figure 1: Emittance coupling between longitudinal and transverse plane.

Copyright © 2013 CC-BY-3.0 and by the respective authors

plane to another, equipartitoning is required. Condition of equipartitioning is:

$$\frac{T_t}{T_l} = \frac{k_t \epsilon_t}{k_l \epsilon_l} = 1 \qquad (1)$$

where T_t and T_l are temperatures in transverse and longitudinal plane respectively. In order to achieve efficient acceleration, focusing periods vary along the linac. Therefore, it is difficult to satisfy equipartition condition through out the linac. In this scenario, free energy transfer from one plane to another is suppressed by proper selection of working points (phase advance per period) in tune space where nonlinear space charge modes are stable. The Hofmann stability diagram [5] represents stability region in tune space that distinguishes stable modes from those which lead to coupling. Figure 2 shows working points of lattice that corresponds to Fig. 1. It can be noticed that some points are placed in stop-bands (region where space charge modes are unstable). It explains the reason of emittance exchange shown in Fig. 1.

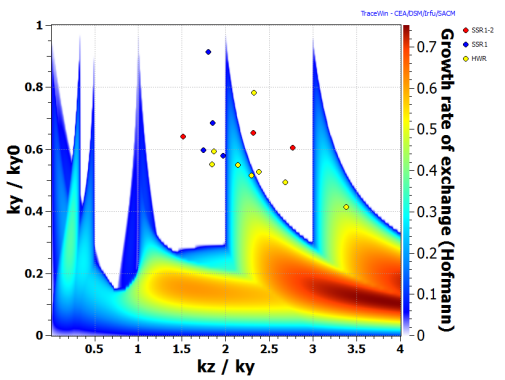

Figure 2: Hofmann stability chart: Distribution of working points in tune space.

The baseline design of Project-X CW linac involves no emittance exchange between the planes. Emittance growth [2] with respect to initial emittance is less than 4% in longitudinal plane, $\sim 10\%$ and 14% in horizontal and vertical planes respectively.

ACCEPTANCE

In high intensity linac, acceptance parameter is a vital mean to measure linac performance in term of beam losses. It is determined by largest beam size that can be transmitted through the linac without any particle losses. Thus, large beam acceptance corresponds to high tolerances against errors. A choice of physical aperture of beamline elements sets transverse acceptance of the machines. Preliminary beam-dynamics studies using numerical simulation codes helps to make optimal choice of aperture. Figure 3 shows transverse acceptance of 1 GeV SC CW linac for Project-X. An input distribution (shown in red) is generated with relatively very large emittance than nominal beam emittance in horizontal plane and relatively smaller in others. Distribution is tracked through the linac. Area occupied by initial coordinates of transmitted particles (shown in green) trace the acceptance of linac in this plane. It can be observed that transverse emittance is sufficient to accommodate 6σ beam (shown in blue).

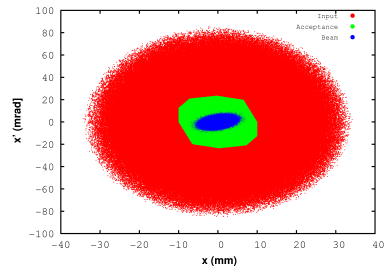

Figure 3: Transverse acceptance (green) of 1 GeV SC CW linac of Project-X with 6σ beam.

The complexity of ion linac is associated with the fact that beam velocity changes significantly during acceleration along the linac. Thus, to achieve efficient acceleration, different families of cavities are used along the linac. The Project-X SC CW linac is segmented into three section on the basis of operational frequencies of cavities (162.5 MHz, 325 MHz and 650 MHz). A careful matching is required between these sections otherwise it may introduce a discontinuity in average longitudinal force per period and limits longitudinal acceptance of the linac. In order to investigate most sensitive section in SC CW linac, longitudinal acceptance is analyzed at different locations in SC CW linac. It is found that longitudinal acceptance is primarily limited by the SSR2 section and no significant degradation is observed in subsequent sections. Figure 4 shows longitudinal acceptance after each section in linac. It is large enough to enclose 6σ beam (black). Thus no losses have been

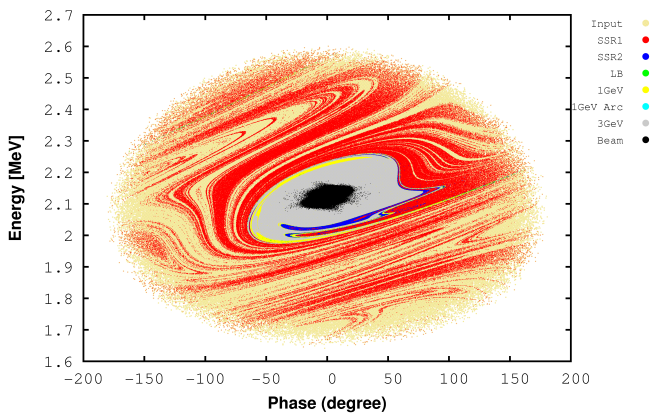

Figure 4: Longitudinal acceptance of SC CW linac of Project-X with 6σ beam (black).

observed for nominal operation of linac. Particles which fall out of longitudinal acceptance (grey region in Fig. 4) are no longer accelerated in linac, hence are not matched with downstream magnetic focusing elements which are designed for fully accelerated particles and consequently,

Copyright © 2013 CC-BY-3.0 and by the respective authors

they are lost due to transverse mismatch. Typically, the high intensity linac are designed to obtain large longitudinal acceptance in order to deal with longitudinal halo that usually results in beam losses at high energy part of linac.

HALO DEVELOPMENT

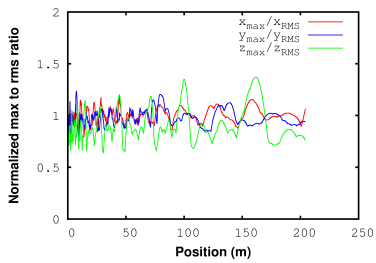

Figure 5: Normalized *maximum to RMS ratio* in all planes along 1 GeV SC linac.

The existence of beam halo is an important characteristics of the high intensity ion beam. Typically, beam halo is developed in low energy section and it is acquired large amplitude in high energy section that results in particle losses. It is most concerned aspect of the design of high intensity machine in the regime of stringent beam losses limit. There are several definition to quantify beam halo [6] but an important figure of merit that can be incorporated during lattice design is *max to RMS ratio*. It is ratio of maximum displacement to the RMS size of matched beam. Figure 5 shows *max to RMS ratio* normalized to initial value along the 1 GeV CW linac. Keeping this ratio close to one ensures that halo amplitude does not grow up along the linac. It is also useful to identify location of halo formation. It can be noticed from Fig. 5 that location around 100 m and 160 m is sensitive to longitudinal halo formation in linac.

Beam Mismatch

Beam mismatch is major source of halo development in linac. Studies are performed in order to analyze the impact of initial mismatch on halo formation for 1 GeV SC linac. Variation of 20% and 60% in initial Twiss Parameters in all planes are applied. All simulations are performed using a 6σ Gaussian distributed beam of 10^6 particles. Figure 6 shows longitudinal particle distribution at the end of linac for three cases no mismatch, 20% and 60% beam mismatch. Redistribution of particles can be observed in presence of mismatch which results in more particles in tail of distribution (radius >3). It is due to core oscillations that results in energy transfer from core movement to single particle orbit. It can also be noticed that redistribtion occurs faster in case of 60% mismatch (radius $\sim$ 2) than 20% (radius $\sim$3). It is a consequences of additional "free energy" introduced via mis-matched in the system. Similar

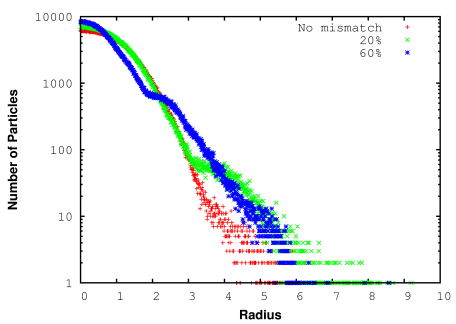

Figure 6: Longitudinal particle distribution at the end of 1 GeV linac (Radius = $|\sigma|$).

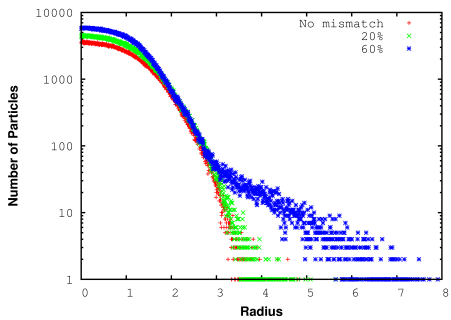

Figure 7: Transverse particle distribution at the end of 1 GeV linac (Radius = $|\sigma|$).

behavior is observed in horizontal plane. Figure 7 shows horizontal particle distribution at the end of linac. It can be noticed that only 60% mismatch results in significant halo development.

CONCLUSION

Controlled emittance growth and low beam losses are main objectives of the design of high intensity ion linac. Equipartition among the planes and avoiding stop-bands in the Hofmann stability diagram are possible way to avoid emittance exchange in presence of non-linear space charge forces. Large machine acceptance and suppression of mechanisms that lead to halo development are essential for reliable operation of the linac. Design of 1 GeV SC CW linac for Project-X is sufficiently robust to sustain stable operation even in presence of spread in design parameters. No beam losses are observed along the linac even in presence of 60 % initial mismatch of the beam.

LAYOUT OF PROJECT-X FACILITY: A REFERENCE DESIGN*

A. Saini†, J.-P. Carneiro, D. Johnson, J.-F. Ostiguy, N. Solyak, V. P. Yakovlev
Fermilab, Batavia, IL 60510 USA.

Abstract

Project-X is a proposed high intensity proton facility to be built at Fermilab. It will be a multi-user facility which can support several experiments simultaneously. In the current scenario, the facility would be built in three stages. Each stage is associated with compelling scientific programs and is in synergy with existing Fermilab infrastructure. This paper presents the current reference design and discusses the main motivations and requirements driving the optics and physical layout.

INTRODUCTION

Project-X is a proposed high intensity proton facility to be built at Fermilab. Given the present economic environment, a staging strategy has been developed. The facility would be built in three stages. Each stage is associated with compelling scientific research programs and planned so that construction of each new stage has minimal influence on the operation of preceding ones. This approach has the benefit of limiting downtime during construction. A schematic of the Project-X facility is shown in Fig 1. A detailed description of the staging approach is presented elsewhere [1].

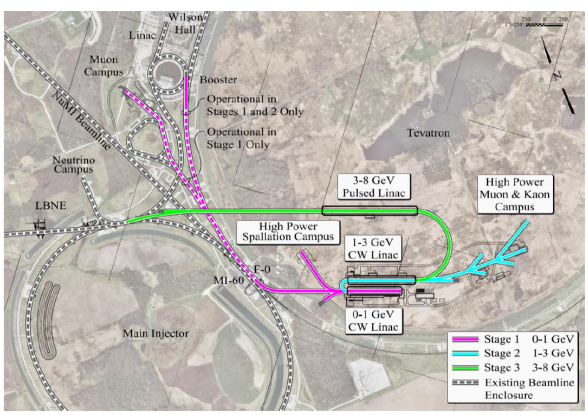

Figure 1: Layout of Project-X facility.

Success of the Project-X facility is critically dependent on the robustness of the superconducting (SC) continuous wave (CW) linear accelerator (Linac) design. While the reference design parameters [1] have been established, the optics is still evolving to incorporate technical constraints and to address issues that may potentially cause degradation of beam quality and particle losses. In this paper we describe recent changes in the beam optics.

STAGE -I

The most challenging issues associated with Project-X facility would be addressed at Stage-1 which comprises a room temperature front-end followed by a 1 GeV SC CW linac delivering a 1 MW of beam power.

Ion Source, LEBT & RFQ

The front-end of Project-X consists of an ion source, a low energy beam transport (LEBT) section, an RFQ and a medium energy beam transport (MEBT) section. The ion source [2] operating in dc mode is capable of delivering a beam of H^- ion at 30 keV at maximum current of 10 mA. It is followed by the LEBT which includes three solenoids, a slow switching dipole magnet, a chopper assembly and diagnostic devices to characterize the beam. The chopper consists of a kicker and a beam absorber. It will primarily be used to produce variable low duty pulses during commissioning; it can also serve as pre-chopper to assist the MEBT high bandwidth chopping system. A detailed description of the LEBT layout and its component was presented elsewhere [1].

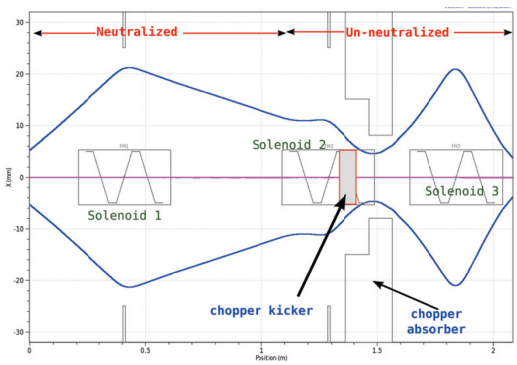

Figure 2: $3\sigma_{RMS}$ transverse beam envelope along LEBT (shown for fully neutralized operation).

A LEBT with solenoidal focusing usually requires neutralization to mitigate strong space charge defocusing. However, chopping of a neutralized beam can be problematic because the typical neutralization time is a few tens of micro-seconds, resulting in a time dependent optical perturbation. The Project-X LEBT design attempts to address this issue by incorporating two regions: (i) a fully neutralized region which extends from exit of the ion source to upstream edge of the second solenoid and (ii) an un-neutralized region from that point to the RFQ entrance port. Alternatively, the LEBT can also be operated in fully neutralized regime. Figure 2 shows a $3\sigma_{RMS}$ transverse beam envelope for fully neutralized operation. To

Copyright © 2013 CC-BY-3.0 and by the respective authors

minimize spherical aberrations through the solenoids, the beam transverse size is kept below half of the solenoids radial aperture [3]. Emittance growth in the LEBT occurs in the un-neutralized region and is driven by space charge. The LEBT is followed by an RFQ operating in CW mode at a resonant frequency of 162.5 MHz. It accelerates the beam to 2.1 MeV and provides longitudinal beam structure. Numerical simulations predict 99.8% beam transmission for nominal operation at 5 mA beam current. However, both transmission and output emittances strongly depend on beam matching at entrance of the RFQ. Figure 3 shows the evolution of the normalized RMS beam emittances through the LEBT and the RFQ for two modes of operation of the LEBT: (i) a partially neutralized LEBT (un-neutralized region after second solenoid) and (ii) a fully neutralized LEBT. It can be observed that beam emittances through the RFQ are significantly larger for partially neutralized LEBT operation. This is a consequence of non-linear space charge effects. Beam transmission through the RFQ is also reduced to 98.4 %.

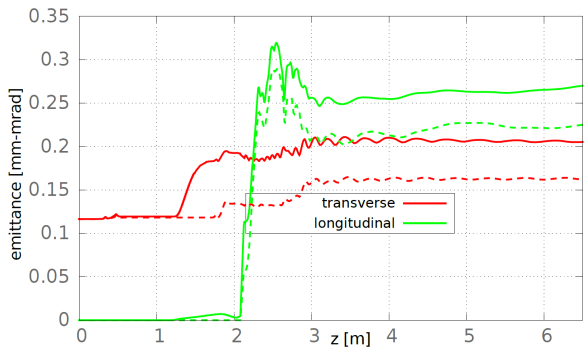

Figure 3: Normalized RMS beam emittances through LEBT and RFQ. Solid: LEBT with un-neutralized section. Dashed: fully neutralized LEBT.

MEBT & 1GeV SC CW Linac

The RFQ is followed by the MEBT and a 1 GeV SC CW linac. In order to improve the robustness of the design, the beam optics has been optimized. It can now accommodate, at the MEBT entrance, a longitudinal emittance larger than the reference design value [1]. The layout and beam optics are discussed elsewhere [4]. Changes in beamline elements are presented in [5]. A significant change is the introduction of a new β_G =0.92 cavity in the high energy 650 MHz section. This cavity has larger aperture (118 mm) which is beneficial in terms transverse acceptance in this section and avoids potential trapping of higher order modes. This cavity is therefor well suited to a future upgrade for higher current operation. The optics described in the reference design report was based on 5-cell, β_G =0.90, 650 MHz cavity (designed with aperture of 100 mm) in high energy section; the new cavity provides similar RF performance with minimal influence on beam optics.

1 GEV EXTRACTION LINE

Stage 1 of Project-X will provide 1 MW of beam power. This power will be distributed between a 1 GeV experimental area and the Booster/Muon campus using a special extraction scheme designed to allow both experimental facilities simultaneously. This is achieved by multiplexing the beam time structure. For stage 2, an additional MW of beam power will be delivered to the 1-3 GeV CW linac using the same extraction line. Figure 4 shows a conceptual layout of the extraction line which includes a vertical deflection unit (VDU) and a horizontally bending Lambertson magnet. The vertical deflection unit is composed of an RF deflecting cavity with trim dipoles positioned at the upstream and downstream ends.

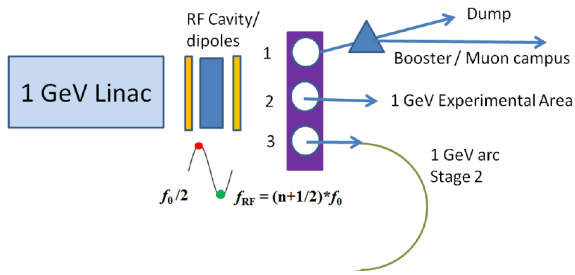

Figure 4: Conceptual design of 1 GeV extraction line.

RF Deflecting Cavity and Trim Dipole Magnets

The RF deflecting cavity at the end of 1 GeV linac splits the beam into two equal parts by imparting equal and opposite vertical kicks to successive bunches. The kick direction depends on the relation between the beam phase and the rf phase. Consequently, with f_0 representing the bunch frequency, the required rf frequency is

$$f_{RF} = (n + 1/2)f_0 \quad (1)$$

where n is an integer. The deflecting cavity at 1 GeV is designed to operate at 406.25 MHz (n and f_0 are equal to 2 and 162.5 MHz respectively). It is capable of providing maximum transverse voltage ($\Delta pc/e$) of 7 MV which corresponds to a deflecting angle θ of 4 mrad at 1 GeV. The trim dipoles on both sides of the cavity are identical and steer the beam in the vertical plane. Table 1 presents a summary of the cavity and dipole setting required to direct the beam to the different experimental facilities at stage I and stage II.

Lambertson Magnet

The VDU is followed by a 3-way Lambertson magnet. If there is no net deflection from the VDU, the beam goes through the field free region along the axis of Lambertson magnet and is delivered to the 1 GeV experimental area. However, when the beam experiences a net deflection from the VDU, it passes either through the upper or lower field region of the Lambertson and is steered horizontally. The direction of the horizontal steering is determined by the

Copyright © 2013 CC-BY-3.0 and by the respective authors

Table: 1 Operational scenarios for the VDU. 4th column (Dipole) is the total deflection from both dipoles.

Stage	Destination	deflecting cavity	Dipole	DSW
1	Muon Campus	+θ	+θ	
	1 GeV EA	-θ	+θ	
	Booster	off	+2θ	
	Dump	off	+2θ	on
2	1 GeV EA	+θ	-θ	
	Booster	off	+2θ	
	Dump	off	+2θ	on
	1 GeV arc	-θ	-θ	

sign of the net vertical deflection (+/-θ) from the VDU. Figure 5 shows beam separation scheme through Lambertson magnet.

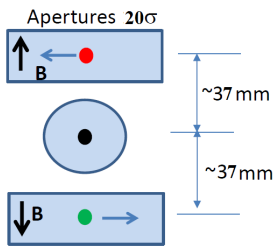

Figure 5: Schematic of 3-way Lambertson magnet. The beam is steered toward the left or the right depending on the sign of the vertical deflection imparted by the VDU.

Beam Optics through 1GeV Extraction Line

Figure 6 shows $1\sigma_{RMS}$ beam envelope through the 1 GeV extraction line. The RF deflecting cavity is set to provide a vertical deflection angle of 3 mrad while each dipole provides a 1.5 mrad vertical steering. A special quadrupole doublet with large aperture of 120 mm is placed just before the Lambertson magnet to cancel the vertical slope of the beam centroid so that it can enter the Lambertson magnet field region in the horizontal plane. The VDU to Lambertson distance is chosen to provide enough beam separation (15 - 20 σ_{RMS}) between deflected and undeflected beam. With the present settings, this separation is 20 σ_{RMS} (37 mm) (as mentioned in Fig 5). The Lambertson magnet is 1 m long; it provides an integral magnetic field of 0.2 T-m, corresponding to a ∼35 mrad deflection in the horizontal plane. The distance from the Lambertson to the first element of each beamline is optimized to provide enough horizontal separation. It can be observed from Fig 7 that introduction of the the extraction line does not contribute to emittance growth. The impact on the downstream optics is expected to be minimal. Minor retuning of the first section of the subsequent stage may be required to match the beam parameters at the entrance.

STAGE -II & STAGE -III

At stage II, 1 MW of beam power will be delivered to the 1-3 GeV SC CW linac through a 180^0 arc for further acceleration. Extraction line at the end of this stage will distribute 3 MW of beam power to different experimental facilities using a concept similar to the one discussed for

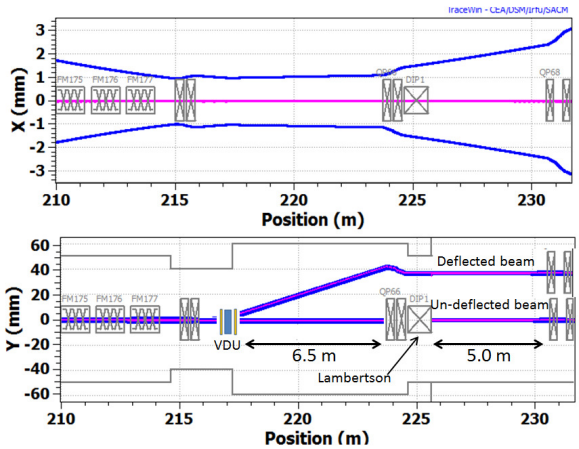

Figure 6: Beam RMS envelope in transverse plane through 1 GeV extraction line.

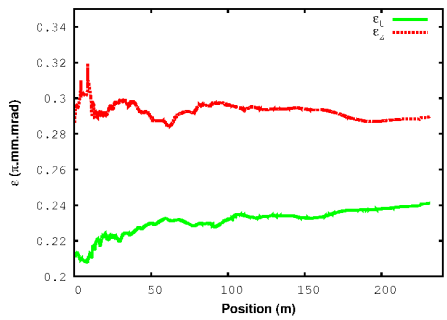

Figure 7: Longitudinal (green) and transverse (purple) beam emittance through stage 1.

the 1 GeV extraction line. In the final stage, 350 kW of beam power will be transported to a 3-8 GeV pulsed linac through another 180^0 arc. Details of the beam optics for the 1-3 GeV CW linac and the pulsed linac are discussed elsewhere [4].

SUMMARY

The beam optics is compatible with the Project-X staging strategy. Furthermore, it provides sufficient acceptance to accommodate, if necessary, larger emittances coming out of the RFQ.

Schempp, IAP, Goethe University, Frankfurt am Main, Germany, J. Haeuser, Kress GmbH, Biebergemuend, Germany

Abstract

Initial acceleration of the beams in the LANSCE linear accelerator at Los Alamos National Laboratory is still presently accomplished through the use of two 750-keV Cockcroft-Walton (CW) based injectors. To reduce long-term operational risks and to realize future beam performance goals, plans are underway to replace the existing H^+ CW injector with a modern replacement, 4-rod Radio-Frequency Quadrupole (RFQ) based front end. Significant technical progress has been made since we last reported on this project. Status and progress of the design and fabrication of the RFQ, the RF system, beam transports, and integrated accelerator test stand will be discussed.

INTRODUCTION

The Los Alamos Neutron Science Center (LANSCE) currently supports a broad user base including the neutron scattering community, isotope production, basic science, and national security programs by providing multiple beams to several diverse experimental areas. The LANSCE linac accelerates negative hydrogen ions (H^-) and protons (H^+) simultaneously. An 800-MeV H^- beam is delivered at 20 Hz to the proton storage ring/moderated neutron production target for a suite of neutron-scattering instruments (Lujan Center), at 40 Hz to an un-moderated spallation target for nuclear physics cross-section measurements and microchip irradiations for industry (WNR), and on-demand at ~1 Hz for proton radiography (pRad), and at 20 Hz for ultra-cold neutron production (UCN). Protons are used for isotope production (IPF) at 100 MeV. High-power operation (10% total RF duty factor; 100 Hz x 625 μs; 16.5-mA peak proton beam current) has provided 800-kW average beam power at 800-MeV but was halted in 1998 after shut-down of the nuclear physics mission that supported high-power beam operations. Upgrades currently underway will restore full 120-Hz operations and allow high-power operation in support of planned new missions [1] that will require MW-level average beam powers.

Beams are delivered to the LANSCE experimental areas on a pulse-by-pulse basis, initially accelerated in two CW-based injectors, for H^+ and H^- beams, respectively. At present, LANSCE delivers up to three different H^- beams based on user requirements. The highest average-current H^- beam (100-125 μA) is first accumulated in the proton storage ring (PSR) and then extracted to the moderated neutron spallation target at the Lujan Center. This beam is chopped to provide an extraction gap in the PSR circulating bunch. By comparison, the WNR facility typically requires a single linac micropulse every few microseconds within the standard 625-μs macropulse. Producing the widely-spaced single micropulses requires the use of a chopper and low-frequency buncher in the H^- injector. These micropulses typically contain about 2.5 times more charge than the standard H^- linac microbunch. The other two H^- beam users, pRad and UCN, have beam requirements that require chopped and pre-bunched beams somewhat similar to the Lujan beam. The present dual-beam CW-based injector scheme for the LANSCE linac is shown in Fig. 1. The two beam species are merged into a common beam transport line and bunched before injection into the drift-tube linac (DTL) with a capture efficiency of approximately 80%.

Typical parameters for the 60-Hz (present maximum beam repetition rate) H^- beams are given in Table 1. Comparing chopping requirements against duty factor for these three beams, two categories emerge: low-duty factor beams with modest chopping requirements (Lujan, pRad) and a high-duty factor beam with demanding chopping requirements (WNR). H^+ beam parameters are also shown in Table 1. Future 120-Hz, H^+ beam requirements are shown in Table 2. An average H^+ beam power of 25 kW (250 μA) is required to be delivered to IPF at 100 MeV. An additional average beam power of 0.75 MW at 800 MeV is expected to be available for other applications beginning in 2017. Several options for enhanced future high-power beam operations can be found in Ref. 2.

Assessment of failure modes of our CW injectors revealed the potential for significant disruption of the beam operations at LANSCE [3] either due to catastrophic failure of major components and/or unavailability of spare parts.

Our strategy to reduce operational risks associated with the current CW-based injector systems involves the eventual replacement of these systems with modern radio-frequency quadrupole (RFQ) based injectors. Reliability is expected to improve due to reduced overall complexity of the systems and by modernization. RFQ accelerators are employed worldwide and have demonstrated stable and reliable operation.

To meet the above requirements while maintaining all existing beam delivery capabilities, including the high duty factor and demanding chopping requirements for the WNR beam, we are considering a 3-RFQ upgrade [3] to the present injector system that would be implemented in a staged approach with development of the H^+ RFQ having highest priority due to its impact on our near-term

high-power performance goals. In this scheme (shown conceptually in Fig. 2), a single 201.25-MHz RFQ will provide bunched but un-chopped H^+ beam of up to 35 mA. A second 201.25-MHz RFQ will provide bunched and chopped H^- beam for Lujan, pRad and UCN. Finally, a third lower-frequency RFQ, at possibly 67 MHz, will produce the intense single H^- linac micropulses for WNR.

Table 1: Typical 60-Hz LANSCE Beam Parameters

Beam/Area	Duty Factor	Chopping Specs
Lujan, H^-	20 Hz x 625 μs = 1.25%	290 ns burst every 358 ns
WNR, H^-	40 Hz x 625 μs = 2.5%	Single micropulse every 1.8 μs
pRad, H^-	1 Hz x 300 μs = 0.03%	20-30, 60 ns beam bursts, variable spacing
UCN, H^-	20 Hz x 625 μs = 1.25%	Variable
IPF, H^+	40 Hz x 625 μs = 2.5%	None

Table 2: Future 120-Hz LANSCE H^+ Beam Parameters

Beam/Area	Duty Factor	Ave. Current
IPF (100 MeV)	20 Hz x 770 μs = 1.54%	250 μA
Area A (800 MeV)	100 Hz x 770 μs = 7.7%	0.75-1.25 mA

We have developed an H^+ RFQ design and beam-transport layout compatible with the existing H^- CW injector that require no changes beyond the merging dipole upstream of the common H^+/H^- beam transport section (See Fig.1). This will allow for early implementation of the new H^+ system, independent of the longer-term plans to implement multiple RFQ injectors. Following completion of the RFQ, the RFQ will first be operated and commissioned on a separate test stand prior to integration at the front end of the LANSCE linac.

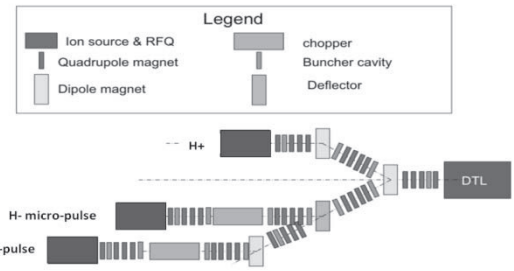

Figure 2: Conceptual layout of the 3-RFQ H^+/H^- injector system for LANSCE.

PROJECT STATUS

RFQ

The final physics design of the 4-rod RFQ has been completed and accepted. The physics design was completed and verified through a joint effort between the Institute of Applied Physics (IAP) at Goethe University, Frankfurt, Germany, and Los Alamos [4].

A final mechanical design review was held in April 2013. Fabrication of the RFQ is expected to take 9-12 months in Germany by our project partner Kress, GmbH, with delivery to Los Alamos before the end of 2014.

The RFQ is required to operate at a high duty factor of up to 15% and must meet strict beam performance requirements. Complementary simulations using the TRACE 2-D/3-D, PARMTEQM and PARMILA codes [5], Beampath [6], the CST Studio suite of codes [7] including Particle Studio, and the ANSYS [8] code were used to validate the design results.

To ensure mechanical and operational robustness of the RFQ, several technical evaluations were completed prior to acceptance of the design [9]. These included: addressing potential structure cooling issues, evaluation of tuning range, impact of stem spacing on frequency and field flatness, impact of vane cross-section and stem geometry on dipole fields, and investigation of end-region field effects on emittance growth and final output energy.

Ion Source and Low-Energy Beam Transport

The extraction geometry of our present H^+ duoplasmatron ion source, normally operated at a 35-kV extraction voltage, has been redesigned to produce a 35-mA beam with a transverse emittance of < 0.02 π-cm-mrad, normalized [10]. Modifications to an existing source and testing will be required to verify the new design.

Although previously a short electrostatic LEBT for beam matching from the ion source to the RFQ was considered, a new 2-solenoid magnetic LEBT has been designed and optimized to transport beams over a wide range of space-charge neutralization and transverse emittance, while allowing sufficient space for diagnostics and a beam deflector [10]. The design layout minimizes the beam size in the LEBT and potential emittance growth due to solenoid aberrations.

Copyright © 2013 CC-BY-3.0 and by the respective authors

RF System

After fabrication of the RFQ is complete, the alignment, tuning, and low-power testing will be done in Germany with Los Alamos participation. High-power testing will be done at Los Alamos and is expected to use the High Power Test Facility at LANSCE [11]. The RFQ will be tested at full peak power and the full 15% duty factor (120 Hz, 1250 μs RF pulse length) using the 201.25-MHz Thales TH781 Intermediate Power Amplifier and associated low-level RF controls capability of the test facility. The estimated full peak power required for the test is 90-100 kW, assuming a realistic surface conductivity and a 15%-20% additional power margin. Design of the final RFQ RF system has not yet started.

Medium-Energy Beam Transport

A new Medium-Energy Transport (MEBT) line to match the RFQ output beam into the DTL has been designed to replace the existing H^+ beam transport line shown in Fig. 1 [12]. The MEBT must be as compact as possible to preserve the beam emittances. To do so, we plan to use multiple compact 201.25-MHz quarter-wave bunchers [13] to minimize the beam phase spread and compact SNS-style MEBT quadrupoles for transverse beam focusing (See Fig. 3). Simulation studies have been completed using the TRACE-3D [5] and PARMILA [5] codes to validate the multi-particle beam dynamics and linac capture (estimated to be 81%).

RFQ Test Stand

Our original plan was to have all necessary preparations for the test stand completed at Los Alamos by the RFQ delivery date so that high-power testing and commissioning with beam could be completed, followed by demonstration over the course of a year of stable operations prior to implementation on the LANSCE linac. However, recent schedule and budget changes require a more phased approach to testing and commissioning of the RFQ.

As mentioned above, preparations are already underway to perform high-power testing of the RFQ. In parallel to fabrication of the RFQ, an intermediate-stage 35-keV ion-source test stand will be assembled, including the LEBT and sufficient diagnostics to confirm performance and reliability of the source, and to match and characterize the beam into the RFQ. Ion-source and high-voltage components have already been procured, with assembly of the test stand to begin soon.

Ongoing efforts to layout the full RFQ Test Stand that will include the ion source, 35-keV high-voltage system, LEBT, RFQ, RF system, MEBT, diagnostics, and controls will continue. These preparations include building support structures and beam transport-line components; procuring magnets, RF systems, and vacuum systems; as well as developing the appropriate diagnostics and controls required.

Particular emphases of the RFQ Test Stand will be long-term reliability and availability of the RFQ and associated systems, and the constraints imposed by dual-species operation of the LANSCE linac on the phase-space distributions of the beam from the RFQ injector. Good measurements of the beam properties, including matching to the DTL, are therefore required during the testing phase of the RFQ [14]. All components of the test stand are being designed to be compatible with implementation as a full replacement system on the LANSCE linac including support structures and all mechanical systems such as vacuum and cooling manifolds, etc.

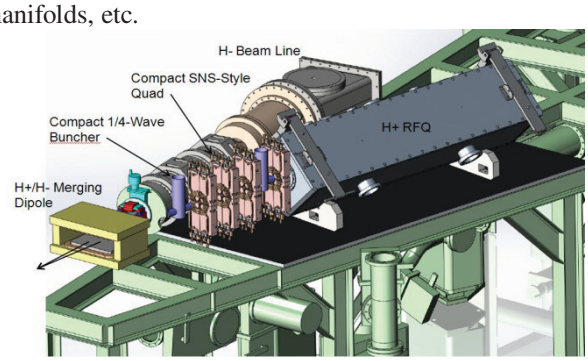

Figure 3: Shown is a preliminary engineering layout of the new H^+ RFQ injector, compact quads, and compact bunchers on the existing LANSCE beam transport line.

EXPERIMENTAL RESULTS FROM A "DIAGNOSTIC" PULSE FOR SINGLE-PARTICLE-LIKE BEAM POSITION MEASUREMENTS DURING ACCUMULATION/PRODUCTION MODE IN THE LOS ALAMOS PROTON STORAGE RING*

J. Kolski†, E. Bjorklund, M. Hall, M. Martinez, and F. Shelley, LANL, Los Alamos, NM, USA

Abstract

Beam position monitors (BPMs) are the diagnostic most used in setting up and documenting the Los Alamos Proton Storage Ring (PSR). One-turn injection can be approximated as single-particle injection with initial betatron position and angle (x_0 and x'_0). The turn-by-turn beam position data from single-turn injection allows measurement of the betatron tune, closed orbit (CO), and injection offset (x_0 and x'_0 at the injection point). In accumulation mode, many turns are injected into the ring, the transverse phase space is quickly filled, and there is no coherent betatron motion. The injection offset, which determines the accumulated beam size and is very sensitive to steering upstream of the ring, is not measurable during accumulation. We review our approach for measuring the injection offset during accumulation, focus discussion on recent experimental results, and compare measurements of the betatron tune, CO, and injection offset in single-turn injection mode and in a "diagnostic pulse" mode.

MOTIVATION

The PSR BPMs[1] are bi-directional, stripline-type with electrode length ∼37 cm (a quarter 201.25 MHz wavelength). The 201.25 MHz longitudinal beam structure, to which the PSR BPMs are sensitive, is imposed during acceleration and decoheres after ∼30 turns in the PSR due to momentum spread and synchrotron motion.

Single-turn injection mode is used to document the PSR. We measure 30 turns of beam position data before the longitudinal beam structure decoheres, which is sufficient to fit the betatron tunes, CO, and injection offset.

Normally, the PSR operates in production mode, where ∼1800 turns are accumulated. With the filled phase space, there is no coherent betatron motion in production mode, so the betatron tunes and injection offset can not be measured, but does yield the CO.

Aside from beam energy, the CO and betatron tunes are independent of machine operation upstream of the ring. The injection offset is very sensitive to steering upstream of the PSR, and we cannot measure this important operational parameter in production mode.

We develop an operation mode we call LBEG+ that enables us to document the PSR by measuring the betatron tunes, CO, and injection offset without affecting delivery of production beam[2]. The scheme is to inject a single turn (diagnostic pulse) on the same machine cycle as the production mode ∼50 μs after the accumulated beam is extracted, see Fig. 1. The 50 μs between production beam and the diagnostic pulse allows the linac RF to recover from the beam-off transient, the injection bump magnets to set to zero, and for residual field in the PSR buncher to dissipate. The diagnostic pulse coasts in the PSR and is lost.

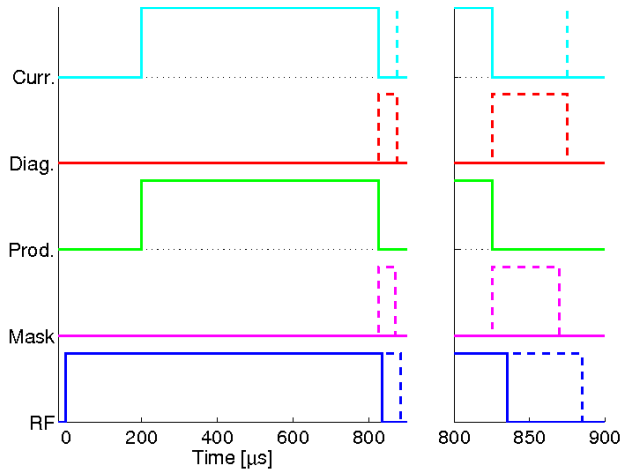

Figure 1: (Color) Timing scheme of one machine cycle for (from bottom to top) the linac RF gate (blue), RF system protect mask (magenta), production beam gate (green), diagnostic beam gate (red), and beam current in transport (cyan) for production (solid lines) and LBEG+ (dashed lines) modes. The right plot focuses on the end of the machine cycle.

LBEG+ AND SINGLE-SHOT MEASUREMENT COMPARISON

Operationally, the hope is for the LBEG+ scheme to replace the single-shot method for measurements of the CO, betatron tune, and injection offset during production. Thus, it is necessary for the CO, tune, and injection offset results measured via the LBEG+ scheme to be equal to the measurements taken in the single-shot scheme. We collected a set of BPM data in single-shot mode, and then collected another set of data in LBEG+ mode for comparison. In this section, we compare the LBEG+ and single-shot results for the CO, tune, and injection offset.

Thirty turns of betatron motion is digitized at each BPM.

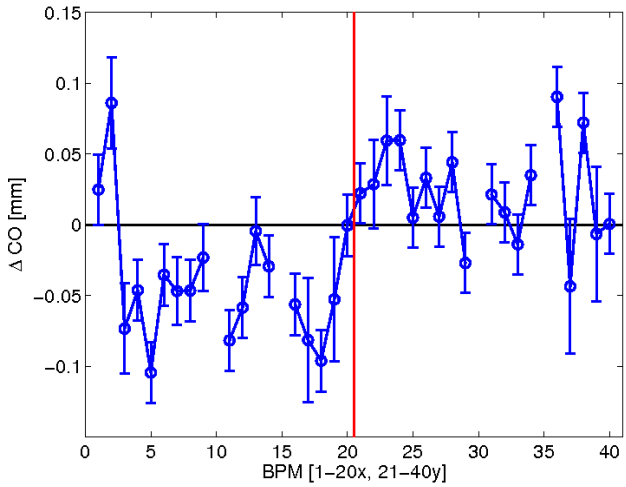

Figure 2: Difference in CO measurements using the single-shot and LBEG+ schemes with one rms uncertainty.

The beam position is fit with a cosine:

$$x_n = A\cos(2\pi\nu(n-1)+\phi) + O_{\text{ffset}} \qquad (1)$$

where A, ν, n, ϕ, and O_{ffest} are the amplitude of betatron motion, tune, turn index, phase, and CO respectively. We also compare the fitted amplitude and phase from single-shot and LBEG+ measurement schemes.

In the comparison plots, we use an ORM BPM indexing convention where BPMs are 1-20 horizontal, BPMs 21-40 are vertical such that BPM 1 and 21 are the horizontal and vertical planes of the first BPM.

Closed Orbit Measurement

The CO describes the accumulated beam centroid position average. For minimum beam loss, we center the CO at all BPMs. The CO measurement results between single-shot and LBEG+ measurement schemes are very similar, Fig. 2, within three rms uncertainties with maximum deviation of 0.1 mm, which is within acceptable tolerance. We conclude the CO measurements yield the same result in both schemes.

Tune Measurement

The tune measurement describes the frequency of betatron oscillation. The tune measurements are very close, Tab. 1, within one rms standard deviation. We conclude that the tune measurement is the same in both single-shot and LBEG+ schemes.

Table 1: Comparison of the Measured Tunes from Single-Shot and LEBG+ Schemes with One RMS Standard Deviation

	ν_x	ν_y
Single-Shot	$0.1898 \pm 4\times10^{-4}$	$0.1870 \pm 2\times10^{-4}$
LBEG+	$0.1900 \pm 4\times10^{-4}$	$0.1870 \pm 2\times10^{-4}$
Difference	2.48×10^{-4}	-5.7×10^{-5}

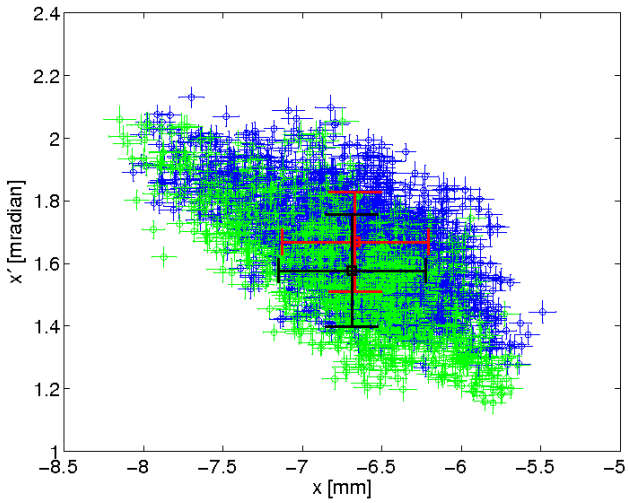

Figure 3: (Color) Horizontal injection offset measurement and the measurement distribution averages with one rms standard deviation from single-shot (blue, red) and LBEG+ (green, black) schemes.

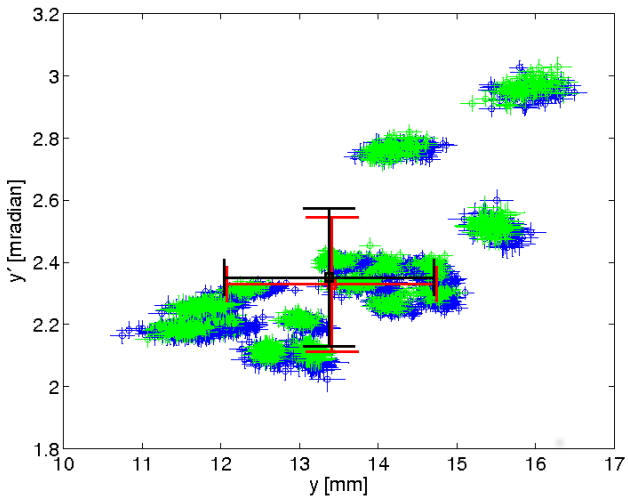

Figure 4: (Color) Vertical injection offset measurement and the measurement distribution averages with one rms standard deviation from single-shot (blue, red) and LBEG+ (green, black) schemes.

Injection Offset Measurement

The injection offset is fit to the turn-by-turn BPM data,

$$x_{i,n} = x_0\sqrt{\frac{\beta_i}{\beta_0}}(\sin\Theta + \alpha_0\cos\Theta) + x'_0\sqrt{\beta_i\beta_0}\sin\Theta - x_{CO_i}, \qquad (2)$$

where $\Theta = 2\pi\nu(n-1)+\mu_{0\to i}$, the indices i, 0, and n indicates values at the i^{th} BPM, the foil, or turn number re-

Copyright © 2013 CC-BY-3.0 and by the respective authors

Table 2: Comparison of the Measured Injection Offsets from Single-Shot and LEBG+ Schemes with One RMS Uncertainty on the Average

	x_0 [mm]	x_0' [mradian]
Single-Shot	$-6.669 \pm 1.1\times10^{-2}$	$1.669 \pm 4\times10^{-3}$
LBEG+	$-6.689 \pm 1.2\times10^{-2}$	$1.577 \pm 5\times10^{-3}$
Difference	2.0×10^{-2}	-9.2×10^{-2}
	y_0 [mm]	y_0' [mradian]
Single-Shot	$13.412 \pm 3.3\times10^{-2}$	$2.329 \pm 5\times10^{-3}$
LBEG+	$13.378 \pm 3.6\times10^{-2}$	$2.351 \pm 6\times10^{-3}$
Difference	-3.4×10^{-2}	2.2×10^{-2}

spectively, x and x' are the phase space position and angle, β, α, and μ are the beta function, its derivative, and the positive phase advance from the foil, and x_{CO} is the CO.

Figures 3 and 4 compare ∼100 measurements of the injection offset from each BPM. For typical operations, we set injection offset to $[x_0,\ x_0',\ y_0,\ y_0'] = [-3.8$ mm, 0.85 mradian, 16.5 mm, 2.8 mradian$]$. Table 2 compares the measurement distribution averages.

The measured injection offsets are quite different from our standard setup. This is an example of how the injection offset can change significantly with upstream tuning and why it is important to be able to measure the injection offset during production.

The islands in Fig. 4 are due to BPM measurement saturation for large beam positions. Each island is measurement from a different BPM, and each BPM has different degrees of measurement saturation depending on the type of BPM and the beam position. PSR BPM measurement saturation is the topic of a future paper.

We observe a statistically significant difference in the injection offset angles between the single-shot and LBEG+ measurements. The deviation is very small, $\sim 10^{-2}$ mradian and within tolerance. We conclude that the injection offset measurement from single-shot and LBEG+ schemes is the same.

Amplitude Measurement

The amplitude of betatron motion can be related to the beta function. Figure 5 compares the amplitude from single-shot and LBEG+ measurements. Note that the measurements agree within 3 rms uncertainties. We conclude the amplitude measurements from single-shot and LBEG+ schemes are the same.

Phase Measurement

The betatron phase can be related to the phase advance and is useful in model verification experiments. Figure 6 compares the phase measurements from single-shot and LBEG+ schemes. We observe a statistically significant and constant offset in the phase difference. The phase deviation is real and is due to the measured difference in injection offset angles discussed previously. Accounting for the very small change in injection offset, we conclude that the phase measurement from single-shot and LBEG+ schemes is the same.

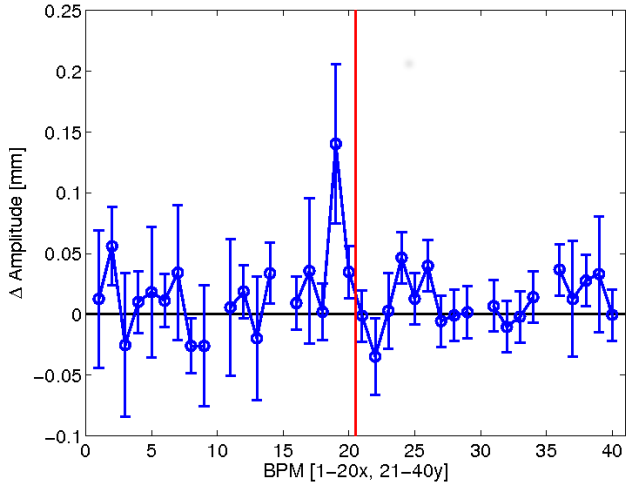

Figure 5: Difference in amplitude measurements using the single-shot and LBEG+ schemes with one rms uncertainty.

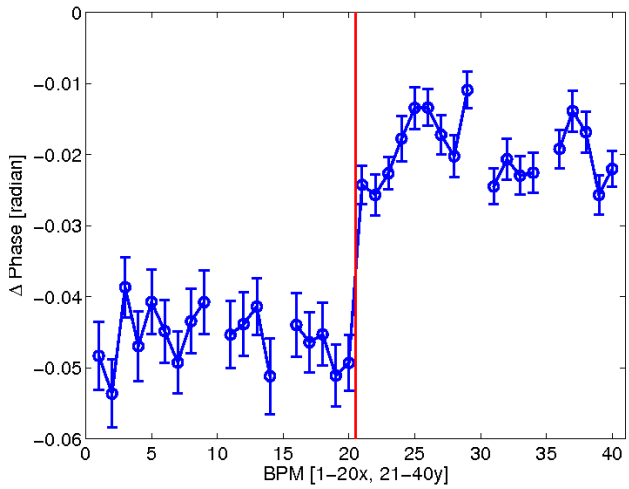

Figure 6: Difference in phase measurements using the single-shot and LBEG+ schemes with one rms uncertainty.

CONCLUSIONS

We demonstrate a proof of principle for the LBEG+ scheme to measure the CO, betatron tune, and injection offset during production. We compare measurements of the CO, tune, phase, amplitude, and injection offset from the single-shot and LBEG+ measurement schemes and show that both methods produce the same result.

DESIGN ANALYSIS OF THE NEW LANL 4-ROD RFQ

S.S. Kurennoy, E.O. Olivas, and L.J. Rybarcyk, LANL, Los Alamos, NM 87545, USA

Abstract

An upgraded front end of the LANSCE linac will include a 4-rod RFQ replacing the aging Cockcroft-Walton injector, initially only for protons. We performed a detailed analysis of the proposed RFQ design using 3D modeling with the CST Studio Suite. The CAD-based RFQ model takes all design details into account. The electromagnetic analysis with MicroWave Studio (MWS) is followed by beam dynamics modeling with Particle Studio (PS) using the MWS-calculated fields. In addition, a thermal and stress analysis is performed with ANSYS, based on the power flux from MWS computations. Simulation results are used for design iterations aimed to satisfy special requirements imposed by an existing common transfer line for different beams injected into the 201.25-MHz drift-tube linac.

INTRODUCTION

LANL is moving forward with replacing the aging Cockcroft-Walton (C-W) injectors with an RFQ-based front end [1] for the LANSCE proton linac. A 4-rod type RFQ design was developed in collaboration between IAP (Frankfurt) and LANL. The LANL RFQ, operating at 201.25 MHz at the duty factor up to 15%, with 35-keV injection and 750-keV final energy, should satisfy special requirements due to its incorporation into the existing medium-energy beam transfer that works with multiple beams, see in [2]. The RFQ will be manufactured by Kress GmbH. We used the RFQ CAD files from Kress imported into CST Studio [3] to create a model of the LANL H^+ RFQ and evaluate its performance.

RFQ MODEL

The imported CAD model was simplified by removing details nonessential for EM analysis such as external supports, etc. The RFQ cavity walls were also removed, leaving only the resonator vacuum volume in the CST model. The resulting model is shown in Fig. 1. Here the RFQ vacuum vessel, in light-blue, is 175-cm long (wall-to-wall), 34-cm wide, and 30-cm high (along the stem direction, z). It also includes wide recesses on the thick end and front walls, of radius 8.5 cm and depth 1.5 cm, followed by 5-cm-long beam pipes of radius 2 cm. The RFQ vanes are supported by 24 stems that are spaced longitudinally with variable period, 75 mm in the center and 69.5 mm for three periods near each end. The tuners electrically short two adjacent stems and can be moved along them (in z direction) to adjust the mode frequency and voltage profile (flatness) along the structure length. The variable stem spacing simplifies tuning the voltage flatness along the structure. Our RFQ model uses the CAD model coordinates: x is along the RFQ axis, and the beam is moving in $-x$ direction (right to left in Fig. 1).

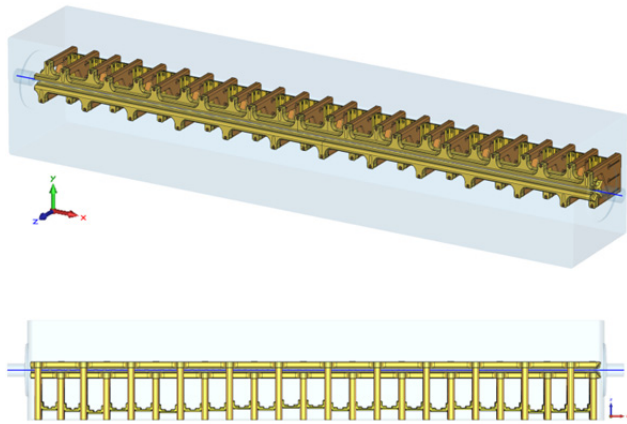

Figure 1: RFQ model (top) and its side view (bottom).

One can see in Fig. 1 (bottom) that the tuners are at different heights: they are adjusted to make the inter-vane voltage flat within ±1%. However, even with all tuners at the same height, the voltage is flat within ±5%, due to the variable stem spacing.

ELECTROMAGNETIC ANALYSIS

We studied the RFQ model using the CST MicroWave Studio (MWS). The mode frequencies and RF fields are calculated by the AKS eigensolver that provides more accurate surface approximations. The RF fields have some interesting features resembling those found in the FNAL 4-rod RFQ, see in [4, 5].

The first is the presence of a small transverse horizontal (parallel to the ground plane) electrical-field component, E_y, on the RFQ geometrical axis, sometimes referred to as a "dipole" component. This is due to the transverse electric fields being stronger between two upper vanes than between two lower ones, which results in the center of the transverse quadrupole field displaced down, to the ground plane, from the geometrical axis by 0.45 mm. The shift is small but not negligible when compared to the 4-mm vane aperture. This effect is known in 4-rod RFQs designed for higher frequencies [6]. The electric-field components on axis: longitudinal E_l, horizontal E_y, and vertical (along the stems) E_z are plotted in Fig. 2 versus the longitudinal coordinate $s = -x$. The fields are scaled to the nominal inter-vane voltage V_0=50 kV. In a similar plot along the axis shifted by -0.45 mm in z, the horizontal component E_y is close to zero, while the other two do not change much compared to Fig. 2.

Another important feature is the longitudinal electric field in the end gaps that separate the vane ends from the RFQ box walls (end-gap bumps). The red curve E_l in Fig. 2 shows the RFQ accelerating field – the oscillating part – produced by the vane modulation. The curve also has two peaks, near the entrance and exit.

Copyright © 2013 CC-BY-3.0 and by the respective authors

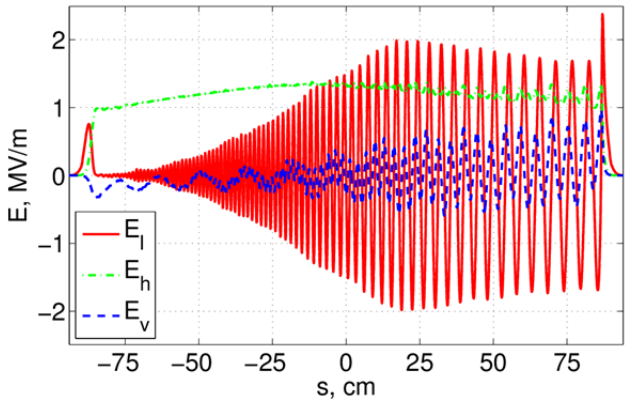

Figure 2: On-axis electric field in the RFQ model.

The RFQ cavity extends from s = -87.5 cm to s = 87.5 cm; the vanes start at s = -86.9 cm and end at 86.9 cm. It would make 6-mm gaps; however, the gaps are effectively wider by 1.5 cm due to the recesses cut out in the end walls and the beam pipes. This is why the entrance-gap peak of the longitudinal field is small. The large near-exit peak is due to a special end-vane design: one pair ends at a modulation maximum, another at minimum.

The end-gap longitudinal field exists because the quadrupole symmetry is broken near the RFQ ends; it would vanish in a perfectly symmetric structure. Moreover, in the end-gap areas there are transverse field components in addition to the usual quadrupole ones. Under some circumstances the end-gap fields, which are neither predicted nor taken into account by standard RFQ design codes, can change the exiting beam parameters such as energy and emittances [4, 5].

One important requirement for the RFQ operation is the inter-vane voltage flatness along the structure. The relative voltages, calculated at the midpoints of all 23 full periods, are presented in Fig. 3 for two cases: all tuners are at the same height, only the frequency is tuned to 201.25 MHz ("initial") and after some tuner adjustments in the MWS model ("tuned"). Even for the initial profile, the voltage was reasonably flat, within ±5% of the average value; this is due to the variable stem spacing.

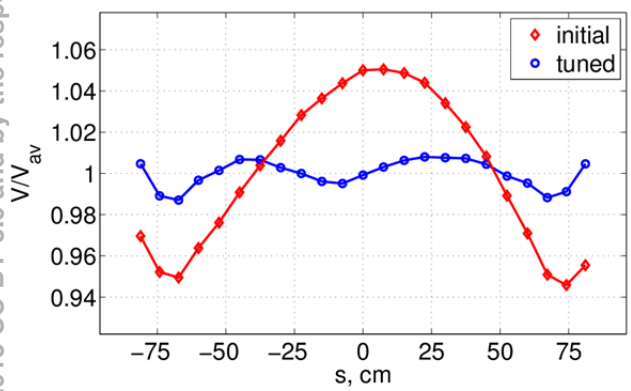

Figure 3: Voltage profile along the RFQ structure.

When all 23 tuners are moved together, by distance h up from the ground plane, the frequency sensitivity is df/dh = 0.75 MHz/mm. The frequency tuning range is comfortably sufficient in this design. In the shown tuned case, the displacements of individual tuner plates range from -9.5 mm to 8 mm.

The calculated maximal field at nominal voltage E_{max} = 23.5 MV/m ($1.6E_K$) is reached near the vane exit end. We use the fields calculated in the tuned case for our macro-particle simulations, and the related heat flux for thermal-stress analysis.

BEAM DYNAMICS RESULTS

The RF fields calculated by MWS are imported into the Particle Studio (PS) PIC solver. For macro-particle simulations, we used "matched" distributions generated with LAACG codes [7]. Matched CW proton beams of 10K macro-particles, one RF period long, were generated for a few different currents at the model boundary from Twiss-parameters that were back-traced from the match point at the RFQ vane entrance. The resulting distributions are converted to CST PS format and injected for 10 RF periods at 35 keV, (β_{in} = 0.0086), and accelerated to 750 keV, corresponding to β_{out} = 0.04. As an illustration, Fig. 4 shows macro-particles in the PS model with 12-mA current at t = 405 ns after the injection of 10x10K particles started. The total number of macro-particles at this moment is about 97.4K, most of them are densely packed in bunches. The particle energy is indicated by color; the energy scale is overlapped on the right. The particles propagate from right to left. More than 10 bunches are formed, due to the longitudinal space-charge push at the train ends; a few leading bunches in Fig. 4 are already accelerated and approaching the exit. Trailing low-energy particles are not captured in bunches.

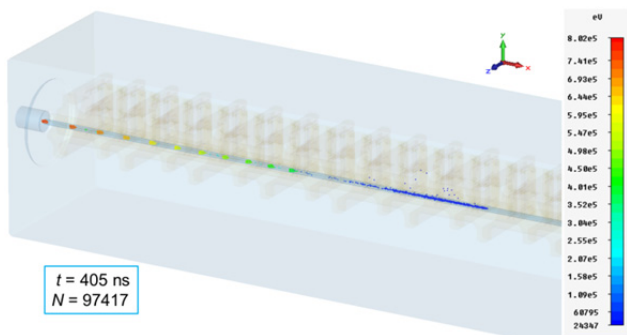

Figure 4: Particles in the RFQ model for 12 mA at 405 ns.

A convenient way to look at energy changes is with phase-space snapshots of the longitudinal phase space x-W (coordinate-energy). In Fig. 5, five such snapshots, from t = 405 ns to 409 ns with 1-ns step, are overlapped. Each snapshot is shown in a different color; together they cover a time interval equal to one RF period. One can see that the bunch energy increases until the end of the modulations (x = -869 mm), then remains constant in the

Copyright © 2013 CC-BY-3.0 and by the respective authors

exit beam pipe (x < -890 mm). Again, the beam propagates from positive to negative x in this model.

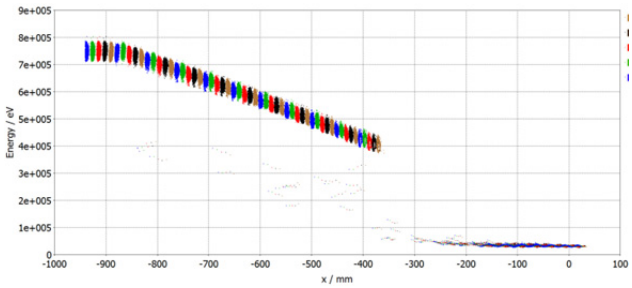

Figure 5: Longitudinal phase-space snapshots for 12 mA.

To exclude effects of space charge in the bunch-train head and tail, we analyzed only 4-6 central bunches from PS simulations with 10x10K beams injected. Some results – the average energy W of exiting bunches, their transverse normalized r.m.s. emittance ε_t, and current transmission – are summarized in Table 1. The initial distribution has a transverse normalized r.m.s. emittance 0.2 π mm·mrad in both transverse planes.

Table 1: PS Results for Different Beam Currents

I, mA	W, keV	ε_t, π mm·mrad	ε_l, keV·deg	transm.
0	756	0.40	20	0.99
12	756	0.55	13	0.97
35	753	0.62	15	0.89

The calculated growth of the transverse emittance, even in the matched low-current case, is large. On the other hand, the longitudinal emittances are smaller than expected. We consider the emittance results preliminary and will investigate this problem further.

THERMAL ANALYSIS

The total dissipated power in the RFQ model for ideal copper surfaces is 77 kW at 100% duty and is distributed as follows: 55% on stems, 28% on vanes, 17% on tuners, and less than 0.5% on the RFQ-vessel inner surface. Since the RFQ will operate at noticeable duty factors, up to 15%, the structure requires adequate cooling. It will be provided by water running at 2.5 m/s through cooling channels. Each stem has a separate inverse-V-shaped cooling channel. There are also cooling channels inside vanes, connected through a few stems to pipes under the ground plane. The heat flux calculated in post-processing MWS fields was used for thermal-stress analysis with ANSYS [8].

In the thermal analysis, a realistic contact copper-copper conductivity between vanes, stems, and tuners was taken into account. The calculated temperature distribution in a structure slice near the RFQ exit is shown in Fig. 6 for the duty of 18% (15% plus additional heating due to realistic surface conductivity). The maximal temperature of 335 K is at the near-end stem and the temperature range is less than 40° C even in this extreme case. Maximal deformations in the RFQ structure reach 80 μm but the relative vane displacements stay below 40 μm (< 0.002″).

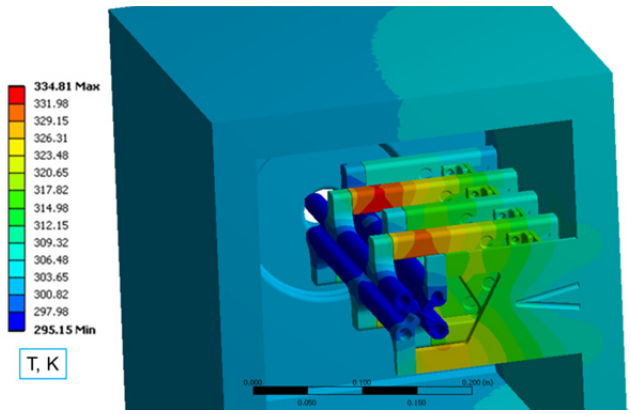

Figure 6: Temperature distribution at 18% duty.

SUMMARY

A detailed study of the new LANSCE 4-rod RFQ was performed with the CST Studio codes. The RFQ model is based on imported CAD files. The RF fields calculated with MicroWave Studio were used for beam dynamics modeling with Particle Studio and for thermal-stress analysis with ANSYS. Our modeling takes into account effects associated with 3-D field asymmetries such as end-gap fields, which are not predicted by standard RFQ design codes. We found that the RFQ output energy and transmission satisfy the design requirements and that the structure cooling is adequate. Reasons for the observed transverse emittance growth will be further investigated.

The authors would like to thank A. Schempp and J. Schmidt (IAP, Frankfurt), J. Haeuser (Kress GmbH), and Y. Batygin, R. Garnett, and J. O'Hara (LANL) for useful information and stimulating discussions.

Abstract

LANSCE provides H^- and H^+ beams to several user facilities for fundamental and applied research, including a 100-MeV, 250-μA proton beam to the Isotope Production facility (IPF). Each beam species is initially accelerated to 750 keV in separate Cockcroft-Walton (C-W) accelerators. Due to the age and possible failure modes of the C-W's and the potential impact of a C-W failure to the IPF program, we have begun the process of replacing the aging H^+ C-W with a modern Radio Frequency Quadrupole (RFQ) accelerator-based system. In addition, the complexity of combined species operations imposes further restrictions on the beam performance and configuration that must be incorporated into the design process. This paper will cover the physics design requirements of this new RFQ and the expected performance based upon the results of PARMTEQM simulations.

INTRODUCTION

The Los Alamos Neutron Science Center (LANSCE) facility has a diverse user program that is possible in part because of the dual species operation, i.e. acceleration of both H^+ and H^- beams. IPF is one of those facilities and receives 100-MeV beam generated by our H^+ injector. IPF is one of only a few installations that produce a key radioisotope for medical procedures used across the nation and so high beam availability and reliability is critical to meeting their programmatic milestones. The H^+ injector utilizes an ~40 year old 750-keV C-W accelerator. The C-W has possible failure modes that include a failure of the accelerator column, which has already been replaced once and required 4 months to complete, and the collapse of a support leg that could lead to a catastrophic failure of the C-W. Concern over the potential likelihood of these types of failures and the severe impact to the IPF program has provided the impetus to pursue an RFQ-based replacement for the H^+ injector.

The RFQ is being designed and verified as a joint effort between the Institute of Applied Physics (IAP), Goethe University, Frankfurt, Germany and Los Alamos. The IAP team used a combination of PARMTEQM [1] and proprietary algorithms to develop the physics design for the 4-rod RFQ, which the Los Alamos team verified using PARMTEQM. Our project partner Kress GmbH, with input from IAP, is responsible for the engineering design and fabrication of the RFQ.

REQUIREMENTS

The new H^+ RFQ will need to provide sufficient beam current to meet present and anticipated future programmatic needs and do so within the context of dual species operation. This includes the capability to operate the RFQ for a range of input beam currents depending upon the requirements of the user programs and the available beam duty factor. The LANSCE dual injector beam line layout that maintains the existing H^- and common LEBTs requires the new RFQ to be located several meters upstream from the entrance to the next accelerating structure, i.e. the 100-MeV drift tube linac (DTL). This places additional constraints on the transverse and longitudinal emittances so that the beam can be transported and properly matched without significant losses. A list of the RFQ requirements and expected performance based upon PARMTEQM simulation results for the IAP-developed physics design are given in Table 1. The frequency and output energy were chosen to be consistent with our present linac base

Table 1: Comparison of the Final, 201.25-MHz 4-rod RFQ Design Parameters with the Design Specifications

Parameter	Specification	Final Design
Injection Energy	35 keV	35 keV
Final Energy	750 keV	750 keV
Transmission	≥ 90%	96%
Peak Current	35 mA	35 mA
Current Limit	≥ 70 mA	60 mA
Output Energy Spread (FWHM)	< 3.0%	2%
Length	< 2.5 m	1.75 m
Peak Electric Field (E_K)	1.7	1.6
Input Trans. Emittance rms (cm-mr, norm.)	0.020	0.020
Exit Trans. Emittance rms (cm-mr, norm.)	0.023	0.022
Exit Long. Emittance rms (deg-MeV @201.25 MHz)	< 0.08	0.071

frequency and nominal injection energy to the DTL. The RFQ injection energy was chosen with the desire to keep it low, which helps reduce the overall length of the RFQ, and taking into consideration the successes of other RFQ projects with similar peak current, injection energy and frequency specifications [2][3]. The transmission specification was chosen to help ensure that the integrated performance of the new RFQ and DTL would have an overall beam capture up through the DTL at least as good as the present C-W based system. The current limit in the design of the RFQ was specified to be twice the maximum design current as a general rule-of-thumb. The output energy spread and longitudinal emittance were chosen to ensure successful transport and capture of the beam from the RFQ and was based upon results from PARMILA [4] beam dynamics simulation of the MEBT and DTL using PARMTEQM beam distributions [5]. The limit on the peak surface electric field was chosen to ensure reliable operation at design field strength. The input emittance represents the maximum that we expect to inject and was based upon the performance of our present duoplasmatron ion source, which we will use with the RFQ injector, and an estimate of the maximum emittance growth that might be sustained in the LEBT. However, based upon measurements of the existing H^+ beam, we expect the nominal input emittance to be somewhat smaller. The RFQ output emittance requirement was based upon expected performance for a carefully designed RFQ and the desired to keep the beam emittance in the MEBT at a level that will allow for easy transport and matching of the RFQ beam into the DTL [5].

EXPECTED PERFORMANCE

The IAP RFQ design was evaluated using the PARMTEQM design and simulation code. The simulations were done using the design parameters provided by IAP. The effects of the end regions that can be important in a 4-rod RFQ require the use of more sophisticated models that combine 3D EM fields with multiparticle tracking. This effort is in progress [6].

The results of the PARMTEQM simulations show the design meets our requirements in all but one aspect, the current limit, which is not significant as will be shown later. Figure 1 shows the beam dynamics along the RFQ and phase space distributions at the end of the RFQ for the design peak current and emittance input beam. The RFQ produces a good quality beam with high transmission. Figure 2 shows the results of the PARMTEQM simulation that indicate the design produces little transverse emittance growth along the RFQ. In initial studies performed by the Los Alamos team, we had found that an RFQ design employing equal transverse and longitudinal current limits, one common approach, produced significant transverse emittance growth. In a follow-on analysis we found that the emittance growth was due to parametric resonance conditions being met, but that could be avoided with properly chosen parameters [7]. This design effectively avoids the parametric resonance conditions and produces a beam with little, ~10%, emittance growth.

Because we plan on operating the RFQ for a range of input beam currents, likely values between 10 and 35 mA,

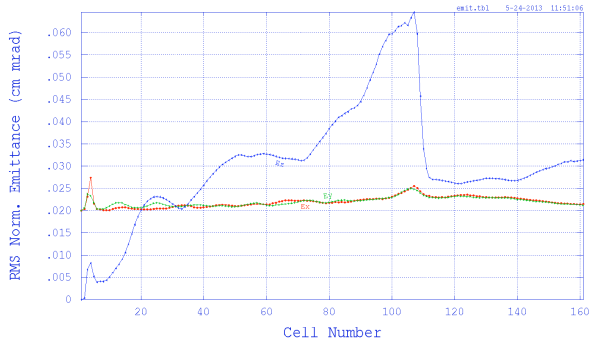

Figure 2: Transverse (red, green) and longitudinal (blue) rms, norm. beam emittances along the RFQ for the design input beam.

depending upon the average current required and the duty factor available for the user programs, we desire good performance over that range. Although the current limit characteristic for this design is somewhat lower than desired, it does not appear to affect the performance well beyond the design point and is therefore not an issue. As shown in Figures 3, 4 and 5, the simulated performance is quite good for input beam currents up to 60 mA, with the transmission falling off to about 80% at that point.

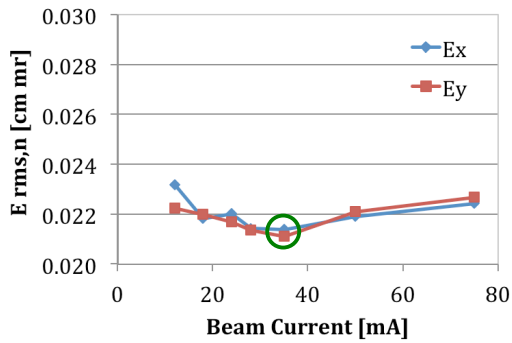

Figure 3: Transverse (red, blue) rms, norm. output beam emittance vs. input beam current. The green circle indicates the 35 mA design point.

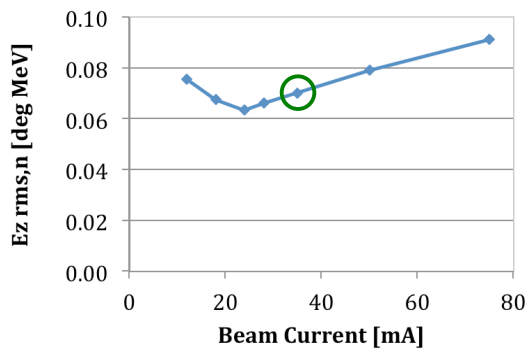

Figure 4: Longitudinal (blue) rms, norm. output beam emittance vs. input beam current. The green circle indicates the 35 mA design point.

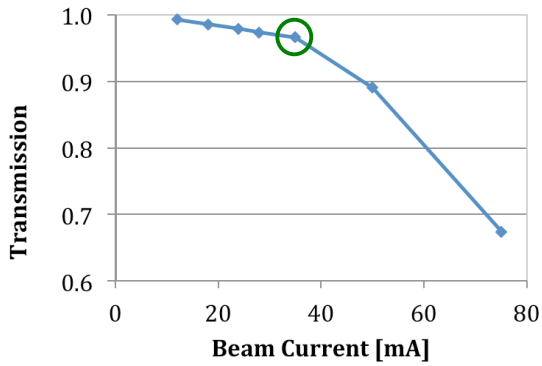

Figure 5: RFQ beam transmission vs. input beam current. The green circle indicates the 35 mA design point.

SUMMARY

The IAP approach has produced an RFQ design that has met the specified beam requirements as simulated with the PARMTEQM code. The performance is equally good for the range of beam currents over which we expect to operate.

GPU ACCELERATED ONLINE MULTI-PARTICLE BEAM DYNAMICS SIMULATOR FOR THE LANSCE LINAC*

X. Pang†, L. Rybarcyk, S. A. Baily, Los Alamos National Laboratory, Los Alamos, NM, 87544, USA

Abstract

A GPU-accelerated online multi-particle beam dynamics simulator is being developed for use in the LANSCE linac operation. The goal is to provide new insights on the beam distribution inside the linac and to help understand the impact of set point adjustments on it. Details regarding the code structure design, GPU programming and performance, code validation and status will be presented.

INTRODUCTION

The Los Alamos Neutron Science Center (LANSCE) linac can provide H^+ and H^- beam up to 800 MeV. Due to a lack of direct beam measurements during high power operation, small adjustments to linac operating set points are made primarily on the basis of beam loss along the linac. To provide more insight on the beam distributions along the linac and to better understand the effects of machine parameter changes on the beam, we are creating a virtual beam diagnostic tool for use in the LANSCE control room [1]. This tool is a Graphics Processing Unit (GPU)-accelerated multi-particle simulator whose beam dynamics algorithms are based upon the ion linac design and simulation code PARMILA [2]. PARMILA is a z-code which uses the R matrices to transfer particles through accelerator elements. The simulator is designed using modern software design techniques and coded in C++ and Python. Using NVIDIAs CUDA technology [3], the algorithms are recast to fully harvest the computing power of a GPU. Once connected to the EPICS control system, the simulator can track the real time machine parameter changes, convert control set points to model quantities and quickly update the simulation.

CODE STRUCTURE

Since the simulator is developed for use in the control room, fast execution and ease of use are both important design criteria. To meet these criteria, a combination of a high-level scripting language, i.e. Python, and a low level compiled language, i.e. C++, were adopted. Figure 1 shows the hierarchy of code layers that allows the user to take advantage of the fast number-crunching kernels written in C++ and CUDA C without having to deal with the complex syntax and the lengthy compilation process that is associated with them. The outermost shell of the code structure that a user directly interfaces with is written in Python. Python is chosen as the high-level scripting language because of its shallow learning curve, pseudo code like syntax, lack of compilation phase, easy integration with the compiled languages and the rich numerical and visualization libraries. Figure 2 shows the major components of the core part of the code that is written in C++ and CUDA C. Following the CUDA convention [3], we refer to the CPU as the host and the GPU as the device in the rest of this paper. The components colored in blue (left) are the ones that reside on the host while those colored in yellow (right) reside on the device. The *BeamLine* component (middle) resides in pinned, or page-locked memory on the host and the information stored is shared between the host and device and denoted by the green block. Each major component is described in detail as follows:

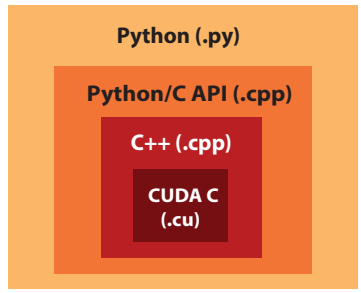

Figure 1: Code hierarchy. Lower level codes are wrapped by the higher level ones.

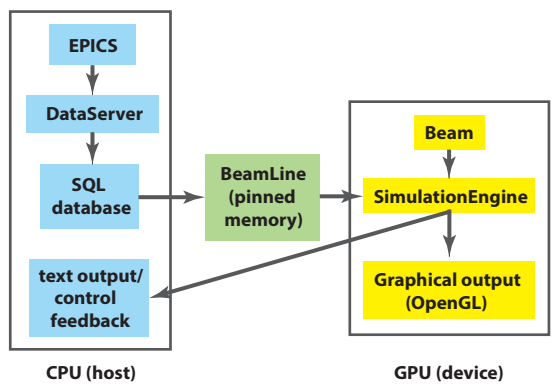

Figure 2: High level code structure and data flow indicated by the arrows.

The *DataServer* reads values from EPICS in multi-threaded fashion and stores the updated values to the SQL database.

The *SQL database* stores all the measured engineering values coming in from the *DataServer*, the conversion algorithms for every controllable accelerator element, and most importantly the converted physics quantities that are

eventually used in the beam dynamics simulations. A central database repository was chosen over flat files to guarantee data consistency and to provide historical tracking of data changes. Due to its light weight, self-contained and server-less features, *SQLite* was picked as the relational database management system (RDBMS) for the simulator.

The *BeamLine* component of the code is a data structure that stores the physics quantities of all the accelerator elements required in the simulation. It is updated in real-time once changes to the SQL database are detected so that the physics model used in the simulation is synchronized with the real world machine parameter settings. This data is stored in the pinned memory. In this way, modifications by either the host or the device can be reflected in the memory spaces of both sides, eliminating the need to first search for the element index for which the changes were made, then explicitly copying the new value from host to device.

The *Beam* class is used to store coordinate information for all the particles and some collective properties of the beam. Particle data are allocated on the global memory of the GPU in the format of structure-of-arrays (SoAs) to facilitate coalesced global memory access in the particle tracking simulation and beam property calculations. In order to reduce the expensive memory traffic between the host and the device, the *Beam* object is allocated on the GPU before the simulation starts and is kept on the GPU until the simulation ends. This class also provides methods to calculate different properties of the beam like centroid, size, emittance and beam loss etc. on the GPU.

The *SimulationEngine* component is the core of this simulator. All the physics algorithms for particle advancing and space charge effects are implemented in the *SimulationEngine*. These algorithms are stored in several CUDA kernel functions and are glued together by two overarching C++ classes, *SimulationEngine* and *SpaceCharge*. The *SimulationEngine* class orchestrates the whole simulation while the *SpaceCharge* class only manages the parameters and functions used in space charge calculations.

The *Output* of the code can be a graphical display, a text file or specific values sent back to the EPICS control system. A graphical display system is being developed using openGL so that simulation results sitting on the GPU can be conveniently displayed without copying back to the host when a graphical output enabled GPU is used.

GPU PERFORMANCE

The performance of the GPU accelerated simulator is compared with that of the optimized single CPU version of the code. The test system used for the comparison is a custom built workstation with Intel Xeon E5520 2.27GHz, 32 Gb of RAM, and a NVIDIA GTX 580 (Fermi architecture), running an x86_64 install of Scientific Linux 6.3 and CUDA 5.0.

The physics algorithm of the code consists of two major parts: particle advancing and space charge calculations. For particle advancing, the instruction level parallelism (ILP) was explored by assigning one thread to process four particles. This allows more computing resources to be used by a thread, more data to be reused and independent calculations within a thread to be processed in parallel, therefore more latency to be hidden. An overall faster execution can be achieved. In the space charge force calculation, particles are first binned onto a mesh and stored in a charge density table. Then an electric field table is calculated based on the charge density. Space charge kicks on the particles are applied by interpolating the electric field table based on individual particle's position on the mesh. Among these steps, the charge density table calculation accounts for the most computing time and is the bottleneck of the overall performance. To avoid the race condition when the density table is updated by multiple threads, the floating point atomic addition in the CUDA is used. This gives us about 12 times speedup in the charge density calculation compared to the CPU version.

Two LANSCE beam lines were used for the overall performance test: part of the H^+ low energy beam transport (LEBT) which consists of 8 quadrupoles, 4.32 meter long drift spaces (divided into 442 segments to apply space charge kicks), a RF cavity and a dipole and the drift tube linac (DTL), which includes 135 quadrupoles, 165 RF gaps and 1.68 meter long inter-tank drift spaces (divided into 171 segments). Typically using 32K particles in the simulation is sufficient to get an accurate estimate of many of the beam properties.

Without calculating the space charge effect, transporting 32K particles through an accelerator element using GPU can be 160 times faster than on a single CPU. Table 1 summarizes the total computing time including the space charge calculations and the speedup of simulations using different particle numbers. The overall performance is dominated by the space charge calculation which consumes between 70% to 90% of the computing time. One simulation through the transport structure on the GPU using 32K particles takes less than a second, whereas on a single CPU, it takes more than half a minute. In an accelerator control room where rapid response from any system is required, a reduction from half a minute to a fraction of a second makes this simulator a viable tool for pseudo-real-time computational turn-around in this demanding environment.

RESULTS

Before relying on the simulator to provide useful insight about the beam evolution in the linac under routine operating conditions, it must first be calibrated. Details about the calibration process is described in [4]. Figure 3 shows that after the calibration, we were able to get an excellent agreement between the results from the actual phase scan measurements made with the LANSCE H^+ beam and the results from the simulated phase scan following the adjustment of the relevant calibration factors. Figure 4 is a screen shot of the EPICS control channels and the simulator outputs for the simulation of H^- beams at LANSCE accelerated from 0.75 to 100 MeV through the DTL.

Table 1: Computing Time and Speedup

Initial Particle Number	Beamline Structure	Overall Time [s]	Overall Speedup
16384	Transport	0.66	45.8
	DTL	0.37	26.7
32768	Transport	0.78	44.5
	DTL	0.47	34
65536	Transport	1.02	42.3
	DTL	0.71	39
131072	Transport	1.48	40.1
	DTL	1.15	45.2
262144	Transport	2.4	39.8
	DTL	2.07	48.6

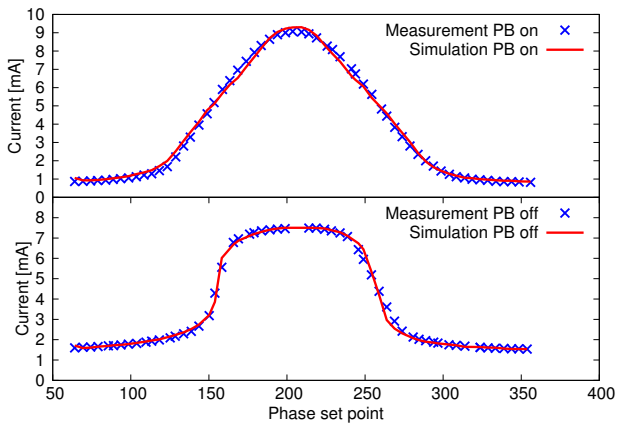

Figure 3: Phase scan measurements (blue x's) of the LANSCE DTL tank 1 with main buncher on and prebuncher on (top) and off (bottom). The simulated phase scan results following calibration factor adjustment are shown in red.

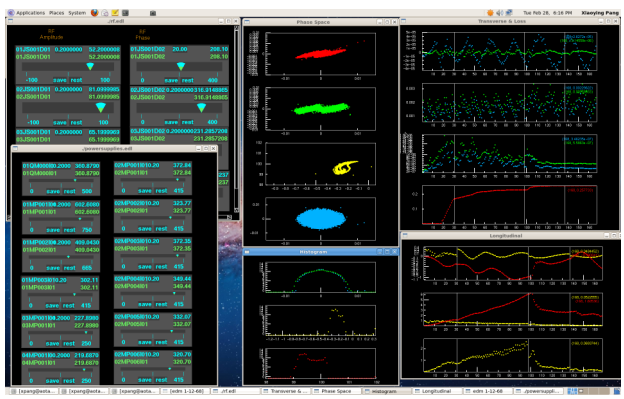

Figure 4: Screenshot of the EPICS control interfaces (left) and the simulator outputs (right).

Numerous beam properties such as phase space distributions and phase space projections at the end of the DTL as well as beam centroid, size, emittance, and fractional beam loss along the DTL are displayed. From this interface, changes that are made to relevant DTL operating parameters can be captured by the simulator and reflected in the simulation results in pseudo realtime. These 2D graphics displays were made using OpenGL, which maintains high throughput as additional communications through the CPU are minimized. This type of interface gives control room personnel additional information regarding beam performance and allows them to better understand the impact of any machine parameter changes to the overall accelerator performance.

STATUS AND FUTURE WORK

Currently, the simulator contains several standard transport elements and the DTL structure. The addition of the coupled-cavity linac (CCL) structure to the code is underway as well as improvements to the Python interface and data I/O. Following that, our near term plans include generation and calibration of the LANSCE CCL in the model and front-to-end simulations of the LANSCE linac from 0.75 to 800 MeV. More long range plans under consideration include simultaneously modeling multiple beam species, addition of other beam loss mechanism, e.g. H- stripping [5] and addition of a new space charge calculation routine based on a 3D Poisson solver.

CONCLUSION

By combining multi-particle tracking simulation algorithms with state-of-the-art GPU technology we have developed a powerful tool for use in the demanding accelerator control room environment. It has many applications not mentioned here [4][6][7]. Although more efforts are needed to further calibrate the existing model and to incorporate more accelerator structures, we believe this approach can greatly enhance operations and performance of existing and future accelerators.

PHASE STABILITY OF THE RF REFERENCE LINE FOR THE FRIB LINAC*

Q. Zhao#, J. Brandon, D. Morris, Y. Yamazaki, MSU, East Lansing, MI 48824, USA

Abstract

The phase stability of rf reference line is usually quite restricted in a high energy linac (very long linac, very high frequency). Due to the change of the ambience temperature in the linac tunnel, the electrical length of reference rf cables may change significantly, which results in unacceptable phase changes in cavities. So, sometimes the reference line is very expensive, for example, made of optical fiber housed in a lengthy thermostatic chamber. The frequencies of FRIB linac cavities are 80.5 and 322 MHz (not very high). We also take advantage of the double-folded linac geometry and feed the reference line in the center of the linac to effectively reduced the reference line by 6 times. Our studies show that the FRIB linac can tolerate up to 12ps phase stability of the rf reference line. Therefore, no is needed for the reference line.

INTRODUCTION

The Facility for Rare Isotope Beams (FRIB) [1], currently under establishment at the Michigan State University, will be a new national user facility for nuclear science. FRIB accelerator is a cw, high power, heavy-ion machine that will accelerate all stable isotopes to energies ≥ 200 MeV/u with a beam power of up to 400 kW. The driver linac consists of a front-end to generate ion beams and boost beam energy, a superconducting linac that is folded into three parallel segments and connected by a stripper station and two 180-degree bending sections, and a beam delivery system to transport output beam into the fragmentation target, as shown in Figure 1. The length of linac footprint is about 150m. Linac Segment 1 consists of 3 β=0.041 cryomodules and 11 β=0.085 cryomodules to increase the beam up to 20 MeV/u followed by a charge stripping system. All the cavities in Segment 1 are Quarter-wave Resonators (QWRs) with operating frequency of 80.5MHz. Half-wave Resonators (HWRs) with higher operating frequency of 322MHz are used for both Segment 2 and Segment 3. There are 12 β=0.29 cryomodules and 12 β=0.54 cryomodules in linac Segment 2 to accelerate beam energies ≥ 150 MeV/u. Additional 6 β=0.54 cryomodules in linac Segment 3 further push beam energies above 200 MeV/u, followed by a FODO quadruple lattice section that is reserved to place more cryomodules for future energy upgrade.

As a new generation national scientific user facility, the performance of FRIB has quite stringent requirements. Therefore, each system and its subassemblies become critical for the operation of such a complex machine. The rf field generated by cavities is one of the key factors that determine the beam performance of the linac. It is a challenging task to achieve good phase and amplitude regulation of the cavities in a large system. There are several types of errors or uncertainties related to the rf field of the cavities in linacs like the FRIB driver linac. For examples, (1) the random rf phase and amplitude fluctuation or jitter that changes very fast and dynamically and is regulated by low level rf controller, (2) misalignment of field axis with respect to the beam axis that is static and may be measureable thus be corrected or compensated, (3) deviation of amplitude settings with respect to the design that is static and determined mainly by calibration, (4) deviation of phase settings with respect to the design that is also static and usually more sensitive than that of field amplitude especially at low energy side, (5) phase change due to the variation of the electrical length of rf cable that is mainly due to thermal effect and thus a slow drift process. Therefore, each of them needs to be evaluated and controlled to meet requirements. In this paper, we discuss exclusively on the topic of the phase drift of the rf reference line for the FRIB linac.

CAVITY PHASE SETTINGS

There are total 330 cavities (including the rebuncher cryomodules between each segment) distributed in the three linac segments of the double-folded FRIB driver linac. All of the cavities (either QWRs or HWRs) have

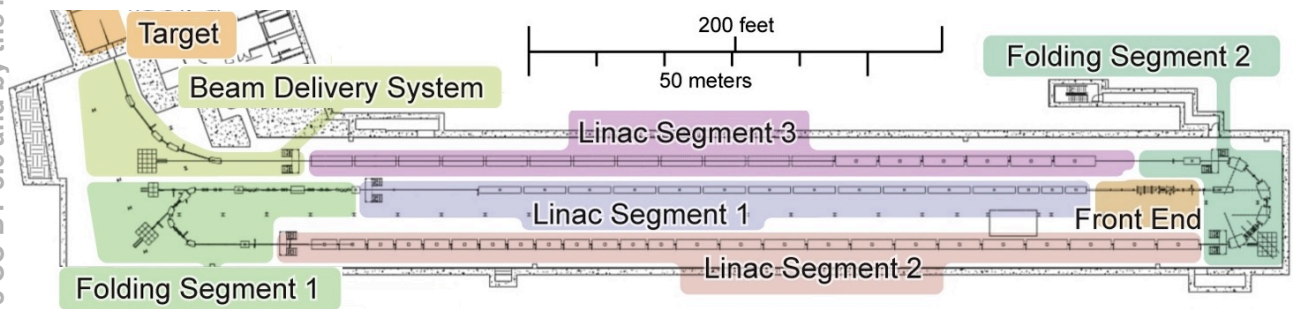

Figure 1: Layout of the FRIB driver linac.

two accelerating gaps excited in π-mode (that means the change of the electric field between the gaps is always opposite but at the same rate). Each cavity is powered individually, thus the amplitude and phase of each cavity can be independently adjusted. The field amplitude of cavity is usually set as high as allowed for reliable operation, while the phase of cavity that the beam experiences when transiting through the cavity (called synchronous phase) is determined by the beam dynamics design of the linac lattice. In a real machine, each cavity must be phase-scanned at least one time with beam by typically measuring the energy change (ΔE) as a function of the phase (φ), as illustrated in Fig. 2. The phase that corresponds the maximum energy is defined zero degree, and thus the synchronous phase φ_s (generally around -30º to tradeoff between the acceleration efficiency and the size of rf bucket) is set by retracting $|\varphi_s|$ degrees from the "zero". Once the synchronous phase is found, the low level rf controller will lock it. This procedure will be applied every cavity sequentially along the beam path. The synchronous phases of all cavities must be well-controlled over a long period of operation, so beam can always be accelerated along the linac synchronously in the stable region.

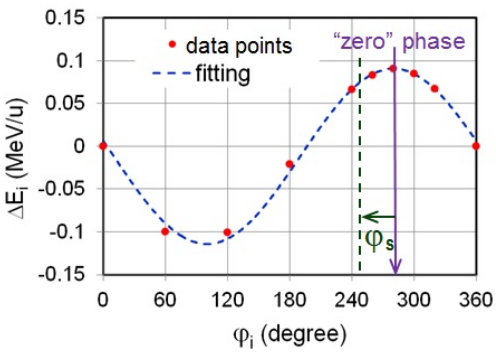

Figure 2: Phase scan of a β=0.041 QWR with uranium beam (q/A=33/238) at 0.5MeV/u to set the synchronous phase of the cavity.

RF REFERENCE LINE

The phase stability of rf reference line is usually quite restricted in a high energy linac where the linac is not only very long but also operates at high frequencies. High performance coaxial cables are widely used for rf reference line. It is well known that phase change in coaxial rf cables is sensitivity to the ambience temperature variations (due to the change of electrical length). So, sometimes the reference line is very expensive, for example, made of optical fiber housed in a lengthy thermostatic chamber. The global temperature at the FIRB linac tunnel will be controlled in the range of 72±6 ºF (22.2±3.3 ºC), which mainly implies some areas (e.g. near room temperature magnets) can have slightly higher temperature while other ones (e.g. near cryomodules) slightly lower. However, long-term temperature drift at a given location during normal operation will normally be much smaller than ±6 ºF.

A typical rf coaxial cable is a composite structure that consists of metal conductors separated by a polymer dielectric. The entire assembly is encapsulated with a polymer jacket. The phase length in degree of such a cable is given by

$$\varphi = \frac{360 f_0 \cdot l \cdot \sqrt{\varepsilon_r}}{c} \quad (1)$$

where c is the velocity of light in vacuum, f_o is the signal frequency, l is the mechanical length of the cable and ε_r is the dielectric constant of the insulating material between the center and the outer conductor of the coaxial cable. Therefore, for a given rf frequency (f_o), the phase change depends on the change of physical cable length (l) and/or the net dielectric constant of the propagation medium (ε_r). The metal conductor changes linearly with temperature, but the behavior of dielectric constant is usually very complicated when the temperature of cable changes.

The FRIB reference line will provide a stable signal of 10.0625 MHz which is compatible with rf system frequencies of 20.125, 40.25, 80.5, 120.75, 161, and 322 MHz. To minimize the temperature related phase change, the reference clock is fed from the center of the linac tunnel into six rf distribution lines through a 6-way splitter, as shown in Fig. 3. In this scheme, the reference line is effectively reduced by 6 times. The length of each linac segment is no more than 140m, so each rf reference line is about 70m long. In addition, low loss, phase stabilized cable (RFS 7/8" LCF78-50J) is selected for the rf reference lines. Foam polyethylene instead of polytetraflouoroethylene (teflon) is used as the insulating material in the cable to avoid the so-called teflon "knee" induced phase instability problem [2] (teflon itself undergoes a quick structural transition around 19 ºC, which results in a rapid change in the dielectric constant and thus an abrupt change in phase length).

To check the relation of phase change with temperature, a 136.8-meter-long coaxial cable (RFS 7/8" LCF78-50J)

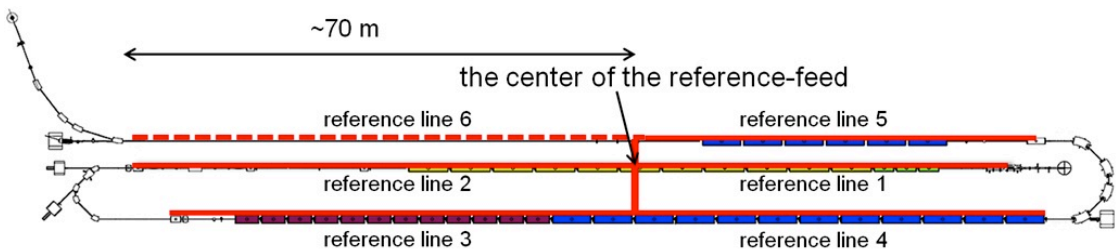

Figure 3: Schematic layout of the reference lines and the center of the reference-feed in the linac tunnel.

Copyright © 2013 CC-BY-3.0 and by the respective authors

from Radio Frequency System (RFS) company, same type as those to be used in FRIB linac, was tested at the FRIB lab with a 10.0625 MHz signal. The cable was rolled up and placed in a room where the temperature can be adjusted and controlled, as shown in Fig. 4. The oscillator, phase detectors and other devices were set up right outside the room, and can be seen through the window. Phase change of 0.105 degrees with respect to 10.0625 MHz was measured between the two different temperatures of 70.3 and 79.8 ºF, which is similar to the expected ambient temperature range within the FRIB linac environment.

Figure 4: Setup of the reference cable test at FRIB lab.

BEAM DYNAMICS STUDY

Beam dynamics study was performed to evaluate the FRIB linac performance with rf phase changes caused by the thermal effect of the rf reference lines. Based on the measured data, for a 100-meter-long cable and 1 degree Fahrenheit temperature increase, total phase change will be 0.06465 degrees at 80.5 MHz. Since the FRIB specs of the global temperature variation within the entire tunnel is 72±6 °F, cable temperature change of 12ºF is assumed in the study. Although this will unlikely happen, because the coherent change of the entire tunnel temperature should be much less than ±6 °F. So, the phase change of each cavity is calculated and shown in Figure 5, where the phase in degree corresponds the rf frequency of each cavity (80.5 MHz for QWRs, 322 MHz for HWRs).

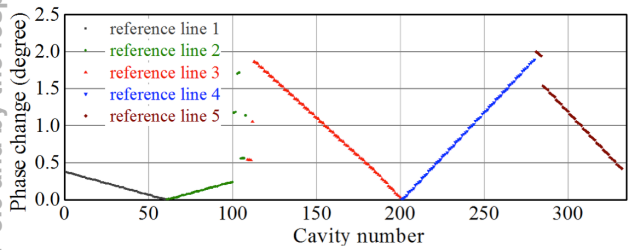

Figure 5: Phase change ("degree" corresponds to the cavity rf frequency) for each of the cavity along the linac.

Multi-charge-state uranium beam [3] carried from the frontend was tracked through the entire linac to the target. The results show the amount of phase change (shown in Fig. 5) is not sensitive to the beam performance. Sampled particle distributions on target are plot in Fig. 6 with the cases of phases changed and unchanged, which indicate the overall impact is insignificant. Although the maximum phase change is ~2 degrees for the HWRs in Segment 2 & 3, and ~0.5 degrees for the QWRs in Segment 1, the phase change between the neighbouring cavities is coherent and very small (unlike rf jitter), the particles still well follow the betatron oscillation in the longitudinal stable region. The amplitudes of the centroid oscillation in longitudinal phase space are negligible, as shown in Figure 7.

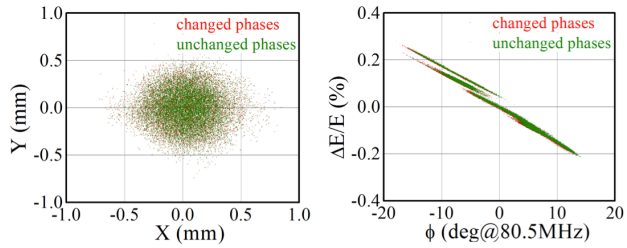

Figure 6: Sampled particle distributions on target with (in red) and without (in green) the phase changes. Both transverse (left) and longitudinal (right) are very similar for the two cases.

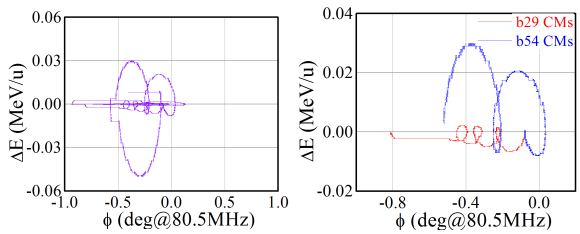

Figure 7: The centroid motion in longitudinal phase space with phase change included for the entire linac (left). Zoom of the Segment 2 only (right). The amplitudes of the oscillation are negligible.

SUMMARY

FRIB will feed the reference clock from the center of the linac tunnel into six rf distribution lines. The long-term thermal related phase change of each line shall be less than 12 ps. Beam dynamics studies using measured data confirm that the phase stability of the rf reference cable meet the requirement.

AN OPTIMIZATION STUDY OF THE TARGET SUBSYSTEM FOR THE NEW G-2 EXPERIMENT*

C. Yoshikawa#, C. Ankenbrandt, Muons, Inc., Batavia, IL 60510, USA
A. Leveling, N.V. Mokhov, J. Morgan, D. Neuffer, S. Striganov, Fermilab, Batavia, IL 60510, USA

Abstract

A precision measurement of the muon anomalous magnetic moment, $a_\mu = (g-2)/2$, was previously performed at BNL with a result of 2.2 - 2.7 standard deviations above the Standard Model (SM) theoretical calculations. The same experimental apparatus is being planned to run in the new Muon Campus at Fermilab, where the muon beam is expected to have less pion contamination and the extended dataset may provide a possible 7.5σ deviation from the SM, creating a sensitive and complementary benchmark for proposed SM extensions. We report here on a study performed on the target subsystem utilizing a new optimization technique that overcomes complexities of asymmetric particle production and depth of focus of a Li lens. This new technique is applied to an apparatus that is optimized for pions that have favourable phase space to create polarized daughter muons around the magic momentum of 3.094 GeV/c, which is needed by the downstream g 2 muon ring.

INTRODUCTION

The New g-2 Experiment at Fermilab [1] aims to measure the muon anomalous magnetic moment to a precision of ±0.14 ppm — a fourfold improvement over the 0.54 ppm precision obtained in the g-2 BNL E821 experiment [2]. The present discrepancy, Δa_μ(Expt. — SM) = (255±80)×10^{-11}, is already suggestive of possible new physics contributions to the muon anomaly. Assuming that the current theory error of 49×10^{-11} is reduced to 30×10^{-11} on the time scale of the completion of our experiment, a future Δa_μ comparison would have a combined uncertainty of ≈ 34 × 10^{-11}, resulting in a 7.5σ deviation from the Standard Model, which will be a sensitive and complementary benchmark for proposed extensions to the Standard Model. Most of the improvement will be due to increased statistics and thus it is essential to maximize production of useful pions that create polarized muons which are in the acceptance of the g-2 muon storage ring. Furthermore, cost considerations favour a design that reuses the existing pbar production subsystem that worked well during the Tevatron operation. Hence, the pion production subsystem will begin with the pbar production subsystem scaled from 8 GeV (kinetic energy) protons to 3.1 GeV/c pions.

A preliminary study [3] revealed complexities in optimizing the target where there is interplay between the asymmetric pion production, the need to have the pions created near the target edges to minimize reabsorption, and the depth of focus of the Li lens. An optimization procedure was proposed in that early study to overcome those complications and its application and result is the focus of the study reported here.

THE LAYOUT

A graphical representation of the Fermilab pbar production target subsystem is shown in Figure 1 as implemented in Ref. [4] in the MARS15 code [5]. The proton beam with kinetic energy of 8 GeV impinges on the default target, which was previously used to create pbars. We considered two spot sizes for the proton. One is what we expect from a simple scaling from 120 GeV operation to 8 GeV. The other is the smallest we believe that can be achieved. Spot size information on both is provided in Table 1. The default pbar production target is a vertical cylinder (in-out of top view in Figure 1) composed primarily of inconel with a chord for the proton beam of ~7.5 cm. Pions produced in the target will be focused by the Li lens (yellow) that is 15 cm long, 1 cm in radius, and has a magnetic field gradient of 256.25 T/m, where the gradient has been scaled for 3.1 GeV/c pions to maintain proper focusing, while keeping the same focusing distance between centers of the target and Li lens of 25.16 cm. The focused pion beam is then collimated and bent through a pulsed magnet (PMAG) with a dipole field of 0.542219 T, also scaled for the 3.1 GeV/c pion beam, and bends the reference by 3 degrees to provide momentum selection.

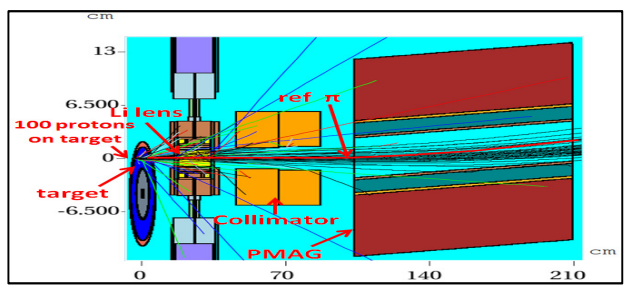

Figure 1: Zoomed in top view of pbar target subsystem.

Table 1: Proton Beam Spot Sizes

Proton spot size description	σ_x (mm)	σ_y (mm)	$\sigma_{x'}$ (mrad)	$\sigma_{y'}$ (mrad)
Default	0.55	1.1066	0.38	0.38
Small	0.15	0.15	0.6366	0.6366

A transition in our simulation between MARS that provides reliable particle generation and G4beamline [6] that is used for particle tracking, pion decay into muons, and effect of beam particles interacting with the beam line elements is shown in Figure 2. The MARS particle tracks that hit the virtual detector are converted and propagated in G4beamline through a set of four quads that refocuses

Copyright © 2013 CC-BY-3.0 and by the respective authors

the beam after the three degree bend from the PMAG. Figure 3 shows 100 such particle tracks traversing the four quads.

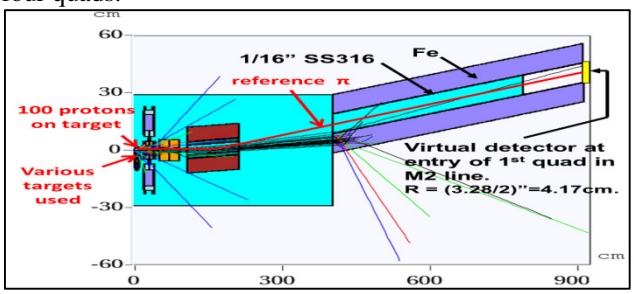

Figure 2: Top view of pbar target subsystem.

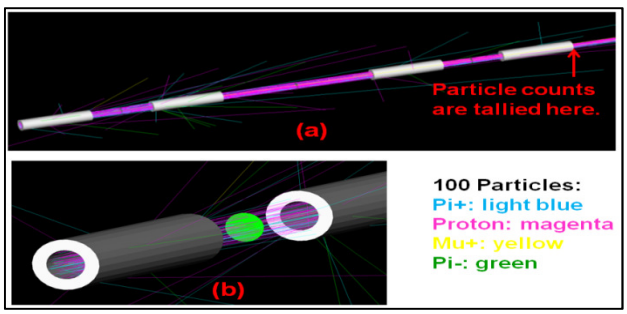

Figure 3: Particles after the conversion into G4beamline and propagated through the 4 quads. (a) Particle yields are tallied at end of the fourth quad with acceptance cuts appropriate for downstream elements. (b) Zoomed in view of particle trajectories between quads that are seen by a virtual detector (green).

The particle yields expected for the g-2 muon ring are estimated by particles simulated to the end of the fourth quad in the Fermilab M2 line as shown in Figure 3(a) and applying the acceptance of those downstream elements, which are:

- P(pi+) = 3.15588 GeV/c +/- 2% (1.02 x P_{magic} +/- 0.02 x P_{magic})
- 40π mm-mrad in each transverse dimension

THE OPTIMIZATION

The previous study [3] utilized thin inconel targets of varying widths, lengths (in direction of proton beam), and orientations (vertical and horizontal). In the current study, we assume pions emanating from the surface in the non-bend plane will give better yields downstream, so we considered only the horizontal orientation. Application of the horizontal slab target into a more realistic one that incorporates cooling would be via a rotating thin walled cylinder with the proton beam hitting either the top or bottom, as shown in Figure 4.

The earlier study also fixed the location of the target center to be at the focal point of the Li lens, while varying the target dimensions. Since pion production is greatest at the upstream end of the target, lengthening the target pushes the location of copious pion production ahead and out of the focal point of the Li lens. The solution to overcome the complexity between varying the target geometry and maintaining focus is to recognize that there will be much less useful pions produced at the downstream end of a long flat target. The procedure involves two stages, where the first optimizes for the location of the upstream edge of the target which is more critical, since that is where pion production is copious. It consists of the following steps as illustrated in Figure 5:

1. Placing the downstream end of a horizontal flat target far downstream as possible, near to the Li lens.
2. The upstream end of the target will be varied starting from the focal point and progressed upstream in each simulated configuration.

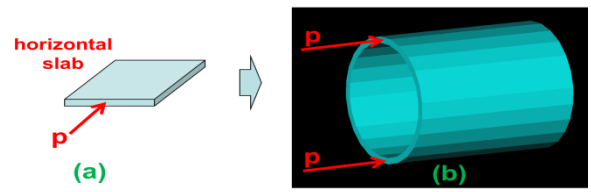

Figure 4: Association of simulated horizontal slab targets and a more practical rotating thin walled cylindrical target to accommodate cooling where protons impinge on either the top or bottom of the cylinder.

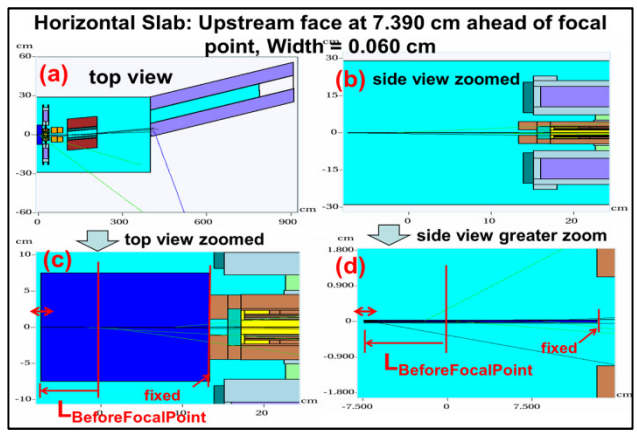

Figure 5: Illustration of optimization for location of upstream target edge. The downstream edge is fixed near the Li lens. The top view is shown in (a) which is similar to that shown in Fig. 2 for the default target. A zoomed in side view is shown in (b), while (d) is further zoomed to show the variation of upstream edge location relative to the Li lens focal point and (c) is similar for the top view.

The geometry of the targets studied, which included varying widths, are given in Table 2 and the anticipated small proton beam spot size described in Table 1 was used throughout the optimization. Results of this first stage of optimization are shown in Figure 6, where it is seen that there are two optimal configurations which provide similar yields:

- $L_{BeforeFocalPoint}$ = 56.12 mm & width = 0.60 mm
- $L_{BeforeFocalPoint}$ = 66.79 mm & width = 0.75 mm

Both configurations will be carried forward into the second stage of optimization.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Table 2: Dimensions and Orientations of Targets Studied. Material of all targets is inconel.

Shape	$L_{BeforeFocalPoint}$ (mm)	Width (mm)
Horizontal Slab	0, 36.95, 73.9, 110.85 λ_{int} : 0, 0.25, 0.50, 0.75	0.60, 0.75, 1.00, 1.25
Default Pbar Target	chord ~75 mm	

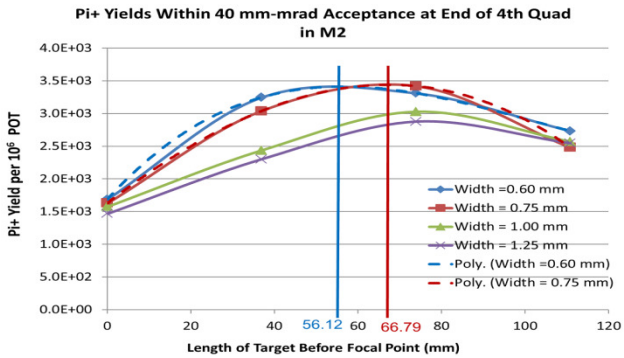

Figure 6: Yield of π^+s in first stage of optimization for location of upstream target edge.

The second stage of optimization consists of simply trimming the downstream end of the target; this automatically maximizes the yield taking into account the effects of:

- Widening birth of pions nearer the surface due to growth of transverse proton beam size as it traverses the target.
- Pions produced near the downstream edge.

The procedure for this second stage of optimization is to fix the location of the upstream edge of the target at locations determined from the first stage and vary the target length. Figure 7 illustrates this procedure for one of the optimal cases elucidated in the first stage.

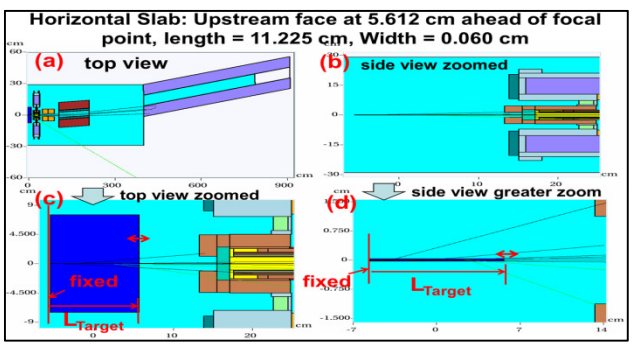

Figure 7: Illustration of optimization for location of downstream target edge. The upstream edge is fixed according to a result of first stage, while the downstream edge is varied. The top view is shown in (a) which is similar to that shown in Fig. 2 for the default target. A zoomed in side view is shown in (b), while (d) is further zoomed to show the variation of the downstream edge location and (c) is similar from the top view.

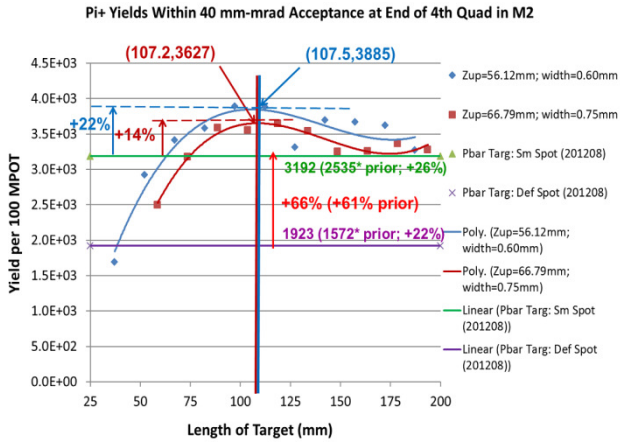

Figure 8: Yield of π+s in second stage of optimization for location of downstream target edge. Values designated "prior" refer to results obtained from MARS version 1510 used in the previous study [3], while the current results (also designated 201208) utilized MARS version 1512.

Results of the second stage of optimization as well as the effect of reducing the proton beam spot size on the default pbar target are shown in Figure 8. It is seen that the reduction of the proton beam spot size on the default pbar target increases the yield of useful pions by 66%! The optimized horizontal slab target using the same small proton beam spot size increases it further by 22%. While an increase of 22% is non-trivial, a cost-benefit and risk analysis resulted in the decision to keep the default pbar target design and reap the large benefit of the anticipated smaller proton beam size.

ACKNOWLEDGMENT

The support, encouragement, and contributions of Chris Polly, Mary Convery, and Dean Still of Fermilab are gratefully acknowledged.

SUMMARY

A study of the New g-2 Experiment target system at Fermilab was performed to optimize the yield of useful pions. An optimization procedure was invented that overcame the complexities of an asymmetric particle production and depth of focus of a Li lens. The best possible target modification yielded a 22% increase over that of the default pbar target and a cost-benefit decision was made by the New g-2 collaboration to resuse the existing pbar target design.

HIGH VOLTAGE STABILIZATION SYSTEM OF CARIBU/ECR FOR ATLAS

Yong Luo, Sergey Sharamentov, Richard Pardo, Rick Vondrasek, Guy Savard
ANL, Argonne, IL 60439, USA

Abstract

With the increased radioactive beam capabilities brought by new CARIBU (Californium Rare Isotope Breeder Upgrade) in ATLAS facility, highest charge breeder efficiency of ECR is desired. Experimental study shows that the best efficiency could be achieved when high voltages (up to 50 kV) of two platforms (CARIBU and ECR) are only different within less than 1V [1]. We have developed a system with some innovative ideas implemented to measure the required tiny voltage difference ratio (~0.002%) precisely and to protect the system too. High voltage (HV) filter is designed to protect it from severe HV sparks and multiple level of relays with high precision medium HV divider are used to protect it from possible power supply failure. Homemade HV divider is used for rough measurement and control. Measurement results are converted to optical signals and then used to control power supplies to achieve the desired platform voltages. The system has been partially tested and will be used in the future.

INTRODUCTION

When developing such a system with very high sensitivity and accuracy as mentioned above, at first we need to consider how to prevent damage from HV shock and power supply failure. We also need to think about how to measure the voltage difference precisely.

In ATLAS facility, both CARIBU and ECR1 are on a common HV platform of 350 kV. Then the 50 kV bias is applied to them on top of the 350 kV with separate power supplies. There are numerous instruments which are biased with different HV or high current power supplies on both platforms. Occasionally, HV sparks may occur. Those HV sparks are fatal to electronic measurement systems if they are not protected. Possible power supply failure is another threat we need to deal with. We cannot eliminate power supply failure, but we can protect the system with an appropriate design.

Using high voltage divider to measure the voltage difference is a simple and tempting idea. But careful study indicates that this approach has un-surmountable problem. Due to variation in resistor resistance caused by temperature and voltage bias variation, typical HV divider may only provide about 1% accuracy. Even for very expensive custom made high voltage divider with 0.1% tolerance, it still cannot provide the accuracy we need here. The high common mode noise also introduces more measurement error.

SOLUTION

Multiple levels of filter circuit are used to protect the system from HV, high current sparks in electrometer [2]. This kind of sixth-order low pass filter can achieve high-frequency attenuation exceeding 10^{+5}. So we adopted this approach for our HV spark protection.

Multiple levels of relay can be used to protect the system from power supply (PS) failure. Details will be explained in design and test section. Relays are turned off when PS fails. Homemade HV divider is used for coarse control and monitoring.

CARIBU side high voltage is used as floating GND for our measurement system. So when the tow platform HVs are very close, accurate measurement can be achieved without introducing big noise.

SIMULATION

Spice simulation is performed on a simplified low pass filter as shown in Fig. 1. In this simulation, a hypothetical high voltage spark source (I1, 20 kA, ~1ns rise time) shown in Fig. 1 is used.

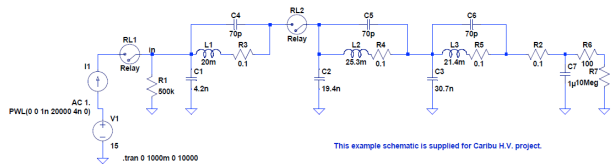

Figure 1: A simplified low pass filter with two relays.

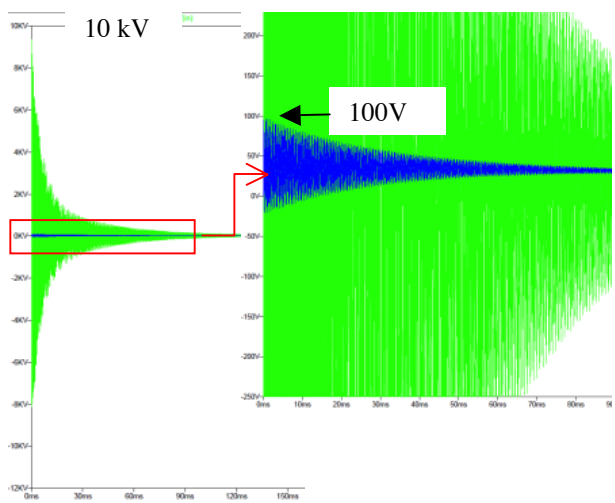

Figure 2: Simulation results of the filter shows the attenuation of HV shock

Copyright © 2013 CC-BY-3.0 and by the respective authors

The filter is similar as that which can be found in [2]. The simulation result is shown in Fig. 2. The plot at left shows the voltage waveform (green colour) at R1. It is about 10 kV peak. After filter, the peak voltage (peak of blue waveform) level drops to about 100V peak at C7/R6. The peak voltage attenuation is about 100 which is 40dB. The inset shows the zoomed view of area inside the red rectangle. Some components such as capacitors and resistors in the low pass filter are HV components.

DESIGN AND TEST

The system has been built by following the block diagram shown in Fig. 3. The voltage difference is measured by Delta V board and then converted to frequency. The frequency is then converted to optical signal and communicated to F-V converter. The signal is converted back to voltage before sampled by ADC. The computer checks the data and then goes back to control power supplies and control the system based on the data and control setting. A typical voltage to frequency converter used is shown in Fig. 4. It can be modified to use as frequency to voltage converter. The voltage after F-V converter can be used to control power supplies directly in case we need it.

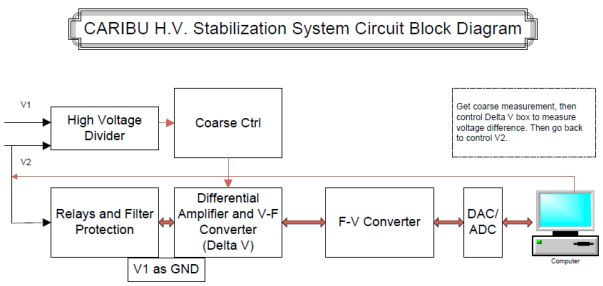

Figure 3: Block diagram of the HV stabilization system.

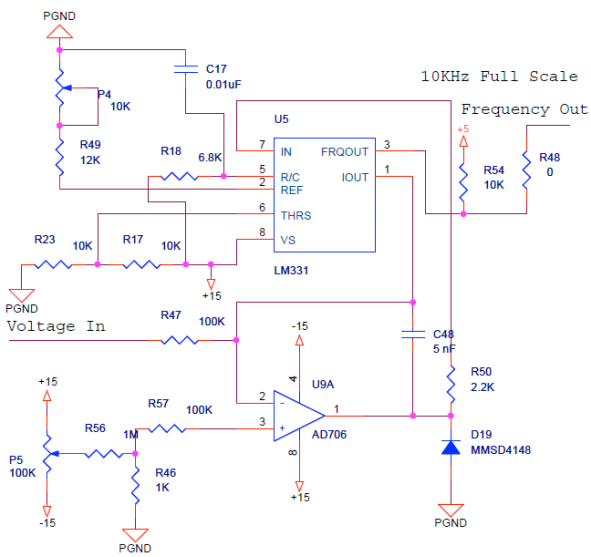

Figure 4: A typical voltage to frequency converter.

A FUG power supply with very high stability (10^{-5}/8h, ^{o}C) is used at CARIBU side platform voltage. This HV is used as the floating ground for the HV stabilization system. Power supply for Delta V board is referenced to CARIBU platform voltage.

A ultra precision medium high voltage divider (0.01% tolerance) with very low temperature coefficient is put on the Delta V board. It makes the accurate measurement feasible while also protecting this board from potential damage caused by medium high voltage up to 1500V after the low pass filter. A precision instrumentation amplifier AD8221 with high common-mode rejection ratio (CMRR) is used after the on-board divider. There is one relay on the Delta V board with release time ~1 ms. The 15 kV and 75 kV relay have release time ~2 ms and 15 ms respectively. Those two relays are RL2 and RL1 in Fig. 1. When there is a power supply failure, the one side voltage drop or increase due to the failure is estimated as 50V/ms, the relays in series are turned off by on-board monitoring circuitry to protect the system. Relays in series here are not for the purpose of protection from HV sparks. They are too slow for this but good for power supply failure protection.

A homemade HV divider provides ~1% accuracy and is used for coarse measurement and control in the system. Coarse control board is on 350 kV common HV platform and communicates with Delta V board through optical fiber cables.

The built system is show below in Fig. 5. The zoomed view of the low pass filter board and Delta V board is shown at right with the shield removed.

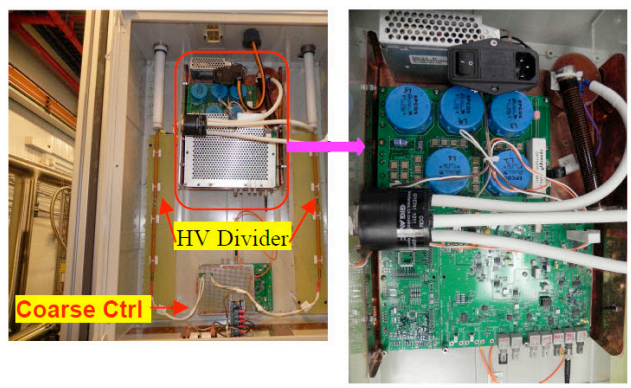

Figure 5: A simplified low pass filter with two relays.

Figure 6: F-V converter and control unit.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Figure 6 shows the front and back panels of the F-V converter and control unit. This chassis can be placed on any platform close to ADC/DAC and it connects with Delta V board through optical fiber cables.

The whole system has been tested on bench and had some field tests too. Field test verified that it can stand at least 50 kV isolation which is one of the design goals. The voltage difference can be measured precisely to ~100 mV or less which exceeds another design goal of 1V. Final user interface software is in progress and the unit will be used in future in our facility.

DESIGN AND SIMULATION OF THE ARGONNE INFLIGHT RADIOACTIVE ION SEPARATOR (AIRIS)*

B. Mustapha#, M. Alcorta, B.B. Back and P.N. Ostroumov
Physics Division, ANL, Argonne, IL 60439, USA

Abstract

A new inflight radioactive ion separator (AIRIS) is being designed for the ATLAS facility at Argonne. AIRIS will be used to separate and produce secondary radioactive beams from the interaction of ATLAS primary beams in a production target. AIRIS will be at least 10 times more efficient than the existing radioactive beam capability. We have made significant progress in the design and simulations of AIRIS including full 3D models of all the elements to consider their real dimensions and produce realistic 3D fields. The resolving power of the device has been studied for several reaction cases using realistic cross sections and kinematics. In addition to the magnetic separation of the device, an RF sweeper is being designed to take advantage of the time separation of the different beams and reject the primary beam tail and other potential contaminants in order to produce higher purity secondary beams. The latest AIRIS design and simulation results will be presented and discussed.

AIRIS AT ATLAS

The Argonne Tandem Linac Accelerator System is undergoing an efficiency and intensity upgrade [1]. Most of the stable beams will have their intensities increased by one to two orders of magnitude. To take advantage of this intensity upgrade and enhance the radioactive beam capabilities at ATLAS, a new inflight radioactive beam production and separation system is being proposed. The new system will consist of a production target placed at the end of ATLAS followed by an ion separator called AIRIS. Figure 1 shows the location of AIRIS downstream of ATLAS and upstream of any experimental area. The main constraint on the AIRIS design is to preserve stable beam operations by moving the target out and using AIRIS as a transport line. For this purpose, AIRIS should have the same beam axis as ATLAS and the existing beamline. A broadband design has been proposed and developed for AIRIS [2]. It consists of four dipoles and four multipoles (quadrupoles) as shown in Figure 1. The original design was developed and simulated using COSY [3]. In this work, we have performed detailed simulations and parameter feasibility studies using the code TRACK [4], which has led to the new design parameters listed in Table 1. The dimensions and spacing of the elements have changed but not the overall layout.

Table 1: AIRIS Design Parameters

Parameter	Value
Number of dipoles	4
Dipole bend angle, deg	22.5
Dipole radius, m	1
Dipole full gap, cm	10
Max. dipole field, T	1.75
Number of quadrupoles	4
Quadrupole length, cm	30
Quadrupole full aperture, cm	15
Max. quadrupole field, T	1.0
Shortest drift, cm	20
Total chicane length, m	7.1
Angular acceptance, mrad	50
Dispersion at mid-plane, mm/%	1.2

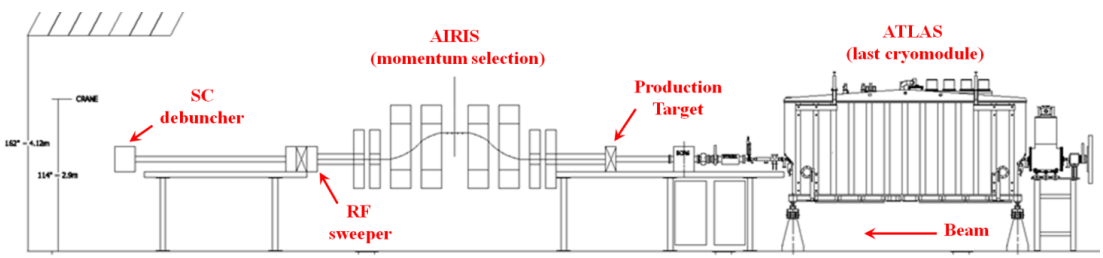

Figure 1: AIRIS, designed to be installed downstream of ATLAS and upstream of experimental areas for the production and separation of radioactive beams. An rf sweeper and a SC debuncher are included.

TRACK FOR ION SEPARATOR DESIGN AND SIMULATION

The beam dynamics code TRACK has recently been modified for more accurate transfer matrix calculation of any element up to the second order in particle coordinates. These calculations were benchmarked against COSY's results with excellent agreement, as will be shown later. Combining the new features with the existing TRACK capabilities, we were able to study the AIRIS design in more detail, which allowed us to produce more realistic element parameters. TRACK can now be used for the design and simulation of any ion separator.

Benchmarking Against COSY

Figure 2 shows a comparison of transverse beam emittance along AIRIS calculated for a 14 MeV/u $^{14}O^{8+}$ beam using ray-tracing in TRACK and different order matrices in COSY. We clearly see that from 2nd to 5th order, COSY's results converge towards TRACK's results, which should be equivalent to infinite order.

Integration Steps in Bending Magnets

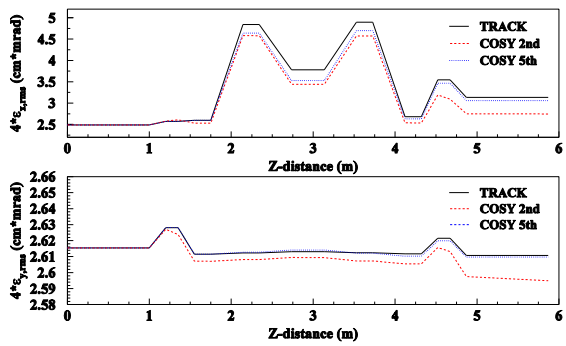

Figure 2: Transverse beam emittance along AIRIS calculated with TRACK and COSY at different orders.

Due to the curvature of a charged particle trajectory in a bending magnet, we expect a dependence of ray-tracing results in TRACK to the number of integration steps used for tracking. Figure 3 shows the dispersive horizontal beam centroid along AIRIS calculated in TRACK with increasing number of integration steps in the dipoles. We can see an improvement in the precision from 100 to 500 steps where it seems to saturate because we don't see a significant change when using 5000 steps.

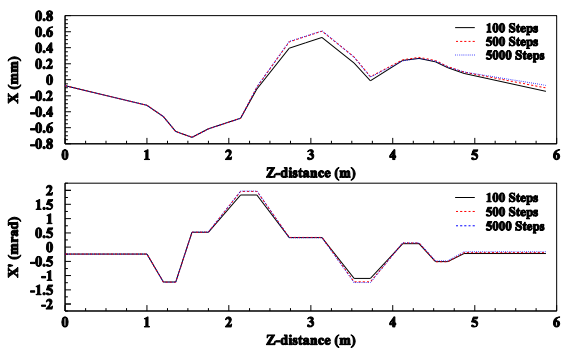

Figure 3: Horizontal (dispersive) beam centroid along AIRIS calculated in TRACK with different number of integration steps in the dipoles.

TRACK's 2nd Order Matrix for Correction

Using the 2nd order matrix calculation in TRACK and an internal optimization procedure, developed for high-order beam correction, we were able to optimize the sextupole component strength for a 2nd order correction. The results are shown in Figure 4.

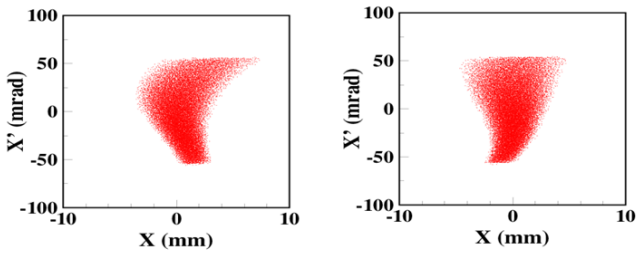

Figure 4: Horizontal beam phase space in AIRIS's mid-plane before and after 2nd order correction in TRACK.

Acceptance Calculation for Contaminants

TRACK already has an acceptance calculation procedure which could be easily applied to any potential contaminant to the radioactive beam selected in AIRIS. Figure 5 shows different regions of AIRIS acceptance in angle and energy, calculated with different mid-plane selection slit openings, for the $^{14}N^{7+}$ primary beam tail which is a potential contaminant to the $^{14}O^{8+}$ beam of interest. Such a calculation identifies the area of overlap with the primary beam and how to reject it.

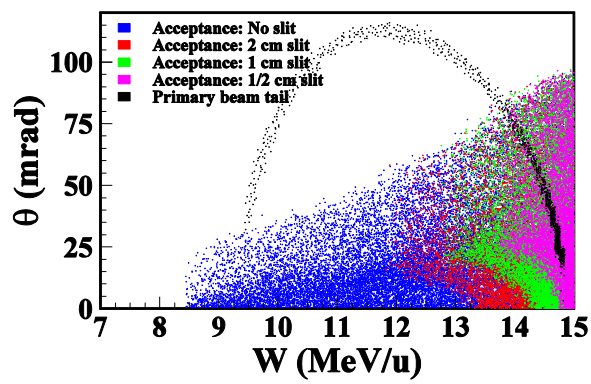

Figure 5: Regions of AIRIS acceptance (colors) calculated with TRACK for the $^{14}N^{7+}$ primary beam tail (black) with different mid-plane selection slit openings.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Multi-Beam and Multi-Charge States

TRACK was the first beam dynamics code to support simultaneous tracking of multiple beams and, in particular, multi-charge state beams. It was used to prove and demonstrate the simultaneous acceleration of multiple charge states of a uranium beam in ATLAS [5]. Figure 6 shows one example of multi-beam simulation and one example of multi-charge state simulation applied to study the overlap of the different beams and select the beam of interest at the AIRIS mid-plane.

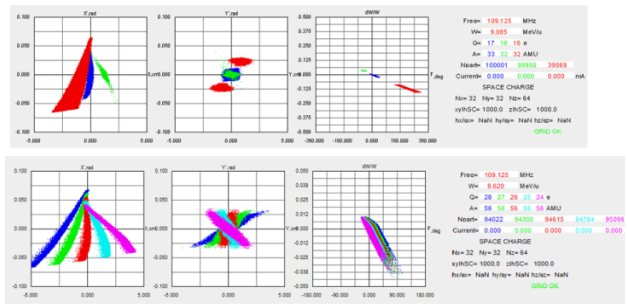

Figure 6: (top) Multi-beam phase space plots at AIRIS mid-plane for the $^{33}Cl^{17+}$ beam of interest and the $^{32}S^{16+}$ primary beam core and tail. (bottom) Multiple charge states of a ^{56}Ni beam at AIRIS mid-plane.

From Hard-Edge to 3D-Field Models

TRACK has internal models for most elements. These models range from simplified hard-edge to models with more realistic fringe fields. TRACK also supports external 3D fields calculated with other software. Although not always required, 3D field models could reveal more realistic non-linear effects. Figure 7 shows the $^{14}O^{8+}$ phase space in the AIRIS end plane simulated with hard-edge and 3D models for the dipoles and quadrupoles. We clearly see more beam distortions and tail formation in the 3D field case.

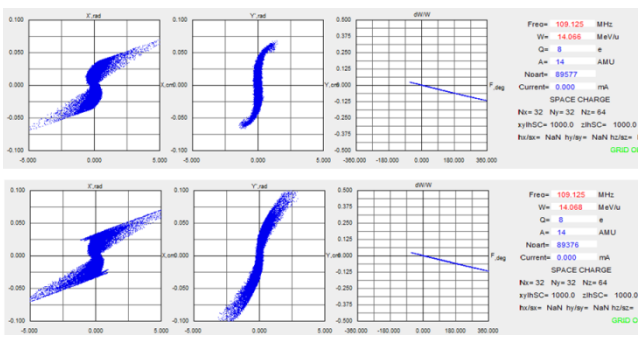

Figure 7: $^{14}O^{8+}$ phase space plots at the AIRIS end-plane calculated using hard-edge models (top) and 3D-field models (bottom) for the dipoles and quadrupoles.

3D MODELING OF AIRIS

In order to produce a more realistic model for AIRIS and check the feasibility of its elements, we have developed preliminary 3D designs for the dipoles and quadrupoles. For this purpose, EM-Studio of the CST package [6] was used and Figure 8 shows the full 3D model for AIRIS. The 3D modelling was essential to modify the AIRIS design parameters considering limitations on element dimensions, spacing and fields.

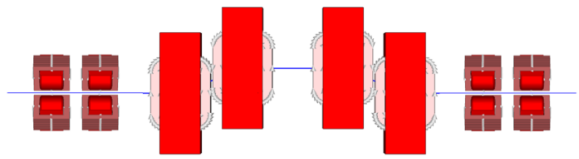

Figure 8: Full 3D model of AIRIS showing the dipoles and quadrupoles.

EXAMPLE OF AIRIS RESOLVING POWER

In order to study AIRIS's resolving power, we have simulated several radioactive beams. Realistic nuclear reaction models [7, 8] were used to generate the distributions for the secondary beam of interest, the scattered primary beam and the potential contaminants produced in the same reaction. Figure 9 shows an example of AIRIS performance in separating the secondary $^{56}Ni^{28+}$ beam of interest from the primary beam and other contaminants produced in the interaction of a 10 MeV/u ^{54}Fe beam on a carbon target.

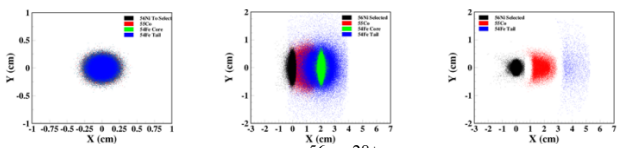

Figure 9: Separation of the $^{56}Ni^{28+}$ beam of interest from the primary beam and other contaminants. (left) All beams superposed at the target. (center) Clear separation of $^{56}Ni^{28+}$ (black) from the $^{54}Fe^{26+}$ primary beam core (green) at the AIRIS mid-plane. (right) Clear separation of $^{56}Ni^{28+}$ (black) from other contaminants, $^{55}Co^{27+}$ (red) and $^{54}Fe^{26+}$ primary beam tail (blue), at the AIRIS end-plane.

DIAGNOSTICS FOR THE LANSCE RFQ FRONT-END TEST STAND*

R. C. McCrady#, Y. K. Batygin, I. N. Draganic, C. M. Fortgang, R. W. Garnett, S. S. Kurennoy, J. F. O'Hara, E. R. Olivas, R. J. Roybal, L. J. Rybarcyk, Los Alamos National Laboratory, Los Alamos, NM 87544, USA.

Abstract

Plans are underway at the Los Alamos Neutron Science Center (LANSCE) to replace the existing H^+ Cockcroft-Walton injector with a modern 4-rod Radio-Frequency Quadrupole (RFQ) based front end. This will provide protons for injection into the downstream linac, where H^- ions are also accelerated. This dual-species operation of the linac imposes constraints on the injectors, resulting in particular requirements on the transverse and longitudinal emittances and phase-space distributions of the beam from the RFQ proton injector. Good measurements of these quantities are therefore required during the testing phase of the RFQ injector. In this paper we describe the measurements to be made and plans for the systems for carrying out the measurements.

INTRODUCTION

The existing injectors at LANSCE for protons and H^- ions are based on Cockcroft-Walton (CW) generators and have been in use since the initial construction circa 1970. These CW-based injectors provide unbunched beams of protons and H^- ions at 750 keV with very little uncertainties in the beam energies. Precise matching of the beam energies is required for good dual-beam operation of the subsequent portions of the linac consisting of drift-tube linac (DTL) and coupled-cavity linac (CCL) sections. Additionally, the high average currents of the beams require good transverse matching from the injectors into the DTL to prevent large beam spill that results in high radiation fields.

An effort is underway to replace the proton injector with an RFQ-based system [1]. The initial phases of commissioning this system will involve operation in a test stand to characterize the system and to ensure that it operates as desired prior to installation in the production environment.

The present 750 keV beam-transport lines from the CW injectors to the DTL are rather long, at about 16m. The two beam species are merged in a 9° dipole magnet about 2.3 meters upstream of the DTL and pass through an RF buncher and a 4-quadrupole matching lens in the common section after the merging magnet. The 18° separation between the two beamlines upstream of the merging magnet limits the transverse space available for equipment in the two beamlines. For this reason, the RFQ must be placed rather far upstream of the DTL, about 4 meters. This distance, combined with the large energy spread of the beam produced by the RFQ, necessitates the use of 2 additional RF bunching cavities in the new proton transport line (shown in Fig. 1) in order to maintain a bunch length that will fit easily into the acceptance of the DTL. For this reason it is imperative that we measure the longitudinal bunch shape of the beam; ideally a full longitudinal phase-space distribution would be measured.

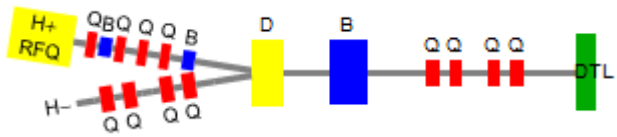

Figure 1: The proposed beam transport line from the proton (H^+) RFQ to the DTL. Also shown is a portion of the H^- transport line. Beamline elements are denoted by letters: Quadrupole magnets (Q), Dipole magnets (D) and Bunchers (B). Three of the bunchers are quarter-wave resonators, and one is a larger pillbox-style cavity.

The stringent requirements on the performance of the system drive the requirements for beam-measurement systems. In particular, we intend to measure beam current, transverse phase space, longitudinal bunch shape, and energy. The diagnostic systems for characterizing the beam produced by the new injector are described in the following sections.

TEST STAND

The RFQ-based proton injector will consist of a duoplasmatron proton source, a 35 kV accelerating column, a two-solenoid low-energy beam transport (LEBT), the RFQ, and a 750 keV medium-energy beam transport (MEBT) to the DTL.

We plan a phased approach to development of the RFQ test stand. The first phase will allow characterization of the LEBT that will transport the 35 keV beam from the source and extraction column to the entrance of the RFQ. The second phase will allow measurements of the beam delivered by the RFQ to assess its performance. The third phase will test the MEBT that will transport the beam from the RFQ to the DTL. Figure 2 shows the test stand phases and the associated beam measurements.

In the first phase, where the beam is not bunched, beam current and transverse emittance are of greatest importance. The beam energy is determined by the column voltage which can be measured precisely. The current and emittance provide input to models of the beam evolution in the LEBT. These models will be used in the process of transverse matching of the beam into the RFQ. We plan to have an emittance-measurement station near the middle of the LEBT; this apparatus will remain in place when the system transitions to the production

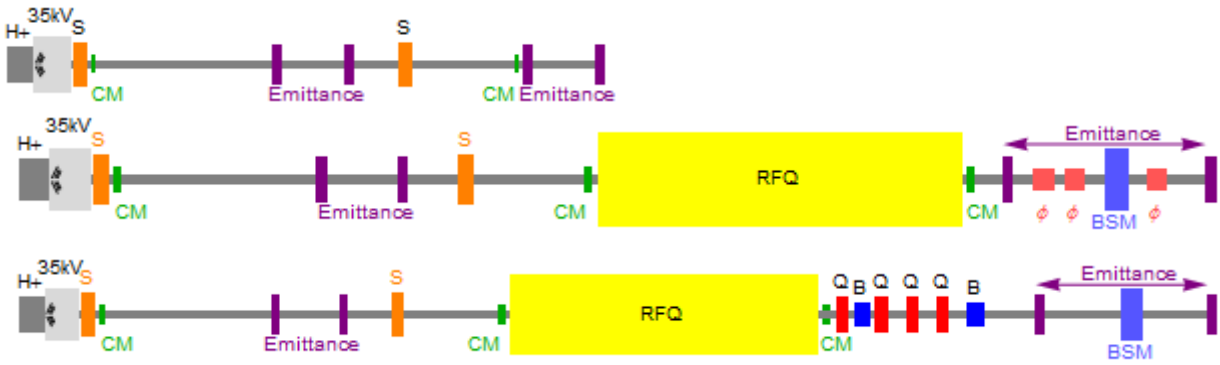

Figure 2: Phases 1 (top), 2 (middle), and 3 (bottom) of the RFQ test stand. Shown are the H^+ source, the 35kV accelerating column, two solenoid magnets (S), quadrupole magnets (Q), bunchers (B), beam-current monitors (CM), bunch-shape monitors (BSM), beam-phase monitors (ϕ), emittance-measurement stations, and the RFQ. Phase 1 allows testing the performance of the source and LEBT, including transverse matching into the RFQ. Phase 2 allows assessment of the RFQ performance, and Phase 3 allows characterization of the MEBT.

environment. An additional emittance station will be placed at the eventual location of the RFQ entrance. This will allow a direct measurement of the transverse phase space of the beam and provide a test of our models for predicting the match based upon measurements with the upstream emittance station.

The transverse evolution of the beam in the LEBT depends strongly upon space charge. The presence of multiple ion species (H^+, H_2^+, H_3^+) complicates modeling of the beam. We plan to remove most of the contaminating species near the middle of the LEBT in order to simplify the modeling of the beam within the RFQ. Beam-current monitors will be placed at a few locations along the LEBT, with one very close to the RFQ entrance.

TRANSVERSE PHASE SPACE

Presently at LANSCE we use several slit-and-collector emittance-measurement systems [2] in the 750 keV transport lines. These have proven to be very successful in tailoring the beams for injection into the DTL and for establishing other transverse conditions needed for proper beam bunching and collimation.

The slit-and-collector technique requires device actuators and many channels of analog signal conditioning and digitization; therefore they are costly. They also require scanning the slit across the beam, so a single measurement requires many beam pulses, making a single-pulse measurement impossible. However they also provide a complete phase-space measurement, allow an direct comparison to our existing LEBT performance, and the ability to distinguish the desired proton beam from other ions that are produced by the duoplasmatron proton ion source [3]. Additionally we have a great deal of experience with dealing with the subtleties of emittance measurement with this type of device, in particular the influence of secondary electrons produced by the beam interactions with the slits and collectors. While this type of scanner is relatively expensive to produce, several spares exist at LANSCE that can be exploited for the RFQ test stand.

Two other types of emittance measurement systems are under consideration: the Allison-type scanner [4] and the pepper-pot method [5]. These two methods have advantages and disadvantages in comparison to the slit-and-collector method, but the prospect of developing a new system and quickly gaining experience with it make it relatively unattractive from financial and logistical viewpoints.

BEAM CURRENT

Beam-current measurements are necessary for assessing the performance of the injector and provide space-charge information for the models of the beam evolution in the transport system. The LANSCE injectors typically produce 800μs-long beam pulses at 120Hz. The standard beam-current measurements are made using 100-turn toroidal current transformers with integrating electronics to provide an output signal that reproduces the beam-current time structure with a bandwidth of about 100 kHz. This system will meet most of our needs. Additional Pearson-type off-the-shelf current transformers may be used where higher bandwidth is needed for diagnosing problems.

BUNCH LENGTH

We have purchased a bunch-length measurement system [6] from INR and it is currently in fabrication. As mentioned above, the bunch length is a critical parameter for this injector due to the long distance from the RFQ to the DTL. While a full longitudinal phase-space measurement would be necessary to predict the evolution of the bunch, the projection of bunch length can validate models of the RFQ and beam-transport line.

The system will have a resolution of 1° of the 201.25 MHz RFQ frequency; this will fulfill the purpose mentioned above. This type of measurement requires partial interception of the beam by a tungsten wire, so it

Copyright © 2013 CC-BY-3.0 and by the respective authors

can be used with minimal impact during production operation.

BEAM ENERGY

Measurement of the beam energy is especially important for this system due to the use of two beam species in the linac. Directing both beams into the center of the linac acceptance provides a less problematic beam downstream in terms of uncontrolled beam spill.

A few options are available, but finding a technique to measure the RFQ output energy with high resolution is difficult. Options under consideration are: 1) magnetic spectrometer, 2) beam phase / time of flight, 3) solid-state detectors with scattered beam particles.

Detecting primary-beam protons scattered from a gaseous or solid target with solid-state detectors has been used previously in the commissioning of RFQs [7,8]. Resolution of a few keV is typical. While high-purity germanium detectors cooled to liquid-nitrogen temperature would be capable of <1keV resolution, this cooling is not possible without interposing some material in the path of the beam particles; this material would harm the resolution and provide a source of uncertainty in the absolute energy measurement.

A time-of-flight measurement using beam phase monitors [9] can provide energy resolution of a few hundred eV. Calibration of the system to provide an accurate absolute measure of kinetic energy is non-trivial, but can be accomplished.

Beam phase measurements can be made with a precision of <0.25°. To preserve this precision, mechanical alignment tolerances need to be about ±40μm. Uncertainties in cables lengths and in RF components could easily spoil the precision. We envision an in-situ absolute calibration using a metal conductor along the center of the beampipe.

The Fermilab PIP RFQ project, [9] used a system of three phase monitors to measure their RFQ output beam energy. Two of them were spaced at about 15 cm to provide a coarse measure of the beam velocity, and another was placed about 56 cm from the first to provide a fine measurement. Precision improves with greater spacing, but two complicating factors increase with the spacing: 1) Uncertainty in the number of RF cycles between the detectors; 2) De-bunching of the beam as it travels. We are evaluating these two factors to determine a set of phase-monitor spacings that will provide acceptable precision and accuracy for our measurements.

While beam-phase measurements can provide a precise measure of the average beam energy, it doesn't easily provide information on the energy distribution. We are evaluating the need for this type of measurement. A magnetic spectrometer is a good candidate to provide information on the energy distribution. To get good resolution in a magnetic spectrometer, two optical conditions are required: a small monochromatic spot size and high dispersion. Additionally, precise information about the path of the incoming beam is required. This can be accomplisheded with a pair of collimating slits. A fine map of the magnetic field is also needed to develop a map of the beam energy versus position at the exit of the magnet.

A magnet designed for use as a low-energy spectrometer is available at LANSCE; it has a bend angle of 120° and the pole faces are oriented to provide good focusing in the bend plane. Initial studies indicate that this magnet could provide sub-keV resolution, though space charge can compromise the resolution considerably.

A multi-wire electronic readout of the system would provide good dynamic range. Sub-millimeter wire spacing would be required in order to maintain resolution. The system used for the emittance scanners is a good candidate for the readout. Another possibility for readout is a phosphor/camera system.

SUMMARY

Several types of measurements are needed on the test stand for the new LANSCE proton RFQ in order to characterize the system performance, especially because of the dual-species operation of the downstream linac. We have identified systems for each measurement that can be implemented without extensive system development.

DESIGN AND COLD TEST OF A 17 GHz OVERMODED HYBRID PBG ACCELERATOR CAVITY*

JieXi Zhang†, Alan M. Cook, Brian J. Munroe, Michael A. Shapiro, Richard J. Temkin
MIT PSFC, Cambridge, MA 02139, USA

Abstract

An overmoded hybrid Photonic Band Gap (PBG) structure used as an accelerator cavity has been theoretically designed. The PBG structure consists of a triangular lattice of dielectric (sapphire) and metallic rods. The birefringence of the sapphire affects the PBG eigenmodes and must be taken into account. The PBG cavity formed by rods in between two copper plates will be operated in a TM_{02} mode at 17 GHz. Arrangement of the rods for higher-order-mode (HOM) damping demonstrates high frequency selectivity. Comparison with a disk-loaded waveguide (DLW) cavity gives a perspective of the dielectric PBG structure operated at an accelerating gradient of 100 MV/m. Cold test of a single hybrid PBG cell presents a high-Q resonance at 17 GHz. A standing-wave (SW) hybrid PBG structure will be tested in TM_{02} mode at 17 GHz.

INTRODUCTION

A periodic photonic structure, whose dispersion relation has photonic band gaps (PBG), can be applied to accelerators due to its good frequency selectivity [1]. A travelling-wave (TW) multi-cell metallic PBG structure has demonstrated successful acceleration of electrons with gradient of 35 MV/m [2]. More SW metallic PBG structures have been studied with high power breakdown tests at both SLAC and MIT [3, 4].

A theoretical study of a dielectric PBG structure was presented by Shapiro et al. [5]. A detailed design with isotropic sapphire rods using the commercially available code Ansys High Frequency Structure Simulator (HFSS) was reported in PAC11 [6]. The dielectric band gap allows a TM_{02}-mode operation without competing with the lower-frequency TM_{01} mode since the latter is not supported in the band gap. The TM_{02} mode helps in geometry design for a high frequency of 17 GHz and mitigates the central high field away from the innermost rods. Simulations showed an accelerating gradient of 100 MV/m with lower magnetic field than the metallic PBG structure, which may reduce the breakdown rate in high power testing. A sapphire rod structure was previously built and cold tested but not tested at high power [7].

In this paper, we analyze a sapphire PBG periodic unit cell with an anisotropic (birefringent) dielectric constant. 2D cross-section design in HFSS will give an optimal configuration of a hybrid PBG structure containing both dielectric rods and metallic rods. A single cell 3D structure has been theoretically designed and the cold test result will be presented.

ANISOTROPIC BAND GAP MAP

Sapphire is an optically anisotropic material with permittivity changing with the electromagnetic (EM) wave frequency [8]. At 17 GHz, with the orientation of the C-axis of the sapphire rods parallel to the particle beam axis in our design, the permittivity of the sapphire rod is $\epsilon_r = [9.398, 9.398, 11.587]$ by interpolation from [8].

Figure 1 shows the band gap map of a periodic sapphire lattice with the above anisotropic permittivity calculated in HFSS, as well as the comparison with an isotropic lattice of $\epsilon_r = 9.398$. The eigenmode frequency is normalized to $\omega b/2\pi c$ and the lattice is characterized by ratio $\frac{a}{b}$ with the rod radius a and the lattice spacing b. The lowest band gap can confine the TM_{02} mode while the TM_{01} mode is radiated out through the dielectric lattice.

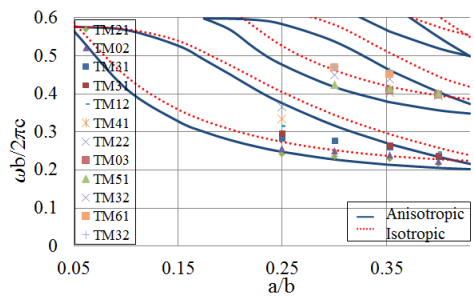

Figure 1: Band gap map of sapphire with isotropic and anisotropic permittivity.

In HFSS, to model a "2D structure", a very thin PBG layer is made with perfect E boundaries on top and bottom to limit the eigenmode solutions to TM modes. The calculated normalized frequencies of different modes in the 2D PBG structure are shown in Fig. 1; this helps to determine the design point $\frac{a}{b} \sim 0.35$, where the TM_{02} mode sits in the center of the band gap and few other modes are present in the same gap. The only HOM that is of concern is the TM_{31} mode. The final parameters of $a = 1.58$ mm and $b = 4.47$ mm have been chosen based on the 3D design shown later. Varying the arrangement of rods to achieve an improved Q of the TM_{02} mode and a reduced Q of the TM_{31} mode will be described in the following section.

CAVITY MODE IN 2D DESIGN

The birefringence of sapphire results in a discrepancy between the 2D and 3D simulations, but the study of the

2D cross section of each mode with distinct rod patterns provides a basic idea of how to improve the Q of the TM_{02} mode and damp the HOMs. Figure 2 shows how the diffractive Q of the TM_{02} mode increases as we include additional rows of concentric sapphire rods. This shows that a large number of rods are needed in a pure dielectric cavity to get a Q of the TM_{02} mode that is comparable to the Q of the TM_{01} mode in a DLW ($Q > 1000$), leading to a large cavity geometry. To increase the diffractive Q of the TM_{02} mode, metallic rods are added to the outermost row.

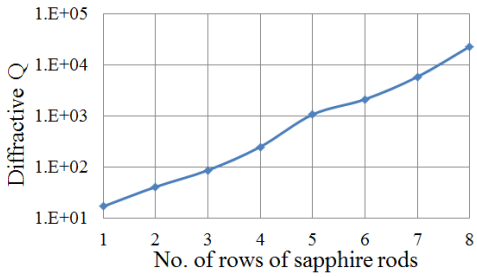

Figure 2: The diffractive Q vs. the number of concentric rows of sapphire rods.

Removing some rods makes the structure more azimuthally uniform and creates damping channels for the HOMs, which improves the Q of the TM_{02} mode and degrades the Q of the TM_{31} mode significantly. A 60° symmetric wedge of the optimal 2D structure is shown in Fig. 3, showing the E fields of the TM_{02} and TM_{31} modes. The calculated Q of the TM_{02} mode is ~ 6500 and the Q of the TM_{31} mode is ~ 30.

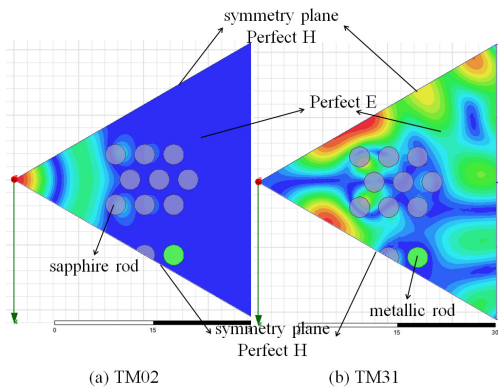

Figure 3: The 60° wedge cross section of E field of (a), the TM_{02} mode, and (b), the TM_{31} mode in the 2D model of the hybrid PBG structure.

SINGLE CELL 3D DESIGN

Based on the 2D design, a 3D HFSS model of a periodic single cell with three rows of sapphire rods and one row of metallic rods is shown in Fig. 4. Rods are inserted into two copper plates to form a cavity and irises are shaped to couple 17 GHz RF power. Design parameters are listed in Table 1.

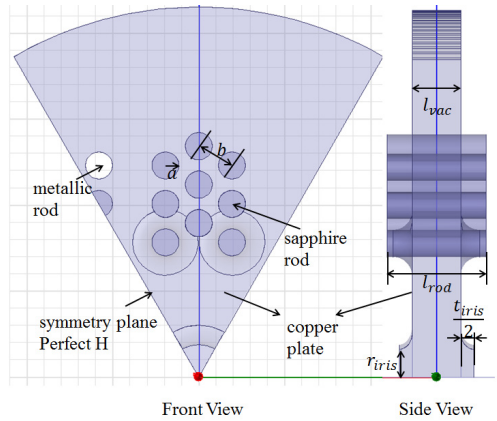

Figure 4: The 3D HFSS model of the periodic single cell hybrid PBG structure.

Table 1: Design Parameters of the Periodic Single Cell Structure

a **(mm)**	b **(mm)**	l_{rod} **(mm)**
1.58	4.47	11.68
r_{iris} **(mm)**	t_{iris} **(mm)**	l_{vac} **(mm)**
3.765	3.07	5.68

By using "Master" and "Slave" boundaries in HFSS, a phase shift of 180° is forced on the ends of irises to form a periodic boundary condition. The comparison of the EM field profile between the hybrid PBG cell (TM_{02} mode) and DLW cavity (TM_{01} mode) with the same irises is shown in Fig. 5, for an accelerating gradient [9] of 100 MV/m in each case.

The comparable field profile indicates a possibility to apply the hybrid PBG structure in high-gradient accelerators. The simulated result is listed in Table 2 as well as the experimental cold test measurement discussed next.

Table 2: Results of the Single Cell Structure

	f **(GHz)**	Q
Sim.	17.19	5800
Exp.	17.12	2700

SINGLE CELL COLD TEST

Cold test of a single cell of the hybrid PBG structure has been performed using a Vector Network Analyser (VNA) at MIT as shown in Fig. 6. Two antennas are held by three-axis translation stages to send and receive signals. Q is measured through the transmission parameter S_{21} [10].

Copyright © 2013 CC-BY-3.0 and by the respective authors

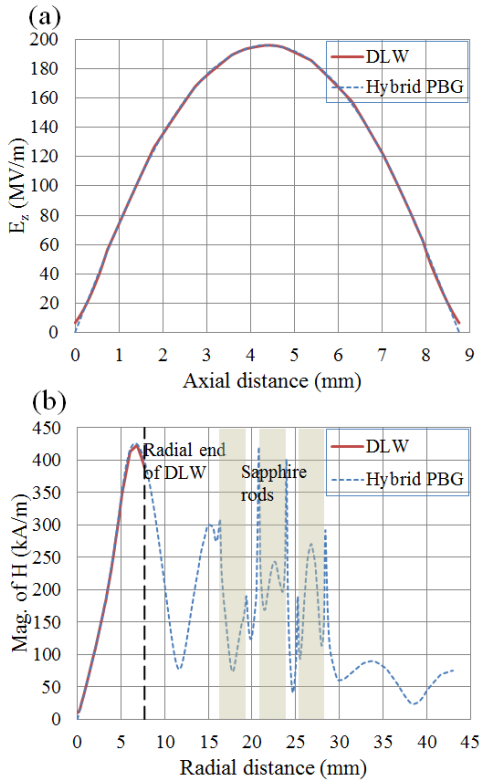

Figure 5: Comparison of the Hybrid PBG cell and the DLW cell of (a), E field axial profile and (b), H field radial profile.

The experimental result is shown in Fig. 7 with a single resonance at 17.12 GHz with $Q = 2700$, as listed in Table 2. No other modes are observed. The differences between theory and experiment in Table 2 may be due to approximations in the theory or fabrication errors. However, the presence of a single resonance close to the design frequency is very promising for future hot test experiments.

CONCLUSION

A hybrid PBG structure consisting of anisotropic dielectric rods and metallic rods has been optimized with 2D and 3D design in HFSS. With an accelerating gradient of 100 MV/m, the field profile of the single hybrid PBG cell is comparable to a DLW cell. A transmission measurement of a single cell of the hybrid PBG structure has been obtained in cold test, showing a single resonance at 17.12 GHz with a Q of 2700, providing a promising future for accelerator applications.

A SW 3-cell hybrid PBG structure is under design. By using the high power 17 GHz Haimson klystron at MIT, breakdown tests can be performed on the multi-cell structure.

RESULTS FROM THE LINAC COMMISSIONING OF THE RARE ISOTOPE REACCELERATOR - ReA*

Walter Wittmer†, Daniel Alt, Thomas Baumann, Carla Benatti, Shannon Wayne Krause, Alain Lapierre, Daniela Leitner, Ling-Ying Lin, Fernando Montes, Samuel Nash, Randall Rencsok, Jose Alberto Rodriguez, Michael Syphers, Eugene Tanke, Xiaoyu Wu (NSCL, East Lansing, Michigan)

Abstract

ReA [1] is a radioactive ion beams post accelerator currently being completed at the National Superconducting Cyclotron Laboratory at Michigan State University. ReA is designed to reaccelerate rare isotopes to energies of a few MeV/u following production by projectile fragmentation and thermalization in a gas cell. The facility consists of five main components: an electron beam ion trap (EBIT) charge breeder, an achromatic charge over mass separator, a radiofrequency quadrupole (RFQ) accelerator, a superconducting radio frequency linear accelerator (SRF LINAC) and a transport line into the experimental hall. The first sections up to the SRF LINAC of ReA have been commissioned in the last two years using an offline stable ion beam source and heavy ion beams from the EBIT charge breeder. The final section, transporting beam from the LINAC into the experimental hall, was completed and commissioned this summer. This paper presents the results of the SRF cryo module characterization and the progress of the machine optics model.

INTRODUCTION

The Facility for Rare Isotope Beams (FRIB)[2], a 400kW superconducting heavy-ion driver LINAC, will produce beams of exotic nuclear species with increased intensity of up to three orders of magnitude more than the CCF after fast fragmentation. ReA will reaccelerate these beams with improved characteristics for experiments. Initially the energy of the Rare Isotope Beams (RIBs) will be 3 MeV/u with future upgrades reaching 12 MeV/u. Currently ReA is coupled to the Coupled Cyclotron Facility (CCF) at the National Superconducting Cyclotron Lab (NSCL) at Michigan State University and provides beam of up to 2.4 MeV/u.

Stable beams are accelerated to energies of approx. 100 MeV/u by the CCF and fragmented on a solid target. The secondary beam, comprised of a melange of fragments, is separated achromatically in the A1900 fragment separator. The selected isotope is then thermalized in a He gas cell and extracted at energies up to 60 keV. Following mass selection at a dipole magnet the beam is injected into the Electron Beam Ion Trap (EBIT) where it is charge bred. The beam is then extracted at 12keV/u (RFQ injection energy) and transported through a Q/A achromatic charge-over-mass separator for charge selection and accelerated in the LINAC. The initial acceleration occurs in a four rod RFQ to an energy of 600 keV/u. The beam is then rebunched in a rebunching module with a single quarter wave cavity ($\beta = 0.041$) followed by an accelerating module containing six cavities of the same type. Next, the beam is delivered into the experimental hall. The final accelerating cryo module, comprised of 8 quarter wave cavities ($\beta = 0.085$), is currently in construction and will complete the initial ReA3 installation next year.

The commissioning of the current installation of the reaccelerator has been successfully completed following a commissioning experiment where a ^{37}K ($T_{\frac{1}{2}} = 1.23$s) beam was delivered to the ANASEN [3] detector.

SRF LINAC

The first rebunching module comprises a single quarter wave cavity ($\beta = 0.041$) and two superconducting 9 Tesla solenoids with integrated steering magnets. The second accelerating module houses 6 cavities and 3 solenoids of the same type. Both modules are shown in Figure 1.

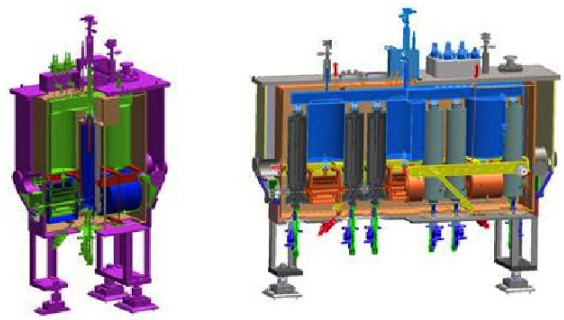

Figure 1: On the left the rebunching cryo module is shown with its cavity at the center between the solenoids. The right shows the first accelerating module with one cavity at each end and groups of two separated by the three solenoids.

Dipole Calibration and Energy Spread Measurement with CAESAR Detector

An experimental setup consisting of an Aluminum target inside the high-efficiency CsI(Na) scintillator array (CAESAR) [4] was used to obtain an energy calibration of a bend magnet, located after the second accelerating module, to measure the beam energy spread and to test the performance of the LINAC.

Preliminary analysis of the measurement data show good agreement of the derived energy spread and the predicted from the machine model as well as for the beam energy. A detailed analysis is ongoing an will soon be published.

Beam Based Cavity Amplitude Calibration

The initial calibration of the cavity amplitude was based on measurements performed in the SRF test dewar. It was soon noticed that the error of this calibration exceeded 10% and the calibration was repeated with beam based measurements. Two sets of measurements were performed. The first utilized a foil silicon detector where the beam is scattered through a gold foil to reduce the beam intensity and then the energy is measured with a silicon detector. The energy loss due to scattering has to be taken into account. The cavity phase is varied over 360 degrees and the beam energy is measured as shown in Figure 2. After calibrating

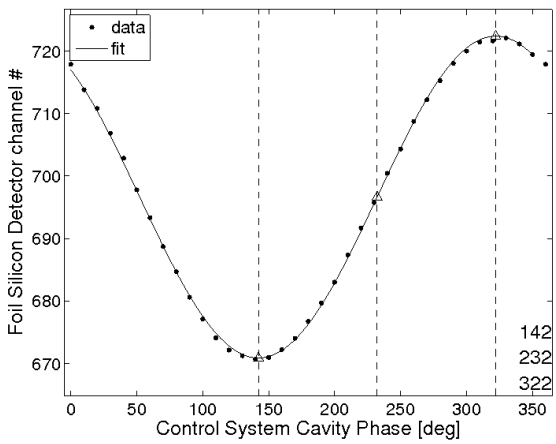

Figure 2: SRF cavity phase scan measured with a foil silicon detector. The dots represent the measured data, the line the fitted curve and the triangles with dashed lines, the location of maximum deceleration, zero crossing for the bunching slope and maximum acceleration.

the detector with an ^{241}Am source the energy difference between maximum deceleration and acceleration can be calculated. This allows calculating the accelerating field.

The second method uses two Beam Position Monitors (BPMs) [5] installed after the second cryo module and allows measuring the beam energy by means of time of flight measurements. A detailed description can be found in [6].

The established calibration factors have been verified with the bend magnet field, calibrated with the CESAR detector described above, and scattering measurements with the ANASEN detector. In both cases the differences were smaller than 2% which can be attributed to the uncertainty of the LINAC cavity phasing.

MACHINE MODEL

The DYNAC [7] code has been chosen for machine modeling based on its capability to simulate all devices in the ReA3 beam line except the EBIT. This includes the multi harmonic buncher, RFQ, superconducting quarter wave cavities, electrostatic and magnetic elements. This allows using a single code when performing beam optics calculations compared to 4 different sequencial codes.

SRF Quarter Wave Cavity Kick Measurements

An analytical model predicting the kick of a SRF quarter wave cavity (QWC) has recently been published [8]. A series of measurements were conducted with the goal to verify the model. If successful, it will allow to measure the cavity offset in the transverse position and minimize the overall kick the beam receives. Adding this effect to the machine model will improve its capability in the control room.

The asymmetric geometry of the QWC results in a vertical kick of the beam depending on the vertical displacement within the accelerating gap, the speed or energy of the particle upon entrance, as well as the cavity amplitude and phase. The location of the third cryo module is currently a drift space with a diagnostic station at each end capable of measuring the beam position. This allows measuring both position and angle of the beam exiting the second existing cryo module.

A first set of measurements was conducted using a molecular hydrogen beam H_2^+ at an RFQ energy of 600 keV/u. A parallel offset was induced to the beam trajectory through the last QWC of the LINAC, which was phased to the bunching zero crossing. The cavity amplitude was varied at each trajectory until the beam was lost in the drift space. A result of this measurement is shown in Figure 3.

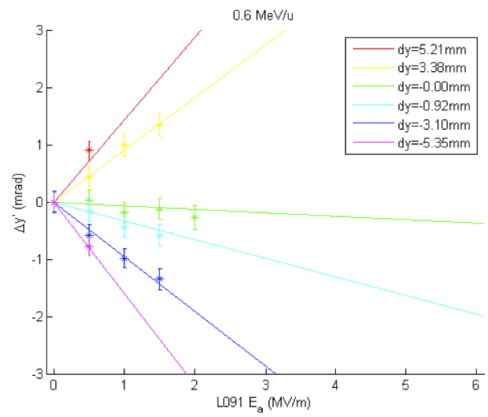

Figure 3: Vertical deflection angle vs. cavity voltage. Each line is the model prediction for different vertical displacement within the cavity from the beam's position. The diamonds including error bars represents the measured data.

All results agree with theoretical predictions. Based on this success a second series of measurements is planned for this fall, repeating this measurement at different beam energies and at different cavities.

Results of the Application of the Model During Beam Line Commissioning

The model was completed beginning of 2013 and has been benchmarked in the accelerator over the past couple of months. The first practical application of the machine model occurred during the commissioning of the final beam line, connecting the ReA LINAC to the experimental end station. The beam line elements were set to their design values and the beam was transported to the end of this approx. 30-meter long line within three hours. During the following commissioning, the design optics in this area was preserved and the injected beam properties adjusted. Figure 4 shows the simulated (left) and measured (right) transverse beam profile on a scintillating viewer crystal in the

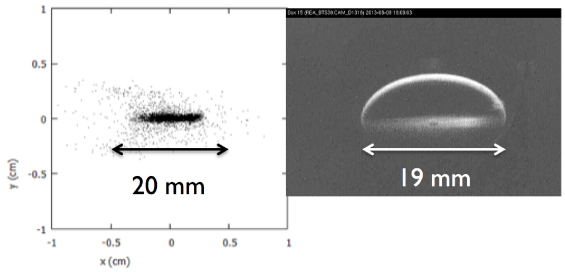

Figure 4: Transverse beam image in the location of a beam diagnostic station in the newly commissioned beam line. The left shows the simulated beam profile, the right the measured beam image.

diagnostic station. This particular location is at a high dispersion point, which explains the large horizontal beam.

To analyze the machine model a comparison of all settings was performed. Figure 5 shows as example the quadrupole magnet analysis. The first six magnets are located after the long drift and are part of the achromat that brings the beam line from the ReA deck onto the floor. The settings are optimized to cancel the dispersion. The following six quads are used to match the beam into the second achromat and final focus into the experimental end station. The settings of these element matches precisely the model. Only the final focus doublet needed to be adjusted. Overall the differences are small. The SRF cavity and RFQ settings are the same for model and machine. The solenoids in the SRF LINAC are deviating to a degree that is not fully understood. A possible source is a difference transverse emittance after the RFQ, as used in the simulation and in the machine. Work is ongoing to measure the emittance at this location. With the initial conditions of the beam entering the SRF LINAC section determined and the technique described in this paper, the benchmarking of the machine model will be completed.

The longitudinal emittance is fully understood. The model for the RFQ and SRF QWC is used to setup the beam. The transverse beam optics is well understood and a complete machine model will be available once the source for SC solenoid differences have been identified and incorporated in the model.

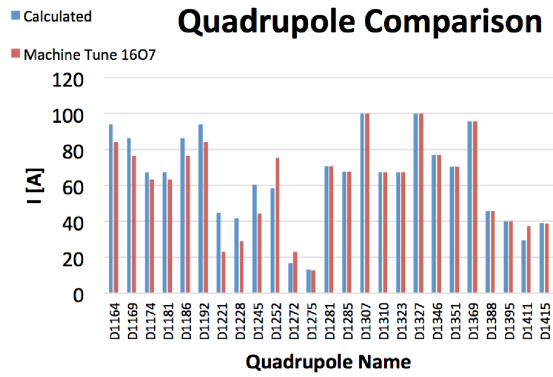

Figure 5: Comparison of quadrupole settings from machine model (blue) and as applied in machine (red).

CONCLUSIONS

The commissioning of the existing LINAC has been successfully completed and has shown a high level of reliability during the first beam delivery. The third cryo module is expected to be installed and commissioned by the end of summer next year. The experience and methods established during the initial commissioning will allow the integration of the final cryo module within a short period.

The machine model, implemented in a single code, has been established starting from the exit of the EBIT to the experiment's target point. The simulated longitudinal beam representation has been within 2% difference when compared to the measured beam. This has been verified by the measurements of the CAESAR and ANASEN detectors. The transverse description shows good agreement except in the cryo module area. Work is ongoing to determine the source of this difference.

Abstract

Electron cooling was proposed to increase the luminosity of the Relativistic Heavy Ion Collider (RHIC) operation for heavy ion beam energies below 10 GeV/nucleon. The electron cooling system should be able to deliver an electron beam of adequate quality in a wide range of electron beam energies (0.9-5 MeV). An attractive option is to use electron bunches produced with the superconducting RF (SRF) injector. Such a scheme of cooling with bunched electron beam is also a natural approach for high-energy electron cooling which requires RF acceleration. In this paper, we describe the requirements and design aspects of such an approach.

INTRODUCTION

Mapping the Quantum-Chromo-Dynamics (QCD) phase diagram is one of the fundamental goals in the heavy-ion collision experiments. The QCD critical point is a distinct feature of the phase diagram, the existence of which is predicted by various QCD models. The beam energy scan phase-I (BES-I) runs for physics, motivated by the search of the QCD critical point, were successfully conducted at RHIC in 2010-11. During BES-I physics runs data sets were collected for Au+Au (center of mass) energies of 7.7, 11.5, 19.6 and 39 GeV. Driven by physics and the BES-I results, the future physics program called BES-II is proposed for Au+Au energies below 20 GeV (γ=10.7). However, required event statistics is much higher than previously achieved and relies on significant luminosity improvement in RHIC at energies below γ=10.7. Electron cooling was proposed to increase luminosity of the RHIC collider for heavy ion beams at these low energies [1-2].

In a collider, the maximum achievable luminosity is typically limited by the beam-beam effects. For heavy ion beams significant luminosity degradation via the bunch length and the transverse emittance growth comes from the intra-beam scattering (IBS). For low-energy RHIC such IBS growth can be counteracted with electron cooling. If IBS were the only limitation, one could achieve a small hadron beam emittance and bunch length with the help of cooling, resulting in a dramatic luminosity increase. However, as a result of low energies, the direct space-charge force from the beam itself is expected to become the dominant limitation [3-4]. The main role of electron cooling for the lowest energy points is thus to counteract IBS: this prevents transverse emittance growth and intensity loss from the RF bucket due to the longitudinal IBS. As the energy is increased, the space-charge effect on the hadron beam becomes smaller which permits additional cooling of the transverse or longitudinal emittances of the hadron beams. This, in turn, allows us to reduce the β^*, providing larger luminosity gain. Recently, operation with long ion bunches and a new low-frequency RHIC RF system was suggested which should help to mitigate some observed limitations of beam lifetime at low energies offering a better path towards luminosity improvement [5-6].

This electron cooling technique requires electron beam to co-propagate with the same velocity as the ion beam in a localized portion of circular collider called the cooling section. An electron beam up to 5 MeV kinetic energy is needed to cover the full energy range of interest.

Such Low Energy RHIC electron Cooler (LEReC) based on the SRF linac is presently under design at BNL.

COOLING CONSIDERATIONS

The energies of electron beam needed for low-energy RHIC are sufficiently high (0.9-5 MeV), which allows us to consider cooling using bunched electron beam. One of the challenges for bunched beam cooling is providing beam transport of electron bunches without significant degradation of beam emittance and energy spread. A low-frequency 84.5 MHz RF gun can provide relatively long electron bunches. As a result, even for high bunch charges, space-charge effects remain under control. One can then deliver an electron beam of the necessary quality to the cooling section. In addition, the use of long ion bunches [5-6] allows us place several electrons bunches on a single ion bunch, which in turn relaxes requirements on charge in individual electron bunch and should allow us to achieve good beam quality needed for cooling.

Since non-magnetized cooling significantly simplifies electron beam transport and reduces the cost of the cooler, it was chosen as our baseline approach. Due to a relatively low beam current required for our cooler (Table 1), an approach with zero magnetic field on the cathode and thus no magnetic field in the cooling section is feasible. Short solenoids will be placed every 2 m to correct the angular spread accumulated due to the electron beam space-charge self field in the cooling section.

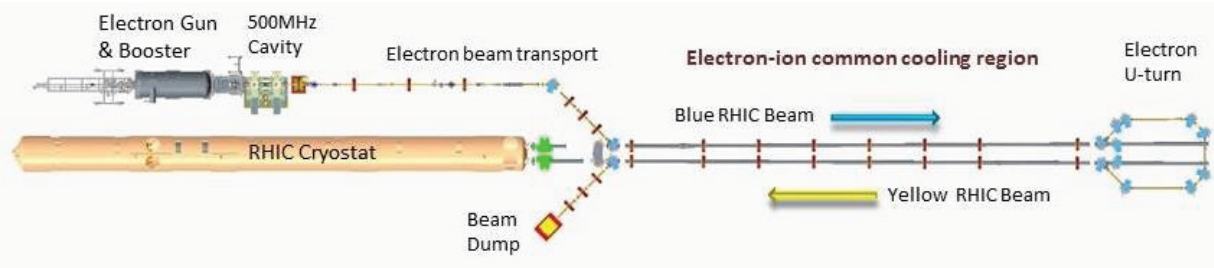

Figure 1: LEReC beam line layout. The cooling sections will be located in a RHIC warm region.

The use of undulators for recombination suppression in the cooling section is compatible with approach chosen. However, the use of undulators would require significant engineering additions to the cooling section while, in our case, the expected benefit for luminosity with recombination suppression seems rather modest. Thus, the recombination suppression with undulators is presently not included in the LEReC baseline.

ELECTRON ACCELERATOR

Beams for LEReC will be provided by a short SRF linac [7], which comprises a quarter wave resonator (QWR) photoemission electron gun, a QW SRF booster cavity and a normal conducting harmonic cavity to correct RF-induced energy spread. The two SRF structures will be housed in the same cryomodule with a superconducting solenoid in between the cavities. Preliminary optimization of the cavity shape is performed in collaboration with Argonne National Laboratory. Electron beam will be accelerated to the required energy and then transported from the SRF accelerator to the first cooling section in the Blue RHIC ring, cool ions in the first cooling section, turned around between Blue and Yellow RHIC rings (U-turn), cool ions in the Yellow ring and transported to the beam dump, as shown in Fig. 1.

Electron beam will be generated by illuminating a multi-alkali (CsK_2Sb or NaK_2Sb) photocathode with green (532 nm) light from a laser. The photocathode is inserted into a 84.5 MHz quarter-wave SRF cavity thus forming an SRF photoemission electron gun. The photocathode is located in a high electric field. Immediate acceleration of the electrons to a high energy reduces emittance degradation caused by a strong non-linear space-charge force. The low RF frequency of the gun reduces the effect of RF curvature on the beam.

The SRF gun will produce bunch trains (several bunches) with relatively long electron bunches, about 1 ns, at 84.5 MHz bunch repetition frequency. The bunch train repetition rate will be the same as the repetition rate of ion bunches in RHIC. The optical system will allow creating dedicated bunch patterns for different RHIC energies and ion bunch lengths with several bunches at 84.5 MHz frequency followed by a long gap corresponding to the frequency of ion bunches. For example, for very long ion bunches at lowest energies with new 4.5 MHz RHIC RF we can place up to 9 electrons bunches on a single ion bunch (see Fig. 2).

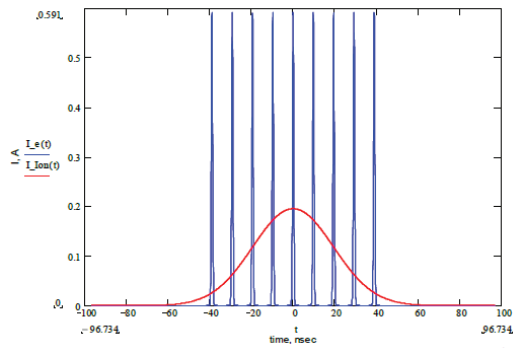

Figure 2: Nine electron bunches (blue) placed on a single ion bunch (red). Example for long ion bunches with proposed 4.5 MHz RHIC RF at $\gamma = 4$, time is in ns.

COOLER PARAMETERS

The requirement on the transverse angles of electron beam in the cooling section is given by the angular spread of the ion beam. For example, for the rms normalized emittance of 2.5 mm-mrad at γ=4.1, and 30 m beta function in the cooling section, the ion beam rms angular spread in the lab frame is 0.14 mrad. The ion beam will have rms longitudinal momentum spread in the range of σ_p=4-5×10^{-4}. This sets requirement on the rms momentum spread of electron beam of < 5×10^{-4}.

To keep the transverse angles of electron beam at an acceptable level (< 0.15 mrad) an integral of residual transverse magnetic field in the space used for cooling should be kept below 1 Gauss·cm (at γ=4). Shielding of residual magnetic field to such a level could be provided by several concentric cylindrical layers of high permeability alloy or by the correction coils.

Some cooling section space is taken up by very short (10 cm) weak (200 G) solenoids (to control angular spread due to the space charge), steering dipoles and beam position monitors to keep the electron and ion beam in close relative alignment. Diagnostics details for the LEReC project can be found in Ref. [8].

Since the electron beam does not have any magnetization, space used by the solenoids will be lost from the cooling process. Longitudinal field of 1 G produces rotational angles of 75 μrad at γ=4. Presently, design of these solenoids, placed every 2 m, is being optimized to maximize the space between them which satisfies requirement on B_z < 1 G. To allow for about 12 meters of effective cooling the full length of the cooling

Copyright © 2013 CC-BY-3.0 and by the respective authors

section, including solenoids, is presently 14 m. Basic parameters of electron beam are shown in Table 1 (see [9] for details). The charge per bunch needed depends on the energy at which cooling is applied and which RF system is being used in RHIC. For example, for γ=4 and 4.5 MHz RHIC RF the use of a bunch train allows us to split the total charge of 4 nC required for cooling, into 9 bunches with 0.44 nC per bunch. Although electron bunch occupies a small portion of the ion bunch, all ions could be cooled as a result of the synchrotron oscillations. To provide effective cooling of ions with different amplitudes a slow motion of the electron bunch through the ion bunch ("painting") is desired. With the present scenario of many electron bunches spread through the ion bunch such a painting maybe not necessary.

Table 1: Electron Beam Parameters

Electron Beam Energy	0.9-5 MeV
Charge per Bunch	0.4 –2 nC
Electron Beam Current	20-40 mA
RMS Norm Emittance	< 2.5 mm mrad
Transverse Angles	< 0.15 mrad
RMS Energy Spread	$< 5 \times 10^{-4}$
Bunch Length	750 ps

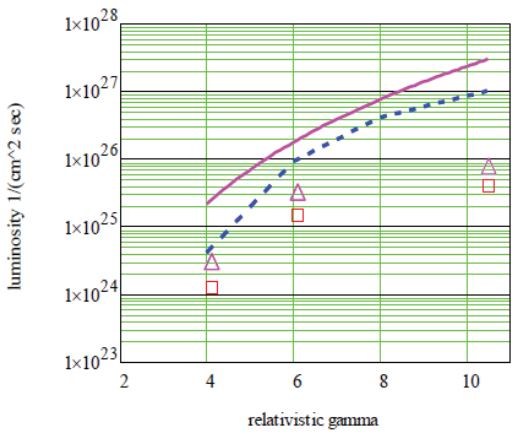

Figure 3: Luminosity in RHIC with and without the electron cooling upgrade. Red squares: measured average per store luminosity in BES-I; magenta triangles: measured maximum luminosity; blue dash line: luminosity with cooling (present RHIC RF); magenta top line: with cooling and long ion bunches (new RF system).

PERFORMANCE WITH COOLING

Projection of potential luminosity improvement as a function of energy is shown in Fig. 3. One can see that close to 10-fold improvement from cooling may be expected only at highest energies if one uses existing 28 MHz RHIC RF system (blue dash line in Fig. 3). At the lowest energies expected luminosity improvement could be rather modest (see [10] for details). A proposed low-frequency RHIC RF system (4.5 or 9 MHz) would allow for longer ion bunches and significant transverse cooling at low energies; the projected performance with this system is shown by the magenta curve in Fig 3. Performance in either scenario may be lower than indicated, due to remaining uncertainties in the beam lifetime improvement from cooling.

CHALLENGES

Successful operation of LEReC cooler requires stable and reliable CW operation of the SRF gun with electron beam current up to 40 mA. A long lifetime of the photocathode inside such a gun with a charge per bunch up to 2 nC is also required. Demonstration of some of the unique and challenging features is being planned with the existing 704 and 112 MHz SRF guns at BNL.

The achievement of very low transverse angular spread for the electron beam is challenging and is being addressed by a proper beam transport and engineering design [9]. The attainment of required low energy spread in the electron bunch relies on shielding of the longitudinal space-charge force with the vacuum chamber, use of long electron bunches and minimization of the length of beam transport. The repeatability of low energy electron transport is challenging due to remnant fields in the optics and hardware. Electron beam with small emittance and energy spread should be provided for several energies of interest. Quality of the beam should be preserved through the entire beam transport since the same beam will be used for cooling in both RHIC rings.

Besides many technical issues, this will be the first electron cooler to cool beams under collisions. This puts special requirements on the control of the ion beam profile under cooling. Careful optimizations between electron cooling and ion beam lifetime will determine how close one can actually get to the projected luminosity improvement.

RHIC MACHINE STUDIES TOWARDS IMPROVING THE PERFORMANCE AT 2.5 GEV *

C. Montag, H. Huang, G. Marr, A. Marusic, G. Robert-Demolaize, T. Shrey, V. Schoefer, S. Tepikian, K. Zeno, BNL, Upton, NY 11973, USA

Abstract

To search for the critical point in the QCD phase diagram, Au-Au collisions at beam energies between 2.5 and 15 GeV/n are required. While RHIC has successfully operated at 3.85 and 5.75 GeV/n, the performance achieved at 2.5 GeV/n is not sufficient for a meaningful physics program. We report on dedicated beam experiments performed to understand and improve this situation.

INTRODUCTION

During the next 5 - 10 years, one of the major RHIC physics programs will be the search for the critical point in the QCD phase diagram, shown in Figure 1. This search requires a gold beam energy scan in the range between 2.5 and 15 GeV/nucleon, which extends well below the RHIC design energy range from 10 GeV/n at injection to 100 GeV/n at store.

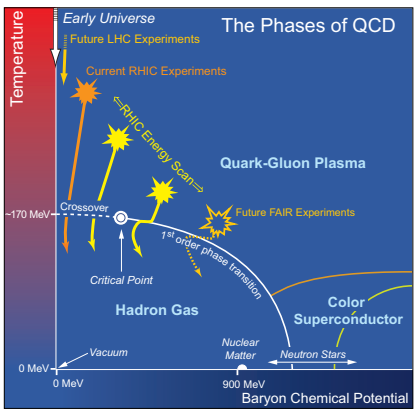

Figure 1: The QCD phase diagram, with the critical point expected in the center-of-mass energy range between $\sqrt{s_{\mathrm{NN}}} = 5$ and 30 GeV

Operating RHIC below its design energy range is very challenging for a number of reasons. First of all, beam emittances are large, resulting in a lower limit on the β-function at the interaction point, and therefore in low luminosity. Large space charge tune shifts are encountered even with moderate beam intensities. Last but not least, the multipole errors in the accelerator magnets are optimized at full energy, while they are an order of magnitude larger below the nominal injection energy.

ΔQ_{sc}	0.035	0.047	0.012
τ_{beam} [sec]	1000	1500	3000

In the first phase of the beam energy scan in FY2010 and FY2011, RHIC operated at three different energies at and below its nominal injection energy [1, 2]. During these runs, beam lifetimes of roughly 15 minutes to one hour were achieved at gold bunch intensities of $0.5 \cdot 10^9$ to $1.1 \cdot 10^9$ ions per bunch; at the lower energies these intensities were limited by the space chage tune shift. Table 1 lists the beam parameters achieved during these runs.

In FY2012, RHIC operated for the first time successfully at a quarter of its nominal injection energy, namely at 2.5 GeV/nucleon [3]. During that test, beam lifetimes of approximately 4 minutes were achieved, see Figure 2. The bunch intensity was limited at $4 \cdot 10^7$ Au ions per bunch because of an injection efficiency of only 10 percent. Due to this short beam lifetime, only 27 bunches per ring were injected, since filling 110 bunches takes about two minutes per ring.

At these low bunch intensities, most of the RHIC beam instrumentation does not work properly, making it virtually impossible to understand and improve the machine performance. Most importantly, the transverse beam size and therefore the emittance were unknown because the ionization profile monitor (IPM) could not operate reliably.

EXPERIMENTS

In an effort to understand the single particle performance of the RHIC lattice at 2.5 GeV/nucleon Au beam energy, protons with the same rigidity of 19.3 Tm were injected and stored at an energy of 5.86 GeV, as listed in Table 2. Due to the different charge-to-mass ratio Z/A of protons compared to gold ions, the relativistic Lorentz factor γ is about

Copyright © 2013 CC-BY-3.0 and by the respective authors

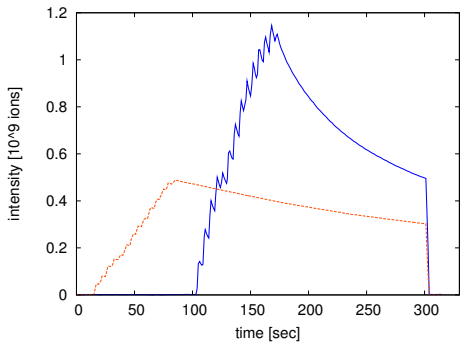

Figure 2: A typical Au-Au store at 2.5 GeV/n beam energy during a test run in 2012. While 27 bunches are being injected into the Blue ring, the intensity in the Yellow ring decreases by some 25 percent due to the short beam lifetime

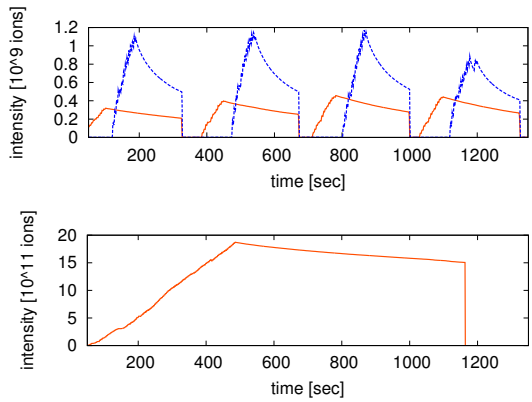

Figure 3: Comparison of the lifetime performance of typical Au-Au stores at 2.5 GeV/n in the Blue and Yellow ring (top) with a typical proton store at 5.86 GeV (bottom) in the Yellow ring

Table 2: Beam Parameters During the 5.86 GeV Proton Test Experiment

ramp	pp13-6GeV
$B\rho$	19.3 Tm
E	5.86 GeV
E_{kin}	4.92 GeV
γ	6.25
p	5.79 GeV/c
f_{rev}	77.187 kHz
h	363

a factor 2.5 higher than for gold ions at the same rigidity. Assuming identical normalized emittances ϵ_N for the two species, this results in smaller transverse beam sizes. Furthermore, the space charge tune shift

$$\Delta Q_{\mathrm{sc}} = -\frac{Z^2 r_p}{A}\frac{N}{4\pi\beta\gamma^2\epsilon_N}\frac{C}{\sqrt{2\pi}\sigma_s} \qquad (1)$$

for protons is also reduced by a factor $Z/(A\cdot\gamma^2) = 2.5^3$ as compared to gold ions with identical bunch charge $Z\cdot N$, normalized emittances ϵ_N, and bunch lengths σ_s.

After some tuning, intensities of $4\cdot 10^{10}$ protons per bunch were routinely injected and stored, with beam lifetimes of approximately one hour, as shown in Figure 3. Compared to the experience with gold ions in the same RHIC lattice, this was a huge improvement.

To characterize the single-particle performance of the lattice, we measured the dynamic aperture by two different methods. In the first attempt, we injected proton bunches with intentionally mis-steered orbits and measured the resulting beam emittances using the RHIC polarimeter target as a slow wire scanner. Mis-steering the injection orbit resulted in a drop of the injection efficiency and therefore the resulting stored beam intensity, Figure 4, thus indicating that an aperture limit was reached. During injection, losses were observed only in the RHIC abort kicker area, which is geometrically the tightest aperture at injection. Applying orbit bumps in an effort to reduce the losses in that location proved unsuccessful, which indicates that the beam orbit was well centered in the 2" × 3" aperture. However, regardless of the mis-steering efforts, the RMS beam sizes measured by the polarimeter target, at $\beta_x = \beta_y = 25\,\mathrm{m}$, remained constant at $\sigma_x = 2.4\,\mathrm{mm}$ and $\sigma_y = 2.0\,\mathrm{mm}$ which indicates that the beam already filled the available aperture even when it was injected without any intentional mis-steering, see Figure 6. At the abort kickers with $\beta_x = 41\,\mathrm{m}$, $\beta_y = 119\,\mathrm{m}$, this corresponds to RMS beam sizes of $\sigma_x = 3.1\,\mathrm{mm}$ and $\sigma_y = 4.4\,\mathrm{mm}$. These values are small compared to the abort kicker aperture, so it is safe to assume that the measured acceptance is limited by the dynamic aperture rather than the physical aperture.

This observation was confirmed by a second experiment in which the stored beam was transversely blown-up by the RHIC tunemeter. Again, this experiment resulted in RMS beam sizes of 2.4 mm horizontally and 2.0 mm vertically at the polarimeter. Furthermore, we observed a shrinking bunch length while the tunemeter was exciting the beam transversely, see Figure 5. We therefore conclude that the dynamic aperture is smallest for particles with large momentum deviation $\Delta p/p$.

The measured beam sizes of 2.4 mm horizontally and 2.0 mm vertically at the IPM with $\beta = 25\,\mathrm{m}$ correspond to RMS geometric emittances of $\epsilon_x = 0.23\,\mathrm{mm\,mrad}$ and $\epsilon_y = 0.16\,\mathrm{mm\,mrad}$. In contrast to this, Au beams with an RMS geometric emittance of $\epsilon = 0.73\,\mathrm{mm\,mrad}$ have been routinely stored at 3.85 GeV/nucleon. This indicates a dynamic aperture that is at least a factor 3 larger at the 50 percent higher rigidity of 29.7Tm at 3.85 GeV/nucleon compared to 19.3 Tm at 2.5 GeV/nucleon Au, or 5.86 GeV protons. The root cause of this large difference is not

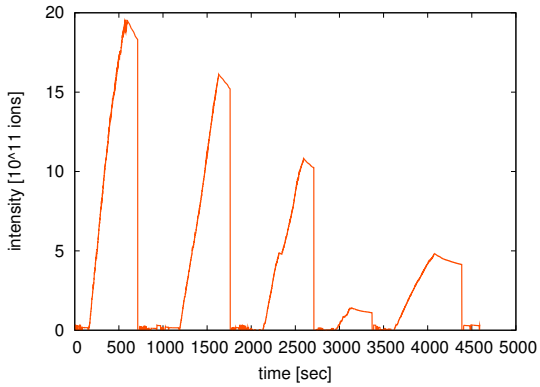

Figure 4: Total intensities of 110 bunches during the dynamic aperture measurement with mis-steered injection

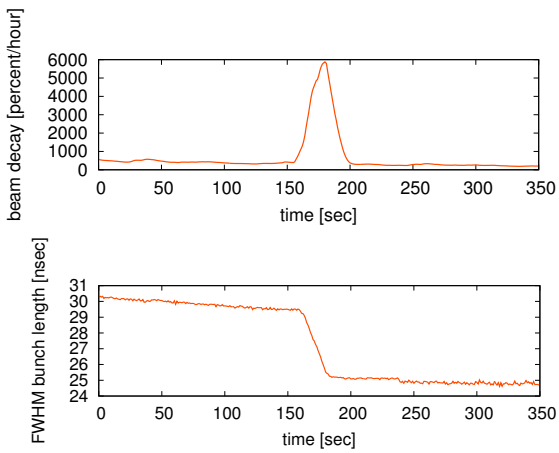

Figure 5: Hourly beam decay (top) and average bunch length during the dynamic aperture measurement using transverse emittance blow-up via the RHIC tunemeter

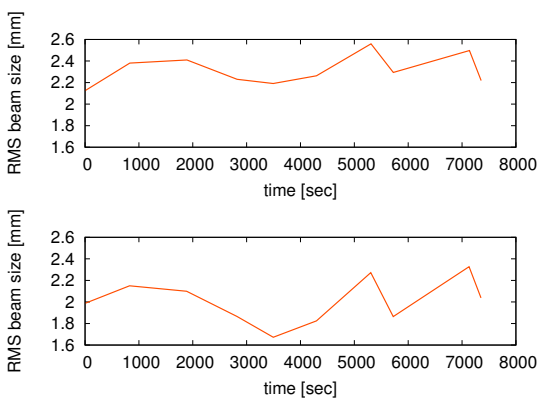

Figure 6: RMS beam sizes measured by using the RHIC polarimeter target as a wire scanner during the dynamic aperture studies

yet understood. Tracking studies are currently being performed in an affort to understand and improve the dynamic aperture at 2.5 GeV/nucleon Au.

SPACE CHARGE

Based on the measured emittance $\epsilon = 0.16\,\mathrm{mm\,mrad}$, corresponding to a normalized emittance of $\epsilon_n = 1\,\mathrm{mm\,mrad}$, an RMS bunch length of $\sigma_s = 3\,\mathrm{m}$, and a bunch intensity $N = 4 \cdot 10^{10}$ protons/bunch, the space charge tune shift achieved during our experiments with 5.86 GeV protons can be computed as

$$\Delta Q_{\mathrm{sc}} = -0.065, \tag{2}$$

which is consistent with the space charge tune shift limit of $\Delta Q_{\mathrm{sc}} \approx -0.05$ observed with Au beams at 3.85 and 5.75 GeV/nucleon.

Assuming the same geometric emittance of $\epsilon = 0.16\,\mathrm{mm\,mrad}$ for 2.5 GeV/nucleon gold, corresponding to a normalized emittance of $\epsilon_n = 0.4\,\mathrm{mm\,mrad}$, and a bunch length of $\sigma_s = 3\,\mathrm{m}$, this same space charge tune shift would be reached at a bunch intensity of $N_{\mathrm{Au}} = 8 \cdot 10^7$ gold ions per bunch, which is a factor 5 less than what was achieved at 3.85 GeV/nucleon. With 111 bunches per ring, this would result in a luminosity of $L = 2 \cdot 10^{22}\,\mathrm{cm^{-2}sec^{-1}}$.

CONCLUSION

Measuring the dynamic aperture of the 2.5 GeV/nucleon Au lattice by injecting and storing protons at the same rigity resulted in a dynamic aperture that is at least 3 times smaller than that for 3.85 GeV/nucleon Au. Improving this is the key to a higher beam intensity at the space charge limit, and therefore to higher luminosity. Tracking studies, including a frozen space charge model, are currently under way to understand and improve the dynamic aperture. However, multipole errors at these low energies are only known for a single dipole and a single quadrupole, which limits the predictive power of these simulations somewhat. As the next step, it is planned to inject gold beams with emittances taylored to the measured dynamic aperture to study the beam lifetime under these conditions.

BURN-OFF DOMINATED URANIUM AND ASYMMETRIC COPPER-GOLD OPERATION IN RHIC*

Y. Luo, W. Fischer, M. Blaskiewicz, J.M. Brennan, N. Kling, K. Mernick, T. Roser,
Brookhaven National Laboratory, Upton, NY, USA

Abstract

In the 2012 RHIC heavy ion run, we collided uranium-uranium (U-U) ions at 96.4 GeV/nucleon and copper-gold (Cu-Au) ions at 100 GeV/nucleon for the first time in RHIC. The new Electron-Beam Ion Source (EBIS) was used for the first time to provide ions for the RHIC physics program. After adding the horizontal cooling, 3-D stochastic cooling became operational in RHIC for the first time, which greatly enhanced the luminosity. In this article, we first review the improvements and performances in the 2012 RHIC ion runs. Then we discuss the approaches to achieve the burn-off dominated uranium beam lifetime at physics stores. And we also discuss the low copper beam lifetime in the asymmetric copper-gold collision with different intra-beam scattering (IBS) and stochastic cooling rates and the operational solutions to maximize the integrated luminosity.

PERFORMANCES

Improvements

The first high energy U-U collisions in RHIC were enabled by the versatile new Electron-Beam Ion Source (EBIS) [1]. EBIS can produce beams of essentially any ion species, and can switch rapidly between two different species. It was used for the first time to provide ions for the RHIC physics program.

To counter the intra-beam scattering (IBS) caused emittance growth in the RHIC heavy ion runs, stochastic cooling was implemented in RHIC in the past few years [2]. The longitudinal system was implemented in the Yellow ring in 2007, and longitudinal cooling in the Blue ring and the vertical stochastic cooling in both rings in 2010. In 2012, by adding cooling in the horizontal plane, full 3-D stochastic cooling became operational for the first time in RHIC for both rings.

In the previous 2010 and 2011 Au-Au runs, we observed large beam loss after RF re-bucketing and at store with the vertical cooling on. These losses were from particles with large off-momentum deviation. For the 2012 ion run, we chose a lattice with integer tunes (28, 29), which are 3 units lower than what was used in the previous ion runs. With this lattice, simulation shows that the off-momentum dynamic aperture increases from 2 σ to 5 σ with the maximum relative off-momentum deviation $\Delta p/p_0 = 0.0018$ [3].

*This work was supported by Brookhaven Science Associates, LLC under Contract No. DE-AC02-98CH10886 with the U.S. Department of Energy.

The RHIC orbit feedback system became operational for the first time in the 2011 proton run. In the 2012 ion run, with numerous improvements in the control software and hardware, the orbit feedback became more robust. Together with tune/coupling feedback, the RHIC beam control feedback systems greatly reduces the beam time necessary for machine start-up and store tuning [4].

U-U Run

The 2012 RHIC U-U run began on April 19, 2012 and ended on May 15, 2012. The physics mode lasted for 22 days. Figure 1 shows the integrated luminosities for the two physics detectors PHENIX and STAR, together with their minimum and maximum projected luminosities. The minimum projected luminosity was based on the bunch intensity 0.6×10^9. However, the typical bunch intensity at the beginning of store was 0.3×10^9.

The luminosity in the U-U run was greatly enhanced with 3-D stochastic cooling. With 3-D cooling, the rms normalized transverse beam emittance was cooled down to 0.42 π mm mrad in 2 hours from 2.2 π mm mrad at the beginning of store. Figure 2 shows the luminosity with and without stochastic cooling. With 3-D cooling, the peak luminosity was 3 times the initial one, which was observed for the first time in a collider. The integrated luminosity per store is about 5 times that without any cooling. Despite the lower bunch intensity the integrated luminosity goals of both detectors were reached.

Figure 3 shows an example of the Zero Degree Calorimeter (ZDC) coincidence rates from the two detectors STAR and PHENIX, the actual beam loss rates, and the burn-off contributions to the beam loss in one store (fill number 16830). As mentioned above, this year we adopted a lattice which provides a large off-momentum dynamic aperture. The particle loss due to the momentum aperture limitation was essentially eliminated. Together with stochastic cooling, the beam loss was almost entirely due to burn-off [5], which is also the first time this was observed in a collider.

Cu-Au Run

The 2012 RHIC Cu-Au run began on May 15 and ended on June 25. Physics mode ran for 38 days. 3-D stochastic cooling was operational on May 23. Figure 4 shows the integrated luminosities for PHENIX and STAR. The achieved integrated luminosities for both detectors were above the maximum projection. We also reached

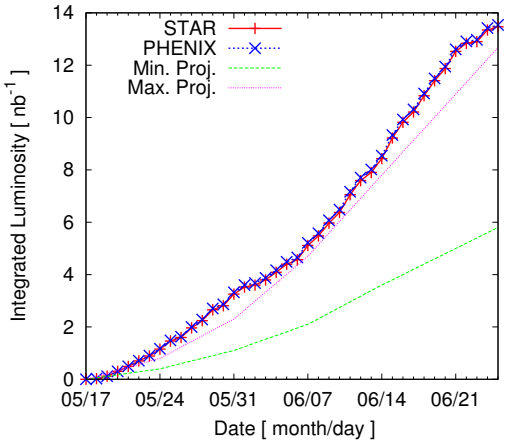

Figure 4: Integrated luminosities in 2012 RHIC Cu-Au run. The minimum and maximum projections are shown.

PHENIX's narrow vertex integrated luminosity goal. Narrow vertex luminosity only counts the collisions within ± 10 cm of the IP.

Figure 5 shows the averaged bunch intensities at the beginning of the store. To boost the bunch intensity in RHIC, double bunch merging in the Booster and AGS was tested and implemented. In principle, double bunch merging in the Booster and AGS could increase the bunch intensity in RHIC by a factor of 4. However, since double bunch merging increased the ion beams transverse and longitudinal emittances, careful tuning of the Booster, AGS, and the AGS-to-RHIC transfer line was always required. Continuous efforts were also made to improve the transmission efficiency from RHIC injection to store by fine tuning the working points, chromaticities, and transition loss. The Cu bunch intensity was doubled and the Au bunch intensity increased by 50% through out the course of the Cu-Au run. We achieved the most intense ion bunch in RHIC up to date.

In the Cu-Au run, Cu bunch intensity was more than 3 times the Au bunch intensity. The IBS emittance growth rate of the Cu beam is half of that of the Au ion beam, while the stochastic cooling rate of the Cu beam is one third of the Au ion beam. In the beginning of this run, we observed large Cu beam losses which were caused by the beam-beam interaction between the Cu and Au bunches with different transverse beam sizes. To maintain the Cu beam bunch intensity and to maximize the integrated luminosity, we intentionally reduced the Au beam's cooling rate in the first several hours of each store.

BURN-OFF DOMINATED BEAM LIFETIME IN U-U COLLISION

Beam Loss in Previous Runs

In the RHIC heavy ion runs, the IBS increases the longitudinal and transverse emittances. With a smooth ring

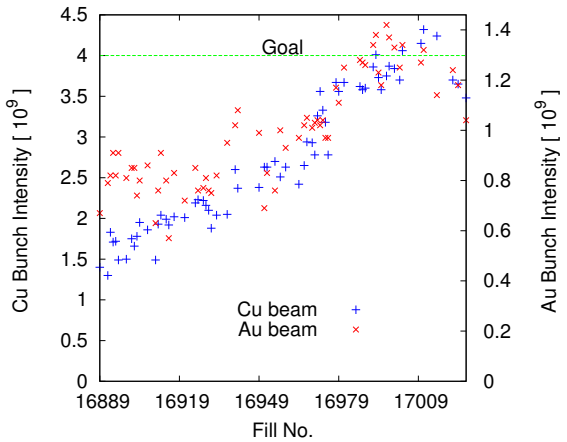

Figure 5: Averaged bunch intensities at the beginning of each individual store in the 2012 RHIC Cu-Au run.

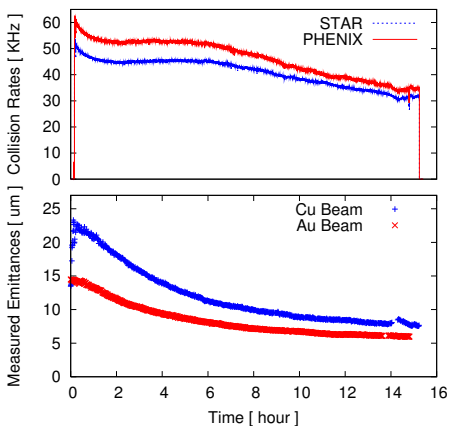

Figure 6: Experimental rates and beam transverse emittances in one physics store in 2012 RHIC Cu-Au run.

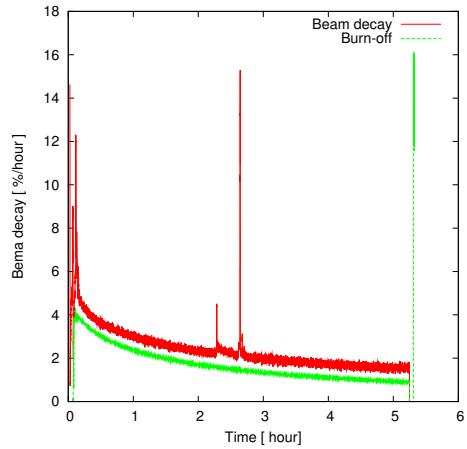

Figure 7: The Au beam decay in 2007 with only longitudinal cooling. RHIC Fill number is 9039.

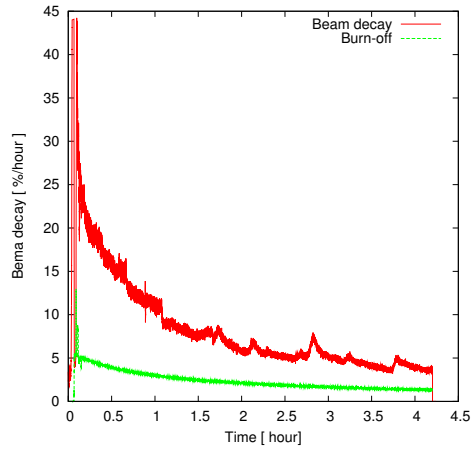

Figure 8: The Au beam decay in 2011 with only longitudinal cooling. RHIC Fill number is 15843.

approximation, the longitudinal and transverse IBS growth rates can be calculated as [6]

$$\tau_{||}^{-1} = \frac{1}{\sigma_p^2}\frac{d\sigma_p^2}{dt} \frac{r_i^2 c N_i \Lambda}{8\beta\gamma^3\epsilon_{n,rms,x}^{3/2} < \beta_x^{1/2} > \sqrt{\pi/2}\sigma_l\sigma_p^2}, \quad (1)$$

$$\tau_{\perp} = \frac{\sigma_p^2}{\epsilon_x} < \frac{H_X}{\beta_x} > \tau_{||}^{-1}. \quad (2)$$

According to Eqs. (1) and (2), it is possible to reduce $< \frac{H_X}{\beta_x} >$ to reduce the transverse emittance growth coupled from the longitudinal plane[7, 8]. Therefore, during the 2008-2011 RHIC ion runs, we used a lattice with FODO phase advances increased in the arcs and the integer tunes increased by 3 units. We named this lattices as "IBS-suppression" lattices and the previous lattices as "standard" lattices.

However, during the 2008-2011 RHIC heavy ion runs with the IBS-suppression lattice, we observed a large beam loss after RF re-bucketing and during store with transverse cooling [3]. RF re-bucketing aims to shorten the bunch length to increase luminosity but it increases the beam momentum spread. RF re-bucketing takes place in the beginning of the store without collision. The bunch's maximum momentum deviation is increased from 0.9×10^{-3} to 1.7×10^{-3} with RF re-bucketing.

Figures 7 and 8 show the beam decays in the Yellow ring in the fill 9039 in the 2007 Au-Au run and in the fill 15843 in the 2011 Au-Au run. In both fills, there was only longitudinal cooling. Along with the total beam decay, we also show the beam decay contributed by the beam burn-off due to luminosity. The burn-off is calculated from luminosity and the analytical value of total cross section of Au-Au collision. The IBS-suppression lattices caused much more non-luminosity particle loss than the standard lattices.

Off-Momentum DA

With longitudinal cooling, the beam loss in the longitudinal plane is eliminated. If there is any beam loss, it should happen in the transverse plane due to the limited transverse off-momentum dynamic aperture. From Figs. 7 and 8, the IBS-suppression lattices have smaller off-momentum dy-

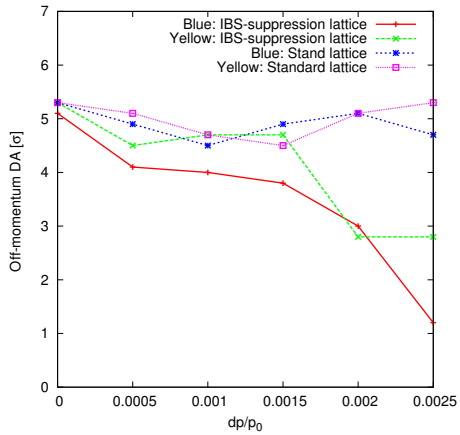

Figure 9: Off-momentum dynamic apertures with IBS-supression lattices and standard lattices for both rings.

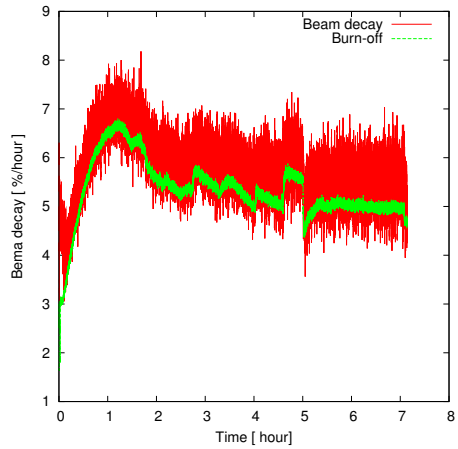

Figure 10: The Au beam decay in 2012 with transverse and longitudinal cooling. The beam loss was almost entirely from burn-off.

namic aperture than the standard lattices. In the 2011 Au-Au run with the longitudinal and vertical cooling, we observed about 50% of particle loss was non-luminous. According to Eq. (2), small transverse emittance increases the longitudinal IBS growth rate.

Figure 9 shows the calculated off-momentum aperture for both Blue and Yellow rings with IBS-suppression and standard lattices. For the IBS-suppression lattice, the off-momentum dynamic aperture begins to drop sharply to below 4σ when the relative momentum deviation is bigger than 0.0015. While for the standard lattice, the off-momentum DA is better than 4.7σ up to $dp/p_0 = 0.0025$. With RF re-bucketing, the RF bucket height is 1.9×10^{-3}.

Based on the beam loss observations in the previous runs and the calculated off-momentum apertures, we decided to adopt standard lattices for the 2012 U-U and Cu-Au runs. In the 2012 U-U run, 3-D stochastic cooling was fully operational in RHIC. The typical bunch intensity in RHIC is 0.3×10^9. Comparing to the previous Au-Au operation, the IBS growth rate is smaller and the stochastic cooling is more efficient.

Figure 10 shows the Au beam decay and the burn-off contribution in Fill 16830. With transverse cooling on, the initial luminosity is not the highest. Accordingly, the luminosity burn-off continues to increase until the peak luminosity is reached. The beam loss is almost entirely from the burn-off [5], which means that there is almost no loss due to limited transverse off-momentum dynamic aperture with the standard lattices.

BEAM-BEAM INTERACTION IN ASYMMETRIC CU-AU COLLISION

Different IBS and Cooling Rates

The IBS growth rate is proportional to $N_i Z^4/A^2$ while the stochastic cooling rate is proportional to $1/N_i$, where N_i is bunch intensity, Z and A are the ion charge state and atom number. In the 2012 Cu-Au run, the bunch intensities for the Cu and Au beam were about 4.0×10^9 and 1.3×10^9 respectively at the end of the run. Therefore, the IBS emittance growth rate of the Cu beam is half of that of the Au ion beam, while the stochastic cooling rate of the Cu beam is one third of the Au ion beam.

In the beginning of this run, with full cooling power for both beams, we observed that the Cu beam lifetime was significantly reduced when the two beams' emittances were quite different. The bigger difference between the emittances of the two beams was, the more Cu beam loss was observed. Later on we concluded that the bad Cu beam lifetime was caused by the beam-beam interaction between the Cu and Au beams with different transverse beam sizes [9]. As an example, Figure 11 shows the measured transverse emittances and the beam decays with 3-D cooling with full cooling power from the beginning of store.

Beam-Beam Interaction

For ion collisions, the beam-beam parameter, or the linear incoherent beam-beam tune shift, for the weak beam is

$$\xi_1 = -\frac{N_{i,2} r_p}{2\pi\epsilon_{n,rms,2}} \times \frac{Z_1 Z_2}{A_1}. \quad (3)$$

Here r_p is the classic proton radius. $\epsilon_{n,rms,2}$ is the rms normalized transverse emittance. The Z and A are the ion's charge state and atomic number. The subscript 1 is for the weak beam and the subscript 2 is for the strong beam.

In the previous RHIC Au runs, the beam-beam interaction was negligible since the beam-beam parameter was -0.003. In the 2012 Cu-Au run, when turning on 3-D cooling with full cooling power for the two beams from the beginning of store, the beam-beam parameter for the Cu beam reached -0.011 from initially -0.004.

Here we perform numerical simulation to calculate the beam-beam effect to the Cu beam's dynamic aperture. Figure 12 shows the Cu beam's dynamic aperture in the first 4.5 hours in the store. The measured bunch intensity and

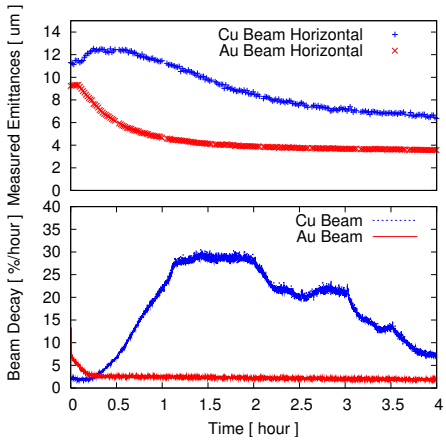

Figure 11: Bunch intensities and measured emittances in Cu-Au run. The fill number is 16911.

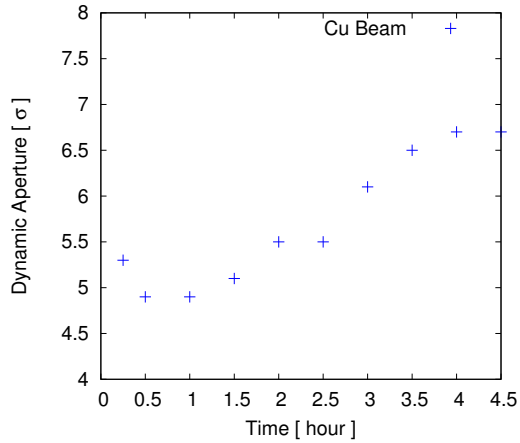

Figure 12: Calculated off-momentum dynamic aperture for fill 16911.

emittances in Fig. 11 were used. In this study, the initial relative momentum deviation is set to $dp/p_0 = 0.0015$. The dynamic aperture is given in units of Cu beam's rms transverse beam size. From Fig. 12, when the Au beam was fully cooled at 1 hour from the beginning of store, the Cu beam's dynamic aperture is lowest. With slow cooling of the Cu beam emittance, the Cu beam's dynamic aperture is slowly increased.

To avoid the large beam loss in the Cu beam and to maximize the integrated luminosity, we decided to turn off or reduce the Au beam's cooling gain in the beginning of the store until the Cu beam got cooled. Figure 13 shows the beam emittances and beam decays in the fill 16917 where we intentionally turned off the Au vertical cooling between 0.5 hour to 1.5 hour into the store. When the Cu and Au beam emittances were comparable to each other, then we turned on the yellow vertical cooling again. By doing so, we kept the Cu beam decay below 6%/ hour. Later on in the rest of 2012 Cu-Au run, we continued to balance the luminosity and the beam decay through the Au beam's stochastic cooling gains. The Cu beam decay was kept below 4%/hour in the whole stores. And the store length was set to 14 hours, which is the longest store length for the RHIC heavy ion runs.

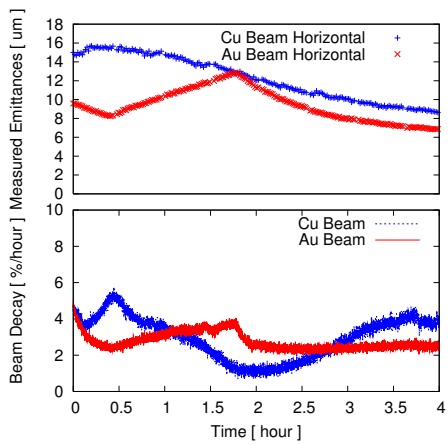

Figure 13: Bunch intensities and measured emittances with reduced Au cooling rate. The fill number is 16917.

CONCLUSIONS

The 2012 RHIC heavy ion run was a great success. It marked the first collisions of high energy U-U and Cu-Au ions in RHIC. With a versatile EBIS, powerful 3-D stochastic cooling, and double bunch merging in the injectors, high precision beam control systems, and many efforts of machine fine tuning, we reached both detectors' integrated luminosity goals. In the U-U run, with a new lattice which gives a higher off-momentum aperture and 3-D cooling, the particle loss is dominated by the burn-off. In the Cu-Au run, due to different IBS and cooling rates from both beams, we intentionally slowed down the Au beam cooling rate in the Yellow ring in the first several hours to match the two beams' transverse beam sizes and maximize the integrated luminosity.

Abstract

A multi-MW proton facility, Project X, has been proposed and is currently under development at Fermilab. We are carrying out a program of research and development aimed at integrated systems testing of critical components comprising the front end of Project X. This program, known as the Project X Injector Experiment (PXIE), is being undertaken as a key component of the larger Project X R&D program. The successful completion of this program will validate the concept for the Project X front end, thereby minimizing a primary technical risk element within Project X. PXIE is currently under construction at Fermilab and will be completed over the period FY12-17. PXIE will include an H^- ion source, a CW 2.1-MeV RFQ and two superconductive RF (SRF) cryomodules providing up to 25 MeV energy gain at an average beam current of 1 mA (upgradable to 2 mA). Successful systems testing will also demonstrate the viability of novel front end technologies that are expected find applications beyond Project X.

PXIE GOALS AND PLAN

A unique feature of Project X [1] is the capability of delivering a MW-range proton beam to several experiments quasi-simultaneously with a beam structure that can be adjusted to each experiment's needs. In the suggested scheme, this is achieved as follows:

(a) Prepare a "nearly CW" beam, in which many RF buckets may be empty but the beam current, averaged over several μs, is constant. The undesired bunches are removed in the Medium Energy Beam Transport (MEBT) by a chopping system. This quasi-CW beam has a repetitive time structure (RS).

(b) Accelerate the prepared beam. The optimum solution requires acceleration by SRF cavities after MEB at 2.1 MeV;

(c) Distribute the beam to experimental stations by an RF separator at 1 GeV and 3 GeV.

The RF separation of bunches successfully supports multiple experiments operation at CEBAF [2]. The acceleration with SRF at low energies has been used for a long time at ANL [3] (at much lower average currents) and recently is being commissioned at SARAF [4], but has not been demonstrated at parameters required for the Project X. The wideband chopper, needed to prepare bunch patterns, is a unique device currently beyond state of the art.

The PXIE program [5] will address both (a) and (b) with the specific goals of demonstrating effective bunch-by-bunch chopping of the CW beam delivered from the RFQ and efficient acceleration of the 1 mA RS beam with minimal emittance dilution through at least 15 MeV.

PXIE consists of an H- ion source (IS); a Low Energy Beam Transport (LEBT); a CW 2.1-MeV RFQ; a MEBT; two SRF cryomodules (CM) operating at 2K - a Half Wave Resonator (HWR) and a Single Spoke Resonator (SSR1); a High Energy Beam Transport (HEBT); and a beam dump (Fig.1).

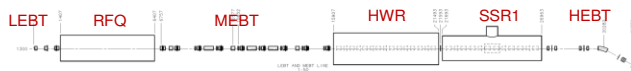

Figure 1: PXIE layout.

The concept of PXIE subsystems was described in [5]. The end-to-end simulations can be found in [6]. Main beam parameters are shown in Table 1.

Table 1: Nominal Beam Parameters at the Exit of Each Section

	IS/ LEBT	RFQ	MEBT	HWR	SSR1
Energy, MeV	0.03	2.1	2.1	11	25
Average current, mA	5	5	1	1	1
Time structure	DC	CW	RS	RS	RS
$\varepsilon_\perp$, μm					< 0.25
$\varepsilon_\parallel$, keV-ns					≤ 1

* $\varepsilon_\perp$ is the rms normalized transverse emittance, and $\varepsilon_\parallel$ is the rms longitudinal emittance.

The PXIE design and construction is being carried out by a collaboration between Fermilab, ANL, LBNL, SLAC, SNS, and Indian laboratories in a staged approach.

The beam is planned to pass through the LEBT in FY14, through the RFQ in FY15, and full PXIE parameters are expected to be demonstrated by the end of 2018.

STATUS OF SUBSYSTEMS

The ion source has been procured from D-Pace Inc. [7], was characterized and used in the beam dynamics studies at LBNL, and presently is being assembled at Fermilab.

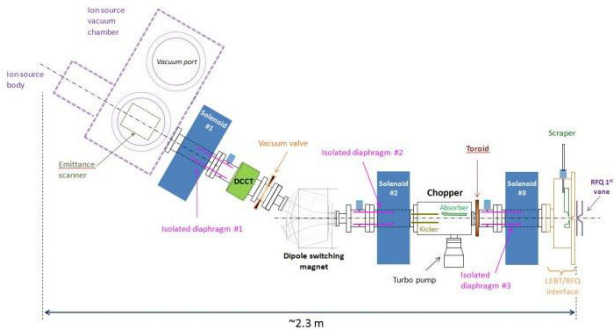

Figure 2: Conceptual design of the LEBT.

The LEBT has been conceptually designed (Fig. 2). The 2.2 m distance between the ion source and the RFQ entrance ensures a low hydrogen flux from the ion source into the RFQ. Because the design of the Project X front end includes two ion sources for redundancy, the final PXIE assembly will include a combining dipole magnet though only one ion source will be used. Focusing is provided by three solenoids. A chopping system will be used for several purposes: to generate a pulse mode during commissioning, in a normal operation, to shut down injection into the RFQ for machine protection, possibly, to interrupt the beam for the residual ion removal from the MEBT, and, if found necessary, to assist the MEBT chopper.

One of the concerns is a growth of effective emittance due to neutralization following chopper pulses. To address this, the LEBT will be assembled first in a simple, straight configuration, in which the beam can be neutralized either along the entire line or only upstream of the chopper. In the latter case, the large distance to the IS allows effective clearing of the residual ions by combination of a positive potential on a stopping electrode and a constant transverse electric field. The ion removal solves the issue with temporal changes of the beam envelope but increases the emittance growth due to space charge [6]. Experiments will show which mode is preferable. Presently, the LEBT elements are at various stages of designing, procurement, and assembly.

The 4-vane, 4.4 m 162.5 MHz RFQ (Fig. 3) has been designed and the fabrication has started in August, 2013 at LBNL. The detailed description of the RFQ design and status can be found in Ref. [8], and the design of the coupler is described in Ref. [9]. The complete assembly of the RFQ is planned to be delivered to Fermilab at the end of 2014.

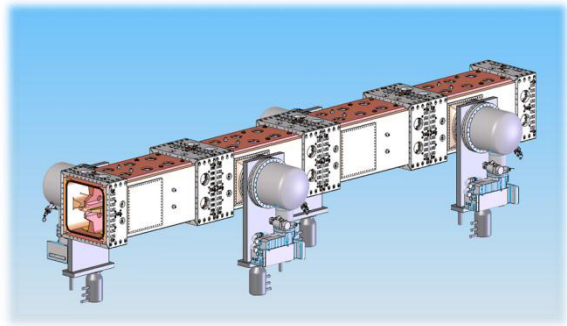

Figure 3: The RFQ conceptual design [9].

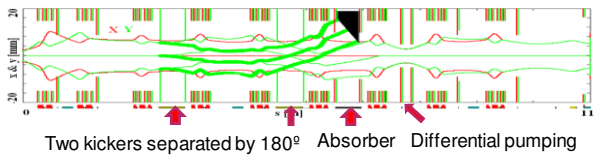

Figure 4: Scheme of MEBT optics and the beam envelope. The thin lines are the central trajectory and 3σ envelope (ε_{rms_n}=0.25 mm mrad) of the passing beam, and the thick lines are the Y envelope of the chopped-out beam. Red- quadrupoles, blue- bunching cavities.

The design of the ~10 m MEBT was presented in [10], and the beam trajectory is shown in Fig. 4. Its most challenging part is the chopping system that forms the required bunch pattern by deflecting the undesired bunches of the initially CW beam into an absorber. This deflection is made by two broadband, travelling-wave kickers separated by 180º of the betatron phase advance and operating synchronously. The electric length of each kicker is 0.5 m, the plate separation is 16 mm, and the plate voltage with respect to ground is ±250V. The plates have opposite polarity voltages for bunch passing and removal. Presently two versions of the kicker, distinguished by the characteristic impedance of the kicker structure (50 and 200 Ohm), are being developed.

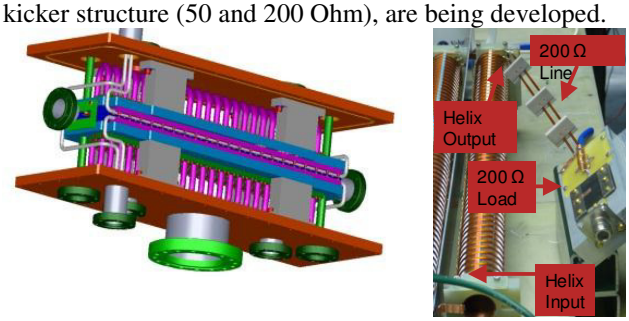

Figure 5: The MEBT kicker. A 3D model of the 50-Ohm kicker (left). Part of the vacuum box is removed for the presentation purpose. A model of the 200 Ohm kicker (right).

In the 50 Ohm version, the beam is deflected by the voltage applied to planar electrodes connected in vacuum by coaxial cables with the length providing the necessary delays (Fig. 5). The kicker prototype is being assembled.

Copyright © 2013 CC-BY-3.0 and by the respective authors

RF and thermal properties of an 8-plate model with electrodes and cable in the final version were successfully tested. The kicker will be powered by a commercially available RF-amplifier with a specially shaped driving signal [11].

The 200 Ohm kicker [12] consists of two helixes wound around grounded cylinders (Fig. 5). Presently it is at the stage of the pre-prototype fabrication.

The 200 Ohm kicker will be driven by broadband, DC coupled GaN switches in push-pull configuration being developed at Fermilab [12]. Operation of a single switch up to 500 V was demonstrated, and recently a fully functional 100V driver was successfully tested.

The kickers displace the undesired bunches by ~$6\sigma_y$ to the absorber surface. The absorber is specified to withstand 21 kW, twice the full nominal beam power, focused into a spot with $\sigma_{x,y}$ ~2mm. A preliminary conceptual design is complete, and ¼-size prototype has been successfully tested with an electron beam (Fig. 6). Preliminary results can be found in Ref. [13].

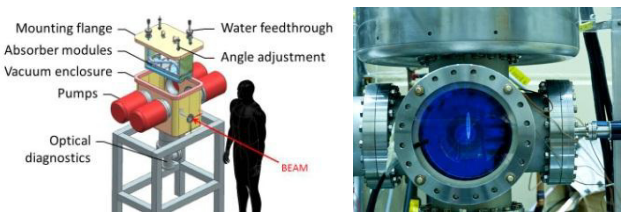

Figure 6: Absorber development: a conceptual design (left). Right – the OTR image of a 5.5-kW, 9-mm electron beam (bright ellipse) on the surface of the absorber prototype.

Transverse and longitudinal focusing in MEBT will be provided by 25 quadrupoles combined into doublets and triplets, and by three 162.5-MHz bunching cavities, correspondingly. The cavities are at the final stage of mechanical design at Fermilab. The quadrupoles and dipole correctors have been designed at BARC in India, and the prototypes are being tested.

The PXIE SRF cryomodules are being fabricated at ANL (HWR) and at Fermilab (SSR1). The HWR cryomodule [14] contains 8 162.5-MHz, nominally 1.7 MV, β = 0.11 cavities and 8 SC solenoids, with built-in dipole correctors and a BPM attached to each solenoid. Design of cavities and the cryomodule is complete (Fig. 7). Prototypes of the RF coupler and solenoid with dipole correctors have been build and successfully tested. Nb parts for all cavities have been fabricated, and two cavities will be tested in FY14.

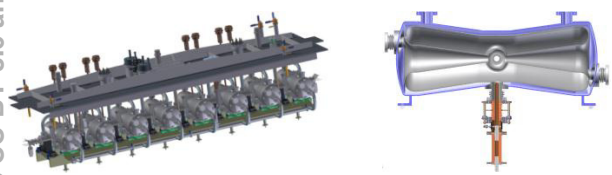

Figure 7: HWR CM design: a cavity-solenoid string attached to the top lid (left), a cavity with a coupler (right).

The SSR1 (Fig. 8) cryomodule consists of eight 325-MHz single-spoke resonators (β = 0.22) and 4 solenoids. Similar to the HWR CM, all solenoids will have corrector coils and BPMs. The conceptual design of the cryomodule is complete, and most of elements are at the stage of technical design.

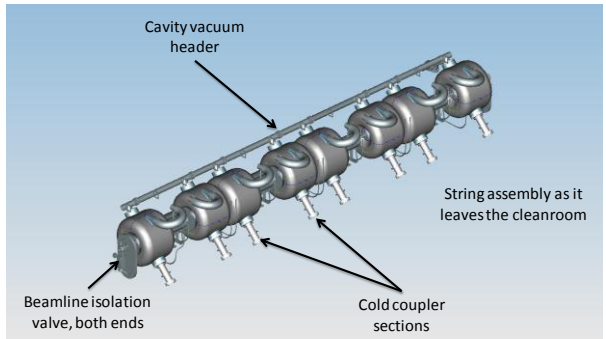

Figure 8: The SSR1 cavity and solenoid string assembly.

Details of the SSR1 cavity development is reported in [15]. The bare cavity and the He vessel are shown in Figure 9. The first SSR1 cavity prototype was manufactured by ZANON, the cavity was tested at Fermilab's Vertical Test Stand (VTS) and outfitted with a helium vessel. The second prototype was manufactured by ROARK, tested and showed acceptable performance. Subsequently, ten other SSR1 cavities were manufactured and delivered to Fermilab.

Figure 9: SSR1 cavity, bare (left) and dressed (right).

The SSR1 is followed by the HEBT that accommodates the beam diagnostics to measure the beam properties and the beam extinction for RF buckets emptied by the MEBT chopper. Its design is at the conceptual stage (Fig. 10) as well as is the PXIE beam dump at the end of the beam line.

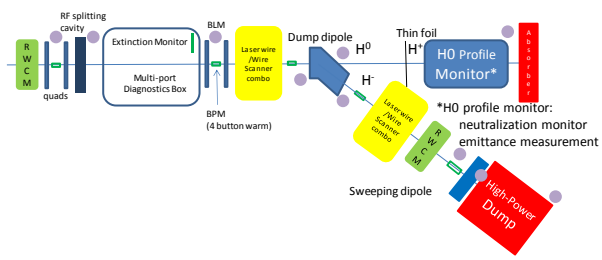

Figure 10: The HEBT scheme.

The PXIE will be located in the existing Cryomodule Test Facility (CMTF) building which will also include an enclosure for ILC and Project X cryomodules testing. A

cryo-plant supporting operation of both installations, which will have 500 W cooling power at 2 K, is under construction. The upstream portion of the PXIE cave, long enough to accommodate the warm portion of PXIE, has been assembled with concrete shielding blocks. The infrastructure, controls, and diagnostics are at various stages of design and implementation.

HIGH POWER (MW-CLASS) TARGETS FOR PARTICLE BEAMS

E.J. Pitcher, European Spallation Source ESS AB, Lund, Sweden
C. Densham, Rutherford Appleton Laboratory, Abingdon, UK

Abstract

Many applications that use accelerators are demanding ever-higher beam powers, which place greater demands on accelerator design and operation. Equally demanding is the design of targets that can operate safely and optimally at these power levels. High-power target design considerations include performance optimization, heat load, radiation damage and lifetime, safety, operability, reliability, and for pulsed beams, dynamic stresses from thermal cycling. The design and operation of these targets draws upon the experience gained in operating lower power targets.

HEAT LOAD

Heat load in high-power targets can be a major driver in target design. For traditional targets made of solid metal, heat load is normally limited by heat flux at the target-coolant interface. Deposited power density goes linearly with beam power and inversely proportional to beam spot area on target. One way to address higher beam power is by increasing the size of the beam spot on target.

As beam power on target increases, so does the engineering complexity of the target. Solutions that are viable at low power, such as cooling at the periphery, are no longer viable. Figure 1 shows a spent tungsten target from the Manuel Lujan Neutron Scattering Center at Los Alamos National Laboratory [1]. This target is a solid cylinder of tungsten, 10 cm in diameter by 7.5 cm long, encased in an Alloy 718 shell that served to contain the water which passed over the tungsten surface to carry away the 60 kW of heat deposited by the 800-MeV proton beam. Two features are clearly evident. First, the target is broken into four quadrants, most likely caused by unacceptably high thermal stresses in the target. Second, substantial corrosion of the tungsten has occurred, which is due to the creation of short-lived highly oxidizing radicals in the cooling water. These radicals have been shown to be highly corrosive to tungsten [2]. Radioactive spallation products within the tungsten enter the coolant stream as the tungsten corrodes, leaving the cooling components, such as filters, ion exchange columns, highly radioactive.

At the megawatt level and higher, innovative solutions to the problem of target cooling have been proposed, such as flowing liquid metal [3,4,5,6] and rotating solid targets [SNQ, SNS TS2, Bilbao, ESS]. A liquid metal target, such as that shown in Fig. 2, has the potential to handle very high power densities due to its high heat capacity. Two liquid metals that have been successfully demonstrated as spallation targets are mercury [4,5] and lead-bismuth eutectic [6]. Lithium is proposed as the target material for the International Fusion Materials Irradiation Facility, (IFMIF) with a baseline 10 MW, 40-MeV deuteron beam. This project is now completing its engineering development and demonstration phase, including development of the lithium target [7].

At the megawatt level, full-scale thermal testing of the target prior to putting it into service is difficult and normally cost prohibitive. This is compounded by the complexity of trying to simulate the power deposition profile of the accelerator beam. As a consequence, normally small-scale tests are conducted instead. These tests are normally designed to validate uncertainties that may exist in the data or models in the simulations used in the thermo-mechanical design of the target.

SAFETY

Targets for high-power accelerators become radioactive as a consequence of beam-induced nuclear reactions within the target. For >100-MeV beams, a good rule of thumb is that the radioactive inventory within an accelerator target is on par with a nuclear fission reactor with one order of magnitude less power, e.g., a 1-MW proton beam on a spallation target will have a radionuclide inventory, as measured in becquerels, on par with that of a 100-kW fission reactor. This inventory will generate decay heat, or afterheat, following beam shutdown that must be removed in a robust and reliable manner.

Because of the risk to workers and the public presented by this radioactive material, designers of high-power targets do well to adopt a “safety by design” philosophy, whereby safety is an omnipresent consideration in the design optimization process. A number of recently designed high-power targets [APT, SNS, MTS] draw from the safety philosophy developed for the nuclear

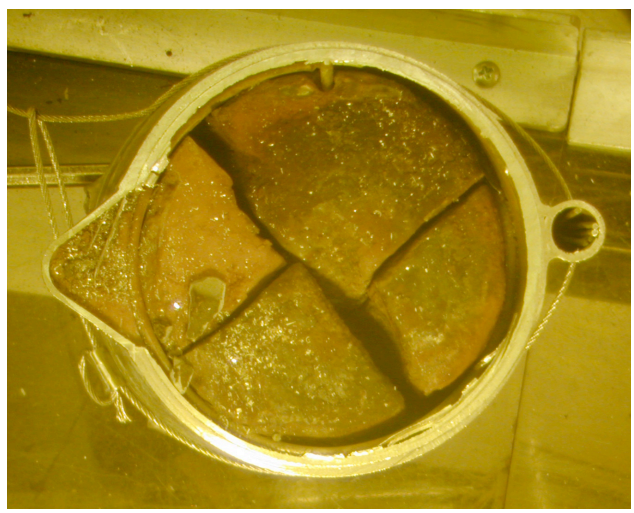

Figure 1: Broken and corroded Lujan Center tungsten target (from [1]).

Copyright © 2013 CC-BY-3.0 and by the respective authors

industry. First, hazards are identified, and initiating events that may produce these hazards are postulated. Those events with high frequency of occurrence and potentially high consequences are then selected as "design basis accidents." These postulated accidents undergo quantitative analyses to assess potential radiation doses to workers and the public. If needed to keep such doses within acceptable limits, mitigations are identified and incorporated into the design. These mitigations are credited safety controls that normally require a higher pedigree of design, procurement, installation, testing, and maintenance. Wherever possible, incorporation of passive safety features into the design is preferred over reliance on credited controls, as passively safe features are usually simpler to analyze (and therefore defend to regulators), more reliable, and lower cost.

PERFORMANCE

With respect to targets, beam power increases are normally addressed through the introduction of greater coolant volume fraction within the target, more structural material to accommodate larger thermal and mechanical stresses, larger gaps between components for ease of servicing, and similar features, which normally contribute to a degradation in target performance, for instance neutron production or neutrino production. A general rule of thumb is that an increase in beam power will not result in a proportional increase in performance, but rather will be proportional to (beam power)$^{0.8}$.

OPERATIONS

High-power targets operate in intense radiation environments. If the beam passes through water that is used to cool the target

As the radioactive inventory increases, the infra-structure required to operate accelerator targets becomes more substantial. Normally hot cells are located near the target operating position, and target maintenance or replacement requires a means to transfer the activated target from its operating position to the hot cell or other appropriate facility where the target can be prepared for disposal.

Transport of spent targets can require substantial infrastructure. This process normally requires shielded casks approved for the transport of radioactive material on public roads or railways. One example, shown in Fig. 2, is the cask used to transport the spent MEGAPIE target to less than 1 km, from the SINQ facility at the Paul Scherrer Institute to the Zwilag facility, where it was cut up for post-irradiation examination [MEAPIE PIE].

RADIATION DAMAGE AND LIFETIME

The structural material of high power targets is subjected to the most severe radiation damage of any application, more than fusion reactor first walls and fuel cladding in fast reactors (the fuel itself, a non-structural material, sees greater radiation damage). The damage is due both to displacements of atoms from their lattice sites and from the production of helium atoms that can cause embrittlement. Figure 4 shows the cross sections for proton-induced atomic displacements and helium production in iron. The displacement cross section is somewhat insensitive to the proton energy, while helium production increases steadily with increasing energy.

RELIABILITY

Target systems generally exhibit greater reliability and availability than high-power accelerators that drive them. This is due to the far fewer number of components in a target station as compared to a modern accelerator. However, the significant cost associated with some of the major systems of a target station usually preclude the ability to keep one or more spares in inventory. Further, many of the components must be handled and replaced remotely, which is labor- and time-intensive. The result is that, while target station component failures are usually rare, when they happen they have the potential to bring the facility down for weeks, or in the worse case, months.

CONCLUSIONS

Target designers are meeting the challenge of building targets that handle the ever-increasing beam power that today's modern accelerators are capable of delivering.

BEAM INSTRUMENTATION FOR HIGH POWER HADRON BEAMS

A. Aleksandrov
Oak Ridge National Laboratory, Oak Ridge, TN 37830, USA

Abstract

This presentation will describe developments in the beam diagnostics which support the understanding and operation of high power hadron accelerators. These include the measurement of large dynamic range transverse and longitudinal beam profiles, beam loss detection, and non-interceptive diagnostics.

INTRODUCTION

Beam instrumentation is an important part of any accelerator. Modern machines are equipped with large numbers of diagnostics for measuring various beam parameters as illustrated by the Spallation Neutron Source diagnostics map in Fig. 1. Many of the diagnostics systems are common for different types of accelerators and accelerated particles but some can work in specific conditions only. In this paper we will discuss beam instrumentation systems used for megawatt-class hadron machines with relatively low energy of no more than a few GeV (essentially non-relativistic beams). There is a significant number of operating and emerging accelerators in this class, such as SNS, PSI, J-PARC, ESS, FRIB, Project-X and others. The major factors specific for these machines are related to their high average beam power:

- Small fraction of lost beam is of importance. Large dynamic range diagnostics are required to follow the dynamics of these small fractions.
- The damage threshold is reached quickly with high average beam power. Diagnostics systems for machine protection must have a fast response.
- The power density in the beam core can be very large. This can prevent the use of interceptive diagnostics.
- The average peak beam current is large. The space-charge effects can be significant and affect operation of some types of diagnostics.

Another important factor is the use of a superconducting RF linac for all or part of the acceleration. Although this is not a necessary requirement and some high power accelerators, like the PSI cyclotron, do not use it, the majority of new projects include high power superconducting linac in the design. This adds two more important factors:

- New damage mechanisms related to the superconducting cavities. Additional diagnostics may be required to protect the SRF linac [1].
- The SRF technology requires maintaining a very clean environment for the cavities and the surrounding vacuum chambers. This can impose severe restrictions on the design of the diagnostics in these areas up to complete a ban on using interceptive diagnostics, like in the case of the SNS SRF linac.

In the following sections we will discuss how the above factors affect the diagnostics requirements and the design choices.

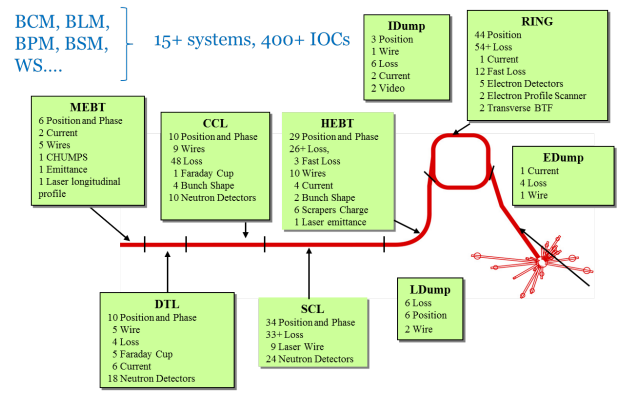

Figure 1: The Spallation Neutron Source diagnostics map.

MACHINE PROTECTION FROM LOST BEAM

Protecting the machine from damage by the lost beam is the most important application of the beam instrumentation. The main damaging factors are:

- Mechanical damage (melting, cracking, erosion). This mechanism is most important at lower energies (<10 MeV), where penetration depth for beam particles is relatively small. The damage threshold depends on many factors but typically it is of the order of magnitude of few hundred watts per meter, which represent a fraction of lost beam of few persent or higher. This level of fractional beam loss can be detected by a Differential Beam Current Monitor (DBCM) measuring beam current difference at two locations along the accelerator.
- Activation of the accelerator equipment. This mechanism is more important at higher energies and the commonly accepted threshold of 1 W/m is used for protons above 100 MeV, which corresponds to a very small fractional loss of $10^{-5} \div 10^{-7}$. As this threshold is significantly lower than the mechanical damage threshold, protection from the activation will automatically provide protection from the mechanical damage. Radiation Monitors (RM) are typically used for protection from small fractional beam loss at high energy [2].

The two above mechanisms are common for all types of the accelerators and a well-established protection strategy typically includes DBCMs at energy below 10 MeV, RMs

Copyright © 2013 CC-BY-3.0 and by the respective authors

at energy above 100 MeV and a combination of both in the transitional region. As was mentioned in the introduction, the use of SRF technology adds additional damage factors:

- Thermal load on the cryogenic system from the lost beam. The threshold is typically about 1W/m and it does not depend on the beam energy.
- Degradation of SRF cavity electrical strength due to repetitive instantaneous loss with the total energy deposition of about few hundreds of Joules.

At the beam energy above 100 MeV, the protection from the first factor is provided by the RMs as the threshold is the same as for protection from the activation. The situation becomes difficult in the region between 10 MeV and 100 Mev, where the 1 W/m thresholds is too low for detection by both DBCM and RM. As there is no high power SRF linac in operation at that low beam energy there is no established strategy for cryo-system protection.

The second factor was discovered during the SNS SRF linac operation. The baseline SNS Machine Protection System (MPS) did not provide protection from a sporadic loss of 100% of beam current within a 30-50 μs period of time because such events were considered to be safe if they happen so infrequently that the average lost power does not exceed 1 W/m. As the lost fraction is significant the RMs respond within a few microseconds but the signal propagation time within the MPS from the detector to the beam shut-off mechanism is typically of 15-30 μs so that overall response time is of 20-35 μs. A fast DBCM with a dedicated line to the beam shut off-device, as illustrated in Fig. 2, is being implemented for SRF linac protection at SNS [3]. The expected response time of 5-6 μs is mostly limited by the propagation time in the cables.

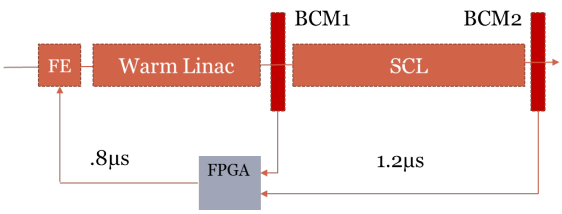

Figure 2: Diagram of the Fast DBCM protection system for the SNS Super Conducting Linac.

BEAM CURRENT AND POSITION MEASUREMENTS

Diagnostics for measuring the beam current and center of mass position are required for tuning of any accelerator independent of power. Typically, non-interceptive types of detectors are used: current transformers and electromagnetic pickups. With higher average beam power one can expect stronger signals from the detectors. An important caveat is that accelerator tuning is usually done at significantly lower beam power than in operation therefore the diagnostics should have a sufficient dynamic range or an adjustable gain to cover the required range of the signal strength. Also, depending on how the beam power reduction is implemented, an increased time response range maybe required. For example, the operational SNS beam parameters are 26 mA peak current, 1ms pulse width at 60 Hz repetition rate; the linac tuning is done with beam current reduced to 5 mA, pulse width shortened to 1 μs at 1 Hz. The reduced parameters are on the edge of the minimum design parameters for the beam position and phase monitors and do not provide the best signal-to-noise conditions but they had to be adopted to ensure the SRF linac safety.

TRANSVERSE BEAM CHARGE DISTRIBUTION MEASUREMENTS

Beam charge distribution measurements, usually in form of profiles or emittance, are the most challenging for high power beams. The biggest problem is that one has to have a "probe" inside the beam to sample the charge at different locations and the probe should be able to survive under a high beam power density. For high power beams specifically, as mentioned before, the dynamics of small fractions of the bunch are of interest, which requires measurement with large dynamic range. Typically, a dynamic range of 10^6 is desirable for understanding beam loss mechanism at the level of 1 W/m for 1 MW average beam power. In addition, if pulsed or chopped beam is accelerated, the diagnostics should have time resolution sufficient to resolve detail of the beam time structure. As we will show below, it is very difficult to combine all three requirements: non-intercepting, large dynamic range and good time resolution, in one diagnostic system.

Many different types of probes have been tried for high power beams. The results are summarized in Table 1 showing the best parameters demonstrated at high power hadron machines. The two numbers in parentheses show the expected parameters the existing systems are believed to be able to achieve with well understood modifications. We will discuss these options in more details in the next sections.

Table 1: Typical Parameters for Transverse Beam Charge Distribution Diagnostics

	Dynamic range	Time resolution	Non-intercepting
Solid material (wires, screens)	10^5 (10^6)	10 ps	No
Photons (laser beam)	10^2 (10^4)	10 ns	Yes
Charged particles (electrons, ions)	10	10 ns	Yes
Gas (residual, jet)	10^2	1 μs	Yes

Intercepting Diagnostics with Large Dynamic Range

The wire scanner is a typical example of a profile measuring system using solid material as a probe. As shown in Table 1, wire scanners can provide a very large

Copyright © 2013 CC-BY-3.0 and by the respective authors

dynamic range and a good time resolution. The simplest way of measuring the result of the beam interaction with the wire is to measure the charge collected on the wire. Figure 3 shows a typical transverse beam profile measured using the charge collection method at SNS. The system has a dynamic range of 10^5, which is currently limited by the digitizer resolution. It is believed the dynamic range can be improved further by upgrading the digital electronics. The advantage of the charge collection method is its simplicity and low cost. The disadvantage is the slow time response. It is not practical to achieve a good time resolution simultaneously with a large dynamic range for the charge collection method because the system bandwidth has to be limited in order to separate the DC coupled charge on the wire from the AC coupled signal induced by the electrostatic field of the beam.

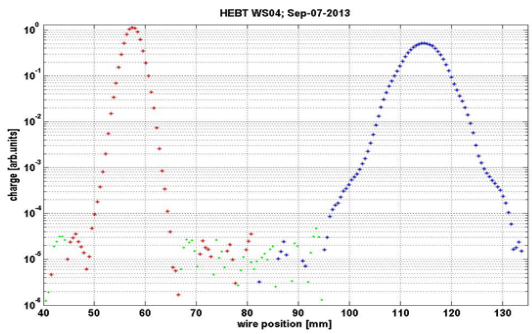

Figure 3: Typical transverse profiles measured with a wire scanner at SNS (red is vertical; blue is horizontal).

Measuring the number of beam particles scattered by the wire is another popular method of obtaining a signal from wire scanner. An example of an advanced wire scanner system of this type is described in [4] and a typical measured profile is shown in Fig. 4. The system allows profile measurements with very high temporal resolution of about 10 ps by detecting the arrival time of each scattered particle. The reported dynamic range is 10^5.

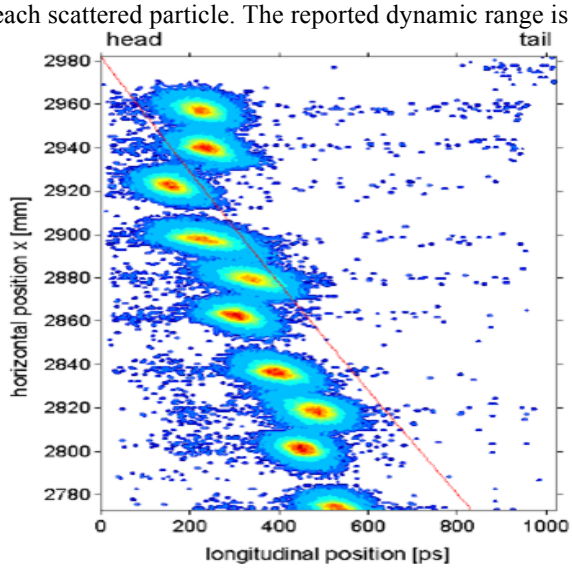

Figure 4: Typical transverse profiles with high temporal resolution measured at PSI (from [4]).

Important conditions for achieving large dynamic range in wire scanner measurements are good vacuum and small beam loss in the vicinity of the device. These conditions are difficult to satisfy at the low energy end of a linac or in the injector. A simple solution is to use a slit instead of the wire and measure charge collected in a Faraday Cup behind the slit. An example of slit system with large dynamic range and good temporal resolution is given in [5].

Non-Intercepting Diagnostics

The intercepting diagnostics discussed above are well developed, can provide large dynamic range and good temporal resolution, but they cannot be used if the beam power density is too high or clean environment requirements forbid any intercepting devices. Non-intercepting diagnostics are highly desirable in these situations. A very good general review of non-intercepting beam instrumentation is given in [6]. In this section we will give more focus to the techniques tested with high power hadron beams.

Laser Wire: A laser beam can provide an excellent probe for beam profile measurements if the interaction of the beam particles with the photons has a significant cross-section. In the case of H^- beam the cross-section for electron photo-detachment is large and peaks at the wavelengths of readily available commercial lasers as shown in Fig. 5. By crossing the beam with a narrow laser "wire" and detecting the products of the photo-detachment reaction (H^0 or electrons) the beam profile can be measured. An example of a large scale laser wire system with multiple measurement locations is described in [7]. It is possible to measure not just the profile but also the beam emittance using the laser wire as a slit as described in [8]. An example of an emittance measurement for a 1 GeV H^- beam at SNS is shown in Fig. 6. The profiles and emittance can be measured with high temporary resolution if a pulsed laser is used (about 10 ns for a typical Q-switched Nd-YAG laser). The dynamic range of about 10^2 of the SNS laser wire is limited by spurious reflections of the laser beam.

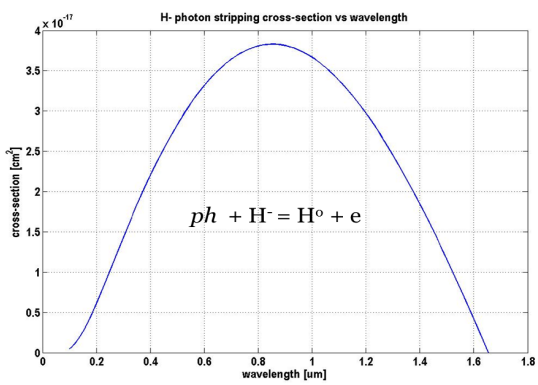

Figure 5: Electron photo-detachment cross-section vs. photon wavelength for H^-.

Copyright © 2013 CC-BY-3.0 and by the respective authors

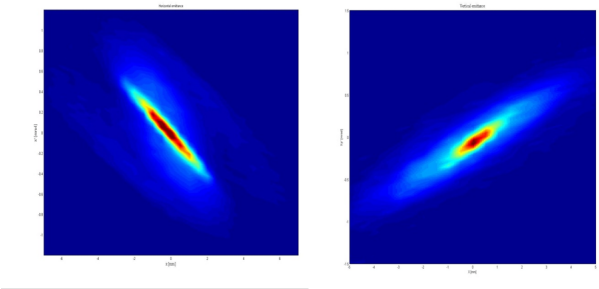

Figure 6: A typical emittance measurement using the SNS laser emittance monitor.

It is believed, based on the signal-to-noise measurements, that with proper engineering improvements the dynamic range could reach 10^4 or higher. In this case, the laser wire would be a rare case of the perfect diagnostic: non-intercepting, large dynamic range and with good temporal resolution. The biggest limitation of this diagnostic is its applicability for H^- beams only.

Ionization Profile Monitor (IPM): The Ionization Profile Monitor (IPM) is a popular non-intercepting diagnostic for beam profile measurement, widely used in proton and ion accelerators, especially in synchrotrons [6]. Its principle of operation is based on imaging of the ionization trace left by the beam in the residual gas by transferring the products of the ionization (ions or electrons) to a position sensitive charge collector. The dynamic range of an IPM is limited by the residual pressure gas and the ionization cross-section and typically does not exceed ~100. The time response can be of the order of few nanoseconds if electrons are collected. In order to mitigate distortion of the image by the space charge force of the beam a guiding electrical and/or magnetic field is used. In the case of high intensity beams the required field strength becomes the major factor determining the size, complexity and cost of the device. An example of an IPM designed for the SNS accumulator ring is shown in Fig. 7.

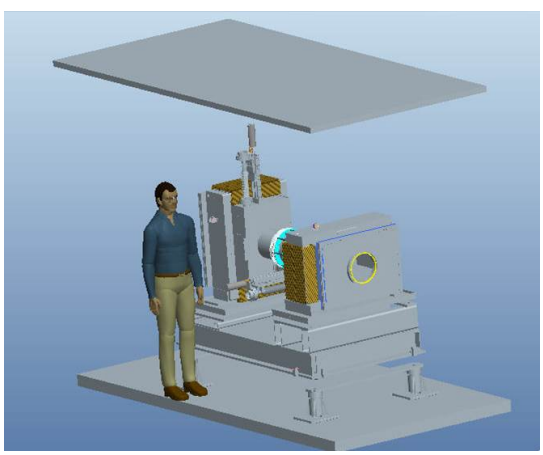

Figure 7: A model of an IPM design for the SNS accumulator ring.

Electron Beam Probe: The beam space charge force, detrimental for the IPM operation, can be used to an advantage in another type of transverse profile monitor: the electron beam probe [9]. The principle of operation is based on measuring the deflection of low energy electrons (or ions), typically in the 10 – 100 keV range, moving across the measured high intensity ion beam. The ion beam profile can be derived from the electrons deflection pattern under certain conditions. The dynamic ran is fundamentally limited by the principle of operation to a relatively low number of 10-15. The temporal resolution of few nanoseconds can be achieved with pulsed electron probe beam. An example of time resolved single turn profile measurement in the SNS accumulator ring is shown in Fig. 8.

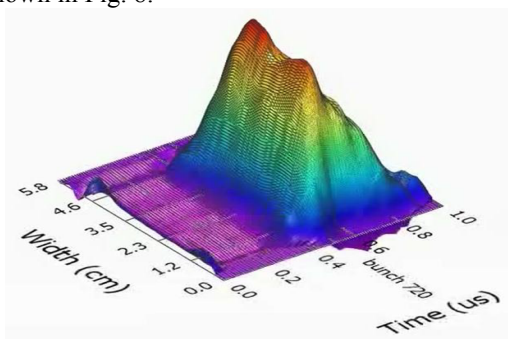

Figure 8: A typical result of a one turn transverse profile measurement with the electron beam probe monitor in the SNS accumulator ring.

Residual Gas Luminescence Monitor: Another type of a device not sensitive to the space charge forces of the high intensity beam is the residual gas luminescence monitor [6]. Its principle of operation is based on optical imaging of the residual gas luminescence induced by the measured beam. A relatively weak signal due to low cross section of the process, especially at high energy, requires long integration times and limits the dynamic range to no more than ~100.

LONGITUDINAL PROFILE MEASUREMENTS

Measuring the longitudinal bunch profile in high power non-relativistic beams is challenging for the same reason as transverse measurements discussed above: the necessity to put some kind of a probe inside the bunch. Naturally, the same types of probes used for the transverse measurements have been tried for the longitudinal diagnostics. The results are summarized in Table 2.

Table 2: Typical Parameters for Longitudinal Bunch Profile Diagnostics

	Dynamic range	Time resolution	Non-intercepting
Solid material (wires, screens)	10^4	1 ps	No
Photons (laser beam)	10^2	10 ps	Yes
Charged particles (electrons, ions)	?	?	Yes
Gas (residual, jet)	?	?	Yes

Copyright © 2013 CC-BY-3.0 and by the respective authors

Beam Shape Monitor (BSM)

Similar to the transverse measurements, the best results in terms of dynamic range and temporal resolution are achieved with an intercepting diagnostics using a metal wire as a probe. The BSM (aka Feschenko device) is a widely used device of this type [10]. Its principle of operation is based on measuring the profile of a low energy electron bunch created by the secondary emission from a wire positioned inside the measured ion beam. The electron bunch profile is measured using the RF deflection technique. A dynamic range of 10^4 with temporal resolution of a few picoseconds can be achieved as illustrated by Fig. 9. Further reduction of the temporal resolution is limited by space charge distortion of the low energy electron bunch. The dynamic range is limited by the ion beam scattering in the wire.

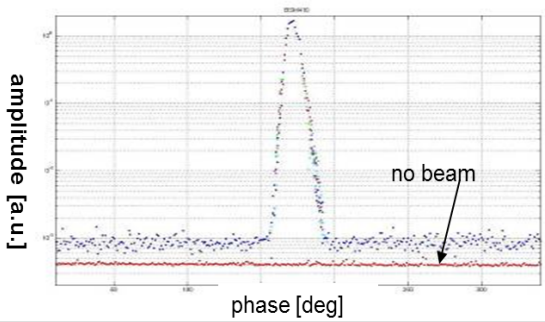

Figure 9: A typical measurement of the longitudinal bunch profile in SNS linac using BSM.

Laser Wire

The only operationally demonstrated non-intercepting type of longitudinal profile diagnostic with a good temporal resolution of few tens of picosecond and dynamic range of ~100 is based on the electron photo-detachment form H^-, similar to the laser wire described above [11]. A typical measurement of the longitudinal bunch profile in the SNS injector is shown in Fig. 10.

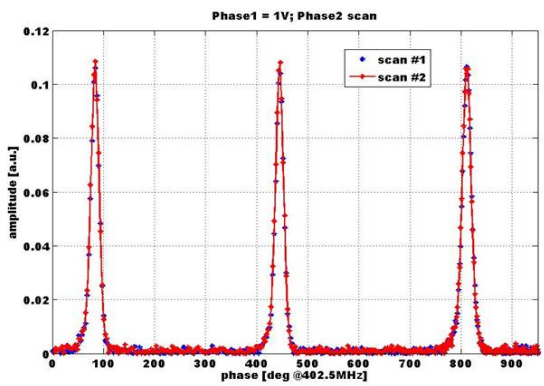

Figure 10: A typical measurement of the longitudinal bunch profile in the SNS injector using the laser wire

The dynamic range in this case is limited by a relatively poor vacuum at the device location. The temporal resolution is limited by the transverse ion beam size. The method is applicable for H^- beams only and this is its major limitation.

Non-intercepting BSM

There is an ongoing effort to develop a longitudinal diagnostic based on the IPM principle [12]. There are significant obstacles to overcome: complex electro-optical transport line, low signal and distortion from the ion beam space charge. A typical measurement with a low intensity heavy ion beam is shown in Fig. 11.

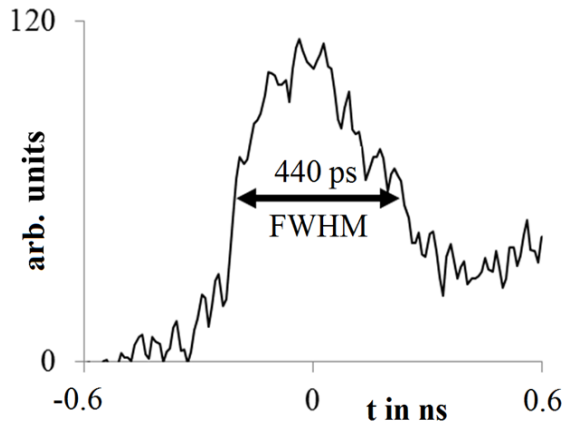

Figure 11: A typical measurement of the longitudinal bunch profile at GSI using the non-intercepting BSM (from [12]).

A FAST ROTATING WIRE SCANNER FOR USE IN HIGH CURRENT ACCELERATORS*

T. Moore, N.I. Agladze, I.V. Bazarov†, A. Bartnik, J. Dobbins, B. Dunham,
S. Full, Y. Li, X. Liu, J. Savino, K. Smolenski
CLASSE, Cornell University, Ithaca, New York 14853, USA

Abstract

We have developed a cost-effective, fast rotating wire scanner for use in accelerators where high beam currents would otherwise melt even carbon wires. This new design uses a simple planetary gear setup to rotate a carbon wire, fixed at one end, through the beam at speeds in excess of 20 m/s. We present results from bench tests, as well as transverse beam profile measurements taken at Cornells high-brightness ERL photoinjector, for a beam energy of 4 MeV and beam currents up to 35 mA.

INTRODUCTION

Recently, a new regime of beam parameters has become accessible with the advent of very intense photoinjectors, such as the Cornell ERL photoinjector, which feature very high average beam currents (up to 100 mA) and low transverse beam emittances (<1 mm-mrad rms normalized) [1, 2]. The beam energy out of the photoinjectors is near or below 10 MeV, with very large beam powers (on the order of MW) contained inside a small beam cross-section (diameter of 1 mm or less).

This parameter range poses special challenges for diagnostics at full beam current operation, particularly due to the beam's high charge density. First, the beam power density is high enough that any material intercepting the beam will melt on the order of 10's of microseconds or less. Second, the beam energy is low enough that synchrotron or diffraction radiation, which are often the method of choice for beam profile measurements at higher energies, are generally not available without introducing strong magnetic fields or placing apertures undesirably close to the beam for diffraction radiation.

One obvious candidate for a beam profile diagnostic capable of measuring MW type electron beams is a wire scanner that can sample the beam profile at a suitable transverse resolution (on the order of microns or even better) [3]. However, particle beams with small transverse dimensions and high intensities require a wire scanner with a very fast scanning speed, as these beams can melt even carbon wires - one of the best materials for withstanding extremely high temperature rises[4]. For example, a beam current of 100 mA and both an electron beam diameter and a wire diameter of $34\mu m$, like those found in the Cornell photoinjector, require a minimal scanning speed of 20 m/s. In this paper, we describe the design and show tests of a simplified wire scanner capable of reaching this speed and optimized for a large quantity reproduction, resulting in significant cost reduction.

WIRE SCANNER CONSTRUCTION

The principle of operation of the new wire scanner is illustrated in Fig. 1. It consists of a stationary gear G_1 and a smaller gear G_2 rotating around the gear G_1. The blade attached to the gear G_2 holds the carbon fiber cemented on its end. If the center of the small gear moves with the linear velocity v_g then the fiber scanning speed is

$$v_s = v_g\Big(\frac{R}{R_2} + 1\Big), \tag{1}$$

where R_2 is the radius of the gear G_2 and R is the distance from the center of the gear G_2 to the electron beam. Uncertainty of the beam position along the fiber results in the scanning speed variation

$$\frac{\delta v_s}{v_s} = \frac{\frac{\delta R}{R_2} + 1}{\frac{R}{R_2} + 1} \approx \frac{\delta R}{R}, \tag{2}$$

where it is assumed that $\delta R \ll R, R_2$. In the current prototype $R = 82.4$ mm, so for $\delta R = 5$ mm the relative scanning speed variation is $\delta v_s/v_s = 0.061$. This value sets the absolute precision of the transverse bunch profile measurement.

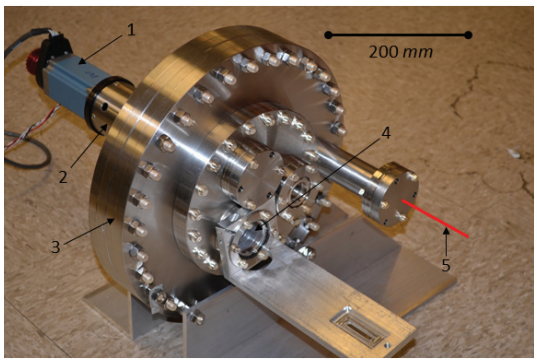

Figure 2: A photograph of the wire scanner. (1) - stepper motor; (2) - ferrofluidic rotary feadthrough; (3) - vacuum flanges; (4) - vacuum flange with viewports; (5) - beam direction.

A photograph of the wire scanner is shown in Fig. 2. The only custom made parts are the aluminum gear box and the fiber holding blade. These are installed between a pair of standard high vacuum flanges with a 337 mm outer diameter and an inner hole with a 152 mm diameter. Another set of two vacuum flanges of diameter 203.2 mm enclose the setup. One of the flanges is equipped with three optical view ports for monitoring the carbon fibers condition between scans. The rotation is provided by a ferrofluidic rotary feedthrough (Thermionics FRMRE-275-38CL) driven by a stepper motor. The maximum scanning speed is determined by the moment of inertia of the rotating parts (motor rotor, rotary feedthrough, gear box, and the blade), the friction in the gears and ball bearings, and the maximum torque rating of the rotary feedthrough. The gears and ball bearings were lubricated with Dicronite - a high vacuum compatible lubricant. Bench tests confirmed that mechanical friction is sufficiently small, and, with the existing moment of inertia of the system and torque limit of the feedthrough (1.06 Nm) scanning speeds can reach up to 30 m/s.

The starting position at the beginning of the scan is chosen so that the fiber is located slightly outside of the beam pipe. During the acceleration stage, the gear G_2 makes an almost complete revolution around the gear G_1 and the carbon fiber reaches its maximum velocity when it crosses the center of the beam pipe. Afterwards, the mechanism is decelerated and the fiber is stopped just outside the beam pipe, opposite its starting position. In order to avoid abrupt changes in the wire's acceleration, which lead to excessive vibrations, the velocity profile is programmed to follow a smooth sinusoidal curve for a nominal scanning speed of 20 m/s.

BENCH TESTS

In contrast to other wire scanners described in the literature [3, 5], the carbon fiber is attached to the rotating blade only by one end, so that a large amplitude vibration – up to 1 mm or more – can be easily excited. This should be compared to typical wire vibration amplitudes not exceeding $10\mu m$ in instruments with stretched wires fixed at both ends [6]. The oscillation speed will add to the wire scanning speed and, as a result can, affect the beam profile measurement. In the prototype instrument the oscillation frequency of the wire, $\omega = 75 \pm 2$ Hz, was determined experimentally by shining a laser onto the vibrating wire and tuning the laser pulse frequency until the image of the wire, obtained using a standard CCD camera, became stationary. Given the maximum amplitude of the oscillation $A_0 = 5mm$ (as determined by direct observation with the video camera), the wire scanning speed can be modulated by up to $\omega A_0 = 0.4m/s$.

In order to verify these estimates, a bench test designed to measure speed variations along the wire due to oscillations was performed. Specifically, a modulated laser was used to capture multiple images of the moving wire in a single CCD frame. The wire scanner was evacuated to a pressure of approximately 10^{-7} torr during these tests, and the laser beam was sent through the beam pipe using two flanges with optical windows. Figure 3 shows a frame obtained for a wire moving at 20 m/s using a laser pulse duration of 7 μs and a pulse frequency of 8 kHz. The laser pulse frequency of 8 kHz causes the wire oscillations to manifest as a slight broadening of the image. The laser light scattered by optical imperfections is removed by subtracting the frame without the wire.

The wire speed was calculated by measuring the distance between adjacent wire images in the scanning direction, and the results are shown in Fig. 4. Wire speed variations are observed both along the wire and in the scanning direction, pointing to the presence of the higher order vibrations. The average speeds determined at two wire scanning positions -2.0 mm and 0.4 mm are 20.2 $\pm$ 0.2 m/s and 20.0 $\pm$ 0.3 m/s respectively. The uncertainty is well within the estimate of 0.4 m/s based on the assumption that the amplitude of the fundamental wire vibration is less than 5 mm. The conclusion is that the wire scanning speed uncertainty is approximately (0.3 m/s)/(20 m/s) = 0.015, or 1.5%.

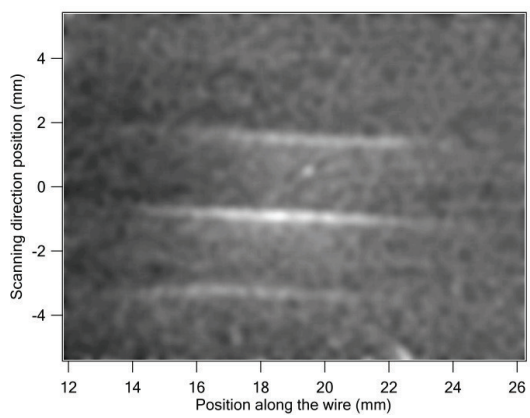

Figure 3: Three images of a wire captured on a single camera frame during a scan. The wire is moving at 20 m/s in the upward direction.

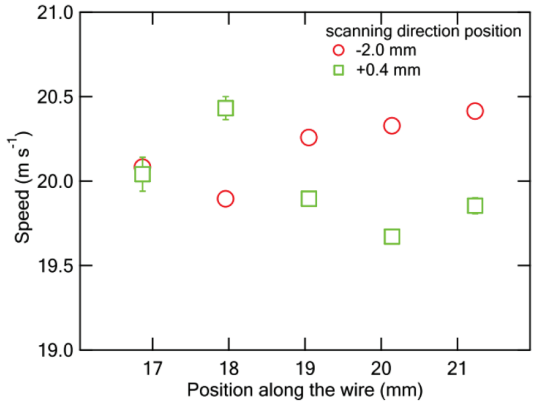

Figure 4: Wire speeds calculated at different locations along the adjacent wires shown in Fig. 3. The circles represent values calculated using the top and middle wires, while the squares use the middle and bottom wires. The error bars are smaller than the symbol size for some points.

BEAM TESTS

Beam tests of the new wire scanner were performed after installation in the chicane section of the Cornell ERL photoinjector [2]. X-rays produced when the wire crosses the electron beam were detected using a combination of a scintillator crystal and a silicon photomultiplier sensor (MicroSM-60035-X13 by SensL). The detector output was sampled at a rate 2 million samples per second with the aid of a digital acquisition device (Agilent U2500A USB DAQ). At a scanning speed of 20 m/s, this corresponds to a distance sampling interval of $10\mu m$, compared to the $34\pm1\mu m$ diameter of the carbon fiber used in these experiments. Data acquisition can be triggered either by the stepper motor controller (DMC-2183 by Galil Motion Control) at a preset wire position, or by the control software after a fixed time interval.

In order to test the dynamic range of the instrument, several sets of tests were performed for beam currents varying from $250\mu A$ to 35 mA, at a beam energy of 4 MeV and a bunch repetition rate of 1.3 GHz. The measured beam profiles were normalized by subtracting an offset and dividing the amplitude by the value of the current in mA. Results are shown in Fig. 5. The total area under the curve is preserved, confirming the good linearity of the detection system. As bunch charge is increased, a systematic broadening of the profile is observed that is the result of space charge repulsion.

At low beam currents the profiles can be obtained using a luminescent viewscreen. Figure 6 shows a comparison of the viewscreen and wire scanner profiles measured for the same beam current of $20\mu A$, which was obtained by decreasing bunch charge to 0.015 pC. A regular beam loss monitor photomultiplier was used for the wire scanner signal detection this time. Both curves are in very close agreement, confirming that both diagnostics are consistent for low bunch charge values.

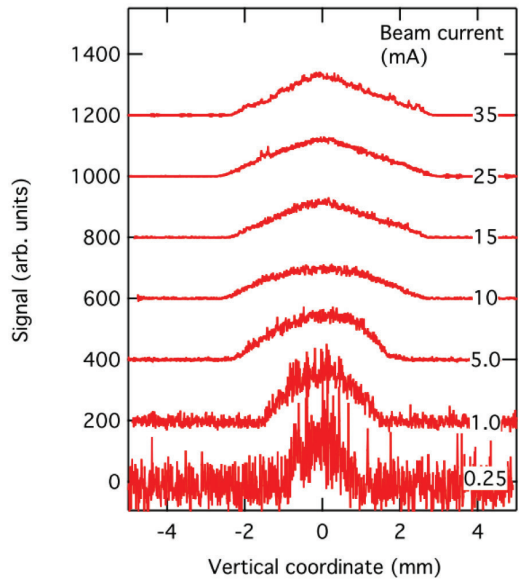

Figure 5: Wire scans at different beam currents, where the data is normalized to 1 mA current.

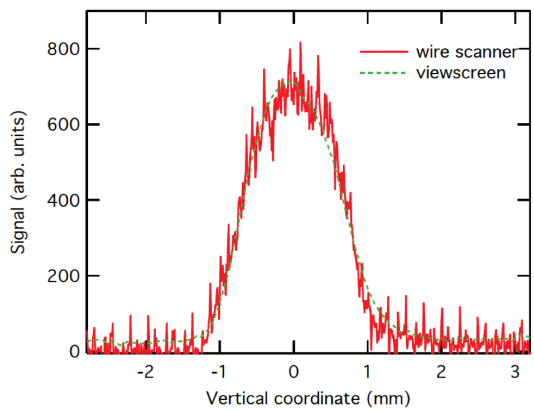

Figure 6: Comparison of the beam profile obtained with the wire scanner (solid line) and the luminescent viewscreen (broken line) for $20\mu A$ average beam current (0.015 pC bunch charge).

THE DOE-HEP ACCELERATOR R&D STEWARDSHIP PROGRAM*

Eric Colby, Michael S. Zisman#, U.S. Department of Energy, Washington, DC 20585, USA

Abstract

Since the Accelerators for America's Future (AfAF) Symposium in 2009, the U.S. Dept. of Energy's Office of High Energy Physics (DOE-HEP) has worked toward broadening its accelerator R&D activities beyond its support of only discovery science to include medicine, energy and environment, defense and security, and industry. Accelerators play a key role in many aspects of everyday life, and improving their capabilities will enhance U.S. economic competitiveness and the scientific research that drives it. In 2011, a community task force was initiated by DOE-HEP to develop more fully the information from the original AfAF Symposium. Subsequently, a DOE-HEP concept (coordinated with the other cognizant Office of Science program offices) was developed for accelerator R&D stewardship. Here, we describe the evolution of the stewardship task starting from its origins in the ongoing DOE-HEP accelerator R&D program, the mission of the new program, and initial steps being taken to implement it. Several initiatives are currently being considered to launch the program, and these will be indicated. Involvement of the accelerator community in developing ideas for future stewardship activities will be crucial to the ultimate success of the program.

ORIGIN AND MOTIVATION

Although DOE-HEP has historically taken a broad view of its accelerator R&D program, an effort to examine stewardship needs more formally began in 2009 with the sponsoring of the Accelerators for America's Future Symposium [1]. The report from this symposium, published in 2010 [2], identified the importance of accelerator technologies to broad sectors of the U.S. economy, including discovery science, medicine, defense and security, energy and environment, and industry. It also called out the needs for improved interagency, inter-program, and industry-agency coordination, and highlighted the value of expanded training and education of accelerator scientists and engineers.

In 2011, the Senate requested [3] DOE to prepare a 10-year strategic plan for "accelerator technology research and development to advance applications in energy and the environment, medicine, industry, national security, and discovery science." In preparation for developing such a strategic plan, Dr. Jim Siegrist, Associate Director of Science for High Energy Physics, in consultation with other Office of Science (SC) Associate Directors, asked Norbert Holtkamp from SLAC to convene a community task force to review and expand upon the findings of the earlier AfAF report. This group met during the period November 2011–February 2012 and provided information to:

- identify research opportunities with potential for broad national benefits
- summarize the status of key research and technology areas identified
- identify possible impediments to successful accelerator R&D stewardship activities for the broad user base envisioned

The task force report [4] was very helpful in preparing the DOE-HEP strategic plan, which was sent to Congress in October 2012.

DESCRIPTION OF STEWARDSHIP

Relationship with Current Program

The ongoing HEP accelerator R&D program develops the basic science and technologies needed to design, build, and operate state-of-the-art accelerators. Such accelerators are essential for making discoveries in HEP. Moreover, as is clear from the studies in Refs. [2] and [4], accelerators are likewise essential for serving the broader communities of medicine, defense and security, energy and environment, and industry as well as the discovery science community.

As indicated schematically in Fig. 1, there is already a strong connection between current R&D thrusts and stewardship program needs. The center portion of the figure lists the 8 program thrusts of the current HEP accelerator R&D program. The columns on the left indicate the science goals that motivate the program, namely, the desires for higher particle or photon beam quality, for higher beam intensity, and for higher beam energy (or, equivalently, more compact accelerators) and how they overlap with the program thrusts. The columns to the right indicate the overlap between the broader accelerator community needs and the ongoing R&D program thrust areas. The complete overlap with the needs of discovery science is by design, as this community has, to date, been the only consumer of the R&D work. It is interesting, however, that there is also substantial overlap with the needs of the other accelerator communities. We conclude from this that the existing skill set is already well matched to the needs of the broader accelerator community.

Accelerator Stewardship Mission

The mission of the accelerator R&D stewardship program is to support fundamental accelerator science and technology development of relevance to many fields, and to disseminate accelerator knowledge and training to the broad community of accelerator users and providers.

Carrying out this new mission—in addition to carrying out the current HEP programmatic accelerator R&D effort—will be accomplished through:

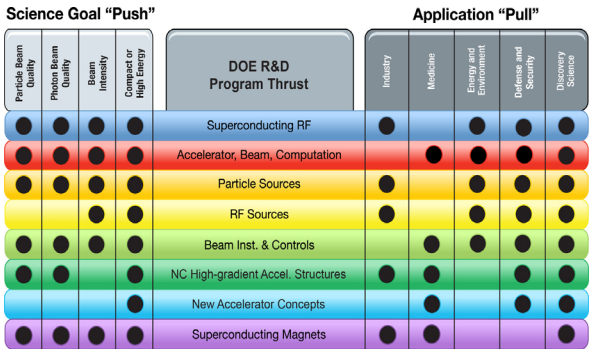

Figure 1: Connections between accelerator R&D thrust areas, science goals, and application needs (adapted from Ref. [4]).

- Facilitating access to national laboratory accelerator facilities and infrastructure for both industrial and other U.S. governmental agency users or developers of accelerators and related technology
- Working with accelerator user communities and industrial accelerator providers to develop innovative solutions to critical problems, to the benefit of both the broader user communities and the DOE discovery science community
- Serving as a catalyst to broaden and strengthen the community that relies on accelerators and accelerator technology

These elements are part of the accelerator R&D strategic plan.

STEWARDSHIP PROGRAM INITIATION

The steps envisioned to launch the stewardship program include:

1. Immediately augmenting existing programs to provide opportunities for industrial and federally funded users at DOE facilities by increasing support staff and funding for test facilities
2. In the mid-term (2–5 years), identifying a few topical areas with high impact for focused work; each area will have its own stakeholder board
3. In the longer term (5–10 years), select additional topical areas for focused work; new stakeholder boards will be created as topics are identified

In the steady state (depending, of course, on available resources), the HEP goal is to support at least three topical areas at any given time.

In preparation for item 1, an initial survey of available national laboratory infrastructure and capabilities was carried out in 2012. A follow-up meeting with the national laboratories to plan for stewardship activities at their test facilities is planned for early 2014.

Several potential topical areas have been identified for mid-term support (item 2). These include: improved particle beam delivery and control for cancer therapy facilities; laser development addressing the specific needs of the accelerator community, namely, high peak power, high average power, and high electrical efficiency; and energy and environmental applications of accelerators. One motivation for this last possibility is shown in Fig. 2, which gives the projected energy use of the SC accelerator laboratories compared with the anticipated mandated reductions. The SC accelerator complex energy usage is ~1000 GW-hr/yr, and is currently projected to increase about 50% by 2018. Without substantial improvements in efficiency, the challenge in meeting the mandated reductions is obvious.

For the longer term topics, we expect to solicit community input via workshops and discussions with other federal agencies.

Initial Topical Workshops

For the first two topics being considered under item 2 above, workshops were held to assess needs in these areas. The first, the Ion Beam Therapy Workshop, was organized jointly by DOE-HEP and the National Cancer Institute and took place in Bethesda, MD, from January 9–11, 2013. The second, the Laser Technology for Accelerators Workshop, was organized by LBNL and took place in Napa, CA from January 23–25, 2013. Both meetings were small and tightly focused, with attendance by invitation only. Representatives from the stakeholder agencies were also in attendance. Reports from the two workshops [5, 6] are available on the DOE-HEP website. A limited number of industrial observers were accommodated at each workshop, but did not participate in the preparation of the workshop reports.

Criteria for "Good" Accelerator R&D Stewardship Activities

In this section we provide some initial guidelines on choosing candidate activities for accelerator R&D stewardship. These should not be interpreted as hard and fast rules, but rather as an indication of the criteria that might be applied in the evaluation process.

1. The application must involve accelerators or accelerator-related technology having synergy with and benefitting the primary HEP mission.

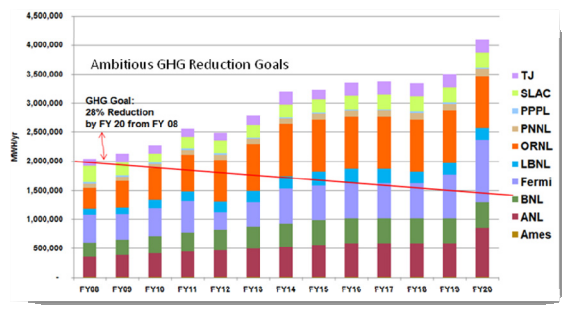

Figure 2: Projected energy usage of the SC accelerator complex through FY20 (bars). The red line indicates the decrease of 28% in green-house gasses (GHG) from FY08 to FY20 mandated by EO13514.

Copyright © 2013 CC-BY-3.0 and by the respective authors

2. There must be non-trivial intellectual involvement of the institution.
   Good: build an accelerator technology component (usually WFO*)
   Better: design an accelerator technology component (possibly WFO)
   Best: design, build, and test an accelerator technology component (stewardship)
3. The activity must be reasonably consistent with the mission of the institution and minimally impact its primary SC program(s).
   Good: activity maintains core skill or facility needed for the mission
   Better: activity expands core skill or facility needed for the mission
   Best: activity develops new core skill or facility needed for the mission
4. The institution must arguably be the best provider of the capability or service (and not compete with an existing business).
   Good: capability not unique, but institution is nearby to customer
   Better: capability is leading and institution is nearby to customer
   Best: capability is unique to provider
5. The customer benefitting from the stewardship activity must endorse the goals.
   Good: customer participates in task definition and writes letter of support
   Better: customer and institution partner; some cost sharing from customer (e.g., 1:10)
   Best: customer and institution partner; substantial cost sharing from customer (e.g., 1:1)

HOW YOU CAN ENGAGE

As we launch the accelerator R&D stewardship program, it is important that the accelerator community participate fully in its implementation. This can be done in a number of ways:

- Read the stewardship program description [7] and workshop reports found in Refs. [4–6].
- Respond to the Test Facilities Pilot Program call (national laboratories only) by identifying potential test facility customers and understanding their needs, and by responding to the meeting charge when it comes out.
- Prepare for topical area calls by starting to gather ideas and thinking about potential Collaborative Accelerator Research Teams (CARTs); be aware of related calls, e.g., the NIH P20 call for a National Center for Particle Beam Radiation Therapy Research [8] and the new DOE SBIR/STTR topical area for laser technology.
- Propose new, challenging topical areas; these should be "customer driven" and result in a potential solution that is broadly useful within a time frame of ≤ 10 years.

TAKE-HOME MESSAGES

Here we summarize the main points of the accelerator R&D stewardship program.

- Eligibility for the program will be broad; it is not a national-laboratory-only program.
- The "customer" must actively desire and participate in the activity; a pure technology push by potential providers is not sufficient.
- Activities should accrue some measureable intellectual benefit to HEP.
- Stewardship topical areas should address high-impact challenges on a roughly 5–10 year timescale; the intent is to solve problems and move on to other challenges.
- Handling intellectual property (IP) remains a challenge; existing WFO mechanisms provide a precedent, but IP will likely need to be handled case-by-case.

ACKNOWLEDGMENTS

We would like to thank Jim Deye (NCI) Cathy Bailey (NCI), and Christie Ashton (DOE) for help organizing the Ion Beam Therapy Workshop, and Wim Leemans and Martha Condon (both LBNL) for help organizing the Laser Technology Workshop. We are grateful to our DOE-HEP colleagues Jim Siegrist, Michael Procario, Glen Crawford, and L.K. Len for support and encouragement in launching the accelerator R&D stewardship effort.

ADVANCES IN PHOTOCATHODE TECHNOLOGY AT CORNELL UNIVERSITY*

S. Karkare†, I. V. Bazarov, L. E. Boulet, M. Brown, L. Cultrera, B. Dunham, N. Erickson, G. Denham, A. Kim, B. Lillard, T. P. Moore, C. Nguyen, W. Schaff, K. W. Smolenski, H. Wang, CLASSE, Cornell University, Ithaca, New York, USA

Abstract

Beam brightness from modern day photoinjectors is limited by the photocathode. A multifaceted photocathode development program has been undertaken at Cornell University with a goal to develop the ultimate photocathode which has high quantum efficiency, low mean transverse energy, quick response time and a long lifetime. Positive affinity cathodes like CsK_2Sb and Na_2KSb have been grown using different kinds of alkali metal sources (alkali-azide and pure metal), characterized and tested in the Cornell ERL photoinjector. Novel layered structures of various III-V semiconductors like GaAs and AlGaAs grown using Molecular Beam Epitaxy (MBE) and activated to negative electron affinity using Cs and NF_3 are also being investigated. Surface and photoemission diagnostics like Auger spectroscopy, LEED, RHEED and the 2D-electron energy analyzers have been connected in vacuum to the photocathode growth and preparation chambers to fully characterize the surface and emission properties of the materials grown. A Monte Carlo based simulation has also been developed to predict photoemission from layered semiconductor structures and help design novel structures to optimize the photoemission properties.

INTRODUCTION

Photocathodes used in photoinjectors that power modern and future 4^{th} generation light sources like the ERL's and FEL's have extremely stringent requirements. Moreover, the maximum achievable beam brightness from photoinjectors is limited by the photocathode [1]. For example, the photocathode in the Cornell ERL injector is required to have a high ($> 3\%$) QE (quantum efficiency) at 520nm laser wavelength, short ($<$ 2ps) response time, minimum possible MTE (mean transverse energy) with typical values being 150meV and a long lifetime during high current ($\sim$100mA) operation. Metallic cathodes are rugged and have a fast response time, but have very low ($< 0.1\%$) QE. Semiconductor cathodes provide a high QE in the visible and UV range. For this reason semiconductor cathodes are the choice for several photoinjectors around the world. However, they have very stringent vacuum conditions for longevity [2].

Several of the key emission properties required from semiconductor cathodes are conflicting. For example, at longer wavelengths, negative electron affinity (NEA) semiconductor cathodes give a small MTE ($\sim$25meV) but have a long ($>$100ps) response time [3]. Furthermore, the detailed physics of photoemission and the origin of the key photoemission properties like QE, response time and MTE are not well understood for semiconductor cathodes. This is largely due to lack of conclusive and self-consistent experimental data hampered by the demanding vacuum requirements and experimental difficulties associated with measuring key photoemission properties of MTE and response time from these cathode materials.

EXPERIMENTAL FACILITIES

A campus-wide photocathode investigation program has been initiated at Cornell University in order to address the need for experimental data. Both positive electron affinity (PEA) alkali-antimonide and NEA semiconductor photocathodes are under investigation. The alkali-antimonide photocathode growth chamber and GaAs activation chambers are connected in vacuum to surface analysis chamber with auger spectroscopy, RHEED and LEED capabilities. Abilities to measure spectral response, surface QE scan, activate NEA semiconductor cathodes using Cs and NF_3 while measuring QE at different wavelengths simultaneously have also been incorporated. Advanced photocathode diagnostics such as the electron energy analyzer [4] to measure simultaneously, transverse and longitudinal electron energy distributions have also been developed and added to the setup. Figure 1 shows the picture of the multipurpose vacuum system devoted to photocathode research. The entire assembly is under ultra high vacuum with a pressure of less than 10^{-10} Torr throughout and less than 10^{-11} Torr in the GaAs preparation chamber and the surface analysis chamber. Samples can be transferred from one part of the assembly to another in vacuum via use of magnetically coupled transfer arms.

Multialkali photocathodes developed and characterized here can be transferred to the Cornell ERL injector for studying their performance in a DC photoemission gun under high voltage (350kV) and high beam currents ($>$ 70mA) [5] via a vacuum suitcase capable of maintaining a pressure of a few 10^{-10} Torr during the transfer. Another facility is a semiconductor MBE reactor used to grow and activate III-V semiconductor photocathode structures. New layered structures of GaAs/AlGaAs can be grown with graded doping levels in order to optimize photoemission characteristics. These structures, once grown in the MBE reactor can be capped with a thick As layer and be transported in air to either the multipurpose photocathode

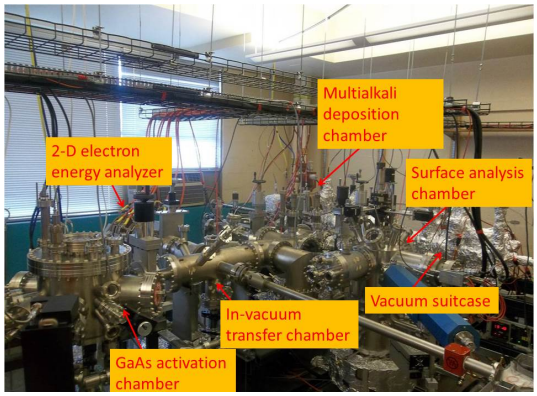

Figure 1: Photocathode growth and analysis chamber.

research chamber or to the DC photoemission gun, without contaminating the surface. The As layer can then be removed by heating the surface to about 350°C for one hour prior to the NEA activation.

ALKALI-ANTIMONIDE CATHODES

Characterization and High Current Operation

Various multialkali cathodes are routinely grown for use in the Cornell ERL injector using ALVATEC [6] alkali metal sources. Cs_3Sb, K_2CsSb and Na_2KSb have been successfully grown and characterized w.r.t their spectral response, MTE and response time in the photoinjector [7, 8, 9]. The results obtained have been summarized in Table 1. It can be seen that Na_2KSb gives a noticeably lower MTE than the Cs cathodes. Further Na_2KSb is also known to withstand higher temperatures making it more suitable for high current operation. Successful high current operation has been demonstrated by extracting 65mA of beam current from Na_2KSb cathode in the Cornell photoinjector for a period greater than 8hrs. The QE degradation during this operation had a 1/e lifetime constant of 66hrs [9].

Table 1: QE, MTE and Response Time Characterization of Multialkali Cathodes

Cathode	QE @ 532nm	MTE @ 532nm	Response time
Cs_3Sb	4-5%	160meV	$<$ 2ps
K_2CsSb	7-10%	160meV	$<$ 2ps
Na_2KSb	4-7%	120meV	$<$ 2ps

Investigating Alkali Metal Sources

Although multialkali cathodes have been successfully and reliably grown with the ALVATEC alkali metal sources, it has been found that the exact reproducibility of the growth process is difficult. The alkali metal flux changing over time and between individual dispensers is the main reason causing this lack of reproducibility. This makes it difficult to automate the cathode growth process. With this goal in mind various alkali metal sources are being investigated.

Along with ALVATEC sources, alkali antimonide cathode growth has been successfully demonstrated at Cornell using SAES dispensers [10], alkali azides and pure metal alkali sources. SAES dispensers are easy to handle and very reliable but have some drawbacks. They have to be heated to a temperature exceeding 600°C for alkali metal evaporation. Furthermore, the alkali metal flux from these sources is very small and hence they need to be placed very close to the substrate, increasing the substrate temperature due to radiative heating from the substrate and hindering cathode growth.

Alkali azides are stable compounds in air and decompose to release alkali metal vapor and nitrogen only when heated close to the melting point at about 300°C. This makes them easy to handle outside vacuum. They are cheap and the flux of alkali metal released is large. However, during the alkali metal evaporation the nitrogen released can cause the pressure to rise above 10^{-5} Torr. Very fine temperature control (to a fraction of a degree) of the furnaces is required to avoid excess pressure in the chamber. Such tight temperature control is one of the challenges to a successful use of these sources.

Pure metal alkali sources have been tested to some extent and have been found to be easy to operate for photocathode growth. But, pure alkali metals are strongly reactive and hazardous to handle in open air. A proper facility to insert these sources into the vacuum chamber through an inert gas atmosphere needs to be developed to avoid handling difficulty. Considering the stability and reliability of the sources, the pure metal alkali sources appear to be optimal. The above results are summarized in Table 2.

III-V SEMICONDUCTOR CATHODES

Monte-Carlo Simulation of Photoemission

A Monte-Carlo based simulation has been developed to explain the process of photoemission from GaAs [11]. This simulation is based on Spicer's 3-step photoemission model. Electrons are excited by photons from the valence band to the conduction band. The electrons are then transported within the GaAs bulk. During this transport they undergo scattering with phonons and holes and lose energy. The ones that reach the surface can get emitted into vacuum via tunneling through a surface potential barrier. This simulation successfully describes the spectral response and response time of GaAs cathodes without the use of any ad hoc parameters. Upon assumption of an elastic surface scattering that causes electrons to be emitted in a cosine angular distribution w.r.t. the surface normal, the Monte-Carlo code gives MTE values very close to the measured ones [12]. The exact value of NEA is extremely sensitive to the vacuum conditions and surface cleanliness. It can differ from activation to activation and hence is the only free parameter allowed in the simulations. The code has now been extended to layered structures with graded doping.

Table 2: Comparison of Alkali Metal Sources

Source	Capacity	Stability	Thermal load on substrate	Effect on vacuum	Handling outside vacuum
SAES	Poor	Good	Significant	Negligible	Stable in air
ALVATEC	Good	Poor	Not measurable	Negligible	Stable when unused
Azides	Good	Poor	Not measurable	Rises to 10^{-5} Torr	Stable in air
Pure metal	Good	Good	Not measurable	Negligible	Needs inert gas environment

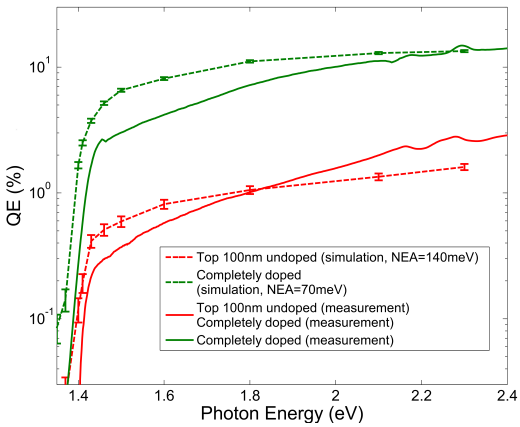

Figure 2: Measured and simulated spectral response of layered and non-layered GaAs cathode.

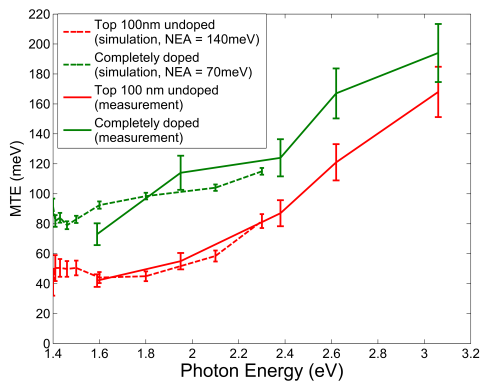

Figure 3: Measured and simulated MTE of layered and non-layered GaAs cathode.

Layered Structures

Novel layered structures of GaAs/AlGaAs with graded doping can be grown to optimize photoemission properties. So far layered structures have been grown to maximize QE [13]. The Monte-Carlo modeling predicted a simple structure consisting of 100nm undoped GaAs layer over a substrate doped to 5×10^{18}cm^{-3} using carbon would have a smaller MTE and a smaller QE as compared to completely p-doped GaAs. Such a structure was grown using MBE and activated to NEA. The MTE and spectral response were found to be in reasonable agreement with the values obtained from the Monte-Carlo simulation [14]. Figs. 2 and 3 show the comparison of the spectral response and MTE, respectively, of the layered and non-layered structures.

FUTURE WORK

We have concluded that pure metal sources are optimal for growing alkali-antimonide cathodes reproducibly. Developing an automated growth procedure using pure metal sources and growing advanced alkali-antimonide cathodes like the S-20 photocathode and characterizing it are among the next natural steps. The Monte-Carlo simulation has already allowed us to predict and realize new low emittance cathodes.This opens a way to systematic theory-driven investigations of more complicated layered structures optimizing certain photoemission properties. Simulations are continually being improved by including new relevant physics especially pertaining to the surface. Capability of activating and characterizing NEA cathodes within the MBE growth chamber is being implemented to skip the step of As capping and to ensure a clean and atomically flat surface.

CONTINUED DEVELOPMENT AND TESTING OF CARBON NANOTUBE CATHODES AT RADIABEAM*

J.J. Hartzell#, L. Faillace, R. Agustsson, S. Boucher, A. Murokh, A. S. Smirnov, RadiaBeam Technologies, Santa Monica, CA 90404, USA
B. C. Regan, W. Hubbard, UCLA, Los Angeles, CA 90095, USA

Abstract

RadiaBeam is continuing to develop carbon nanotube (CNT) cathodes for DC-pulsed and radio frequency (RF) driven electron sources. CNT cathodes, if fully realized, are capable of producing very high current density with low thermal emittance, due to ambient operating temperature. Experimental results of CNT cathodes are presented, including the high-voltage tests, and life time studies. CNT cathodes potential applications in accelerator science and microwave industry are discussed, and near term plans to test the CNT cathodes in the RF environment are presented.

INTRODUCTION

Carbon nanotubes are allotropes of carbon with a cylindrical nanostructure and exceptional electrical and mechanical properties [1]. They are typically fibers with a diameter of 1 to 50 nm, coming in either single-wall or multi-wall strands and an aspect ratio of up to 1000. Due to this very high aspect ratio, they have extremely large field enhancement factors, allowing efficient emission of electrons [2] at fields of only a few MV/m. Stable currents of more than 1μA have been measured from a single CNT fiber [3]. CNTs can also be fabricated in large, dense arrays, making them ideal as a cathode material. Peak current densities as high as 50 A/cm^2 have been reported from a macroscopic cathode operating in pulsed mode [4].

The use of a cathode fabricated with CNT technology has a high potential to replace thermionic cathodes in vacuum electronic devices, such as TWTs. Due to their high field enhancement factor, it is possible to operate in a "cold" field emission regime with relatively high current densities and affordable voltages in a much wider temperature range, including at room temperature [5]. Moreover, CNT cathodes are able to provide high current beams from a very small total gun size.

CNT CATHODE PRODUCTION

After early initial testing, we have focused on producing CNT cathodes via electrophoretic deposition (EPD) (see Figure 1). This method has proven to be rapid and economical. We are able to produce and characterize approximately one cathode per week. This allows us to produce a large number of samples with varying properties (deposition density, annealing temperatures, etc) to find the best combination of performance and durability.

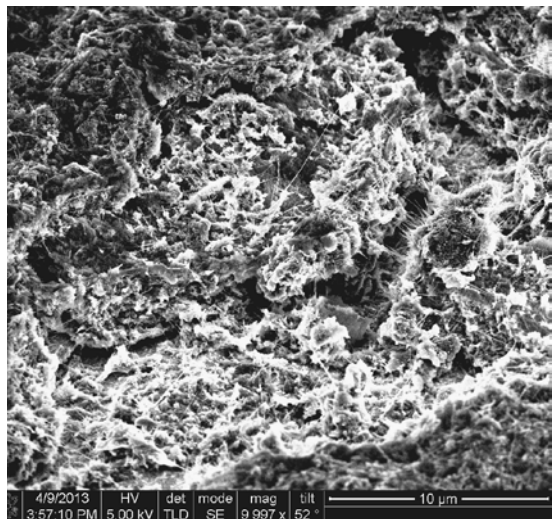

Figure 1: EPD deposition showing a very high density of CNTs.

As compared to earlier efforts, we have modified the substrate design to reduce the time required for machining and to accommodate the compact chemical vapor deposition (CVD) furnace that we helped our collaborators build. Our plan to eventually test the CNT cathodes inside the RF Gun at A0 (Fermilab) led to a design that has a reusable holder and removable cathode substrates. Figure 2 shows the new reusable holder with a variety of substrates ready for deposition.

As we are near the point of having optimized our EPD process, we are beginning early production tests of the CVD process. A computer controlled quartz tube furnace and digital mass flow controllers comprise the basic CVD production system. Unlike EPD, CVD allows us to grow CNTs directly on the substrate, offering more control of the microscopic properties of the deposition. We begin with elemental nickel nanoparticles (20 nm diameter, MKnano), which we suspend in isopropanol and then spin-coat onto the desired substrate. Since single nanotubes tend to grow from each nanoparticle and tube diameter is proportional to catalyst size [6] we check nanoparticle density via SEM to ensure they are sufficiently dispersed. For initial CVD process optimization we used silicon wafers as growth substrates, exploring the gas flow and temperature parameter space and characterizing samples in a SEM to develop a suitable growth recipe. We then adapted this recipe for growth of CNT on Ni nanoparticles dispersed onto Cu substrates, as we eventually wish to grow nanotubes directly onto copper cathodes. After a few trial growths, adjusting to reduce the significant amount of carbon which deposits onto the copper as graphene, we were able to successfully grow carbon nanotubes directly onto copper surfaces (See Figure 3).

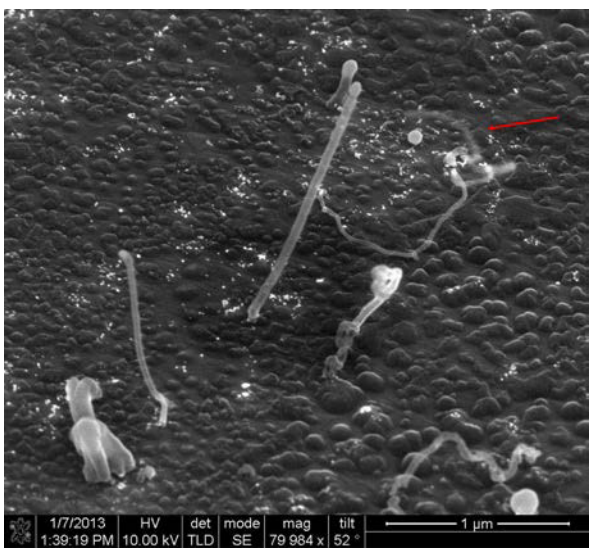

Figure 3: CNTs deposited onto a copper substrate via CVD. The red arrow points to a blurred CNT, indicating that it was only attached at one end, and was free to vibrate in the SEM.

CNT CATHODE TESTING

In order to be used in the gun (both DC and RF) for injection into an accelerator, the cathodes must have a sufficient current emitted at reasonable electric fields. Our initial goal is to make cathodes that are stable at ~20MV/m. We employ a pulsed mode test station for initial characterization. The test station has a variable gap of 0-25 ± 0.02 mm, can apply 0-2.5 kV, and a minimum pulse length of 5 µs.

For each cathode we study, we perform a series of individual runs, each at the same fixed electrode spacing. Each run consists of measuring the current while incrementally increase the voltage from 0 V until the cathode arcs. We then turn off the power supply to allow the system to stabilize and then repeat. Doing this allows us to progressively increase the maximum electric field the electrodes will support until we reach a stable operating point. From measuring the emitted current across the voltage range after each arc, we can clearly see that the emitted current is reduced as each arc damages a portion of the CNTs (see Figure 4). Once we reach a certain electric field, any loosely attached pieces of carbon are pulled off or a particularly long CNT is burnt off the cathode, initiating an arc. After the breakdown, the cathode can support a stronger field, albeit at a lower current, until the next breakdown. To confirm this idea, we used adhesive tape to mechanically remove all but the most strongly attached CNTs from the cathode the repeated the test. This substantially increased the voltage handling at the expense of reducing the emitted current.

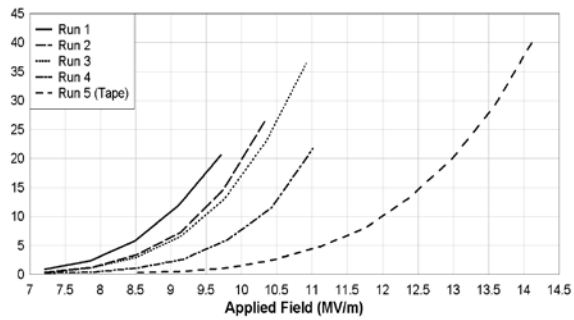

Figure 4: A series of runs on the same cathode, each ending in a breakdown. A final run after using tape to clean the cathode improves the voltage handling.

After using pulsed mode testing to evaluate a large number of cathodes, we select the best candidates and begin lifetime studies in a CW mode test station. This test station also has a variable gap of 0-25 mm, but the voltage range is extended up to 20 kV and continuous average current of 110 mA. A custom fabricated water cooled anode can dissipate the full energy the power supply can deliver.

Preliminary results show that after an initial burn-in period of approximately 4 hours, the cathode emission stabilizes at about 70% of the initial current (see Figure 5). Some degradation of emission is expected as the longest CNTs erode until all of the CNTs are approximately the same length and emitting the same average current.

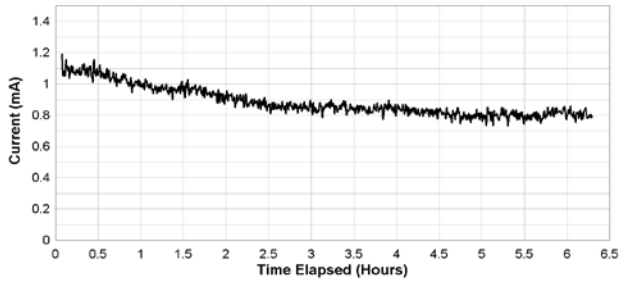

Figure 5: Lifetime study of small CNT cathode showing initial decay of current, stabilizing after approximately 4 hours.

PLAN FOR TESTS IN RF ENVIRONMENT

The initial high power tests inside an RF gun will be performed at the FNAL-A0 beamline at Fermilab. As discussed, our cathode design is compatible with their interchangeable cathode system. After verification in an RF environment, we will test our cathodes in a dual-frequency gun Radiabeam has designed and will fabricate (which will be given to Fermilab for general use after the experiments). The dual frequency gun uses the interference of a harmonic frequency with a primary accelerating frequency to effectively gate the emission of the CNT cathode to the proper phase of the acceleration RF. Since the CNT cathodes have a distinct threshold voltage, unlike thermionic cathodes, the bunch length can be made much shorter, eliminating the need for a bunching structure before injection into the accelerator.

We have started the RF design and engineering of a DESY/PITZ-like High-fidelity Gun. The preliminary 3D model is shown in Figure 6. The RF power is fed from the beam output pipe by means of a rectangular-coaxial transition. This will allow us to keep perfect field symmetry inside the Gun cells, eliminating any higher order mode field components that can deteriorate the beam quality. The cooling system, also shown in the picture, permits very high repetition rate operation.

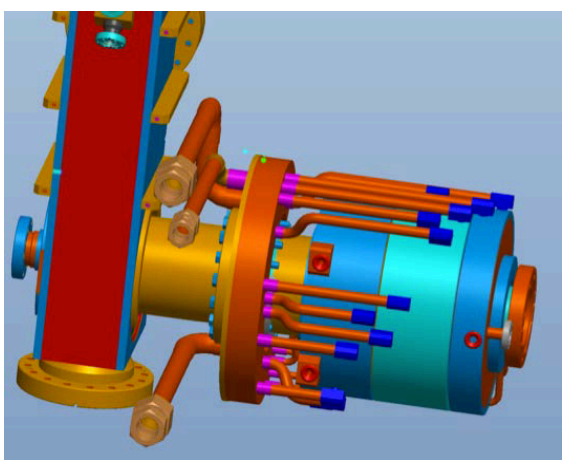

Figure 6: 3D CAD model of the high-fidelity RF Gun (Pitz-like).

This gun design will be adapted to use two frequencies (1.3 and 3.9 GHz) over the next several months. Fabrication is scheduled to begin in early 2014. The RF power test of the high-fidelity gun will be performed at Fermilab, with the CNT cathode, by the end of August 2014.

CONCLUSIONS

In summary, Radiabeam has made significant progress in bringing CNT cathodes to the point of experimental evaluation. Further testing must be done to fully characterize the emission and the lifetime, particularly for cathodes produced via CVD. The upgrades to the pulsed mode test system have greatly increased our throughput of samples, speeding up the optimization of our deposition processes. The CW mode test station was built and is evaluating samples under 100% duty cycle conditions to ascertain the effective lifetime of CNT cathodes.

NOVEL METHODS FOR EXPERIMENTAL CHARACTERIZATION OF 3D SUPERCONDUCTING LINAC BEAM DYNAMICS

A. Shishlo#, ORNL, Oak Ridge, TN 37831, USA

Abstract

This paper describes an approach to measure initial Twiss parameters in transverse and longitudinal directions at the entrance of a linac with independent short accelerating cavities. For the transverse plane the usual technique of transverse profiles is used, and for the longitudinal direction a recently developed non-intercepting method is applied. The new method is based on a beam position monitor amplitudes analysis. The applicability of the methods are discussed and demonstrated on an example of the Spallation Neutron Source superconducting linac.

INTRODUCTION

Beam loss in accelerators should be low enough to allow "hands on" maintenance. This goal is achieved by a good design of the machine and a precise tuning before the operation phase. According to its design, the superconducting linac (SCL) of the Spallation Neutron Source (SNS) accelerator should be a almost loss-free part of the machine due to large apertures and low residual gas pressure. During the commissioning, it was found that SCL had significant beam loss and could be activated above the "hands on" maintenance level when the beam power reaches a design value of 1.4 MW. Fortunately, this beam loss was reduced to an acceptable level by reducing the strength of the quadrupoles in the SCL without a clear understanding the loss mechanism. After that, the power of SNS accelerator was not limited by SCL beam loss. Recently, the SCL beam loss mechanism was identified as intra-beam stripping (IBSt) [1,2]. IBSt is a process of stripping one loosely-bound electron from one of two H^- ions colliding inside the bunch. The neutral hydrogen atom created in this collision will not see any focusing fields, and it will be lost on the beam pipe. The reaction rate of IBSt is proportional to the square of the particle bunch density, so the reducing of the SCL quadrupole strengths made the beam bigger transversely and reduced the density and beam loss. The process of a quadrupole focusing fields tuning is and was a purely empirical beam loss reduction based on readings of Beam Loss Monitors (BLM). All previous attempt to use a model based approach to the SCL loss reduction failed, and this paper is an attempt to explain why we did not succeeded before.

RATIONALE

IBSt beam loss is defined by the core of the bunch where the most particles are located. It allows us to describe this loss with a simple envelope model instead of complicated and slow particle-in-cell tracking codes. After certain assumptions (the Gaussian particles distribution in the bunch), the only parameters needed for the loss calculation are Twiss parameters of the bunch for all three directions along the linac [1]. To calculate these Twiss parameters we need the following components:

- A validated envelope tracking accelerator model.
- The measured initial Twiss parameters for all three dimensions.

The present work describes how to get these components for the SNS superconducting linac tuning. The problem of loss reduction based on this model and the initial Twiss parameters is a subject of future studies.

THE SNS SUPERCONDUCTING LINAC

The SNS superconducting linac consists of Medium and High Beta sections named in accordance with the two types of superconducting cavities designed for geometrical relativistic β= 0.61 and 0.81 beams. The first section has 11 cryomodules with 3 cavities in each module, and the High Beta section has 12 modules, 4 cavities per module. Each 805 MHz cavity has independent control of the field gradient and phase. According to the design, the cavity field gradients in each section should be all the same, but in reality they are not. Instead, the gradient of each cavity is set to be as high as possible for stable operation. The input energy of the SCL is 185.6 MeV; the output energy is about 930 MeV, and it is defined by existing cavity gradients; the design peak current is 38 mA and the design energy 1 GeV. The bunch frequency of 402.5 MHz is defined by a normal conducting part of the linac. The SCL has 32 stripline beam position monitors (BPMs) installed along the linac between cryomodules and in the cavity-free part of SCL. The BPMs measure the transverse positions of the beam, the arrival phases of the bunches, and the amplitudes of the Fourier harmonics of the bunch longitudinal distributions at the bunch frequency. The SCL is also equipped with 9 Laser Wire (LW) Stations to measure transverse profiles of the beam. Four LWs are installed at the beginning of each of the two sections (one LW after each of the first four superconducting cavities) and one LW at the end of SCL.

XAL ONLINE MODEL

All simulations and analysis performed for this work used the XAL Online Model (OM) [3]. The OM is an envelope tracking accelerator code similar to TRACE3D [4]. The OM tracks the envelope parameters through the SCL lattice using transport matrices for each quadrupole, each RF gap in the accelerating cavities, and each drift space. The space charge kicks are accumulated in the total

shishlo@ornl.gov

transport matrix describing the transformation of the envelope from the beginning to an arbitrary point in SCL. The parameters of the lattice, such as the quadrupole field gradients, are taken from the control system. The field gradients and phases of the superconducting cavities are found after an analysis of the phase scans. The cavity phase scan is a process of collecting the BPM phases and amplitudes for a cavity phase changing from -180^0 to +180^0. All downstream cavities have the RF pulse blanked so they will not affect the beam, and the number of bunches in the pulse train is limited to about 200 to avoid beam loading of the cavities. Figure 1 shows the results of a phase scan of the first SCL cavity Cav01a. The phase difference between two BPMs are analysed as a time-of-flight measurement to get the amplitude of the cavity in the online model and the phase of its first accelerating gap. The phase set-point of each cavity was chosen to be 18^0 less than the position of the maximal acceleration (see Fig. 1). These settings are usual for the production tune of SCL.

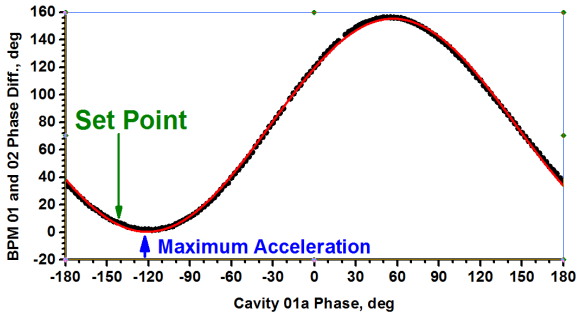

Figure 1: The BPM 01 and 02 phase difference during the phase scan of the first SCL cavity. Points are measurements, and the red line is an OM simulation.

After the online model lattice is initialized we can start the procedure of measuring the initial Twiss parameters for the transverse and longitudinal directions. In the presence of space charge forces these tasks are coupled, and they should be performed by iterations. We intend to do this in the future, but here we present analyses of the transverse and longitudinal data that were acquired about one year apart just to demonstrate the applicability of the methods. We will start with the algorithm and data analysis for horizontal and vertical directions.

TRANSVERSE PROFILES ANALYSIS

To get the initial Twiss for the horizontal and vertical directions from multiple profile measurements we will use the techniques described in [5]. Let's consider one direction. The transformation coordinates of the particle between the beginning of the lattice and the profile measurement device are defined by the transport matrix from the envelope model

$$\begin{pmatrix} x_1 \\ x_1' \end{pmatrix} = \begin{bmatrix} m_{11}^{(1)} & m_{12}^{(1)} \\ m_{21}^{(1)} & m_{22}^{(1)} \end{bmatrix} \cdot \begin{pmatrix} x_0 \\ x_0' \end{pmatrix}, \quad (1)$$

where x_0, x_0' and x_1, x_1' are coordinates of the particle at points 0 and 1, and $m^{(1)}$ is a transport matrix. By calculating the square of both sides of the first equation of the (1) system and averaging over the whole ensemble of particles in the bunch, we have the expression for the squared RMS beam size $\langle x_1^2 \rangle$

$$\langle x_1^2 \rangle = (m_{11}^{(1)})^2 \langle x_0^2 \rangle + 2 m_{11}^{(1)} m_{12}^{(1)} \langle x_0 x_0' \rangle + (m_{12}^{(1)})^2 \langle x_0'^2 \rangle,$$

where $\langle x_0^2 \rangle$, $\langle x_0\, x_0' \rangle$, and $\langle x_0'^2 \rangle$ are the correlations of the coordinates for the initial state. By using several profile monitors or modifying the optics of the lattice we can get as many different transport matrices $m^{(i)}, i = 1, \ldots, N$ and equations for the beam RMS sizes as we want. All this information can be represented by the following matrix equation

$$\begin{bmatrix} \langle x_1^2 \rangle \\ \cdots \\ \langle x_N^2 \rangle \end{bmatrix} = \begin{bmatrix} m_{11}^{(1)^2} & 2 m_{11}^{(1)} m_{11}^{(1)} & m_{12}^{(1)^2} \\ \cdots & \cdots & \cdots \\ m_{11}^{(N)^2} & 2 m_{11}^{(N)} m_{11}^{(N)} & m_{12}^{(N)^2} \end{bmatrix} \cdot \begin{bmatrix} \langle x_0^2 \rangle \\ \langle x_0 x_0' \rangle \\ \langle x_0'^2 \rangle \end{bmatrix}. \quad (2)$$

Assuming we have the measured RMS beam sizes s_1, s_2, … s_N we can find the initial correlations $\langle x_0^2 \rangle$, $\langle x_0\, x_0' \rangle$, and $\langle x_0'^2 \rangle$ by minimizing the sum

$$S = \sum_{i=1}^{N} \frac{\left(s_i^2 - \langle x_i^2 \rangle\right)^2}{\sigma_i^2}, \quad (3)$$

where σ_i denotes the rms error of the measured s_i^2. This error is obtained from the fit to the i-th profile which determines s_i.

The equation (3) is a typical linear Least Square Method problem, and the solution is

$$\begin{bmatrix} \langle x_0^2 \rangle \\ \langle x_0 x_0' \rangle \\ \langle x_0'^2 \rangle \end{bmatrix} = (M^T W M)^{-1} M^T W \begin{bmatrix} s_1^2 \\ \cdots \\ s_N^2 \end{bmatrix}, \quad (4)$$

where M is $N \times n$ matrix from equation (2) and W is a diagonal weight matrix

$$W_{ii} = 1/\sigma_i^2 . \quad (5)$$

A symmetric 3 x 3 covariance matrix

$$C = (M^T W M)^{-1} \quad (6)$$

defines the errors for the initial correlation values found from (4)

$$\sigma_{\langle x_0^2 \rangle} = \sqrt{C_{11}}, \quad \sigma_{\langle x_0 x_0' \rangle} = \sqrt{C_{22}}, \quad \sigma_{\langle x_0'^2 \rangle} = \sqrt{C_{33}} . \quad (7)$$

After the initial correlations are found, the Twiss parameters emittance, alpha, and beta are defined by equations

$$\varepsilon = \sqrt{\langle x_0^2 \rangle \langle x_0'^2 \rangle - (\langle x_0 x_0' \rangle)^2} , \quad (8)$$

$$\alpha = -\langle x_0 x_0' \rangle / \varepsilon , \quad (9)$$

$$\beta = \langle x_0^2 \rangle / \varepsilon . \quad (10)$$

The error of any scalar function of initial correlations $f(\vec{\tau})$

$$\vec{\tau} = [\langle x_0^2 \rangle, \langle x_0 x_0' \rangle, \langle x_0'^2 \rangle]^T \quad (11)$$

is given by

$$(\sigma(f))^2 = (\nabla_{\vec{\tau}} f)^T \cdot C \cdot (\nabla_{\vec{\tau}} f) . \quad (12)$$

Formulas (7) are special cases of this general formula. It also allows estimating the errors for the initial Twiss parameters (8-10).

All together formulas (4 – 12) describe the transverse profiles analysis including the error analysis.

Copyright © 2013 CC-BY-3.0 and by the respective authors

Space Charge Effects

In the presence of space charge the transport matrices in (2) will be dependent on the initial Twiss parameters for the longitudinal and transverse directions. As for the longitudinal Twiss parameters, there are several possible ways to find the initial values. First, we can blindly use the design parameters. Second, for the SCL we can use the methods described in this paper later. For the transverse parameters the transport matrices dependency makes the equation (2) a transcendental one, and there is no exact analytic solution for it.

To solve (2) in the presence of the strong space charge a two steps method was used. In the beginning, a general nonlinear fitting package was used to find the initial parameters that will minimize the S function (3). Then the transport matrices generated by the OM for these initial Twiss parameters were used in (4) and (7) to get a new set of these parameters and their error estimation. If these two sets were close enough assuming their errors, we concluded that the problem is solved. This method does not guarantee a uniqueness of the solution, because the fitting routine can find several local minima. This situation can be resolved by increasing the number of measurements with the lattice configurations providing the reduced errors (7). These additional measurements should be planned ahead by using the preliminary estimation for the initial Twiss. The rule of thumb from [5] is a 90^0/(N-1) betatron phase advance distance between each measurement. The exact effect of each additional measurement should be estimated by (7). Unfortunately, even these measures cannot guarantee a uniqueness of the solution and correctness of the error estimation.

Twiss Parameters Correlations

The diagonal elements of the covariance matrix C (6) include information about errors of $\langle x_0^2 \rangle$, $\langle x_0 x_0' \rangle$, and $\langle x_0'^2 \rangle$ parameters (7), and the non-diagonal elements of C describe their correlations. The graphical representation of these correlations on two dimensional plots like the (β, ε) plane could be very beneficial. As we will show later, sometimes it helps to explain the nature of very high errors of the Twiss parameters. The algorithm for plotting these correlations starts with the diagonalization of C

$$C = (M^T W M)^{-1} = V \cdot D \cdot V^T, \qquad (13)$$

where D is a diagonal matrix, and V is a transformation matrix for the $\langle x_0^2 \rangle$, $\langle x_0 x_0' \rangle$, and $\langle x_0'^2 \rangle$ parameters to a new set of variables $\vec{\theta}$

$$\vec{\theta} = V^T \cdot \vec{\tau}, \quad \vec{\tau} = [\langle x_0^2 \rangle, \langle x_0 x_0' \rangle, \langle x_0'^2 \rangle]^T . \qquad (14)$$

For $\vec{\theta}$ the covariance matrix D is diagonal. Therefore, the errors of $\vec{\theta}$ are defined by the diagonal elements of D (similar to (7)), and they are not correlated. The possible values of $\vec{\theta}$ are inside the rectangular region with the center defined by (14) and widths $\left[2 \cdot \sqrt{D_{11}},\ 2 \cdot \sqrt{D_{22}},\ 2 \cdot \sqrt{D_{33}}, \right]$. The surface points of this region can be easily projected onto any planes representing Twiss parameters correlations.

SCL LASER WIRE PROFILES ANALYSIS

To measure the transverse beam profiles in the SNS superconducting linac we use Laser Wire (LW) stations [6] instead of traditional wire scanners. LW stations perform nonintrusive measurements based on a photo-detachment process. The scans can be done even during 1 MW operation. The dynamic range of the LW measurement is lower than the traditional wire scanners, so in our analysis we used only beam sizes calculated as a Gaussian fit to the profiles. Figure 2 shows a typical laser wire profile with a fit, and the high level of noise does not allow us to calculate RMS of the profile directly. All measurements discussed in this section were performed in 2011 and 2012. Since then the SCL LW system was significantly improved [6].

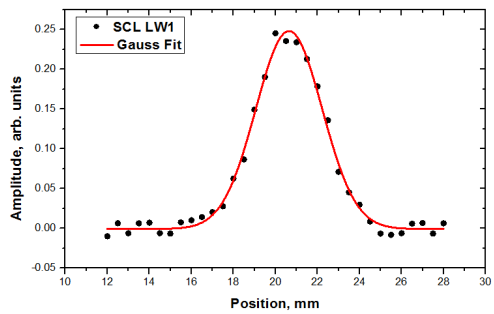

Figure 2: LW1 profile measurement and a Gaussian fit.

Earlier we reported that our attempts to improve SCL beam size beating failed because we could not find the initial Twiss parameters at the entrance [7]. After applying the analysis described in the previous section, it was found that the Twiss parameters errors were too big to make any meaningful conclusions. The detailed study of these errors showed the strong correlation between the emittance and Twiss beta parameter values.

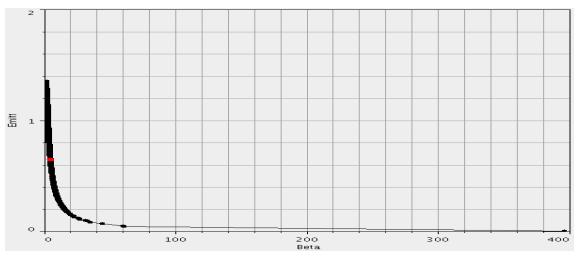

Figure 3: A correlation between the emittance and the beta Twiss parameter. The red dot is a central point found in the nonlinear fit.

As example, Fig. 3 shows this correlation with the region calculated with formulas (13) and (14) from the "Twiss Parameters Correlations" section of this paper. The possible range for the emittance is from almost 0 to 1.4 π*mm*mrad and the beta parameter is from 0 to 400 m. The beta range could be narrowed down if the emittance value is considered as a known parameter.

The initial transverse Twiss parameters measurement was improved after the error control (formulas (6) and (7) and multiple lattice configurations) was implemented. It

Copyright © 2013 CC-BY-3.0 and by the respective authors

was found that the quad gradients should be increased by 10% -15% to reduce the error to an acceptable level.

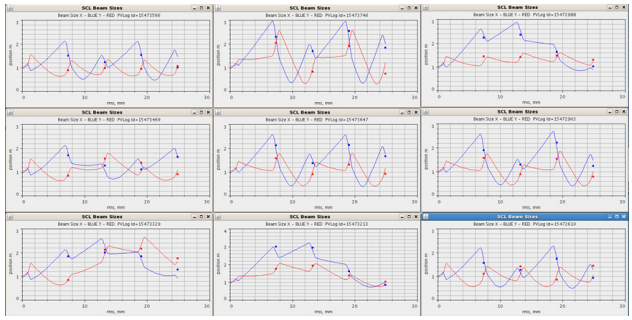

Figure 4: Transverse beam sizes at first 4 LW stations in SCL for 9 different quad settings. Blue and red colors are for horizontal and vertical directions respectively. Points are LW results, and curves are the model with the same initial Twiss.

Figure 4 shows the excellent agreement between LW measurements and the OM simulations for 9 lattice settings. These data were taken for all SCL cavities switched off and a low peak current to eliminate space charge effects. For the production peak currents 28-35 mA and the RF cavities switched on the agreement between the model and LW data was good for the first three LW stations. The measured transverse Twiss parameters at the entrance of SCL for the production tune for 37 mA peak current are shown in Table 1 (emittance normalized, rms). Unfortunately, we could not predict the transverse beam sizes downstream for the whole SCL linac. At that moment, we realized that we need more precise information about the longitudinal Twiss parameters and a verified model for the longitudinal dynamics calculations. The next section will describe our approach to this problem.

Table 1: Transverse Twiss Parameters

Direction	Alpha	Beta [m]	Emittance π*mm*mrad
Horizontal	-0.55±0.22	2.35±0.84	0.40±0.08
Vertical	0.66±0.14	7.7±1.8	0.38±0.05

LONGITUDINAL TWISS PARAMETERS

Recently at SNS, a new method of measuring of the rms longitudinal Twiss parameters of a beam in linear accelerators was developed [8]. The method is based on using sum signals from BPMs sensitive to the longitudinal charge distribution in the bunch. The applicability of the method was verified with direct longitudinal profile measurements by the Bunch Shape Monitor (BSM) at the end of Coupled Cavity Linac (CCL) which is a part of the linac preceding the SCL. The method is fast and simple, and can be used in linear accelerators where interceptive diagnostics are not desirable. The previously developed method based on transmission and beam loss measurements [7, 9] is less accurate and is much more time and effort consuming.

The new method is based on the same formulas (2-10), and the BPMs are used to measure the longitudinal rms sizes.

BPM and Longitudinal RMS Size of Bunch

At the SNS linac the sum signal of a BPM is proportional to the Fourier amplitude of the longitudinal bunch distribution at the frequency of the BPM system

$$u = J \cdot \zeta \cdot 1/I_0\left(\frac{\omega R}{\gamma\beta c}\right), \qquad (15)$$

where J is an amplitude of the beam current harmonic at the BPM frequency ω; ζ is a factor describing the transfer function of the BPM including the pickup geometry, amplifier gain etc.; R is the radius of the pickup aperture; c is the speed of light; β and γ are relativistic factors; and I_0 is the modified Bessel function. In the case of Gaussian longitudinal bunch shape

$$u = Q \cdot \zeta \cdot exp\{-(\omega s_z)^2/2\}/I_0\left(\frac{\omega R}{\gamma\beta c}\right), \qquad (16)$$

where Q is the total charge of the bunch and s_z is the RMS bunch time length. The calibration constant $(Q \cdot \zeta)$ can be measured as BPM amplitude at the production SCL tune when $\omega s_z \ll 1$. Inverting equation (16) with respect to s_z we get the bunch length from the BPM sum signal for formulas (2-10).

The main assumption that was used for the formula (16) is a Gaussian shape of the longitudinal density of the bunch. Figure 5 shows the longitudinal bunch distribution at the end of CCL which has an almost perfect Gaussian shape. For the production tune, during the acceleration of the bunch by SCL cavities, we keep the bunch short enough to avoid non-linear distortion from the cavities and beam loss. Therefore, we are confident that we keep the Gaussian shape of the bunch through the whole SCL.

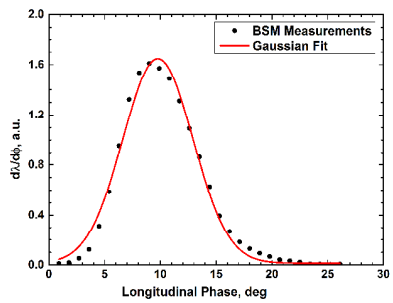

Figure 5: The longitudinal beam profile measured by the BSM in the CCL.

Longitudinal Twiss Parameters Analysis

In [8] it is shown that a simple measurement with a coasting beam is not accurate enough to get useful initial longitudinal Twiss parameters. The errors of these parameters are too big. As a solution, it was suggested to use a phase scan of the RF cavity placed between the initial point and the BPMs. In the case of the phase scan, the number of different longitudinal transport matrices $m^{(i)}$ in (2) increased to $N_\varphi \times N_{BPM}$ where N_φ and N_{BPM}

Copyright © 2013 CC-BY-3.0 and by the respective authors

are the number of the cavity phase points and the number of BPMs, respectively. For a phase scan step of 5^0 $N_\varphi \times N_{BPM} = 72 \times 15 = 1080$ measurements. It is also important that during the scan the cavity performs different focusing-defocusing transformations with the bunch in the longitudinal phase space. Fortunately, we already have the results of the phase scans of all SCL cavities that we used to initialize the SCL lattice of the OM model. A picture of the BPM amplitudes during the phase scan of the first SCL cavity is shown in Fig. 6.

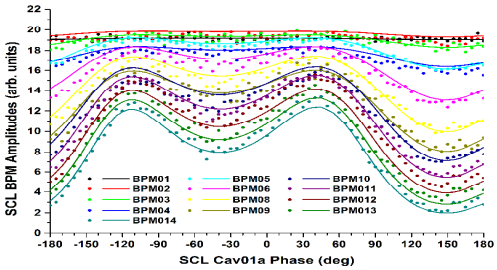

Figure 6: The BPM amplitudes during a Cav01a phase scan. Points are measurements, lines are from OM model.

The phase scan data were taken at the peak current of 30 mA which is different from the 37 mA during the transverse Twiss measurements, but we used the same transverse Twiss parameters anyway. This makes our analysis somewhat inconsistent, and in the future we plan to perform transverse and longitudinal analysis on the same set of data. After the analysis, we found longitudinal Twiss parameters at the entrance of the first SCL cavity are α = -0.78 ± 0.02 , β = 8.1 ± 0.2 [m/rad], ε = 0.60 ± 0.01 [π•mm•mrad] (XAL OM units).

Then we performed the same analysis for each SCL cavity in the Medium Beta section (unfortunately we scanned only this part). This gave us measured longitudinal Twiss parameters along the SCL. We also used the initial Twiss and the initialized OM lattice to simulate the same parameters. The Twiss parameters obtained two ways are shown in Fig. 7.

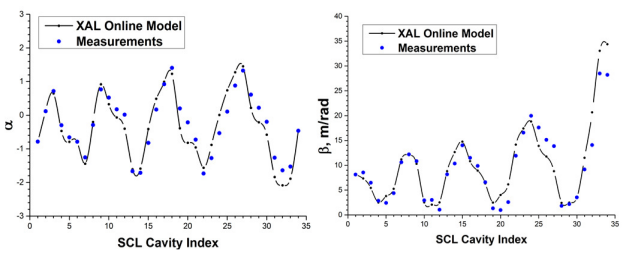

Figure 7: The longitudinal Twiss α and β parameters along SCL.

We have a relatively good agreement between the measured and simulated Twiss, but they do not agree inside error bars. The differences can be explained by the very strong longitudinal over-focusing of the bunch where the space charge effects are strong and the envelope model could be less accurate. Figure 7 demonstrates a poor matching in the longitudinal direction for the existing SCL tune.

CONCLUSIONS

The practical approach to the 3D beam characterization is suggested and tested on the example of the SNS superconducting linac. The new method of the longitudinal Twiss parameters measurement is developed and used. This is the first time the longitudinal parameters have been measured continuously along the linac. The role of the space charge effects should be studied further. The applicability of the XAL OM for the linac tuning is demonstrated.

SPACE-CHARGE COMPENSATION FOR HIGH-INTENSITY LINEAR AND CIRCULAR ACCELERATORS AT FERMILAB*

M. Chung†, L. Prost, V. Shiltsev, Fermilab, Batavia, IL 60510, USA

Abstract

Space-charge effects have long been recognized as a fundamental intensity limitation in high-intensity linear and circular accelerators. As the mission of the US high energy physics program is pushing the Intensity Frontier, it is very timely to explore novel schemes of space-charge compensation that could significantly improve the performance of leading high-intensity proton accelerator facilities such as Project-X. In this work, we present two activities at Fermilab on space-charge compensation experiments based on residual gas ionization: 1) neutralized beam transport of continuous-wave (CW) H^- beam in Project-X Injector Experiment (PXIE); and 2) trapped electron plasmas for space-charge compensation in the newly proposed Integrable Optics Test Accelerator (IOTA) ring. Characteristics of the stability in the beam-plasma system, the dynamics of beam neutralization, and the transition between neutralized and un-neutralized beam transports are discussed for each experiment.

INTRODUCTION

The main idea of space-charge compensation considered in this work is based on the long-known fact that the negative effect of Coulomb repulsion can be mitigated if beams propagate through a plasma column of opposite charge. The plasma column can be formed by beam-induced residual gas ionization and/or by external plasma sources. This idea has been successfully applied to transport high-current low-energy proton and H^- beams into the RFQ in many linacs [1]. In circular machines, partial neutralization by ionization electrons was attempted with notable improvements in beam intensity, namely an order of magnitude higher than the space-charge limit [2].

BASIC DEFINITIONS

The time needed to generate enough electron-ion pairs for full space-charge compensation is called charge-neutralization time [1], $\tau_n = 1/n_g\sigma_i v_b$. The number density of the oppositely charged particles n_p (electrons for positive ion beams; positive ions for negative ion beams) grows linearly with time, and we have $n_p \approx n_b$ or $f_n \approx 1$ after the time duration of τ_n. Here, $f_n = n_p/n_b$ is the fractional charge neutralization. Note that the background gas density $n_g[\mathrm{m}^{-3}] = 3.54 \times 10^{22} \times p[\mathrm{Torr}] \gg n_b$ for nominal pressure range $p = 10^{-7} - 10^{-5}$ Torr. For the 30 keV H^- beam for the PXIE LEBT, $\sigma_i = 5 \times 10^{-20}\mathrm{m}^2$ and $\tau_n \approx 236$ μs for $p = 10^{-6}$ Torr. For a 2.5 MeV proton beam for the IOTA electron column, $\sigma_i = 1.5 \times 10^{-21}\mathrm{m}^2$ and $\tau_n \approx 862$ μs for $p = 10^{-6}$ Torr.

The electrostatic potential created by the uniform beam is $\phi(r=0) = V_s\left[1 + 2\ln\left(r_w/r_b\right)\right]$, where, $V_s = I_b(1 - f_n)/(4\pi\epsilon_0 v_b) > 0$ (< 0) for positive (negative) ion beams. Note that $\phi(r = r_b) = 2V_s \ln(r_w/r_b)$ and $\phi(r = r_w) = 0$. Here, r_b is the radius of the beam with constant density n_b and velocity v_b, and r_w is the radius of a perfectly conducting cylindrical wall.

PLASMA PROCESSES

We consider two cases: an H^- beam and a proton beam. Here, we listed only the dominant plasma processes for the space-charge compensation.

- H^- **beam:**

$$H^- + H_2 \rightarrow H(\mathrm{fast}) + H_2 + e \quad (1)$$

$$H^- + H_2 \rightarrow H^- + H_2^+(\mathrm{slow}) + e \quad (2)$$

$$e + H_2 \rightarrow H_2^+(\mathrm{slow}) + 2e \quad (3)$$

For the case with no solenoidal fields, ionization electrons are expelled by the beam space-charge immediately and the slow ions are oscillating inside the potential well of the beam. Initially, the ion density profile becomes highly peaked around beam center [3]. After a time duration of τ_n, a steady state is obtained. There is a critical value for the gas density, $n_{g,cr}$, in which $\tau_{i,exit} = \tau_n$, i.e., $n_{g,cr} \approx (1/\tau_{i,exit})/v_b\sigma_i$ [1]. Here, $\tau_{i,exit} = r_b/2v_i$ is the average time for an ion to exit the beam, and $v_i = \sqrt{T_i/m_i}$ is the ion thermal velocity. It is often assumed that T_i is on the order of 0.1 eV [1]. When $n_g = n_{g,cr}$, the potential difference between the beam center and edge, $V_s = 0$ and $f_n = 1$ at the steady state. For $n_g < n_{g,cr}$, $V_s < 0$ and $f_n < 1$. In this case, the beam is not fully neutralized and the system is essentially composed of two species ($n_e \ll n_i \sim n_b$). For $n_g > n_{g,cr}$, the beam becomes overcompensated, i.e., $V_s > 0$ and $f_n > 1$. In this case, $eV_s \sim T_e$ and $v_i \approx \sqrt{T_e/m_i}$.

For the nominal pressure range of PXIE, we always have $n_g < n_{g,cr}$, which is good for minimizing stripping loss, but not favorable for achieving full compensation. To achieve full compensation, use of Xe as a background gas is often considered, which decreases the critical density by a factor $\sim$ 45. Also, to reduce the loss of the H_2^+ ions through the longitudinal drift, positively biased electrodes may be used.

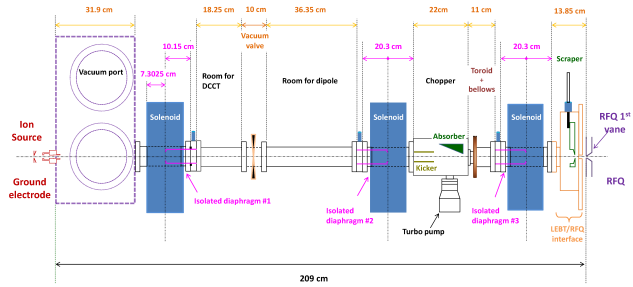

Figure 1: PXIE LEBT layout schematic.

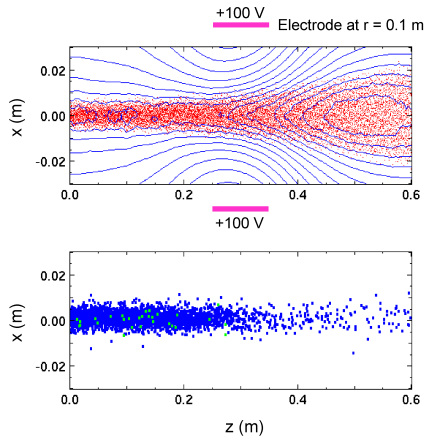

Figure 2: WARP 3D simulation of the transition from neutralized to un-neutralized transports in the PXIE LEBT. Electrode keeps positive ions (blue dots) from drifting into the un-neutralized region. For the un-neutralized region, we assume the vacuum is so good that there is little ionization processes. Note that most electrons (green dots) are expelled.

- **Proton beam:**

$$p + \mathrm{H_2} \rightarrow \mathrm{H(fast)} + \mathrm{H_2^+(slow)} \quad (4)$$

$$p + \mathrm{H_2} \rightarrow p + \mathrm{H_2^+(slow)} + e \quad (5)$$

$$e + \mathrm{H_2} \rightarrow \mathrm{H_2^+(slow)} + 2e \quad (6)$$

Positive ions are expelled by the beam space-charge, but at a much slower rate than the electrons. Therefore, space-charge compensation could exhibit a nonlinear phase in the beginning, particulary at high gas pressure. The ionization electrons have considerably higher thermal velocity than the ions, thus as V_s approaches to zero after a time duration τ_n, the electron loss increases and the space-charge compensation process slows down [3].

On the other hand, when we apply a uniform solenoidal field, the ionization electrons are confined close to the transverse position they are born from, and their density profile is similar to that of the proton beam. For non-relativistic electrons, the Larmor radius is $r_L = (3.37[\mu\mathrm{m}])\sqrt{T_\perp[\mathrm{eV}]}/(B_0[\mathrm{T}])$. In the 0.5 T normal-conducting solenoid considered in IOTA, we have $r_L < 0.1$ mm for perpendicular kinetic energy $T_\perp < 200$ eV.

PXIE LEBT: H$^-$ BEAM

PXIE will have a DC H$^-$ source (30 keV, up to 10 mA), a low energy beam transport (LEBT) system with three solenoid magnets (see Fig. 1), a CW RFQ, a medium energy beam transport (MEBT) system with wideband chopper, and two superconducting cryomoules (HWR and SSR1). The functions of the PXIE LEBT are 1) to transport and match the beam to the RFQ optical inputs; 2) to act as the first layer of the machine protection system; and 3) to provide pulsed (chopped) beam for commissioning of the beam line downstream [4].

Neutralization greatly reduces the beam space charge effects, most importantly, the emittance growth. As mentioned above, the PXIE LEBT should be operating in both pulsed and DC modes. In the pulsed mode, a chopper removes the neutralizing particles, and the beam becomes uncompensated and may behave quite differently than in the completely compensated case. For PXIE, the 5-mA beam space charge is relatively low, for instance, compared to the beam at SNS ($\sim$ 50 mA). Simulations showed that a scheme where the beam would be uncompensated in a part of the LEBT is possible, and such scheme was devised [4]. This scheme will minimize differences of the beam transport characteristics between the pulsed and DC operations, and allows for more space after the chopper for the absorber and diagnostics. Un-neutralized transport can be realized by properly biasing the electrodes and ensuring a good vacuum. However, the beam emittance will increase during the transition from neutralized to un-neutralized transports. In this regard, it is important to investigate whether the emittance growth is acceptable or not (e.g., by measuring the emittance using an Allison emittance scanner).

Up to the second solenoid, on the other hand, neutralization of the beam is maintained in a steady-state manner. Stability of this beam-plasma system can be affected by collective processes, such as dynamic decompensation, and electron and/or ion oscillations [5]. While beam neutralization experiments have been carried out elsewhere (see, for example, Refs. [1, 3, 5] and references therein) space-charge compensation in CW negative hydrogen beams is relatively less well understood. The PXIE LEBT configuration is quite unique as it allows to investigate both the transient and steady-state nature of the space-charge compensation of a negative hydrogen beam. Simulations using WARP 3D PIC code are in progress to address the unique characteristics of the PXIE LEBT (see Fig. 2) [6].

IOTA E-COLUMN: PROTON BEAM

A new storage ring (IOTA) is under construction at Fermilab to demonstrate the concept of nonlinear integrable lattices [7]. After initial experiments on the single-particle characteristics in the IOTA using electron beams, performance demonstrations in the space-charge dominated regime using proton beams will be followed [8]. One of

Copyright © 2013 CC-BY-3.0 and by the respective authors

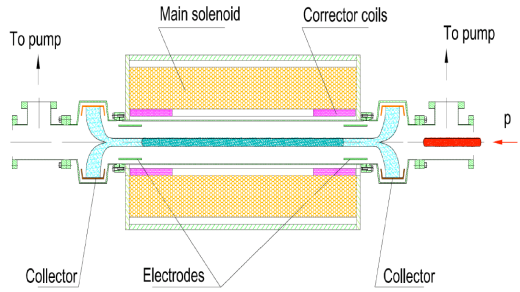

Figure 3: A conceptual layout of the electron-column apparatus for space-charge compensation in the IOTA ring.

the key R&D items is to investigate if space-charge compensation can be realized in the ring. The necessary conditions for effective space-charge compensation in the ring will be 1) the total defocusing effect by beam space charge over the ring is cancelled out by the focusing effect in the electron column; 2) the transverse profile of the electron density is the same as that of the proton beam; 3) the system of electrons and protons is dynamically stable [9, 10]. For the electron column concept considered here, electrons are generated internally through beam-induced residual gas ionization without special electron sources and optics. In the electron column concept, conditions 2 and 3 can be achieved if protons and electrons are immersed in a longitudinal magnetic field which is a) strong enough to freeze the electron density distribution; b) strong enough to suppress the e-p instability; c) weak enough to allow positive ions to escape transversely, in addition to longitudinal draining; and d) well matched to the ring optics to avoid beta-beat excitations.

The interaction between trapped electrons and circulating proton beams is subject to two-stream instability. It will degrade the quality of both the electron column and the main beam. It is well-known that the increase of the confining solenoidal field and Landau damping through momentum spread can suppress the instability. In addition, there are two unique instability suppression possibilities in the proposed experimental setup. One is self-stabilization of the e-p instability by the accumulation of secondary ions. It is observed [2] and also theoretically confirmed [11] that if there are not only electrons but also some residual ions in the cloud, the ions tend to short-out the electrostatic perturbations whose wavelengths are less than the transverse beam size r_b. The residual ion formation could be controlled by the proper choice of working pressure, solenoidal field, and electrode voltage (e.g., see a conceptual apparatus in Fig. 3). The other possibility is to increase Landau damping by a broad tune spread enabled by a special nonlinear lattice in the IOTA ring. This nonlinear lattice is designed to be integrable, and thus can create a large tune spread and zero resonance strength.

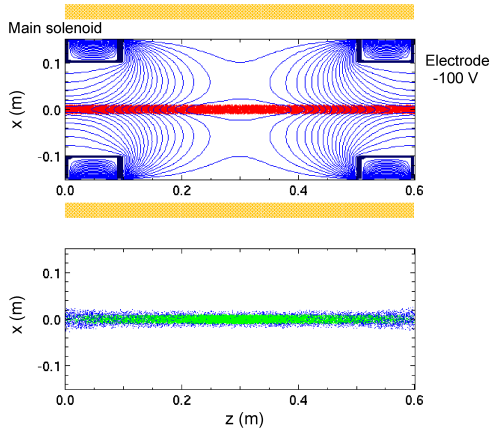

Figure 4: WARP 3D simulation of the plasma formation and trapping in the e-column. A uniform solenoid keeps both electrons (green dots) and ions (blue dots) in the beam path. Ions are slowly escaping longitudinally. To resolve cyclotron motion of the electron, the time step has been set to $\Delta t \leq 0.25 \times 2\pi/\omega_{ce}$.

Simulation of the plasma formation and trapping in the e-column is in progress using WARP 3D code (see Fig. 4). The simulation will eventually be coupled to a tracking code for the ring, to understand the effects of the nonlinear lattice and e-p instability.

CONCLUSION

Two experiments on space-charge compensation (one in a linac, and the other in a ring) are planned at Fermilab. Advanced simulation tools (e.g., WARP 3D PIC code [6]), and dedicated beam/plasma/gas diagnostics and controls could enable detailed understanding of the space-charge compensation processes, and eventually allow to achieve intense beams with improved stability and quality.

EXPERIMENTAL VERIFICATION OF SINGLE-BUNCH ACCUMULATION LIMIT DEPENDENCE ON IMPEDANCE AT THE APS *

V. Sajaev†, B. Borland, Y.-C. Chae, L. Emery, ANL, Argonne, IL 60439, USA

Abstract

One of the unique features of the Advanced Photon Source is operation with a small number of intense bunches — the standard operating mode has 24 16-nC bunches, while in a special operating mode one of the bunches has a charge of 60 nC. Such high single-bunch currents are achieved by a combination of high operational chromaticity and transverse bunch-by-bunch feedback. In the near future, more narrow-gap insertion device vacuum chambers will be installed, which will increase the impedance of the storage ring and make operation with high single-bunch current more problematic. Simulations exist that quantify the effects of increased impedance on the APS single-bunch accumulation limit; however, no direct experimental verification has yet been performed. In this paper, we will present a measurement of the single-bunch accumulation limit as a function of impedance. Different impedance values were achieved by changing the storage ring beta functions.

INTRODUCTION

The Advanced Photon Source (APS) is a 7-GeV third-generation synchrotron light source that has been in operation for almost 20 years. Presently, APS operates in three fill patterns: 24 equally spaced bunches — a pattern that is used for 60% of the time; 324 equally spaced bunches; and a special "hybrid" mode where one 60-nC bunch is separated from a train of weaker bunches by 1.5 μs. Total operating beam current is always 102 mA.

To achieve stable high-current single bunches, we operate at high chromaticities. Before introducing transverse bunch-by-bunch feedback, the operating chromaticity was +7 in both planes for the 24-bunch fill pattern and +11 for the "hybrid" pattern. The biggest downside of operating with high chromaticity is low lifetime. Even though APS operates in top-up mode, there is still a limit on how low the lifetime can be. The introduction of the feedback allowed us to lower chromaticity to +4 for the 24-bunches fill pattern and to +9 for the "hybrid" pattern.

The APS transverse impedance consists of three approximately equal parts [1]: the resistive-wall impedance of small-gap insertion device (ID) vacuum chambers, the geometrical impedance of the transitions from large- to small-gap chambers, and the geometrical impedance of the rest of the ring. Presently, there are 32 small-gap ID chambers installed. Of them, one has a 5-mm full gap, eight chambers have a 7.5-mm full gap, and the rest have an 8-mm gap. All ID chambers are 5 m long and are made of aluminum. At the time this work started, three ID locations were still unoccupied, meaning that three more small-gap vacuum chambers still needed to be installed. This would increase transverse impedance by about 6% and could affect our ability to provide users with 60 nC in a single bunch.

As we work on the APS Upgrade [2], a few things are clear: the lattice will be as strongly focusing as possible resulting in small dynamic aperture and short lifetime, the ID vacuum chambers will have as small gaps as possible resulting in higher impedance, and we still would need to provide high-charge bunches to the users performing timing experiments. In this situation, we need a good understanding of impedance effects in the APS and confidence in our simulation tools. We have developed an experimental program that would allow us to verify our simulation and predictive abilities.

SIMULATIONS

Simulation of the single-bunch accumulation limit is done by multi-particle tracking using `elegant` [3]. The impedance of the whole ring is represented as a single lumped element for each plane using the ZTRANSVERSE and ZLONGITUDINAL elements in `elegant`, which take calculated impedance as input. The ring itself is represented as a linear map of one sector (element ILMATRIX) with chromaticity. Special elements like cavities, radiation effects, etc. can be inserted between sectors. The simulated bunch consists of 200k particles, which is required for correct simulation of longitudinal effects. Wake potentials of all elements are computed using GdFidl [4] and a 1-mm-long bunch, in order to extend the resulting impedance bandwidth. Wake potentials are separated into dipole and quadrupolar components.

The simulated accumulation limit is strongly affected by the injection conditions, namely by the residual oscillations of the stored bunch. First, we used the most realistic approach and simulated both stored and injected bunches. But later we noticed that the losses that occur at the accumulation limit all come from the stored beam and are not affected by the injected bunch. After that, we simplified the simulation to a simple kick of the stored bunch. Ideally, there should be no vertical oscillations occurring after the injection, but due to small coupling inside the injection bump there is always some vertical motion of the

stored beam. This vertical motion is what affects the accumulation limit the most. The amplitude of the vertical motion is a free parameter that we used to reach an agreement with measurement. It was achieved at the amplitude of 0.3 mm. This amplitude of the vertical kick was then used for simulations that were intended to predict changes in the accumulation limit due to impedance variations. Figure 1 shows the result of the accumulation limit simulation as a function of vertical impedance, where the impedance is normalized to the present value. We can see that the accumulation limit changes very quickly in the vicinity of the present impedance value. Therefore, it is important to verify these results before any design decisions are made based on this plot.

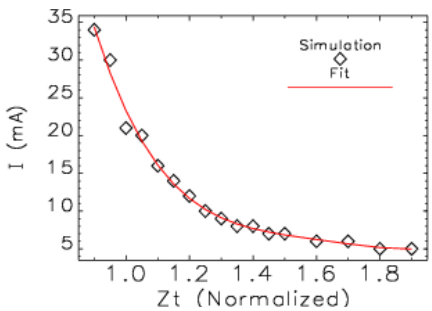

Figure 1: Single-bunch current limit as a function of vertical impedance. The impedance axis is normalized to the value for the current APS storage ring impedance.

To estimate the effect of different small-gap vacuum chambers on the accumulation limit, we have developed a simple spreadsheet that uses scaling laws taken from theory and simulations [5]: the effect of transitions is scaled as gap in the power of 2.4, and the resistive wall effect is scaled as gap in the third power, while the impedance effect is taken from a fit to the data in Figure 1. The spreadsheet was also used to calculate the expected results for the experiments described below.

EXPERIMENTAL RESULTS

The simplest way to vary the effective impedance in the storage ring is to change beta functions at impedance locations. Since about two-thirds of the vertical wake comes from the small-gap ID vacuum chambers, we need to change beta functions at ID locations. For operational convenience, we need to maintain the betatron tune close to its original value of 19.24; therefore, if beta function is increased at an ID location, it has to be decreased inside the sector. About one-third of the vertical wake is generated outside of the ID chambers; therefore, the reduction of vertical beta function outside of the ID chambers decreases the overall effect of beta function change on the effective impedance. Luckily, the simulations showed that the effect on the accumulation limit is still sufficiently large and should be visible in the experiment [6].

Lattice Development

We developed five lattices with vertical beta function in the ID ranging from 3.0 m to 5.0 m with 0.5-m steps. Figure 2 shows a set of five vertical beta functions for one sector (APS consists of 40 nearly identical sectors). The changes to the horizontal beta function were kept to a minimum. Also, when adjusting chromaticity, we excluded the sextupoles located inside the injection bump to keep injection conditions as close to the original as possible. All five lattices were implemented during machine studies. As always, the beta functions were measured and corrected to a high accuracy using the response matrix fit [7].

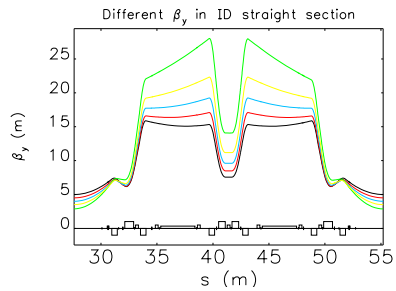

Figure 2: Vertical beta functions of one sector with ID value changing from 3 m to 5 m.

Accumulation Limit Measurement

The measurement of the accumulation limit is simple in essence: the injection is performed into a single bunch until no more charge can be injected or there is a drop-out of the stored bunch. In reality, however, it is hard to achieve a good reproducibility of this measurement because the accumulation limit is a complicated parameter depending on many variables. To ensure that all possible conditions are reproduced as closely as possible, for every lattice we followed the identical procedure:

- the lattice is corrected and coupling is minimized using the response matrix fit;
- the chromaticity is set to +11 in both planes, bunch-by-bunch feedback is tuned off;
- the orbit is well corrected;
- the injection conditions are reproduced — the injected beam trajectory is recovered, the stored beam closed bump in the horizontal plane is matched and spurious vertical oscillations of the stored beam after the kick are minimized;
- rf voltage is always maintained at 9 MV.

Figure 3 shows the results of the accumulation limit measurement for all five lattices as a function of the normalized effective vertical impedance. The accumulation limit is also normalized to the limit of the initial lattice. The vertical error bars show the accuracy of the accumulation limit

Copyright © 2013 CC-BY-3.0 and by the respective authors

measurement. The impedance error bars are calculated assuming 3% errors in the lattice beta functions. We can see a reasonable agreement between measurements and simulations.

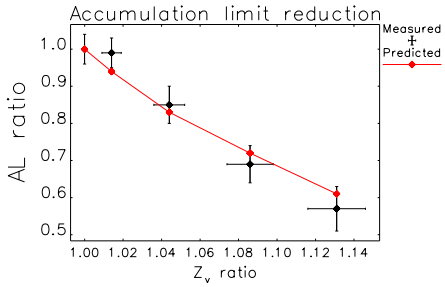

Figure 3: Comparison of measured and simulated accumulation limits as a function of vertical effective impedance.

To further validate our impedance model, two spare small-gap vacuum chambers were installed in two free sectors in May 2013. The expected increase of the vertical impedance due to this installation was 4% and the expected reduction of the accumulation limit was about 3 mA. The accumulation limit measurement procedure as described above was followed to measure the limit before and after the installation. A reduction by 2 mA was measured as shown in Figure 4, where the dependence of the accumulation limit on chromaticity is presented before and after the installation.

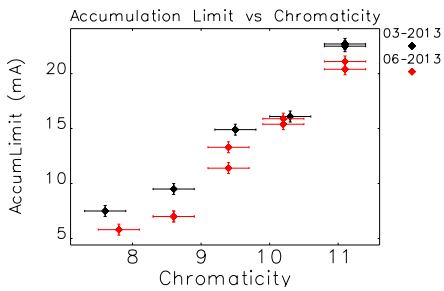

Figure 4: Accumulation limit as a function of chromaticity before and after the installation of two small-gap vacuum chambers.

Local Impedance Measurement

We also have measured the local impedance before and after installation of the two new chambers. The local impedance is obtained by analyzing response matrices measured at different values of the single-bunch current [8]. It is known that impedance acts on the beam as a defocusing element, so a response matrix fit can be used to measure this defocusing effect locally. In detail, the measurement and impedance determination is as follows: With a single bunch in the storage ring, the response matrix measurement is done for several beam currents. Then, the response matrix fit is performed for every measurement. The results of these fits is the set of beta function files — one for each beam current. The beta functions vary slightly from one file to another due to the defocusing effect of the impedance. The betatron phases from these files are combined for every location in the storage ring (for example, for all BPMs) to calculate the local betatron phase slope with current. The result of this processing is the betatron phase slope with current as a function of s along the storage ring. Then, a small number of artificial quadrupoles are used to reproduce the betatron phase slope dependence on s. The strengths of these quadrupoles will be proportional to the local impedance values. Here we need to emphasize that this approach works only for the vertical plane. In the horizontal plane at the APS the tune shift with current is very small due to smaller impedance and due to contributions from quadrupolar wakes that counteract the dipole wakes and make tune shift with current very small. Figure 5 shows the results of local impedance measurements before and after installation of new ID chambers. We can see a clear difference at the locations of the new chambers.

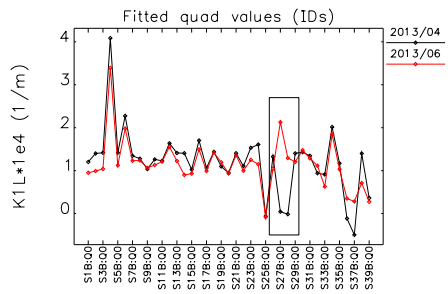

Figure 5: Local impedance distribution before and after installation of new vacuum chambers. A rectange shows where the chambers were installed.

CONCLUSIONS

We have developed a model that predicts how the single-bunch accumulation limit changes with storage ring impedance. We have varied the effective vertical impedance of the storage ring by changing beta functions at the small-gap vacuum chamber locations and measured the accumulation limit as a function of effective impedance. The measurements agreed reasonably well with the predictions. We have also verified the model by installing two new small-gap vacuum chambers and comparing the resulting accumulation limit reduction with predictions.

BEAM PHYSICS IN FUTURE ELECTRON HADRON COLLIDERS

A. Valloni*, O. Bruning, M. Klein, D. Schulte, F. Zimmermann, CERN, Geneva, Switzerland

Abstract

High-energy electron-hadron collisions could support a rich research programme in particle and nuclear physics. Several future projects are being proposed around the world, in particular eRHIC at BNL, MEIC at TJNAF in the US, and LHeC at CERN in Europe. This paper will highlight some of the accelerator physics issues, and describe related technical developments and challenges for these machines. In particular, optics design and beam dynamics studies are discussed, including longitudinal phase space manipulation, coherent synchrotron radiation, beam-beam kink instability, ion effects, as well as mitigation measures for beam break up and for space-charge induced emittance growth, all of which could limit the machine performance. Finally, first steps are presented towards an LHeC R&D facility, which should investigate relevant beam-physics processes.

INTRODUCTION

Particle colliders for high energy physics have been at the forefront of scientific discoveries for more than half a century. Leptons have been used to probe the partonic structure of the proton from the late 1960s, starting in fixed target deep inelastic scattering experiments, and continuing to the *e-p* collider HERA. With the first *e-p* collider HERA, remarkable results have been obtained on the parton structure of the proton, which are now crucial for the interpretation of the LHC data and include the discovery of a high density gluon and sea quark component in the proton. One can thus reflect on the valuable insight gained in revealing the structure of matter and evaluate priorities for future *e-p* or electron-ion (*e-A*) colliders [1]. Despite previous successes, many fundamental physics aspects have not yet been verified experimentally, and several future projects are under consideration in the USA and Europe and have good prospects of becoming operational and deliver results in the next 20 years. These projects intend to extend the knowledge achieved at HERA, and to provide new exploration tools by involving lepton collisions with heavy ions as well as with polarized protons and polarized light ions. These proposed colliders come in two varieties. One is an electron linear accelerator colliding with a proton or ion ring accelerator, the other, an *e*-ring accelerator colliding with a hadron ring. All of the future *e-A* colliders are based on the extension of already existing machines: LHeC at CERN [2], ENC at GSI [3], eRHIC at BNL [4] and MEIC at TJNAF [5]. Two colliders, ENC and MEIC are based on the ring-ring (RR) scenario, while the BNL and CERN teams selected the linac-ring (LR) option with energy recovery. The physics programs to a large degree are complimentary to each other and to the LHC physics [6]. In particular, with highest energies, the LHeC can be made a next Higgs factory. New ideas and technologies are applied in the accelerator designs and the intent of this paper is to present the key accelerator physics issues, referring to 3 possible future machines which are quite different in approach: eRHIC, MEIC and LHeC. This paper is organized as follows. The first part contains a brief overview on the parameter choices of the main future colliders worldwide. The focus here is on an understanding of the central characteristics of each machine and of the various common challenges. In the second part, among all the possible issues that these accelerators present, some selected subjects are described with related studies to analyze and compare the merits of different approaches. Special emphasis will be placed on the clear identification of the beam physics limits and accelerator technology limits highlighting aspects that need to be addressed by further research. The final section contains a summary of the future plans at CERN with special regard to the scientific and technical R&D activity for the development of an LHeC ERL test facility which will allow addressing relevant physics issues.

FUTURE ELECTRON-ION COLLIDERS

Since the very beginning, the focus of the *e-p* and *e-A* colliders studies has centered on achieving ultra-high luminosity and higher center-of-mass energy (CME). The eRHIC and ELIC machines consider their operation at the CME area of 20÷100 GeV, with luminosities ranging in 10^{32}÷10^{34} cm^{-2}s^{-1} values. Compared to the other machines, the LHeC provides the unique possibility of exploring *e-p* collisions in the TeV center of mass regime. The LHeC will collide the 7 TeV protons circulating in the LHC, therefore representing an interesting possibility for a further exploitation of the existing LHC infrastructure investment, with a high energy *e*-beam at a single collision point. As a result of the combination of SC accelerating structures and the energy recovery technique, a luminosity at least 2 orders of magnitude greater than the one achieved by HERA can be reached. The proposed machine layout consists of a 500 MeV polarized injector, two CW 10 GeV SC linacs and a recirculator system. Each beam recirculates up to 3 times through both linacs to boost the energy to 60 GeV. As the beam is focused and collided, it is bent by 180°, and then it is sent back through the first linac, at a decelerating phase. During deceleration the energy stored in the beam is converted to RF energy and the final beam, at its original injection energy, is directed to a beam dump. The baseline 60 GeV ERL option proposed can give an *e-p* luminosity of 10^{33} cm^{-2}s^{-1} (extensions to 10^{34} cm^{-2}s^{-1} and beyond are being considered), a beam current of 6.4 mA, with less than 100 MW total electrical power required.

A similar approach of exploiting an existing beam facility and adding an accelerator for another species is taken in the collider projects eRHIC at BNL. The eRHIC design is based on one of the RHIC hadron rings which can accelerate polarized light ion beams to 100÷130 GeV/nucleon and polarized protons up to 325 GeV, and a new 5÷30 GeV multi-pass ERL to accelerate polarized electrons. It means that eRHIC will cover the CME range from 44.7 GeV to 197.5 GeV for polarized *e-p*, and from 31.6 GeV to 125 GeV for electron heavy-ion collisions. The machine will rely on SRF technology for production and acceleration of electrons, cooling of hadron beams and realizing crab crossing collision scheme. The injection system consists of a 10 MeV linac and 600 MeV single-pass ERL. Two 2.45 GeV SRF linacs in combination with six passes form the main ERL to generate 50 mA of polarized *e*-current. Multiple collision points are possible.

In the present baseline the central part of the proposed MEIC is a pair of figure-8 shaped storage rings, which accommodate the colliding electron and ion beams, respectively. The electron ring is made of normal conducting magnets and will store an *e*-beam of 3 to 11 GeV. The CEBAF SRF linac serves as a full-energy injector into the electron collider ring, requiring no further upgrade for energy, beam current, or polarization beyond the 12 GeV upgrade. The ion collider ring is made of high-field SC magnets and will store a beam with energy of 20 to 100 GeV for protons or up to 40 GeV per nucleon for light to heavy ions. The ion beams are generated and accelerated in a new ion injector complex. In addition, two large figure-8 high-energy collider rings will be added for a future energy upgrade for reaching up to 20 GeV electrons, 250 GeV protons or 100 GeV/u ions. The upgraded high-energy collider can use the same experimental halls and, possibly, the same detectors as MEIC, and the medium-energy ion collider ring would then serve as the final booster in the staged acceleration of ion beams.

CHALLENGES

Each of the future *e-A* colliders faces significant challenges and an intense accelerator R&D program is needed. A list of primary beam dynamics concerns is the following:

- *e*-beam energy losses and energy spread caused by the interaction with the beam environment (cavities, resistive walls, pipe roughness);
- incoherent and coherent synchrotron radiation (SR) related effects: energy losses, transverse and longitudinal emittance increase of the e-beam;
- effective energy loss and energy spread compensation schemes;
- *e*-beam filling patterns; ion accumulation;
- *e*-beam break-up (BBU), single beam and multi-pass;
- *e*-beam-ion and intra-beam scattering effects;
- *e*-beam polarization: depolarization effects;
- possible effects due to crab cavities;
- detailed beam dynamics with coherent electron cooling (CeC);
- beam-beam effects, including the *e*-beam disruption and the hadron beam kink instability.

Some of these topics will be discussed in the following sections.

Electron Beam Polarization

A key feature of *e-A* colliders is high polarization (over 80%) of the *e*-beam at all collision points. Many issues have to be carefully considered, such as a polarized source, self-polarization and depolarization, polarization time, and spin rotator. The MEIC electron ring is designed to store, manipulate and preserve a highly polarized *e*-beam. The MEIC polarized beam is provided by the CEBAF accelerator. Currently, the electron polarization from CEBAF at 6 GeV is above 85%. It is expected that a similarly high polarization will be achieved after completion of the 12 GeV upgrade. The equilibrium electron polarization is arranged to be vertical in the arcs of the figure-8 collider ring and anti-parallel to the arc dipole magnetic fields (see Fig. 1), in order to take advantage of the preservation of polarization by the Sokolov-Ternov (S-T) effect. Longitudinal

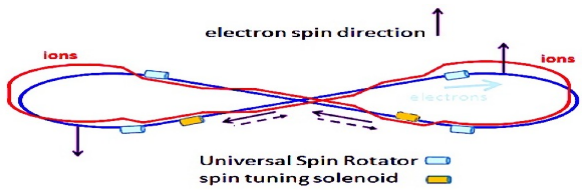

Figure 1: Diagram of polarization orientation at MEIC [5].

polarization is achieved at the collision points by utilizing 90° universal spin rotators (USR) each of which consists of a set of solenoids and dipoles placed at the end of an arc. To eliminate the transverse coupling introduced by the solenoids, each solenoid is split into two equal halves and 5 quadrupoles (in 3 families) are inserted between the halves. One or more spin tuning solenoids are needed to control the closed orbit spin tune and keep it away from resonances. Figure 2 illustrates how the USR works by showing a step-by-step rotation of an electron spin. The equilibrium

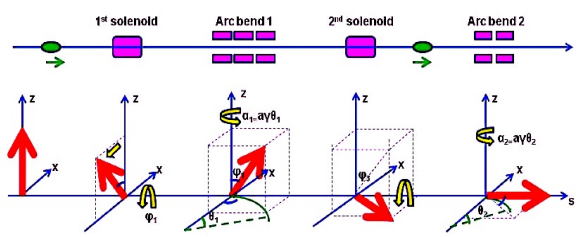

Figure 2: Schematic drawing of the USR at MEIC [5].

beam polarization and its lifetime depend on competition between the S-T effect and radiative depolarization. The calculated equilibrium polarization and lifetime show significant depolarization even with perfect alignment. First calculations confirmed that the spin rotators and the sections between them are the main source of depolarization. The latter must be suppressed by spin matching which can be performed by manipulating the optics and layout of the lattice to achieve spin transparency between the two spin rotators. Regarding LHeC, Fig. 3 depicts the calculated spin vector spread, without any spin rotators, as a function of momentum spread for particles at 20, 40 and 60 GeV. While at eRHIC the loss of polarization is acceptable, for the high energy of LHeC the effective polarization can be reduced by 10% due to the spread of the spin vectors. For this reason to produce longitudinally oriented polarization at the LHeC collision point, a design with two spin rotators has been adopted. A low energy spin rotator first brings the polarization into the vertical direction and later a high energy spin rotator close to the IP realigns the spin vector in the longitudinal direction. The LHeC high energy spin

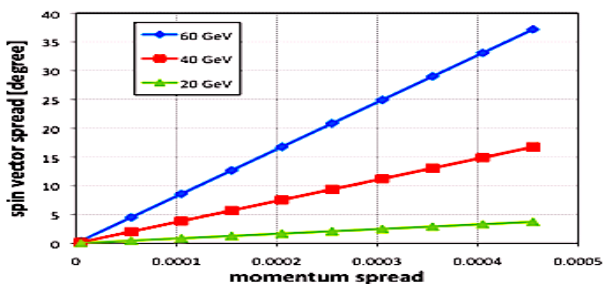

Figure 3: Angular spread of the spin vectors for off-momentum particles at 20, 40 and 60 GeV in the LHeC complex [7].

rotator consists of 4 helical dipoles with alternating helicity, similar to the RHIC proton spin rotator, placed in the straight section between the end of the second linac and the final focusing system. Besides saving space by being short, this approach also has the advantage of providing an independent full control of the direction of the polarization, as well as a nearly energy-independent spin rotation for the same magnetic field. The ∼MW SR power emitted by the 60 GeV *e*-beam passing through the spin rotator determines the minimum length of the system. In the present design, for a 60 GeV *e*-beam, the magnetic fields of the inner and outer pairs are 0.46 T and 0.37 T, respectively [2].

Optics Design and SR in Return Arcs

Control of SR effects on beam phase-space such as cumulative emittance and momentum growth due to quantum excitations is important for a high luminosity collider. In this section we briefly revisit the impact of SR from bending magnets for the intense beam at eRHIC and LHeC. The lattice design for both ERL based machines includes arcs placed above each other connected to the linacs by splitters and combiners. For LHeC a quasi isochronous arc optics design has been adopted, which simultaneously ensures a small value of emittance dilution and low momentum compaction, and therefore mitigates both transverse emittance growth and bunch length increase. The choice of large arc radius (1 km) is dictated by limiting energy loss due to SR at top energy (60 GeV) to less than 1%. Energy losses from resistive wall and coherent SR have both been shown to be negligible compared with the energy loss due to incoherent SR. The standard arc building block is 52 m long, and contains 4 quadrupoles and 2 (split into 10) dipoles. The values of the curly-H function and M_{56} are taylored as required by emittance dilution and isochronicity or beam size conditions, respectively, for arcs of different energies, transiting from a quasi-isochronous optics yielding a small beam size for the 2 lowest energy arcs, to a TME-optics for the 2 arcs at highest energy. The LHeC arc dipoles have a 25 mm gap and a maximum field of 0.264 T, at 60 GeV. The highest energy arc (before the final collision), gives a net normalized emittance increase of 4.5 μm. All the lower arcs together, with less emittance preserving optics, contribute a total of about 25% of the last arc, so that the total emittance dilution is 5.6 μm. At the interaction point, the SR induced RMS energy spread is only $2{\cdot}10^{-4}$, at the final arc, after deceleration, the energy spread reaches about 0.22%, while at the beam dump it grows to a full 4.5%. The *e*-beam looses about 2 GeV over all arc passes and the highest compensating RF voltage required is 750 MV for the energy loss at 60 GeV.

The lattice of the 6-passes for the eRHIC ERL arcs is based on low-emittance near-isochronous arc modules, supporting perfect isochronicity of complete paths. The standard building block is 35 m long, and contains 7 dipoles and 9 quadrupoles. The eRHIC arc dipoles have a gap of 5 mm and, at 30 GeV, a maximum field of 0.43 T. In view of the small gap and high beam current, resistive-wall wake fields and surface-roughness effects are under careful investigation. At 30 GeV peak lepton energy, with a dipole bending radius of 234 m, the total energy loss per electron due to SR is about 770 MeV over all arc passes; at 20 GeV it is only 150 MeV. A single double harmonic compensator at (almost) the highest energy delivering 389 MeV per passage compensates for the energy loss from SR and other, smaller effects like resistive wall and linac-cavity HOMs.

Multipass BBU and Beam-beam

In ERLs, the excitation of HOMs induced by the recirculating *e*-bunches can add up constructively and cause instabilities. Depending on the details of the machine optics, the deflection produced by a mode can translate into a transverse displacement at the cavity after recirculation. The recirculated beam induces, in turn, an HOM voltage which depends on the magnitude and direction of the beam displacement. Thus, the recirculated beam completes a feedback loop which can become unstable if the average beam current exceeds the threshold for stability. BBU is of particular concern in the design of high average current ERLs

Copyright © 2013 CC-BY-3.0 and by the respective authors

utilizing SRF technology. If not sufficiently damped by the HOM couplers, dipole modes with quality factors several orders of magnitude higher than in normal conducting cavities can exist, providing a threat for BBU to develop. The BBU threshold is increased by the natural chromaticity of the arcs if the latter is uncorrected [9]. A thorough suite of simulations to characterize the BBU instability have been conducted for the two ERL based machines LHeC and eRHIC. The LHeC BBU study is based on a new code that assumes point-like bunches and takes a number of dipole wakefield modes into account. A cavity-to-cavity frequency spread of the wakefield modes can also be modelled. In the simulation, one can offset a single bunch of a long train by one unit and determine the final position in phase space of all other bunches. Figure 4 shows the multi-bunch BBU adopting ILC-type (1.3 GHz) and SPL-type (720 MHz) cavities for a bunch with $3{\cdot}10^9$ electrons. The beam remains stable in both cases. Another key limit-

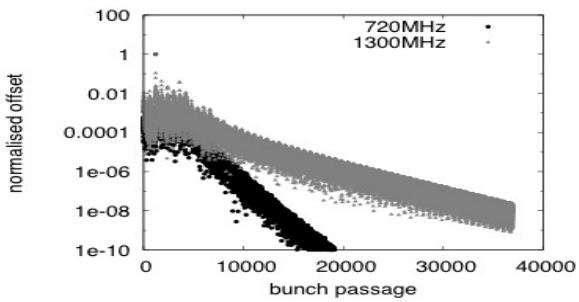

Figure 4: Multi-bunch BBU. Amplitudes along the full simulated train for the baseline lattice of LHeC [8].

ing factor to collider luminosity is beam-beam interactions. These can cause serious emittance growth of the colliding beams and fast reduction of luminosity. In particular the collision distorts the *e*-beam, which may be mitigated by proper matching of the exit beamline. The beam-beam effect can also amplify a perturbation and, thereby lower the BBU threshold. In Fig. 5 multi-bunch BBU including beam-beam effects is shown, again for two different cavity-types and for a bunch with 3×10^9 electrons. The beam remains stable in both cases but with a very small margin in the case of the ILC-type cavities.

Fast Beam-ion Instability

Collision of beam particles with the residual gas in the beam pipe leads to the production of positive ions that can be trapped in the beam. Their presence modifies the betatron function of the beam and can also lead to a BBU-like instability, since bunches with an offset will induce a coherent motion in the ions (and vice versa) [10]. This can in turn lead to a kick of the ions on the following bunches. The LHeC whole racetrack is ~9 km, 1/3 of the LHC circumference, so that ion clearing gaps can be incorporated in the bunch train whose arrival times for successive passes coincide in the linacs and which, in addition, always correspond to the same partner hadron bunches in the LHC (so

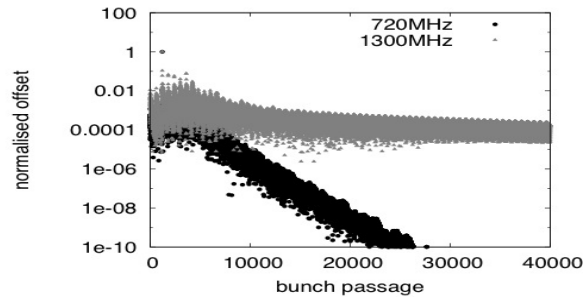

Figure 5: Multi-bunch BBU with beam-beam effect. Amplitudes along the full simulated train for the baseline lattice of LHeC [8].

that the LHC would comprise hadron bunches which collide on every turn and some others which never collide). In these clearing gaps the ions drift away from the beam orbit. A good vacuum quality is also needed to further slow down the build up of a significant ion density during the bunch train passages between successive clearing gaps. For the LHeC cold linacs, with a clearing gap of 10μs every 30μs, partial gas pressures of 10^{-11} hPa at 1.8 K are required at the position of the beam to render the residual fast beam-ion instability harmless, whereas a partial pressure below 10^{-9} hPa should be sufficient in the warm arcs. Similar tolerances apply to eRHIC.

Electron Cooling

Cooling of ion and hadron beams at collision energy is of critical importance for the performance of eRHIC and MEIC. An effective cooling process would allow to cool the beams beyond their natural emittances and also to either overcome or to significantly mitigate limitations caused by the hour-glass effect and intra-beam scattering. New concepts have been proposed recently to cool hadron beams. The most notable one among them is CeC. It is an *e*-beam based cooling system in which the accompanying *e*-beam provides feedback, similar to stochastic cooling, with an extremely high frequency bandwidth (THz range) by use of the FEL amplification mechanism in an undulator. This concept has been adopted for the eRHIC design. A sketch of the schematic layout is shown in Fig. 6. In the modula-

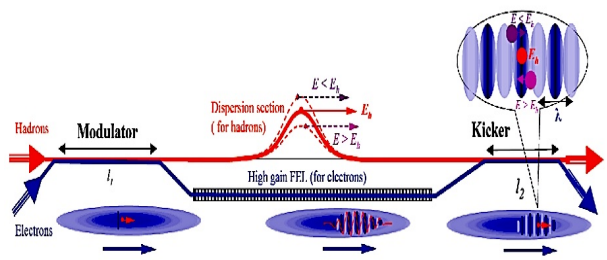

Figure 6: General schematic of CeC [11].

tor, each hadron induces density modulation in *e*-beam that is amplified in the high-gain FEL; in the kicker, the hadrons interact with the self-induced electric field of the *e*-beam

Copyright © 2013 CC-BY-3.0 and by the respective authors

and receive energy kicks toward their central energy. The process reduces the hadron energy spread, i.e. cools the hadron beam. A recent proposal is to use the microbunching instability instead of the FEL process as amplifier for the CeC scheme [12].

The MEIC baseline design does not invoke the CeC method, but it adopts a scheme of multi-stage cooling for supporting its high luminosities. Electron cooling is utilized not only for assisting ion beam formation but also during collisions. The latter is particularly important for preserving the collider luminosity and its lifetime by suppressing IBS induced heating. The scheme utilizes *e*-cooling at four different stages (at the pre-booster, injection and top energy, during collision) of the ion beam life cycle for achieving distinct goals in beam formation and maintenance. Figure 7 illustrates the *e*-cooler based on a magnetized photocathode gun, an ERL and a compact circulator ring. A high charge electron bunch from an injector is accelerated in an SRF linac up to 55 MeV and then sent to a circulator ring with an optically matched cooling channel for the ion bunch. The *e*-bunch circulates a large number of revolutions (up to 100) in the circulator cooler ring before its quality degrades significantly due to intra- and inter-beam scattering, and then returns to the same SRF linac for energy recovery. The *e*-cooling happens in both long straight sections as the circulator ring is placed in the vertex of the figure-8.

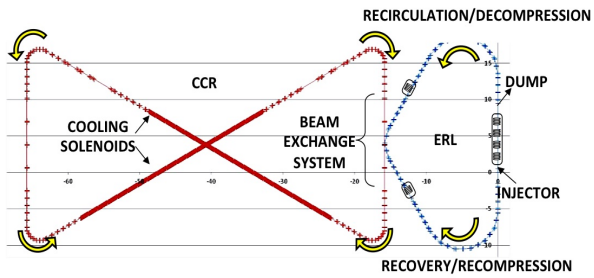

Figure 7: Schematic drawing of an ERL circulator cooling facility for MEIC [5].

FUTURE PLANS AT CERN

The development of a CW SC recirculating ERL for LHeC would prepare for many possible future projects. With some additional arcs, using 4 instead of 3 passes through the linacs, a machine like the LHeC ERL (without energy recovery) could also operate as Higgs factory $\gamma\gamma$ collider. The LHeC project will pursue the construction of a dedicated ERL test facility, the design of which will be prepared over the next two years. This test facilty could later be converted into the LHeC injector, including energy recovery. The purposes are first, confirming the feasibility of the LHeC ERL design by demonstrating stable intense *e*-beams with the intended parameters (current, bunch spacing, bunch length); secondly, testing novel components such as a (polarized) DC electron gun, SC RF cavities, cryomodule design and feedback diagnostics; finally, experimental studies of the lattice dependence of stability criteria. The realization of this facility will allow addressing several physics challenges such as maintaining high beam brightness through preservation of the 6D emittance, managing the phase space during acceleration and energy recovery, stable acceleration and deceleration of high current beams in CW mode operation. The design must also allow addressing other performance aspects such as longitudinal phase space manipulations, effects of coherent SR, longitudinal space charge and ions, halo and beam loss and microbunching instability.

SUMMARY

Electron-hadron colliders provide outstanding research potential. Several proposals aiming at very high luminosity, two-to-four orders of magnitude beyond the luminosity demonstrated by HERA, are under consideration in several laboratories all over the world. All these projects promote advanced research in accelerator physics and technologies. Additional R&D is needed. Further improvements to overcome the state-of-art include investigation of polarized electron guns, high-energy deuteron and proton polarization, integration of the detectors and colliders, high-energy *e*-cooling, high current and high brightness beam ERL operation, along with more detailed studies of multi-bunch BBU, beam-ion instability and beam-beam effects.

ACKNOWLEDGEMENTS

We wish to thank Vadim Ptitsyn and Yuhong Zhang for providing material for this paper. Helpful discussion and valuable input from all members of LHeC Study Group Collaboration are thankfully acknowledged. This work is supported by the European Commission within the oPAC project under Grant Agreement 289485.

COLLIMATION WITH HOLLOW ELECTRON BEAMS: A PROPOSED DESIGN FOR THE LHC UPGRADE*

G. Stancari†, V. Previtali, A. Valishev, Fermilab, Batavia, IL 60510, USA
R. Bruce, S. Redaelli, A. Rossi, B. Salvachua Ferrando, CERN, Geneva, Switzerland
V. Moens, EPFL, Lausanne, Switzerland

Abstract

Collimation with hollow electron beams is a technique for halo removal in high-power hadron beams. The concept was tested experimentally at the Fermilab Tevatron collider using a hollow electron gun installed in one of the Tevatron electron lenses. Within the US LHC Accelerator Research Program and the European HiLumi LHC Design Study, we are investigating the applicability of this technique to the Large Hadron Collider and a conceptual design is being developed. We review some of the main topics related to this study: motivation; halo removal processes; development of hollow electron guns; effects on the proton beam core; and integration in the LHC machine.

INTRODUCTION

Hollow electron beam collimation is a new technique for beam collimation and halo scraping [1, 2, 3]. In a hollow electron beam collimator, a magnetically confined, pulsed, low-energy (a few keV) electron beam with a hollow current-density profile overlaps with the circulating beam over a short section of the ring. If the electron distribution is axially symmetric, the beam core is unperturbed, whereas the halo experiences smooth and tunable nonlinear transverse kicks. The electron beam is generated by a hollow cathode and transported by strong solenoidal fields. The size, position, intensity, and time structure of the electron beam can be controlled over a wide range of parameters.

The technique still relies on robust conventional collimators to absorb particles, but it has several features that can complement a classic multi-stage collimation system. In the case of high-power proton beams, for instance, scraping is smooth, controllable, and the issues of material damage and electromagnetic impedance of the collimator jaws are mitigated. In addition, a depletion zone is generated between the proton beam core and the collimator edges, making local energy deposition less sensitive to beam jitter, collimator movements, orbit and tune adjustments, or fast failures in the case of crab-cavity operation. In the case of ion collimation, it may be possible to reduce uncontrolled losses due to fragmentation. Hollow electron beam collimation is also being evaluated in comparison with other halo scraping techniques, such as tune modulation [4].

Hollow electron beam collimation is based on the technology of electron cooling and electron lenses. Electron lenses were developed for beam-beam compensation in colliders [5], enabling the first observation of long-range beam-beam compensation effects [6]. They were used for many years during regular Tevatron collider operations for cleaning uncaptured particles from the abort gap [7]. Thanks to the reliability of the hardware, one of the two Tevatron electron lenses could be used for experiments on head-on beam-beam compensation in 2009 [8], and for exploring hollow electron beam collimation in 2010–2011 [2, 3]. Electron lenses for beam-beam compensation were built for the Relativistic Heavy Ion Collider (RHIC) at Brookhaven National Laboratory and are currently being commissioned [9].

The Tevatron experiments on hollow electron beam collimation were conducted on antiprotons, mainly at the end of regular collider stores. In some cases, the electron beam was turned on for the whole duration of the fill. Because of the flexible pulsing pattern of the high-voltage modulator [10], the electron beam could be synchronized with a subset of bunches, providing a direct comparison with the unaffected beam.

The technique may provide a unique option to complement the LHC collimation system, but extending it from one machine to another is not trivial. To study these issues, a conceptual design of hollow electron beam collimation for the LHC upgrade is being developed within the US LHC Accelerator Research Program (LARP) and the European FP7 HiLumi LHC Design Study. If approved by the CERN management, this may then develop into a technical design in 2014, with the goal to build the devices in 2015–2017 and install them during the next long LHC shutdown, currently scheduled for 2018. In case of a resource-limited timeline, installation during the following long shutdown in 2022 is also an option.

HALO SCRAPING

For scraping the halo of a 7-TeV proton beam, we envision the inner radius of the electron beam to be placed between about 4σ and 6σ of the LHC proton rms beam size $\sigma = 0.32$ mm. This size is derived from the nominal normalized rms emittance $\varepsilon = 3.75\ \mu$m and the typical amplitude function at the candidate locations, $\beta = 200$ m. Scraping of elliptical proton beams is possible by displac-

* Fermilab is operated by Fermi Research Alliance, LLC under Contract No. DE-AC02-07CH11359 with the United States Department of Energy. ing the electron beam, but for simplicity we focus on round beams.

For stability and for transport efficiency, the field in the guiding solenoids should be as large as possible. Based upon previous experience and technical feasibility, we consider configurations where the gun, main (superconducting), and collector solenoids have fields in the ranges $0.2\ \mathrm{T} \le B_g \le 0.4\ \mathrm{T}$, $2\ \mathrm{T} \le B_m \le 6\ \mathrm{T}$, and $0.2\ \mathrm{T} \le B_c \le 0.4\ \mathrm{T}$, respectively. This implies magnetic compression factors $k \equiv \sqrt{B_m/B_g}$ in the range $2.2 \le k \le 5.5$, which sets the required sizes of the cathode inner and outer radii. The 1-inch electron gun cathode built for this purpose, for instance, has inner radius $r_{ci} = 6.75$ mm and an outer radius $r_{co} = 12.7$ mm. After magnetic compression, these radii translate to $1.2\ \mathrm{mm} = 3.9\sigma \le r_{mi} \le 9.5\sigma = 3.0$ mm and $2.3\ \mathrm{mm} = 7.3\sigma \le r_{mo} \le 18\sigma = 5.7$ mm in the interaction region inside the main solenoid. The LHC primary collimators will be placed at around 6σ from the beam axis.

The scraping experiments at the Tevatron with 0.98 TeV antiprotons were done with peak electron beam currents up to 1.2 A, and halo removal times ranged between seconds and minutes, depending upon the radius and intensity of the electron beam.

The transverse kicks generated by the hollow electron beam are nonlinear and have a small random component due to noise in the electron beam current. These kicks interact with the lattice nonlinearities and with the sources of noise in the machine. Therefore, the kicks needed to obtain a given halo removal rate may not be directly proportional to the magnetic rigidity of the circulating beam — a linear machine with low noise may require larger electron beam intensities.

Tracking simulations in the Tevatron lattice with the Lifetrac code showed that relatively small electron currents can significantly enhance halo removal [11]. The removal rates are sensitive to the shape of the electron beam and to the distribution of the halo population. In the absence of experimental data, tracking codes can give rough but conservative estimates of the removal rates. Numerical simulations of the LHC lattice with the SixTrack code indicated that, in the absence of beam-beam interactions and of diffusion processes, removal of 7-TeV protons with a 1-A electron beam current would be slow [12]. Higher electron yields and different pulsing schemes were therefore pursued to extend the capabilities of the technique.

A 1-inch-diameter hollow electron gun based on a tungsten dispenser cathode was developed and characterized at the Fermilab electron-lens test stand [13, 14]. The perveance of this gun is 5.3 μperv. This implies a peak yield of over 5 A at 10 keV. This yield should be sufficient to have a detectable effect on 7-TeV protons.

One can also exploit the flexibility of the electron beam pulsing pattern. Most of the Tevatron scraping experiments were done with the same turn-by-turn excitation intensity on the bunches of interest, but, for beam-beam compensation purposes, the high-voltage modulator was designed to handle bunch-by-bunch adjustments, with 10%–90% rise times of 200 ns [10]. Fast abort-gap cleaning was achieved by turning on the electron beam every 7th turn, in resonance with the betatron oscillations of the uncaptured beam.

In the LHC, one could certainly change the electron beam current turn by turn, synchronizing the voltage change with the abort gap, for instance. (Bunch-by-bunch adjustments every 25 ns or 50 ns are probably unnecessary.) This flexibility opens up the possibility to operate the hollow electron lens in different pulsing modes: *continuous* — the same voltage is applied every turn; *resonant* — the voltage is changed turn by turn according to a sinusoidal function (possibly including a frequency sweep to cover the tune spread of the halo), or with the same amplitude, but skipping a given number of turns (as in the Tevatron abort-gap cleaning mode); *stochastic* — the voltage is turned on or off every turn according to a random function, or a random component is added to a constant voltage amplitude. These modes of operation were simulated with tracking codes [12]. Both the resonant and the stochastic mode give significant and tunable halo removal rates. While the first is sensitive to the details of the tune distribution (lattice nonlinearities, beam-beam parameter), the stochastic mode is much more robust.

Using collimator scans, it was possible to measure the effects of collisions and of the hollow electron lens on halo diffusion in the Tevatron as a function of betatron amplitude [15, 16]. Diffusivities in action space with and without collisions were also measured at the LHC [17]. Halo suppression is the main consequence of the drift and diffusion enhancement by the electron beam, but we intend to further investigate other important aspects, such as the increase in impact parameters and its effect on collimation efficiency.

UNDESIRED EFFECTS ON THE CORE

The core of the circulating beam is unaffected if the distribution of the electron charge is axially symmetric. One possible cause of asymmetry is the space-charge evolution of the electron beam. Other sources of asymmetry are the bends that are used to inject and extract the electron beam from the interaction region.

The electron beam was turned on for several hours during some Tevatron collider stores. With aligned beams and continuous operation, no deterioration of the core lifetimes or luminosities were observed. Only a limited number of experiments were done in resonant mode (by skipping turns).

The current-density profiles generated by the hollow electron guns were measured in the Fermilab electron-lens test stand as a function of beam current and axial magnetic field. Space-charge evolution of the electron beam profiles is mitigated by increasing the guiding magnetic fields. For main fields above 2 T and beam currents up to a few amperes, we estimate that transverse current-density profiles are practically frozen.

The calculation of the electric fields from the measured current density profiles and the generation of the kick maps

Copyright © 2013 CC-BY-3.0 and by the respective authors

caused by the bends is described in a separate paper [18]. These fields are being used as inputs for tracking simulations to estimate beam lifetimes and emittance growth rates. For the Tevatron lattice and working point, the only azimuthal asymmetry seen to cause extra losses in the core was the quadrupole component in a particular resonant mode (pulsing every 6th turn) [11].

FURTHER CONSIDERATIONS

The bunch structure in the LHC is very different from the one in the Tevatron. This translates into tighter requirements on the electromagnetic impedance of the electron-lens hardware. Another aspect being considered is the possible extension of this technique to different operational scenarios, such as scraping during the acceleration ramp, which do not present impediments in principle, but have never been tested experimentally.

Diagnostic instrumentation includes accurate beam position monitoring of the long electron pulses and measurement of the electron beam profiles with wires or with fluorescent screens, as done at RHIC. A sensitive local loss monitor is also required to verify relative beam alignment. A direct measurement of the halo population, although not strictly necessary, would greatly benefit this project.

The construction cost of each of 2 electron lenses (one per beam) for the LHC is estimated to be 2.5 M$ in materials and 3.0 M$ in labor. Construction of 2 devices would take about 3 years. Reuse of some of the Tevatron equipment, such as superconducting coils, is possible. Each electron lens occupies about 6 m of tunnel length. Installation time is dominated by cryogenic integration (similar to a stand-alone magnet) and requires at least 3 months for warm-up, connections, and cool-down. The Tevatron devices had static heat loads of 12 W for the helium vessel at 4 K and 25 W for the liquid nitrogen shield.

CONCLUSIONS

Experimental and numerical studies are being conducted to support the conceptual design of a hollow electron beam collimator for the LHC, a promising technique for controlled scraping of very intense beams. A hollow electron gun with geometrical features and peak current yields appropriate for the LHC was built. Several electron beam pulsing modes were studied in numerical simulations to extend the achievable halo removal rates. No effects on the beam core are expected in the continuous mode of operation. The effect of imperfections in the resonant and stochastic modes is being evaluated with tracking codes using kick maps generated from measured and calculated electron beam charge distributions. Options for instrumentation and diagnostics were considered. No major obstacles were identified in the integration of the devices in the LHC ring from the point of view of electromagnetic impedance, mechanical engineering, or cryogenics.

Abstract

In the 2013 RHIC polarized-proton run, it was found that the intensity of the RHIC bunch had reached a limit due to the head-on beam-beam interaction at intensity of $2x10^{11}$, as we expected from our simulations [1]. To overcome this limitation, we have planned to implement two electron lenses for beam-beam compensation. During and after the 2013 RHIC run, some e-lens systems were commissioned. The effect of the e-lens warm solenoids on the protons orbit was observed and corrected by orbit feedback. The blue electron-lens system was fully tested, except for the superconducting magnet; the electron beam was propagated from the gun to the collector, and most of the instrumentation for the blue e-lens was commissioned. The straightness of the superconducting solenoid #2 field was measured for the first time. The installation of the yellow e-lens system and two superconducting magnets are underway.

INTRODUCTION

Figure 1 schematically depicts the layout of the electron lens that was used during the 2013 run (A), and will be implemented for the upcoming 2014 run (B).

During the 2013 run, all e-lens warm magnets [2, 3] were ready and tested with proton beam; we placed the superconducting solenoid #1 on the yellow e-lens side and replaced the blue superconducting solenoid with a spare EBIS superconducting solenoid, which was operated at 3T. We tested the blue e-lens system with the electron beam.

For the 2014 run (Figure 1 B), the yellow e-lens system will also be available and the two e-lens systems will be ready for commissioning.

For commissioning the e-lens during the 2013 255 GeV polarized proton run, we first commissioned a new e-lens lattice [4]; then, we studied the effects of e-lens magnetic field on the proton beam with the e-lens warm solenoids. We found that when the currents from the warm solenoids were ramped up, there were some effects on the beam

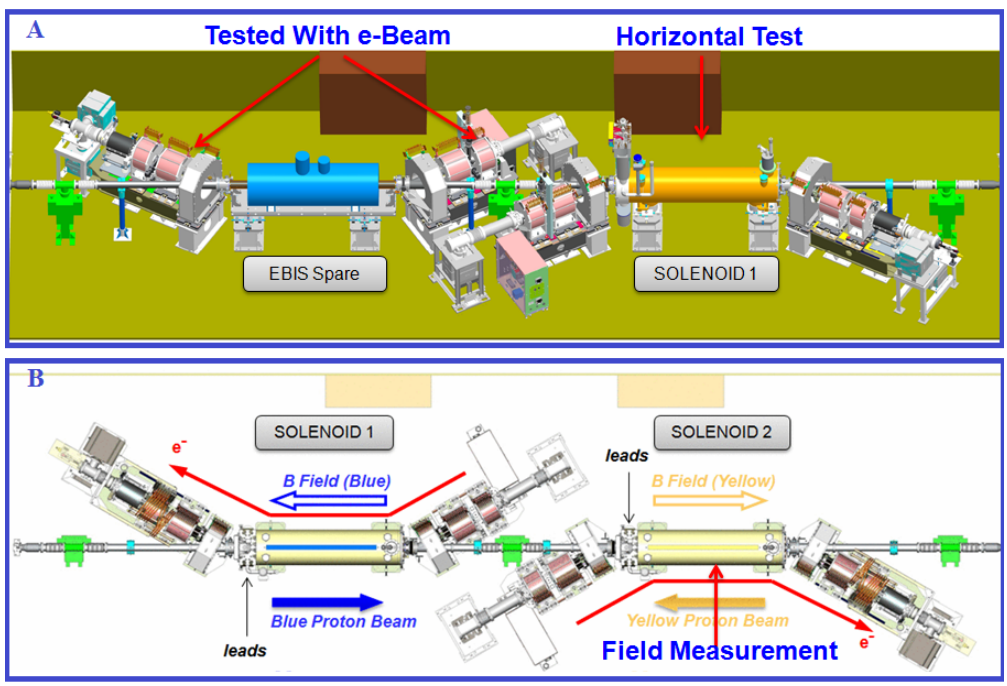

Figure 1: Schematic depictions of the layout of the electron lens during the 2013 run (upper) and the 2014 run (lower).

vertical orbit; we can correct this distortion by beam feedback. There were no apparent effects on beam loss, or on the beam intensity, emittance, or luminosity.

We also tested some instrumentation and applications for single-bunch beam-beam compensation during the 2013 polarized-proton run. Two BPMs were commissioned for the proton beam and electron beam.

For commissioning the blue e-lens, we propagated the electron beam through a system with a 3T EBIS spare superconducting-magnet. The properties of the cathode and the profile of the beam were measured with both a pinhole scanner and a YAG screen. The beam profile has Gaussian distribution. The modulator was commissioned with the 80 kHz and the DC beam for 14 and 9.5 hours respectively.

To further investigate the e-lens system reliability and make it more robust, several scenarios of system failure also were undertaken, such as Machine Protection System failure.

MAGNET EFFECTS DURING PROTON STORE

During the 2013 polarized proton run, we tested the e-lens warm solenoids with a proton beam. According to our simulation [5], the orbit of the proton beam is affected by the e-lens warm solenoids, especially in the vertical plane.

Figure 2 shows the distortion of the proton beam during the ramp-up of the e-lens warm solenoids with the orbit feedback on.

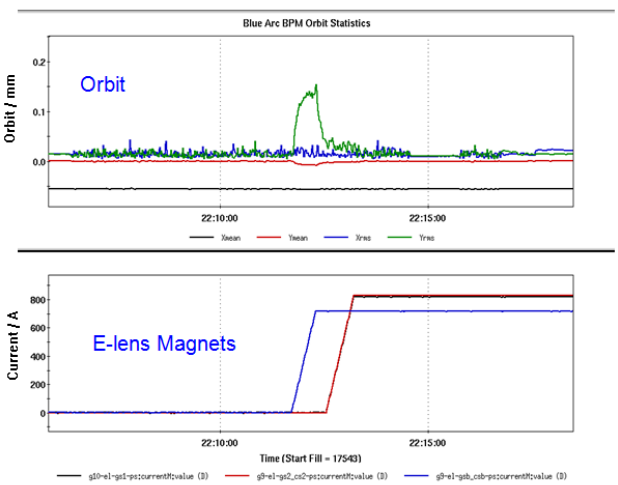

Figure 2: The vertical orbit rms with orbit feedback (top, in mm) and the warm magnet currents (bottom, in A).

The green (Yrms) trace in Figure 2, top, shows that the vertical beam rms position changes (~0.15mm) when the e-lens warm solenoid is ramped up even with the orbital feedback on, but recovered subsequently. A change in the orbit feedback parameters later reduced this effect. The effects on the horizontal plane were less.

Although e-lens warm magnets have some effects on the proton orbit, Figure 3, it is hard to discern any visible effects on RHIC luminosity.

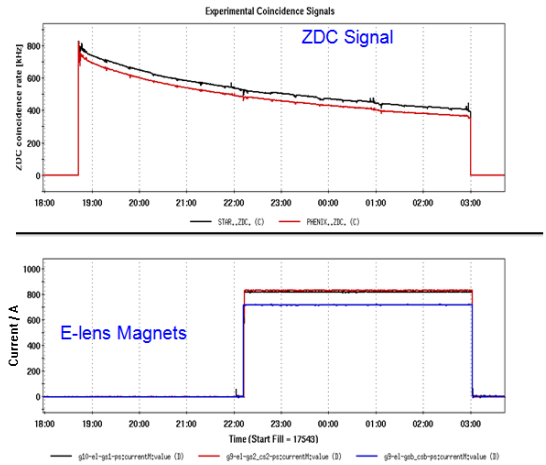

Figure 3: E-lens magnets current (bottom, in A) and luminosity (top).

ELECTRON BEAM COMMISSIONING

The blue e-lens system was fully commissioned with the help of the EBIS spare superconducting magnet, including the electron gun [6] and the collector. Figure 4 shows the perveance measurement of electron gun, which is 1.0×10^{-6} $AV^{-3/2}$.

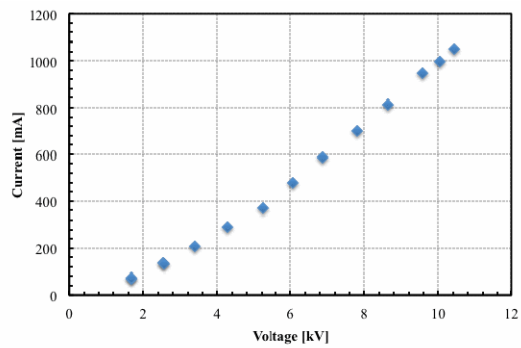

Figure 4: Perveance measurement of the electron gun.

We fully tested the electron beam running modes, and also demonstrated the system reliability. We ran the DC beam (1.256A) and the 80 kHz (parasitic) beam, respectively, for 9.5 hours and 14 hours; they were stopped intentionally for another test.

Figure 5 illustrates the 14 hour test of the 80 kHz electron beam. The bottom plot is the vacuum in the collector, which indicates that electron current was available in the collector; the upper plot, the anode voltage, denotes that the beam current was constant.

We also measured the electron beam profile with a YAG screen and a pinhole scanner [7]. Figure 6A shows the YAG profile for a 70 mA beam; Figure 6B shows the profile measured by the pinhole scanner for 1150 mA beam. The profile is Gaussian, with a small flat top, similar to the profile from the test bench [8, 9]. The total beam radius is 2.76 rms widths; the model yielded a value of 2.8.

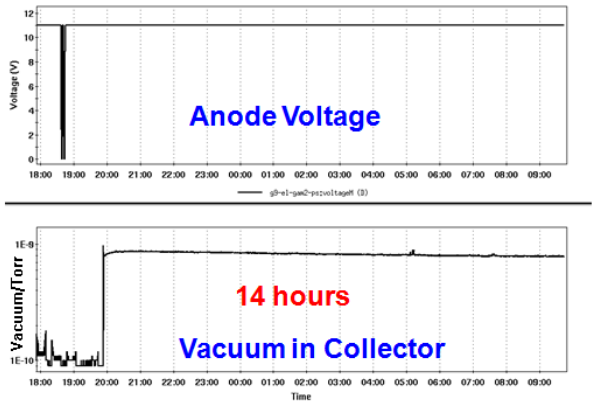

Figure 5: 80 kHz modulator test with more than a 1A beam.

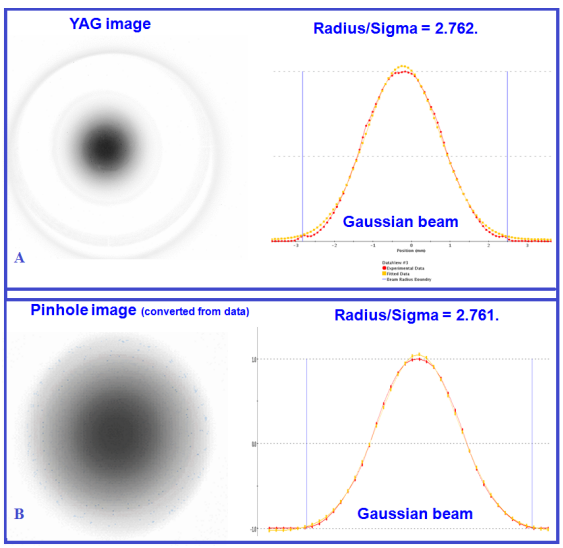

Figure 6: YAG screen (A) and pinhole (B) profile measurements of the electron beam.

E-LENS SUPERCONDUCTING MAGNETS

Two e-lens superconducting magnets were also tested. A horizontal test was done for both solenoid #1 and #2. With only 2 quenches, solenoid 1 reached 5 T. Solenoid #2 reached about 5.5 T. Both magnets have reached 6 T in a vertical test, and are expected to reach 6 T in the cryostat with further training quenches.

Figure 7 shows our measurements for the field straightness test at 2.83 T for solenoid #2, which was obtained at Brookhaven National Laboratory's Superconducting Magnet Department via magnetic needle [10]. The measurement was taken only with main coil and without fringe coil, anti-fringe coil, and correctors.

The green line in Figure7 is the field measurement and the red line is the measured deviation from a straight line. The blue line is the computed deviation after the application of five correctors.

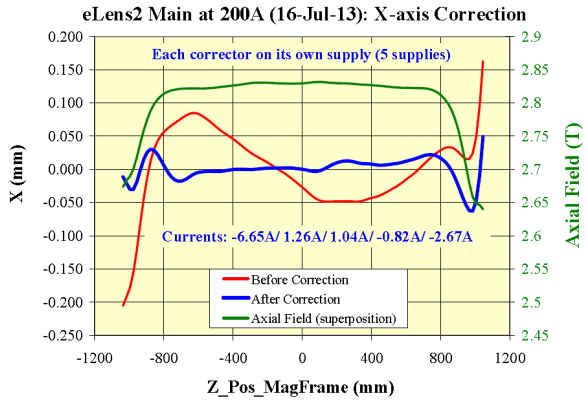

Figure 7: Measurement of the superconducting magnet field straightness in the horizontal plane.

As the blue line in Figure 7 shows, the straightness specification of ±50 μm is satisfied in X plane from about -900 mm to 900 mm without correctors. The uncorrected straightness deviation is even less in the Y (vertical) plane.

HIGH PRESSURE GAS-FILLED RF CAVITIES FOR USE IN A MUON COOLING CHANNEL

Abstract

A high pressure hydrogen gas-filled RF (HPRF) cavity can operate in the multi-Tesla magnetic fields required for a muon accelerator cooling channel. A beam test was performed at the Fermilab MuCool Test Area by sending a 400 MeV proton beam through an 805 MHz cavity and quantifying the effects of the resulting plasma within the cavity. The resulting energy loss per electron-ion pair produced has been measured at 10^{-18} to 10^{-16} J every RF cycle. Doping the hydrogen gas with oxygen greatly decreases the lifetime of an electron, thereby improving the performance of the HPRF cavity. Electron lifetimes as short as 1 ns have been measured, and electron-ion recombination rates are on the order of 10^{-6} cm^3/s. The recombination rate of positive and negative ions in the cavity has been measured on the order of 10^{-8} cm^3/s. Extrapolation in both gas pressure and beam intensity are required to obtain Muon Collider parameters, however the results indicate HPRF cavities can be used in a muon accelerator cooling channel.

INTRODUCTION

A recent White Paper submitted to the 2013 U.S. Community Summer Study of the Division of Particles and Fields by the U.S. Muon Accelerator Program (MAP) outlines a staged Muon Accelerator facility based at Fermilab [1]. The report outlines two main programs; a Neutrino Factory (NF), and a Muon Collider (MC). For the case of a MC, a Higgs Factory and multi-TeV collider are described. Because muons are created with a large initial phase space, the colliders requires significant (roughly six orders of magnitude) cooling.

The only cooling method that can work within the muon's lifetime is ionization cooling, and a so-called Helical Cooling Channel (HCC) has been proposed to do so [2]. The HCC is composed of normal conducting RF cavities arranged in a helix within a solenoidal magnetic field (see Fig. 1 & 2). The RF cavities are filled with a high pressure gas to allow operation in multi-Tesla magnetic fields. A series of six HCC cells, approximately 230 m long, reduces the 6D emittance by a factor of 175,000 [3].

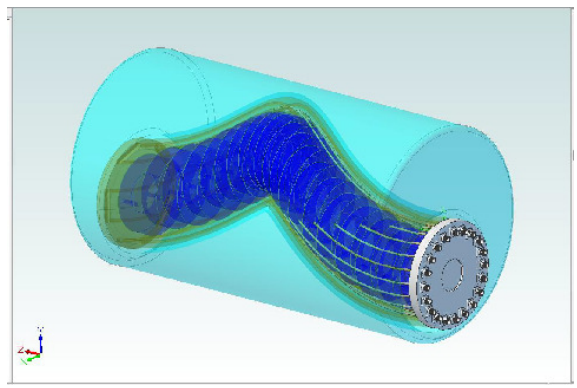

Figure 1: The 2D side view of one cell of the HCC, with components labeled. RF power is fed through the end. The solenoid coils are thermally isolated from the RF cavities [4].

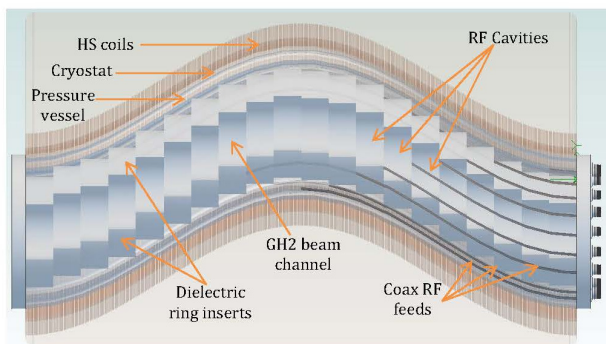

Figure 2: The 3D view of one cell of the HCC [4].

VALIDATION OF HIGH PRESSURE CAVITIES

A high pressure gas-filled RF (HPRF) cavity has been demonstrated to work in an external 3 T magnetic field without an ionizing beam [5, 6]. To validate its use in a HCC, a beam test using the 400 MeV Fermilab linac proton beam was performed at the MuCool Test Area (MTA). The cavity's performance using various beam intensities, gas pressures, dopant concentrations, and electric fields were studied with and without a 3 T magnetic field. Figure 3 shows a schematic of the experimental setup.

As the beam passes through the cavity, it ionizes the gas.

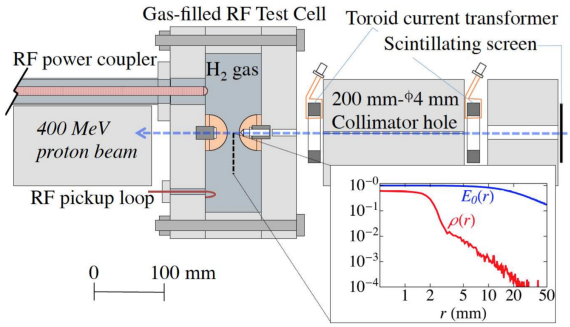

Figure 3: Schematic of the HPRF beam test setup. The beam enters from the right, passing through two collimators before impinging on the test cell. The inset plot shows the normalized electric field amplitude and simulated plasma density distribution as functions of radius.

The number of electron-ion pairs can be calculated:

$$N_{pairs} = \frac{\frac{dE}{dx}\,\rho\,L}{W_i} \tag{1}$$

where dE/dx is the stopping power, ρ is the gas density, L is the path length, and W_i is the average energy required to ionize a molecule.

Due to the high gas density, ionization electrons quickly come into equilibrium with the plasma, and drift with the cavity electric field. The electrons collide with gas molecules and transfer energy from the cavity to the plasma. The amount of energy transfered per charged particle can be evaluated by:

$$dw = q \int v\,E_0\,\sin(\omega\,t)\,dt \;=\; q \int \mu\,E_0^2\,\sin(\omega\,t)\,dt \tag{2}$$

where q is the charge of the particle, v is its drift velocity, E_0 is the amplitude of the electric field, and μ is the particle's mobility. The effect of the entire plasma is called plasma loading. To minimize the loading caused by electrons, an electronegative dopant gas can be used.

The results of the beam test are illustrated in Fig. 4 [7]. It can be seen that the addition of oxygen, present in dry air (DA), greatly decreases plasma loading. Additionally, there is very little difference between data taken with and without an external magnetic field.

The electric and magnetic fields inside the cavity as well as the ionization electrons' kinetic energy that would be present in a HCC were producible. However the maximum gas pressure was 100 atm while in a HCC it would be 180 atm. Additionally, the plasma density peaked at roughly 7×10^{11} cm^{-3} while in a real channel, due to the higher gas pressure and beam intensity, would be roughly 10^{16} cm^{-3}. Because of this, the results obtained in this beam test must be extrapolated to these higher densities.

The energy loss per particle, electron-ion and ion-ion recombination rates, and electron capture (by oxygen) time were measured as functions of electric field, gas pressure, and dopant concentration in order to extrapolate to the HCC parameters listed in Table 1.

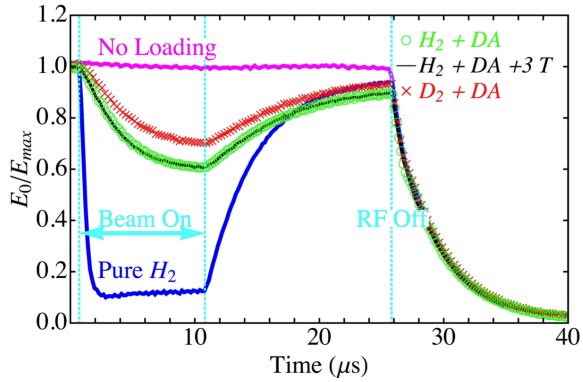

Figure 4: Typical RF envelopes recorded during the beam test. The beam is sent through the cavity once the flat top (E_{max}) has been reached. The magenta curve represents an RF pulse without beam.

Table 1: RF Parameters

Parameter	Unit	MTA Beam Test	HCC
RF frequency	MHz	801-808	325, 650
Gas pressure	atm	20-100	180
Oxygen conc.	%	2×10^{-4}-1	0.2
Peak E field	MV/m	5-50	20
External B field	T	0-3	4-14

Figure 5 shows the results of the electron attachment time, τ as a function of gas pressure. A fit to the data was used to extrapolate the time constant to 180 atm, which corresponds to 0.14 ns, indicated by the black lines on the plot.

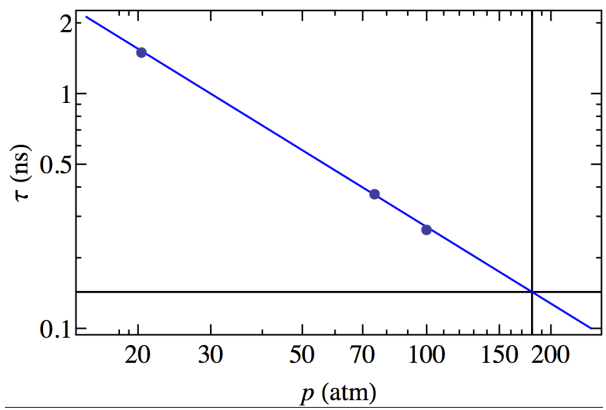

Figure 5: Electron attachment time as a function of gas pressure. The data (points) are taken from hydrogen gas doped with 1% DA (0.2% oxygen), and a fit was used to extrapolate the value of τ to 180 atm. The electron kinetic energy was kept constant at 0.4 eV.

PLASMA LOADING CALCULATION

A calculation of the plasma loading using muon accelerator beam and HCC RF parameters has been done. The beam parameters are given in Table 2. The beam bunches were assumed to be delta functions. The HPRF cavity's

Copyright © 2013 CC-BY-3.0 and by the respective authors

length was 10 cm and the stored energy was 19 J at 325 MHz and 4.7 J at 650 MHz.

The electron attachment time, electron-ion recombination rate, ion-ion recombination rate, and electron energy loss used in the calculation were based on extrapolations of measurements made at the MTA. The ion energy loss was based on classical values for the mobility.

Table 2: Beam Parameters

Parameter	Unit	Value
# of bunches	-	21
Bunch intensity	μ/bunch	10^{11}, 10^{12}
Bunch frequency	MHz	325
Injection phase	degrees	160

The results of the calculations are given in Table 3 & 4, for the two bunch intensities considered. Luminosity requirements dictate the bunch intensity before the final acceleration. To account for losses, the bunch intensity in the cooling channel will be between 10^{11} and 10^{12}.

Table 3: Plasma Loading Results for 10^{11} Muons per Bunch. The percent the accelerating voltage has dropped by the final bunch is given.

Parameter	Unit	325 MHz	650 MHz
Energy dissipated	J	0.292	0.317
% of total energy	-	1.5	6.7
% V_{accel} drop	-	0.8	3.4

Table 4: Plasma Loading Results for 10^{12} Muons per Bunch. The percent the accelerating voltage has dropped by the final bunch is given.

Parameter	Unit	325 MHz	650 MHz
Energy dissipated	J	1.84	1.98
% of total energy	-	9.7	42
% V_{accel} drops	-	5.0	24

It can be seen that, due to the larger stored energy, the 325 MHz cavity is only minimally loaded by the plasma, for either bunch intensity. The 650 MHz cavity experiences considerable plasma loading at the larger bunch intensity. This is due primarily to the buildup of ions over the course of the beam pulse. This is illustrated in Fig. 6. However, results obtained at the MTA indicate that the mobility of ions is smaller than the classical mobility, which was used here. This would have the effect of decreasing the loading due to ions.

CONCLUSIONS

The initial evidence suggests high pressure gas-filled cavities will work in a helical cooling channel for a muon accelerator. Extrapolation of parameters obtained at the MTA suggest that in the highest bunch intensity case, the accelerating gradient the final 10^{12} muon bunch would see would be degraded by 24%. The plasma dynamics inputs into this calculation were all taken to be conservative, and in reality the plasma loading should be less.

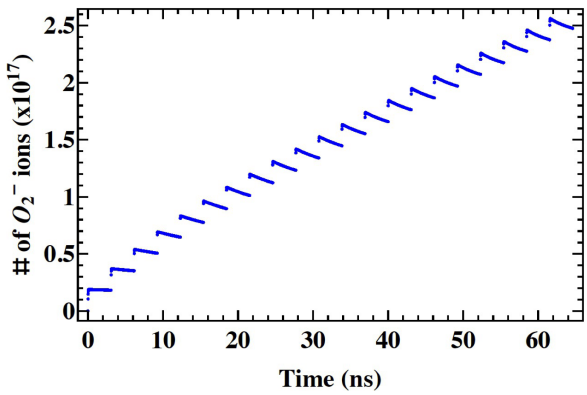

Figure 6: Number of O_2^- ions present in the cavity over the beam pulse.

The effects of higher gas and plasma density must be considered, and simulations [8] are underway to address this. Evidence suggests that higher densities have a positive effect on the cavity's performance.

Additionally, wakefields and beam loading have not yet been considered. These are not issues unique to gas-filled cavities, and may be a serious consideration for $10^{11}-10^{12}$ muons per bunch. The impact and mitigation are being investigated.

Abstract

A new 150 MeV electron storage ring is being built at Fermilab. The construction of a new machine pursues two goals a test of highly non-linear integrable optics and a test of optical stochastic cooling. This paper discusses details of OSC arrangements, choice of major parameters of the cooling scheme and incoming experimental tests of the optical amplifier prototype which uses highly doped Ti-sapphire crystal as amplification medium.

INTRODUCTION

The stochastic cooling has been successfully used in a number of machines for particle cooling and accumulation. Cooling rates of few hours required for luminosity control in hadron colliders cannot be achieved in microwave frequency range (~10^9-10^{10} Hz) usually used in stochastic cooling. Large longitudinal particle density, N/σ_s, used in such colliders requires an increase of cooling bandwidth by a few orders of magnitude. To achieve such increase one needs to make a transition to much higher frequencies. A practical scheme operating in the optical frequency range was suggested in Ref. [1]. The method is named the optical stochastic cooling (OSC). It is based on the same principles as the stochastic cooling but uses much higher frequencies. Thus it is expected to have a bandwidth of ~10^{14} Hz and can create a way to attain required damping rates. Fermilab plans to make an experimental test of the OSC in IOTA ring [2].

In the OSC a particle emits e.-m. radiation in the first (pickup) wiggler. Then, the radiation amplified in an optical amplifier (OA) makes a longitudinal kick to the same particle in the second (kicker) wiggler as shown in Fig. 1. A magnetic chicane is used to make space for the OA and to delay a particle so that to compensate for a delay of its radiation in the OA resulting in simultaneous arrival of the particle and its amplified radiation to the kicker wiggler. A particle passage through the chicane has a coordinate-dependent correction of particle longitudinal position which, consequently, results in a correction of relative particle momentum, $\delta p/p$, with amplitude ξ_0 so that:

$$\delta p / p = -\xi_0 \sin\left(k\,\Delta s\right) . \qquad (1)$$

Here $k = 2\pi/\lambda$ is the radiation wave-number,

$$\Delta s = M_{51}x + M_{52}\theta_x + M_{56}\left(\Delta p / p\right) , \qquad (2)$$

is the particle displacement on the way from pickup to kicker relative to the reference particle which experiences zero displacement and obtains zero kick, M_{5n} are the elements of 6x6 transfer matrix from pickup to kicker, x, θ_x and $\Delta p/p$ are the particle coordinate, angle and relative momentum deviation in the pickup.

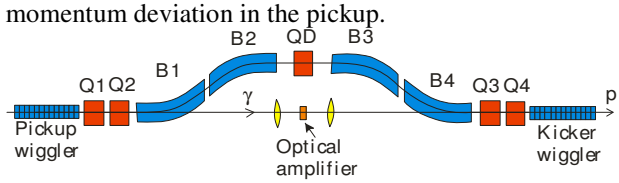

Figure 1: OSC schematic.

For small amplitude oscillations the horizontal and vertical cooling rates per turn are [3]:

$$\begin{bmatrix}\lambda_x\\ \lambda_s\end{bmatrix} = \frac{k\xi_0}{2}\begin{bmatrix}M_{56}-\tilde{M}_{56}\\ \tilde{M}_{56}\end{bmatrix} , \qquad (3)$$

where $\tilde{M}_{56} = M_{51}D_p + M_{52}D'_p + M_{56}$ is the partial slip-factor introduced so that for a particle without betatron oscillations and with momentum deviation $\Delta p/p$ the longitudinal displacement relative to the reference particle on the way from pickup to kicker is equal to $\tilde{M}_{56}\Delta p / p$, and D and D' are the dispersion and its derivative in the pickup. We assume that there is no x-y coupling in the chicane. Introduction of x-y coupling outside the cooling area allows a redistribution of the horizontal damping rate between two transverse planes. The sum of damping rates is: $\Sigma\lambda_n = k\xi_0 M_{56}/2$.

A non-linear dependence of kick on Δs in Eq. (1) results in a dependence of damping rates on amplitudes [3]:

$$\begin{aligned}\lambda_x(a_x,a_s) &= \left(2\,\mathrm{J}_0(a_s)\,\mathrm{J}_1(a_x)/a_x\right)\lambda_x \quad ,\\ \lambda_s(a_x,a_s) &= \left(2\,\mathrm{J}_0(a_x)\,\mathrm{J}_1(a_s)/a_s\right)\lambda_s \quad ,\end{aligned} \qquad (4)$$

where a_x and a_s are the amplitudes of longitudinal particle motion due to betatron and synchrotron oscillations expressed in the units of e.-m. wave phase:

$$\begin{aligned}a_x &= k\sqrt{\varepsilon_1\left(\beta_p M_{51}^{\,2} - 2\alpha_p M_{51}M_{52} + \left(1+\alpha_p^{\,2}\right)M_{52}^{\,2}\right)},\\ a_p &= k\left|\tilde{M}_{51}\right|\left(\Delta p / p\right) \quad ,\end{aligned} \qquad (5)$$

ε_1 is the Courant-Snyder invariant of a particle, and $(\Delta p/p)$ is the amplitude of particle synchrotron motion. As one can see from Eq. (4) each damping rate changes its sign if any of amplitudes exceeds the first root, μ_0, of the Bessel function $\mathrm{J}_0(x)$. That determines that at the cooling area boundary $a_x=\mu_0$ or $a_y=\mu_0$ where $\mu_0\approx2.405$. That yields the cooling area boundaries:

$$\begin{aligned}\varepsilon_{\max} &= \frac{\mu_0^{\,2}}{k^2\left(\beta_p M_{51}^{\,2} - 2\alpha_p M_{51}M_{52} + \left(1+\alpha_p^{\,2}\right)M_{52}^{\,2}\right)},\\ \left(\Delta p / p\right)_{\max} &= \mu_0 \Big/ \left(k\left|\tilde{M}_{51}\right|\right) \quad .\end{aligned} \qquad (6)$$

Although M_{56} and, consequently, the sum of damping rates depend only on focusing inside the chicane, $\tilde{M}_{56}$ and the ratio of damping rates depend on the dispersion at the chicane beginning, *i.e.* on the ring dispersion. Eq. (3) yields the ratio of damping rates,

$$\lambda_x / \lambda_s = M_{56} / \tilde{M}_{56} - 1 \ . \quad (7)$$

The relative cooling ranges are introduced as ratios of cooling area boundaries $(\Delta p/p)_{max}$ and ε_{max} to the rms values of momentum spread, σ_p, and horizontal emittance, ε, established by equilibrium between SR damping and heating. That yields:

$$n_{\sigma s} = (\Delta p / p)_{max} / \sigma_p \ , \quad n_{\sigma x} = \sqrt{\varepsilon_{max} / \varepsilon} \ . \quad (8)$$

As one can see the transverse cooling range does not depend on the dispersion but depends on the beta-function in the pickup wiggler.

BEAM OPTICS

The OSC system will take one of four straight sections with length of ~4 m. The cooling chicane consists of four dipoles with parallel edges (see Fig. 1) To obtain transverse cooling M_{56} and $\tilde{M}_{56}$ have to be different. It is achieved by placing a defocusing quad in the chicane center. Leaving only leading terms in the thin lens approximation one obtains:

$$M_{56} \approx 2\Delta s \ , \quad \tilde{M}_{56} \approx 2\Delta s - \Phi D^* h \ , \\ \lambda_x / \lambda_s \approx \Phi D^* h / \left(2\Delta s - \Phi D^* h\right) . \quad (9)$$

Here Δs and h are the path lengthening and the trajectory offset in the chicane, $\Phi=1/F$ is the defocusing strength of the quad, D^* is the dispersion in the chicane center, and we assume that $dD/ds=0$. The latter condition is required to minimize the equilibrium beam emittance. Similarly, using Eq. (8) one obtains estimates for the cooling ranges

$$n_{\sigma p} \approx \mu_0 / \left(\left(2\Delta s - \Phi D^* h\right) k \sigma_p\right) , \\ n_{\sigma x} \approx \mu_0 / \left(2kh\Phi\sqrt{\varepsilon\beta^*}\right) , \quad (10)$$

where $\beta^* \approx L^2 / \beta$ is the beta-function in the chicane center, and L is its half-length. As one can see from Eqs. (9) and (10) $\Phi D^* h$ determines the cooling dynamics. Using the bottom equation in (10) we obtain:

$$\Phi D^* h \approx \frac{\mu_0}{2kn_{\sigma x}} \sqrt{\frac{A^*}{\varepsilon}} \ , \quad (11)$$

where $A^*=D^{*2}/\beta^*$ is the dispersion invariant in the chicane center. As one can see the given wave-length, beam emittance and transverse cooling range uniquely determine $\Phi D^* h$ and, consequently, the cooling dynamics.

The choice of the wavelength of 800 nm was determined by choice of OA. Although the delay in the OA of 2 mm is quite small it still presents considerable challenges to the beam optics. Without redistribution of decrements it yields an acceptably low longitudinal cooling range, $n_{\sigma p}$ <1. Therefore a redistribution of decrements is required but its value is limited by reduction of the transverse cooling range. Decreasing the ring energy from 150 to 100 MeV reduces the equilibrium emittance and momentum spread and allows obtaining sufficiently large cooling ranges of >2 for both planes. Operation at the coupling resonance redistributes SR cooling rates between horizontal and vertical planes resulting approximately equal equilibrium transverse emittances and, consequently, twice smaller horizontal emittance. Tables 1 and 2 present the main parameters of the ring. The ring optics is symmetric relative to the chicane center. Figure 2 presents the dispersion and beta-functions for half of the ring. The optics was designed to minimize the equilibrium emittance. It requires a minimization of the dispersion invariant $A = \left(1+\alpha^2\right) D^2 / \beta + 2\alpha D D' + \beta D'^2$ in the dipoles. Its initial value of 11 m determined by requirements of OSC is quite large and, if not addressed, would result in an unacceptably large emittance. An adjustment of horizontal betatron phase advances between dipoles was crucial to obtain tolerable transverse emittances. Figure 3 presents the value of A along half of the ring.

Table 1: Main Parameters of IOTA storage ring for OSC

Circumference	40 m
Nominal beam energy	100 MeV
Bending field	4.8 kG
Tunes, Q_x/Q_y	6.36/2.36
Number of particles	$5 \cdot 10^8$
Transverse emittances, $\varepsilon=\varepsilon_x=\varepsilon_y$, rms	11.5 nm
Rms momentum spread, σ_p	$1.23 \cdot 10^{-4}$
SR damping times (ampl.), $\tau_s / (\tau_x = \tau_y)$	1.4 / 0.67 s

Table 2: Major parameters of cooling chicane

Delay in the chicane, Δs	2 mm
Horizontal beam offset, h	20.1 mm
M_{56}	3.95 mm
Dispersion in the chicane center, D^*	307 mm
Beta-function in the chicane center, β^*	8.59 mm
Cooling rates ratio, $(\lambda_x = \lambda_y)/\lambda_s$	1.18
Cooling ranges (before OSC), $n_{\sigma x}/n_{\sigma s}$	2.1 / 3.2
Dipole magnetic field	4.22 kG
Dipole length	10 cm
Strength of central quad, GdL	1.58 kG

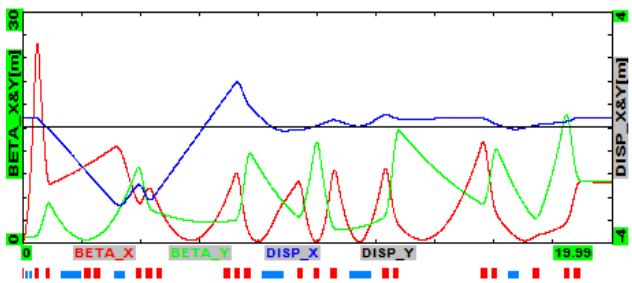

Figure 2: Optics functions for IOTA half ring starting from the OSC section.

OPTICAL AMPLIFIER

Choice of Ti:Sapphire OA has a few advantages. First, it has quite wide bandwidth (~20% FWHM). Second, it allows operation in the CW regime; and third, it can deliver significant amplification with only ~1 mm signal delay. For an OA prototype we bought a highly doped (0.5%wt Ti_2O_3) 2 mm thick Ti: Sapphire crystal from GT Crystal Systems. An estimated low power gain is ~100 (20 Db) with pumping power density of 1.8 MW/cm^2.

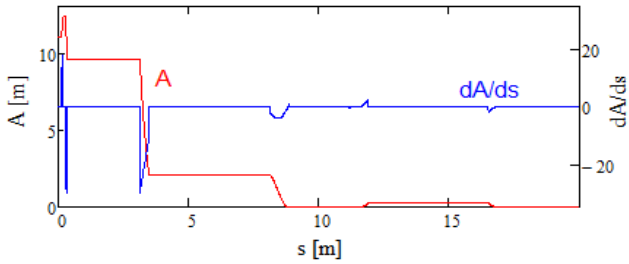

Figure 3: Dependence of the dispersion invariant, A, and its derivative for IOTA half-ring starting from the OSC section. dA/ds is non- zero at dipoles.

Optical system has two lenses (Fig. 1). The first lens focuses the beam radiation on the Ti:Sapphire crystal, and the second one focuses the amplified radiation into the kicker wiggler. The lenses have the same focal length and radius. The focal length was chosen to minimize the size of e.-m. radiation on the Ti:Sapphire crystal. A longer focal length decreases the spot size at the crystal entrance but increases the waist and effects of the field of depth. An optimal value of the focal length is 8 cm with lens radius of 3.5 mm. The lens radius was determined by a compromise between the damping rates growth with the radius and an increase of signal delay leading to a drastic deterioration of beam optics. The choice of lens parameters results in that the most radiation is within cylinder with 30 μm radius where amplification can happen. The radiation of pumping laser follows along beam radiation axis. Windows in vacuum chamber located along the axis allow the pumping light to get in and out together with the amplified radiation. The radiation of pumping laser comes through the same lenses. Additional matching lenses are installed outside the vacuum chamber. The pumping laser radiation is focused into 30 μm cylinder with close to rectangular power density distribution. It determines the laser power to be ~50 W. To reduce the effect of the depth of field a 50 cm gap between the cooling chicane and the wigglers is introduced.

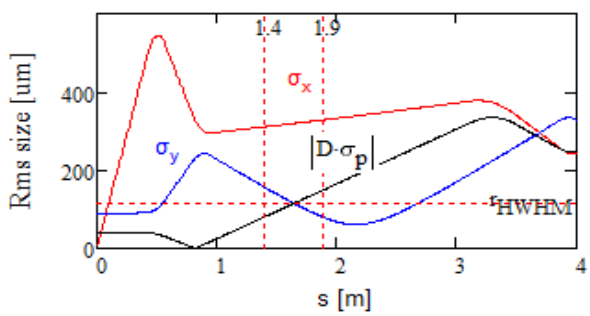

Figure 4: Rms beam sizes (horizontal – σ_x, vertical – σ_y, and due to momentum spread - $|D\sigma_p|$) in vicinity of cooling chicane starting from the center of OSC section. Vertical lines mark location of wiggler. The horizontal line shows diffraction limited spot size (HWHM) of amplified radiation in the kicker wiggler.

Cooling the OA to liquid nitrogen temperature is required. It increases the crystal thermal conductivity resulting in an acceptable temperature difference across the crystal (~8K) and thermal stresses. Cooling also reduces the dependence of refraction index on temperature and, thus, optics distortions related to the high pumping power.

Recently we assembled a prototype OA which will be operating in a pulsed regime to avoid problems with cooling required for CW regime. The goal of the measurements is to determine the dependence of phase and amplitude of amplified signal on frequency. It is achieved by inserting the OA into one leg of Michelson interferometer. The first measurements are expected soon.

COOLING RATES

Parameters of undulators and cooling rates are shown in Table 3. The undulator period was chosen so that the wavelength of the radiation at zero angle would be at the band boundary (750 nm). The cooling rates were computed using formulas developed in Ref. [4] where additional averaging over amplifier band was applied resulting in ~20% reduction of rates. It was assumed that only radiation within 2 mrad enters the OA. It sets the aperture of optical system to 2·3.5 mm and the upper boundary of the band to 850 nm. The effects of e.-m. wave dispersion in the OA amplifier were neglected. It was assumed that the dispersion in the amplifier is included into the gain, *i.e.* $G = 10$ implies an amplitude amplification of 10. Consequently, the dispersion makes the power gain to be somewhat larger than G^2. We also neglected incomplete overlap of light and particle beams in the kicker undulator at the beginning of cooling process when the beam size is determined by SR. Figure 4 shows the rms beam sizes in the cooling section for the uncooled beam. One can see that the beam sizes exceed the radiation spot size. It results in that the initial cooling rates are about factor of 5 lower. For the chosen number of particles in the bunch the system operates slightly below optimal gain at the beginning of cooling process. We would like to stress that even in the absence of amplification (passive system, $G = 1$) the OSC damping exceeds SR damping by more than an order of magnitude (see Tables 1 and 3).

Table 3: Main parameters of OSC

Undulator parameter, K	0.6
Undulator period	4.92 cm
Radiation wavelength at zero angle	750 nm
Number of periods, m	10
Total undulator length, L_w	0.50 m
Length from OA to undulator center	1.65 m
Amplifier gain (amplitude)	10
Telescope aperture, $2a$	7 mm
Lens focal length, F	80 mm
Damp. rates (x=y/s)	160/140 s^{-1}

FREE-ELECTRON LASERS IN THE SOFT X-RAY REGIME*

J. N. Corlett#, LBNL, Berkeley, CA, USA

Abstract

X-ray science in imaging, structure determination, and spectroscopy, as well as diffraction/scattering, requires intense ultrafast pulses in the soft X-ray range, uniquely provided by free electron lasers (FELs). In addition to operational soft X-ray FEL facilities, there are FEL construction projects under way that include soft X-ray laser capabilities, and planned facilities with novel capabilities. This paper provides a review of the exciting field of existing and planned soft X-ray FELs with emphasis on new schemes and new technologies to achieve better performance.

SCIENCE NEEDS FOR SOFT X-RAY FELS

The scientific innovation expected from the construction and operation of X-ray FEL facilities lies in their ability to provide tools that offer extreme spatial, temporal, and energy resolution. Properties of FEL sources are expected to include the ability to reach to the ultrafast timescales of atomic motion (about 100 fs), spin motion (down to about 1 fs), and electronic motion (down to attoseconds), the spatial scale of the atomic bond (down to Angstroms), and energy resolution on the scale of the bond that holds electrons in correlated motion with near neighbors (~10 meV and greater). X-ray FEL sources offer unique capabilities to combine information on atomic length scales with data on full-scale functional systems under realistic operational conditions. In addition, these sources have an intensity and brightness needed to observe the subtlest of nature's secrets at these frontier space, time, and energy scales, and with elemental specificity.

Critical X-ray science in imaging, structure determination, and spectroscopy needs new capabilities in the soft X-ray range, accessing K- and L-edges of the earth-abundant elements, as well as diffraction/scattering in the few to several keV photon energy range. These scientific requirements give rise to the following desirable FEL performance features:

- X-ray time structure
  - Control of longitudinal phase space, with Fourier-transform-limited pulse structure extending from ~100 fs pulses with ~10 meV bandwidths to sub-femtosecond pulses with ~10 eV bandwidths
  - Control of longitudinal pulse shape, amplitude and phase
  - Synchronization and full integration with conventional pulsed laser sources
  - High repetition rate with regularly spaced pulses
- Full transverse coherence
  - Requirements set by real-space imaging, diffractive imaging, and photon-correlation spectroscopy
  - Optical systems to preserve and exploit transverse coherence
- High peak flux and brightness
  - Requirements set by non-linear effects in materials
- High average flux and brightness
  - Short-pulse sources with high repetition rates (100 kHz or greater) providing average flux and/or brightness substantially beyond existing sources
- Tunability, polarization control, and extended photon energies
  - Tunability throughout the transition-metal L-edges and polarization control and modulation
  - Two-color capability for non-linear spectroscopies and X-ray pump/X-ray probe
- High degree of amplitude and wavelength stability
- Multiple simultaneous users

SOFT X-RAY FEL OVERVIEW

High-gain single pass FELs at wavelengths in the EUV and shorter have been operating as photon science user facilities for almost a decade – the TESLA Test Facility (TTF) became the Free Electron Laser in Hamburg (FLASH) in 2003, and user operations began in 2005 with lasing at 25 nm [1]. FLASH now operates at wavelengths in the water-window (~4 nm) and longer. The LCLS at SLAC is the world's first hard X-ray FEL [2], and also operates in the soft X-ray regime with wavelength ~4.5 nm and shorter [3]. Both of these facilities currently operate in SASE mode in the soft X-ray range (although the LCLS also offers a hard X-ray self-seeded mode [4]). FERMI@elettra is a seeded FEL facility, offering improved temporal coherence, with tunable user beam currently offered down to 20 nm [5]. The SACLA facility currently operates the shortest wavelength FEL, in SASE mode [6].

Upgrades of these facilities are planned or are in progress and include development of soft X-ray capabilities, in capacity (adding FEL beamlines), and also in capability by extending the tuning range, seeding (either self-seeding or external laser-seeding) and offering tunable undulators and new operating regimes of pulse duration and time structure. The FERMI team is now commissioning a 2-stage harmonic cascade to reach into the water window [7]. Upgrade plans at SACLA include the re-location of the SCSS test facility as a soft X-ray FEL driver [8]. FLASH-II will add variable-gap undulators in a separate beamline driven by the existing linac, and seeding. LCLS-II is planned to provide self-seeded capability from 0.25–5 nm, using a new CW superconducting linac.

The European XFEL [9], SwissFEL [10], and Korean PAL-XFEL [11] facilities are under construction, and

plan for soft X-ray capability, in SASE or in self-seeded mode.

The FLASH and FLASH-II, European XFEL, and LCLS-II projects are based on superconducting RF technology, and offer very high repetition rate (up to ~100 kHz at each FEL) providing high average photon beam brightness and coherent power. Other facilities and projects use normal conducting accelerators and provide relatively low repetition rate (up to ~100 Hz). Use of normal conducting accelerators operated at high gradient is attractive in allowing for a small facility footprint.

Design studies elsewhere are developing concepts for soft X-ray FELs, including SXFEL (Shanghai), IRIDE (INFN-Frascati), and LUNEX5 (SOLEIL). Other soft X-ray FEL facility design studies have recently come to an end, including the NGLS at Berkeley Lab, and the NLS in the UK.

In addition to facilities, projects, and design studies, there are important R&D facilities contributing to understanding of FEL science and technology. Currently operating single-pass FEL R&D facilities are NLCTA (at SLAC), SPARC (at INFN Frascati), SDUV (Shanghai Institute of Applied Physics), and MAX-Lab (Lund, Sweden). Proposals for single-pass FEL R&D facilities include CLARA (STFC Daresbury).

OPERATING FACILITIES, AND THEIR UPGRADES AND EXPANSION PLANS

FLASH

The FLASH facility is a high-gain single pass SASE FEL driven by a pulsed superconducting L-band (1.3 GHz) linac based on TESLA technology, with maximum beam energy 1.25 GeV [12]. The time structure is a burst mode with up to 3 MHz bunch rate in an 800 μs macropulse, 10 Hz repetition rate, delivering up to 5000 pulses per second. Photon pulses in the wavelength range 4.2–44 nm, with 10–400 μJ per pulse, and duration in the range <50–250 fs, are produced in fixed-gap permanent-magnet undulators of period 27.3 mm. A Cs_2Te photocathode provides electron beam in a normal-conducting L-band RF gun, with charge per bunch 0.02–1 nC. Peak current at the FEL is typically 1–2 kA. Photon tuning is provided by adjusting the electron beam energy, and RF and beam-based feedback systems are used to enhance stability of beam energy, bunch compression, and timing. Development plans include production of shorter pulses, and enhanced temporal coherence through laser-seeding using XUV pulses from an HHG laser, as well as high gain harmonic generation (HGHG) using a UV seed [13].

FLASH-II

FLASH-II adds a second FEL beamline in a new undulator tunnel and a new experimental hall added to the facility at DESY. Driven by the same superconducting linac, both FLASH-I and FLASH-II are to be delivered electron beam in bursts at 10 Hz repetition rate by a beam kicker that will distribute bunches from within each macropulse [14]. Two photocathode lasers are used to generate sub-trains in a macropulse, allowing flexibility in intra-train repetition rate, number of pulses per train, longitudinal pulse shape, and pulse energy for both FELs. The bunch spacing for beam to FLASH-II is 1–25 μs. The undulators are 31.4 mm period, with variable gap, and allow tuning from 4–13.5 nm in SASE mode at beam energy of 1.2 GeV, and longer wavelengths at lower beam energy. Construction is under way, and commissioning with beam is expected to begin in early 2014. Seeded FEL operation is planned, using single-stage harmonic generation from a UV seed laser, and initially radiating in the range 20-40 nm.

LCLS

LCLS demonstrated the first hard X-ray laser operation in 2009, with an S-band (2856 MHz) photocathode gun and 14 GeV linac driving an FEL with 3 cm period fixed-gap permanent magnet undulators [2]. The facility provides photon wavelength from 4.5 nm to 1.2 Å, in pulses of ~3–500 fs, ~2–6 mJ per pulse, at a repetition rate of 120 Hz. Charge per pulse is typically ~250 pC to optimize brightness. Hard X-ray self-seeding at ~8.2 keV results in a factor ~50 reduction in bandwidth compared to SASE, and a brightness increase currently limited to a factor ~3. LCLS upgrade plans include development of capabilities for fs-scale pulses, hard and soft X-ray self-seeding, two-color generation, synchronized THz, multiple-bunch operation, and polarization control [3].

LCLS–II

LCLS-II is a major expansion of the FEL capabilities at SLAC, and plans are being developed to build a new 4 GeV superconducting L-band (1.3 GHz) linac based on ILC/XFEL technology developed for CW operation. The linac will drive two FELs, each an adjustable gap permanent magnet undulator design. Both FELs will be self-seeded, and one tunable over the range 1–5 nm (undulator period ~40 mm), the other 0.25–1.2 nm (undulator period ~26 mm). The latter will replace the existing LCLS undulator, and designed to be driven be either the new linac, or the existing S-band linac (for harder X-ray and higher per-pulse energy capability, at lower repetition rate). Bunch rate from the superconducting linac may be as high as 1 MHz, and each FEL will typically provide ~100 kHz X-ray pulses with uniform spacing, with energy per pulse up to ~2 mJ. A high-brightness, high repetition rate injector such as being developed at the APEX project may be used as an electron source [15]. The facility takes advantage of existing SLAC infrastructure in housing the injector, linac, RF power systems, beam transport, undulators, X-ray beamlines and endstations. This approach offers cost savings, and upgrade paths both in capacity by adding FELs, and capability by implementing new FEL designs. The construction project is estimated to complete in 2020.

Copyright © 2013 CC-BY-3.0 and by the respective authors

FERMI@elettra

The first seeded FEL user facility has been operational for users since 2012, and currently provides continuous tunability from the FEL-1 harmonic cascade over the range 20–65 nm (and longer wavelengths to 100 nm possible with specific machine setup). A UV seed laser is used to modulate the electron beam from a 1.2 GeV S-band (2998 MHz) GeV linac operating at 10 Hz, radiating at up to the 13th harmonic of the seed in 55 mm period variable-gap APPLE-II type undulators with polarization control. Peak current is ~500 A, as opposed to ~kA used in SASE FELs. Pulse energy of up to ~100 μJ can be delivered, and relative bandwidth as low as 0.05% (close to the Fourier transform limit), wavelength stability ~7x10^{-5}, and amplitude variations ~10% (measured in the EUV) [16, 17]. An upgrade to 50 Hz is under way, by implementing a new RF photocathode gun and klystron modulators.

FEL-2 is currently being commissioned, and uses a beam of energy ~1.5 GeV (by activating SLED cavities in the RF power systems) driving a two-stage harmonic cascade using a fresh-bunch approach. The two stages are each high gain harmonic generation FELs. The first stage is seeded by a UV pulse (~260 nm, the 3rd harmonic of a Ti:Sa laser system), and lases at the 4th-6th harmonic. The output of this first stage is used to seed the second stage modulator, using a chicane to delay the electron bunch such that the seed pulse overlaps and modulates an unperturbed ("fresh") part of the electron bunch. The final FEL output is obtained at up to ~65 harmonic of the initial UV seed. Tuning range is nominally 4–20 nm although coherent FEL emission with wavelength as short as 3 nm has been observed [18].

SACLA

SACLA opened to users in 2012 and is currently a hard X-ray facility, producing photon pulses in a range 5–15 keV, with 100-400 mJ per pulse in a duration of ~10–15 fs, at a repetition rate of 10 Hz (60 Hz maximum). The undulators are in-vacuum variable-gap, with period 18 mm. The machine uses an 8.5 GeV, C-band (5.7 GHz), linac, with a novel single-crystal CeB_6 thermionic cathode and combination of VHF, UHF, L-, S-, and C-band RF systems in the injector. Bunch charge is ~100–300 pC, and peak current >3 kA. SASE central wavelength stability is ~3x10^{-4}, and pulse energy variations ~10–20% [6,8].

Upgrades are being pursued to provide additional FEL beamlines (up to 5 and including one soft X-ray), a bunch-by-bunch beam distribution system, hard X-ray self-seeding, higher beam energy (to 9 GeV), and relocation of the SCSS (SPring-8 Compact SASE Source) test accelerator and increasing it's energy to 450 MeV (and potentially 1.4 GeV) to drive a EUV to soft X-ray FEL [8]. The soft X-ray FEL uses in-vacuum undulators with period 18 mm (same as hard X-ray undulators), and initial tuning range is ~15–60 nm, with 50–100 μJ per pulse. First operation of the soft X-ray FEL is planned for autumn 2015. The SCSS was built in 2005 to demonstrate the SACLA concept with a 250 MeV test accelerator, and successfully lased at 50 nm, with HHG seeding at 61.5 nm [19].

CONSTRUCTION PROJECTS

European XFEL

The European XFEL is under construction in Hamburg, Germany, and consists of a 17.5 GeV pulsed L-band (1.3 GHz) superconducting linac serving three initial SASE FELs, delivering photons from 0.05–4 nm in pulses of ~1–100 fs. The time structure is 2700 bunches per 600 μs macropulse, at a repetition rate of 10 Hz (average bunch rate 27 kHz, and a rate of 4.5 MHz within the macropulse). Kickers will provide flexible beam distribution with simultaneous operation of three experiments. Bunch charge is 0.02–1 nC, and average beam power over 500 kW. The injector is a normal-conducting L-band photo-cathode RF gun of the same type in operation at FLASH. The soft X-ray FEL is downstream from a hard X-ray FEL, using the same beam, and has 68 mm period permanent magnet undulators with adjustable gap; the tuning range is extended by adjusting the electron beam energy. Average soft X-ray power is greater than 100 W [20].

SwissFEL

Under construction in Villigen, Switzerland, SwissFEL is an X-ray laser facility with two FEL lines covering the wavelength range from 0.1-0.7 nm and 0.7-7 nm, respectively. An S-band injector delivers beam at 100 Hz to a normal-conducting C-band (5.72 GHz) linear accelerator. Two bunches of charge 10–200 pC are accelerated per RF pulse; one is extracted at 3 GeV for soft X-ray generation, while the other continues to be accelerated to 5.8 GeV for hard X-ray production. The soft X-ray FEL is self-seeded and uses 40 mm period APPLE-II type variable gap undulators with polarization control, and delivers per-pulse energy of ~100 μJ. Commissioning of the linear accelerator and the hard X-ray FEL will start in 2016; funding for the soft X-ray component requires additional approval and construction is planned to begin in 2018 [10].

PAL X-FEL

The PAL-XFEL is under construction, and designed to have three hard X-ray undulator lines at the end of a 10 GeV S-band (2856 MHz) linac, and a branch line at 3.15 GeV for two soft X-ray undulator lines. Initially, one hard X-ray and one soft X-ray FEL will be built. The injector uses an S-band photocathode gun which delivers two bunches of 20–200 pC charge at 60 Hz, bunch delivery to the soft X-ray beamline is to be controlled by a kicker system. A passive wakefield "dechirper" will be used to remove the correlated energy chirp following extraction from the linac [21]. The soft X-ray undulators are planned to be permanent-magnet adjustable-gap devices with 34 mm period, and APPLE-II type for the final few gain lengths to provide polarization control. Photon

wavelength is in the range 1–4.5 nm (longer wavelengths using lower beam energy), with ~90 fs pulse duration. FEL experiments are planned to begin in late 2016 [11].

PROPOSALS AND DESIGN STUDIES

NGLS

The LBNL-led NGLS collaboration developed design concepts for a multi-beamline soft x-ray FEL array powered by a superconducting linear accelerator, operating with a high bunch repetition rate of ~1 MHz. The CW L-band (1.3 GHz) 2.4 GeV superconducting linear accelerator design is based on developments of TESLA and ILC technology, and is supplied by a high-brightness, high repetition rate VHF-frequency photocathode electron gun under development at the APEX facility [15]. 300 pC, 500 A peak current, ~300 fs electron bunches from the linac are distributed by RF deflecting cavities to the array of up to nine independently configurable FEL beamlines with nominal bunch rates of ~100 kHz in each FEL, with uniform pulse spacing, and some FELs capable of operating at the full linac bunch rate. Undulators are ~20 mm period, Nb_3Sn superconducting planar devices to provide optimal performance, and are being developed in an R&D program [22]. Individual FELs may be configured for different modes of operation, including self-seeded and external-laser-seeded, and each may produce high peak and average brightness x-rays with a flexible pulse format, including multiple approaches to deliver two-color X-rays with wide tuning range for each color, and with pulse durations in the range ~0.1–100 fs. RF and beam-based feedback systems, integrated with fiber-based timing and synchronization systems, would provide exceptional photon-beam stability and synchronization control in a high-rate, CW machine [23]. The effort is now stopped.

SXFEL

Baseline technical design studies for the Shanghai soft X-ray FEL (SXFEL) proposal have been completed. The initial configuration is planned to use a 10 Hz normal-conducting linac using S- and C-band technology and would deliver 840 MeV beam energy, driving a laser-seeded harmonic cascade to reach a wavelength of 8.8 nm. Upgrade to 1.2–1.3 GeV would provide photon wavelength down to 3 nm. The facility would be built at the Shanghai Synchrotron Radiation Facility, in collaboration with Tsinghua University [24].

LUNEX5

LUNEX5 is a multi-institution proposal coordinated by SOLEIL, for R&D and demonstration of advanced FEL concepts, including both RF linac and laser wakefield accelerators. Seeded FEL techniques, using in-vacuum cryogenically cooled PrFeB undulators with 15 mm period, would be developed with a 400 MeV superconducting linac, and a 0.4–1 GeV laser-plasma beam. HHG and EEHG seeding schemes would be explored to produce 4–40 nm FEL output in pulses of ~10 fs duration. A conceptual design report is completed, and the project is in an R&D stage [25].

IRIDE

The IRIDE concept under development and based at INFN Frascati [26] is a high brightness particle beams factory based on high duty cycle superconducting linacs. The design concept includes FEL oscillators and SASE and seeded FELs, operating over a very broad spectrum from IR to hard X-ray.

NLS

The NLS team in the U.K. developed a conceptual design for a 1 kHz coherent light source with FELs operating to wavelengths in the range ~1–25 nm, using a 2.25 GeV CW superconducting L-band (1.3 GHz) linac. The pulsed L-band photocathode gun would deliver 200 pC at 1 kHz, driving HHG-seeded FELs to provide temporal coherence and increased brightness. Three initial FELs were conceived, using harmonic cascade schemes and generating ~20 fs pulses. Upgrade paths to higher repetition rate (MHz), shorter X-ray pulses, higher energy photons (to 2 keV), and additional FELs and endstations were identified [27].

WiFEL

A concept for a Wisconsin FEL (WiFEL) has been developed based on a CW superconducting L-band (1.3 GHz) linac fed by a superconducting photocathode gun delivering bunches at MHz rate. A staged approach is suggested that includes incremental build-out of the accelerator and multiple seeded FELs, using harmonic cascades and covering a wavelength range down to ~1 nm, with ~10 fs pulses [28].

MACHINE BASED OPTIMIZATION USING GENETIC ALGORITHMS IN A STORAGE RING *

K. Tian#, J. Safranek, Y. Yan, SLAC, Menlo Park, CA 94025

Abstract

In this paper, instead of applying GA in the conventional numerical calculations, we present a successful experimental demonstration of implementing GA in real machine based optimization. We conduct the optimization of the average vertical beam size of the SPEAR3 storage ring using GA. Beam loss rate is chosen as the sole objective function because it is inversely proportional to the vertical beam size and can be measured quickly in SPEAR3. The decision variables are the strengths of SPEAR3 skew quadrupoles, by varying which we can change both the betatron coupling and the vertical dispersion to search for the minimum beam size. The results in this paper can shed light on new applications of GAs in particle accelerator community, for example, optimizing the luminosity of the high energy collider in real time.

INTRODUCTION

GAs have been successfully applied in areas such as designing injector systems [1], diagnosing and designing accelerating cavities [2], and optimizing beam optics design in storage rings [3]. One core process of the GA is to evaluate objective functions from a given set of decision variables, i.e. knobs to be adjusted for optimum search. In spite of various approaches used in previous efforts, all of them evaluate the objective functions based on numerical simulations using particle tracking codes. In principle, when the optimization targets or their correlating parameters are measurable experimentally, it is possible to use the real machine as the function evaluator to directly measure the objective functions, rather than using a computer model. Compared to the simulation based optimization, the machine based optimization has the most accurate representation of the machine condition that includes all lattice errors. Moreover, when the physics quantities of interest can be measured quickly in experiment but cost long time to be calculated in simulations, the machine based optimization will excel in speed too. One example of such quantity is the luminosity of the high energy colliders. In SPEAR3, we have identified a similar parameter of interest that can be measured nearly instantaneously. In this paper, we report an innovative application of GA to minimize the average vertical beam size of the SPEAR3 storage ring in real time. To construct the GA, we use 13 skew quadrupoles in the storage ring as decision variables and the measured beam loss rates as the objective function. The results can serve as a proof of principle for using GA in machine based optimization.

MINIMIZE THE VERTICAL BEAM SIZE

In a storage ring, circulating electrons are lost due to collisions with gas molecules and electron-electron scattering inside the bunch, where the latter is known as the Touschek effect [4]. As in most modern electron storage rings, the loss of stored beam current in SPEAR3 is mainly due to the Touschek scattering. Thus, one can derive the simple scaling law between beam loss rates *dI/dt* and vertical beam size as shown below:

$$\frac{\left|\frac{dI}{dt}\right|}{I^2} \propto \frac{1}{\bar{\sigma}_y}, \qquad (1)$$

where I is the stored current and $\bar{\sigma}_y$ is the average vertical beam size.

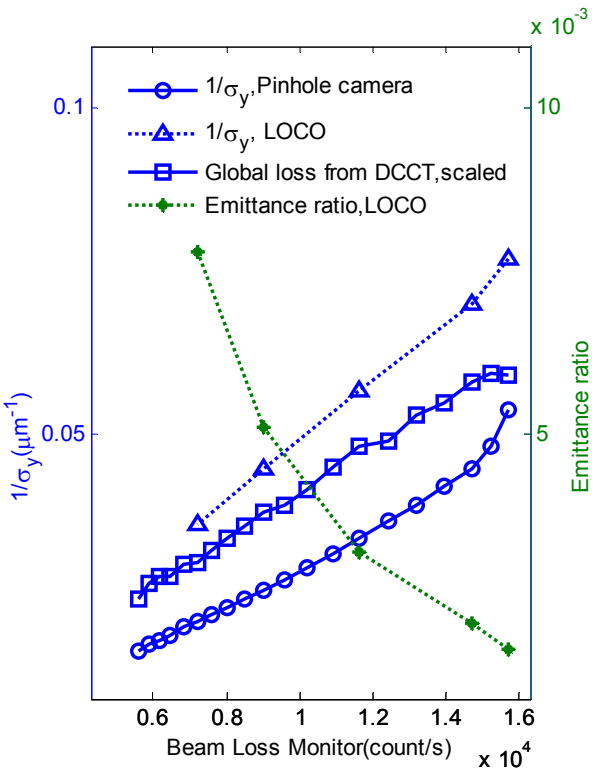

Figure 1: Experiment verification of Eq. (1).

In SPEAR3, Eq. (1) can be directly validated by experimentally measured data. During the experiment, 100 mA beam is filled in SPEAR3. We achieve 20 conditions in the ring by varying all skew quads in a fixed step size. For each condition, we measure the vertical beam size at 1Hz with an x-ray pinhole camera [5]. The beam loss rate is recorded instantaneously at 1Hz by a beam loss monitor (BLM) [6], installed next to the SPEAR3 beam horizontal scraper. The scraper is inserted close to the beam in order to capture nearly all of the beam loss at one point. The global beam loss is also

acquired by recording the current decay during 2-minute period using a dc current transformer (DCCT). The current droop during the entire period of the experiment is less than 4%, thus, the stored current can be considered as a constant for the analysis in Eq. (1). Sampling 5 out of the 20 different cases, we measured the response matrix of the ring for each, and then fit the model to the measured data using LOCO. Emittance ratio and average vertical beam size then can be calculated from the fitted model. All results are shown in Figure 1, where the monotonic relationship of the measured beam loss monitor data, the vertical beam size, and the emittance prove the simple scaling law in Eq. (1).

ALGORITHM DESCRIPTION

In this section, we will detail the formation of a GA based technique in maximizing the beam loss rate of SPEAR3 in real time. The algorithm is based on NSGA – II [7].

Objective Functions and Decision Variables

The normalized beam loss rate measured by the BLM next to the scraper is the single objective function in our GA formation. The currents, which represent the strengths of the skew quadrupoles in SPEAR3, are the independent decision variables. After varying the currents of the 13 skew quadrupoles, the objective function is evaluated from the direct measurement of the BLM. Distinct from most other applications of GA, the accelerator serves as the function evaluator, instead of a numerical or analytical model. The SPEAR3 skew quadrupoles are powered by high precision MCOR power supplies featured with fast switching. The data acquisition from the BLM is also nearly instantaneous.

Genetic Operations

Except the first generation, all sequential generations are generated via the process of genetic operations. We use two of the most popular genetic operators: real-coded Simulated Binary Crossover (SBX) [8] and polynomial mutation [8]. In each genetic operation, one of the two operators is chosen randomly but conforms to a predefined ratio. During a crossover, two parents are picked to create two children, while one child is generated from one parent in the case of mutation. Once a child is created, its corresponding objective function is evaluated. Eventually, an offspring population is generated. Crossover and mutation are governed by the user-configurable nonnegative tuning parameters η_c and η_m respectively. A more detailed discussion of these two parameters can be found in the literature such as reference [8]. In short, these tuning parameters control the probability density function of the likeness between parents and children. For mutation, a smaller η_m represents less probability to have a similar child, which in turn provides a global search to the optimum regardless the parent solution. On the other hand, with a bigger η_m, it is very likely that the child only varies slightly from the parent and the operation is conducting a local search of optimum around the parent. The behavior of η_c is quite similar to η_m: the children tend to be close to one of the parents with large η_c or be randomly generated with small η_c.

The performance and speed of genetic algorithms highly depends on specific problems and can be adjusted with mutation and crossover tuning parameters. We have programmed the code to dynamically adjust these factors according to the diversity of the population in the new generation. It appears that the optimization progresses faster by promoting more global search with relatively small mutation tuning parameters in early generations. When the population starts to cluster toward the optimum region, it helps to save time by using large mutation tuning parameter or shrink the search space.

Replacement, Re-evaluation, and Stopping

To ensure an elitist approach, the current population is replaced by the best solutions chosen from both the offspring and the older generation. To maintain a fixed population size, the remaining solutions are discarded. As the objective functions are measured directly from the SPEAR3 machine, the results may change over time due to variation of machine condition. Therefore, we re-evaluate the surviving solutions from all previous generations every 10 generations. Limited by the machine time available for the experiment, we run the algorithm as long as possible, so normally we stop the program manually after a certain amount of time.

RESULTS

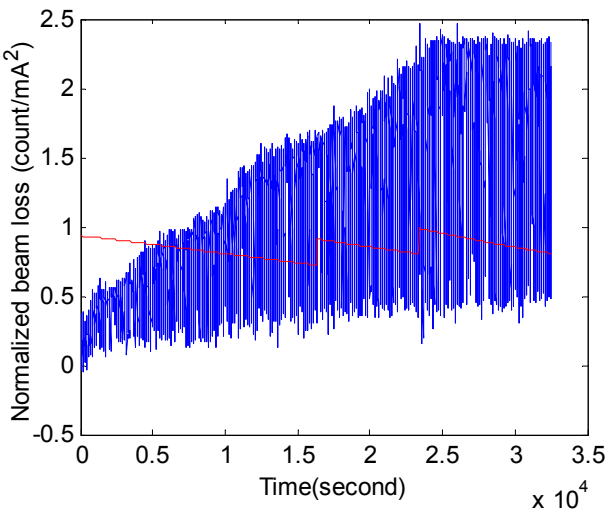

Figure 2: Normalized beam loss rates at the scraper during the experiment at 1Hz update rate.
